**Table 9-1 Definitions for Terms often Associated with River Restoration (NRC 1992; Brookes and Shields 1996; FISRWG 1998)**

Term	Definition	Remarks
Restoration	Reestablishment of the structure and function of ecosystems. Ecological restoration is the process of returning an ecosystem as closely as possible to predisturbance conditions and functions. In the United States “predisturbance” usually refers to pre-European settlement. Because ecosystems are dynamic, perfect replication of a previous condition is impossible.	The restoration process re-establishes the general structure, function, and dynamic but self-sustaining behavior of the ecosystem. It is a holistic process not achieved through the isolated manipulation of individual elements.
Rehabilitation	Partial recovery of ecosystem functions and processes. Rehabilitation projects include structural measures and “assisted recovery.” Assisted recovery refers to removal of a basic perturbation or disturbance (e.g., excluding grazing livestock from a riparian zone) and allowing natural processes (e.g., regrowth of vegetation, fluvial processes) to operate, leading to recovery of ecosystem function.	Rehabilitation does not necessarily re-establish the predisturbance structure, but does establish geological and hydrologically stable landscapes that support the natural ecosystem mosaic.
Preservation	Activities to maintain current functions and characteristics of an ecosystem or to protect it from future damage or losses.	
Mitigation	An activity to compensate for or alleviate environmental damage. Mitigation may occur at the damaged site or elsewhere. It may restore a site to a socially acceptable condition, but not necessarily to a natural condition.	Mitigation is often a permit requirement as part of some nonrestoration type of action; it thus may form the basis for a restoration project.
Naturalization	Management aimed at establishing hydraulically and morphologically varied, yet dynamically stable fluvial systems that are capable of supporting healthy, biologically diverse aquatic ecosystems. Does not require reference to a certain preexisting state.	The naturalization concept (Rhoads and Herricks 1996; Rhoads et al. 1999) recognizes that naturalization strategies are socially determined and place-specific. In human-dominated environments recurring human management and manipulation may be a desired and even necessary ingredient in the dynamics of the “naturalized” system.
Creation	Forming a new system where one did not formerly exist (e.g., constructing a wetland).	Concepts similar to those used in restoration or rehabilitation are often applied to produce ecosystems consistent with contemporary hydrology and morphology.
Enhancement	Subjective term for activities undertaken to improve existing environmental quality.	Stream enhancement projects of the past often emphasized changing one or two physical attributes in expectation that biological populations would respond favorably. But monitoring data were typically limited.
Reclamation	A series of activities intended to change the biophysical capacity of an ecosystem. The resulting ecosystem is different from the ecosystem existing prior to recovery.	Historically used to refer to adapting wild or natural resources to serve a utilitarian purpose, such as draining wetlands for agriculture.

structures (Section 9.5.2). Reach-scale measures include local measures applied over long reaches plus fencing to exclude livestock from stream corridors, channel reconstruction (Section 9.5.1.1.2), floodplain reconnection, dam removal, and revision of reservoir release strategies. Watershed-scale efforts include widespread application of these local and reach strategies plus

programs that address exotic species, land use management, best management practices for forestry and agriculture, and storm water management. Strategies for restoration projects often include activities to promote higher levels of physical dynamism (e.g., flooding, avulsion, island formation, braiding, channel migration) in streams that have been dammed, leveed, or channelized.

On the other hand, many stream systems have been so disturbed by human activities or natural events that they have levels of physical instability that far exceed natural levels to which plants and animals are adapted. Restoration activities in these systems involve recovering stability through flow regulation, revegetation, and building erosion control structures (Shields et al. 1999). A tension exists between restoring the dynamic character of fluvial systems and providing socially acceptable levels of channel stability. During the last 50 years, most efforts at stream manipulation have emphasized stabilization. The shift toward allowing dynamic behavior may be difficult for many stakeholders to accept—given their lack of experience with such approaches. This concept is explored further in Section 9.5.

**9.1.2.2 River Dynamism** Because restoration implies at least a partial return to naturally dynamic structure, processes, and functions, it is useful to consider the characteristics of unmodified or lightly impacted rivers. When viewed over several decades, natural fluvial systems appear to be complex physically and ecologically; well connected vertically between water and substrate, longitudinally between upstream and downstream zones, and laterally between channels and floodplains; and infrequently disturbed by large natural events that keep the system in a long-term state of adaptation to seek balance and stability (Vannote et al. 1980; Williamson et al. 1995a; Bella et al. 1996; Klingeman et al. 1998). The movement of water and the transport of sediment and large woody debris cause the physical features of rivers to change continually. Although channel slope, sinuosity, and floodplain elevation evolve gradually, smaller-scale features such as individual bends, bars, and short bank segments may change rapidly during high flows. Large flows cause extensive interactions between river channels and floodplains. Infrequent disruptive events such as floods, earthquakes, volcanic eruptions, and landslides often trigger systemwide fluvial response. Severe droughts also constitute a type of natural disturbance.

The response of a fluvial system to natural or manmade disturbance varies with the geomorphic context. For example, lightly altered stream systems in regions of mild relief and humid climate (e.g., the United Kingdom or the eastern coastal plain of the United States) approach a conceptual ideal referred to as dynamic equilibrium (Schumm 1977). Bank erosion and bank-line migration typically occur in such a stream, but over a period of, say, several decades, the reach-average channel width, depth, and slope do not change, and sediment outflow is equal to sediment inflow (Thorne et al. 1996a). Furthermore, the average dimensions of such stream channels appear to be power functions of discharge of a certain frequency (see Section 9.3.1). When perturbed, such systems tend to respond in a way that returns the channel dimensions to the equilibrium status or to a new set of equilibrium dimensions. In contrast, systems with high-variance flood-frequency

regimes are governed by extreme floods and exhibit transient behavior without the development of “characteristic” geometries typical of systems in dynamic equilibrium. Such fluvial systems are common in arid, semiarid, and proglacial environments. Flood-dominated streams pose an especially difficult challenge for restoration because system dynamics are pulsed, episodic, and often catastrophic in nature. A single flood can radically reconfigure stream morphology for years, decades, or centuries (Baker et al. 1988).

Stream ecosystems are resilient and well adapted to natural disturbances (Pickett and White 1985). Removal of moderate disturbances causes progressive physical changes (e.g., infilling of pools by sediment) and reduces the ability of biological populations to recover from severe disturbances. Biological changes follow removal of disturbances. For example, the plant community in a large fresh-water marsh in an arid hydrologically closed basin was found to require significant interannual flow variation (Klingeman et al. 1971). In another case, an intermediate frequency of bed-mobilizing events was associated with maximum species richness in a gravel-bed stream (Townsend et al. 1997). Evidently a greater frequency of bed disturbance reduced richness by excluding taxa that could not quickly recolonize in the intervals between disturbances, whereas less frequent disturbance allowed competitive exclusion of species that were capable colonists but poor competitors.

### 9.1.3 Role of Sedimentation Engineering in Stream Restoration Projects

**9.1.3.1 The Engineer as Part of a Team** Comprehensive restoration activities influence the entire fluvial system—including the channel, banks, riparian zone, and floodplain—and address biological processes and functions as well as physical conditions and river flows. Thus, hydrology, hydraulics, sediment transport, and channel morphology must be evaluated for the restoration site and for other potentially impacted areas. Frequently the same engineer or engineering team assumes responsibility for hydrologic, hydraulic, and sedimentation analyses. For example, the same person may perform hydrologic simulation to generate design discharges; backwater computations to predict water surface elevation, depths, velocities, and shear stresses at design discharge; and sediment transport computations to assess potential for erosion and sedimentation. Regardless of the division of labor, the persons charged with sedimentation engineering analyses should be involved in project planning, design, construction, and postconstruction activities (monitoring, operation, maintenance, and management).

Stream channel restoration projects can succeed as engineering exercises but fail dismally as ecological resource recovery efforts. As noted above, the definitions for restoration-type activities imply that the bottom-line objective for these efforts is ecological. It is imperative, therefore, that the engineer obtain guidance and input from

a multidisciplinary team including earth and natural scientists. Communication within such a team is often difficult, because each discipline has its own values, tacit assumptions, and jargon. FISRWG (1998) can be very helpful in cross training among disciplines and facilitating team communication. Successful team function depends upon members working within the confines of their areas of expertise but understanding and interacting with other team members. A hydraulic engineer with a short course in ecology is not qualified to set habitat objectives, whereas a fisheries biologist with a short course in fluvial geomorphology is similarly not qualified to perform geomorphic assessment or channel design. Although many hydraulic engineers have broad experience in river erosion and sedimentation, team participation by geomorphologists (persons with regional experience and advanced degrees) is often necessary if the project locale is characterized by dynamic landforms and channels.

**9.1.3.2 Setting Objectives** Restoration project objectives should be defined early and clearly by stakeholders. Support for a restoration project is usually related to broad social, political, and institutional goals (Smith and Klingeman 1998). For implementation, such goals require rephrasing in terms of achievable objectives with measurable outcomes. Thus, although project goals may be general, project objectives must be specific and quantified to allow clear communication and postproject appraisal. Facilitation by the project manager and by technical experts such as the sedimentation engineer may be needed to convert general goals into achievable objectives, as well as to build consensus among diverse stakeholder groups and to ensure that objectives are clearly stated and not contradictory. For example, some projects may inadvertently adopt mutually exclusive objectives such as (1) the elimination of stream bank erosion and

(2) the restoration of riparian plant communities that depend on erosion and deposition. Setting objectives for restoring physical habitat value to degraded river corridors requires an assessment of current habitat quality and a description of the factors contributing to degradation. As planning and design proceed, additional social or natural constraints may become apparent, and the original objectives may need to be modified accordingly.

#### **9.1.3.2.1 Habitat Assessment and Setting Objectives**

Restoration project objectives often are phrased in terms of habitat manipulation. River corridors are often a rich complex of plant and animal habitats. Each life stage of each species has its own habitat requirements, and these are often expressed as ranges of physical variables. However, because stream corridors contain many species, and because habitat requirements are normally not known with precision, assessing the current status of habitat quantity or quality is inexact and involves professional judgment. Many natural events and human activities degrade habitat (Table 9-2), but the nature and magnitude of the degradation is hard to quantify. The engineer must work closely with biologists or ecologists to obtain an adequate assessment of the current status of habitat quality and to define critical elements that should be addressed in the restoration project. A geomorphologist can assist by identifying the factors responsible for physical habitat characteristics. The engineer may provide expertise in obtaining and interpreting data and model simulations describing physical aspects of habitat such as discharge, bed material characteristics, flow width and depth, current velocity, temperature, turbidity, and dissolved oxygen concentration.

An introduction to quantitative habitat assessment tools including the instream flow incremental methodology and the habitat evaluation procedure is provided by Federal Interagency Stream Restoration Working Group (FISRWG

**Table 9-2 Typical Forms of River Corridor Degradation (FISRWG 1998; SRSRT 1994)**

Basic cause	Typical examples	Types of degradation
Natural events	Floods, landslides, earthquakes, other tectonic events	Alteration of habitat, blockage of access to habitat, change in water quality or quantity
Land use changes	Urbanization, logging, animal grazing, mining, road building	Direct: Damage to banks and bed from animals and machines, pollution. Indirect: Increase in sediment production, water pollution, reduction in shade and organic inputs (leaves and twigs) from riparian zone, perturbation of hydrologic patterns
Flow regulation, withdrawal, or diversion	Dams, irrigation withdrawals, interbasin transfers	Depletion of aquatic habitat, inundation of stream habitat, replacement of natural flow patterns with regulated flow, perturbation of sediment transport patterns
Channel modifications	Channelization, bank protection, clearing, and snagging	Replacement of natural boundaries and geometries, overall simplification of physical complexity and heterogeneity.

1998). Additional tools for evaluating stage, discharge, and other time series variables relative to a reference or undegraded condition are described by Richter et al. (1996; 1998).

#### 9.1.3.2.2 Effects of Project Scale on Objectives

Project scale is a major consideration for stakeholders and the design team in setting objectives (Smith and Klingeman 1998). Project scope and scale control the breadth of restoration options (Klingeman 1998; Smith and Klingeman 1998) as well as the role of sedimentation engineering. Early stream restoration projects were usually small-scale efforts to manipulate physical habitat (e.g., Thompson (2002b)). Similar efforts remain common today. These projects typically focus on local scour and deposition but often do not consider sediment transport beyond the immediate site. Initial successes and failures showed the need to develop approaches that would operate at watershed and ecosystem scales using concepts from physical and biological sciences. A larger-scale project may address major system processes such as channel meandering, ecosystem diversity, and ecosystem complexity.

**9.1.3.2.3 Opportunities Offered by Large-Scale Projects** A broad, integrated approach is usually needed to rehabilitate severely degraded streams. Project planning that addresses habitat collectively rather than for individual species is usually preferred. Such a collective approach (“whole system restoration”) may necessitate actions that address riparian zones, floodplains, and watersheds. General objectives have been suggested for restoring large-scale natural riverine functions (NRC 1992; Williamson et al. 1995a; 1995b; Bella et al. 1996), including the following:

- Restore dynamic ecosystem processes and functions in channels, riparian zones, and floodplains, including flooding, erosion, deposition, and exchange of sediment and organic material between channels and floodplains.
- Restore habitat diversity and complexity, system connectivity, and natural disturbance regimes.
- Provide a means whereby natural processes will function with little human intervention.

As an example of large-scale restoration, consider a channelized stream with extremely degraded aquatic habitat. One restoration strategy might feature the reinstatement of the meandering planform that existed before channelization. Meanders could be restored using strategies that either limited or expanded natural processes. The new channel alignment could be (1) designed and constructed, (2) designed and then allowed to develop through fluvial processes with structural constraints at key points, or (3) allowed to develop without intervention or structural constraint. Comparing these alternatives may require extensive sedimentation engineering analysis. Clearly, option (1) could have the greatest initial cost and create the greatest disturbance of existing conditions but also pose the least risk of subsequent changes, whereas option (3) would tend to be just the opposite—having the least cost and least immediate disturbance but the highest uncertainty regarding the predictability of

subsequent changes. The latter option would require the most challenging sedimentation analyses.

**9.1.3.3 Specific Habitat Restoration Objectives** Habitat goals should be based on the attributes of relatively unaltered aquatic ecosystems or the causes of habitat degradation. General goals (e.g., improve water quality for aquatic organisms) must be supported by more specific objectives (e.g., reduce mean daily maximum water temperature below 17°C) (SRSRT 1994; Williamson et al. 1995a). Specific objectives are often phrased in terms of the same quantities used for habitat evaluation, including the following:

- Streamflow quantity. For example, provide adequate streamflow to meet seasonal needs for particular life stages or particular species or to mirror patterns in a lightly degraded reference system (Richter et al. 1996).
- Water quality. For example, maintain dry-season pool depths to meet temperature criteria.
- Channel dimensions for spawning, rearing, or refuge. For example, modify riffle frequency, increase channel pool volume and maximum depth, or increase the availability of steep or undercut banks.
- Longitudinal channel conditions for movement of organisms. For example, remove barriers or eliminate dewatered reaches.
- Streambank conditions. For example, reduce soil exposure and erosion; increase shade, cover, and refuge; or improve general condition, maturity, and successional opportunities for riparian vegetation.
- Influx and movement of sediment. For example, allow sediment to enter reach from upstream or local sources, provide flows for periodic sediment transport and flushing of substrate, or allow lateral bar formation along channel margins.
- Conditions in spawning gravel. For example, maintain intra-gravel flows when gravel-spawning species are important, such as salmonids.
- Input of organic matter and nutrients. For example, provide healthy riparian zones to ensure direct sources for organic matter and insects or maintain longitudinal continuum of organic matter from upstream sources and to downstream zones.

**9.1.3.4 Scope of Sedimentation Analysis** Stream restoration projects often change channel characteristics that impact sediment transport, including width, depth, slope, planform, bank erosion potential, hydraulic roughness, and bed material gradation. The sedimentation engineer may provide expertise in obtaining and interpreting data and model simulations describing physical aspects of habitat such as discharge, bed material characteristics, flow width and depth, current velocity, temperature, turbidity, and dissolved oxygen concentration. The engineer should also ensure that designs have acceptable outcomes with respect to erosion and sedimentation. Table 9-3 catalogs instability problems associated with various types of channel changes that are often key components of restoration projects.

**Table 9-3 Potential Stability Problems Associated with Stream Restoration Projects**

Modification	Potential stability problems		
	Project reach	Upstream	Downstream
Increase vegetation, woody debris, boulders, and other types of large-roughness elements	Aggradation	Aggradation	Degradation
Increase channel complexity (adding sinuosity or increasing the irregularity of cross-sectional shape and size)	Bank erosion, aggradation	Aggradation	Degradation
Remove of dams or weirs	Degradation upstream from structure, aggradation downstream.	Degradation	Aggradation or degradation, depending on impacts on flow and sediment discharge
Increase number of channel structures (e.g., weirs, spurs, bank covers, etc.)	Localized scour, bank erosion, aggradation	Aggradation	Degradation
Decrease bed slope	Aggradation	Aggradation	Degradation
Increase bed slope	Degradation	Degradation	Aggradation
Enlarge channel	Bank erosion, aggradation	Headcutting	Aggradation

Sedimentation analysis to support restoration design should predict the fluvial response to the project. For example, increasing channel width, increasing hydraulic roughness with vegetation or habitat structures, or decreasing channel slope by adding sinuosity will decrease sediment transport capacity and may lead to channel aggradation. On the other hand, if the restored channel is too steep, bed degradation may occur. Secondary responses may follow. For example, bank erosion may be triggered by bed aggradation or degradation. Even processes such as natural revegetation of a stream corridor can generate adjustments to the channel. Vegetation and in-channel woody debris can influence morphology of channels including the pool and riffle sequence, channel roughness, bank stability, locations of cutoffs, routing peak discharges, sediment routing and discharge, and the distribution of erosion. It follows that formulation of a sediment budget (Section 9.6.2) for the project reach using with- and without-project scenarios is one of the most basic sedimentation engineering tasks to support stream restoration.

**9.1.3.5 Risk Evaluation** Stream restoration projects that experience a significant imbalance between sediment supply and transport capacity either fail (do not deliver the desired benefits) or are not sustainable (have prohibitive maintenance requirements) (Brookes and Shields 1996). Because sediment transport analyses feature high levels of uncertainty, there are no standard approaches for determining what level of sediment transport imbalance is “significant.” The designer must integrate knowledge gained from the stability assessment, preliminary design, and detailed design. The designer is responsible for making the client and other stakeholders aware of

projected performance under various scenarios. For example, the project may experience unacceptable levels of erosion or sedimentation if discharges exceed a specified maximum peak or maximum average over some time period. Critical discharge levels may be lower during and shortly after project implementation. Nevertheless, sediment transport analyses are useful in reducing uncertainty (Johnson and Rinaldi 1998).

Restoration projects also experience failure when they do not generate the desired benefits. Even if the project performs perfectly with respect to water and sediment transport, the target species or communities may respond only weakly or may even decline. Biotic factors such as competition or predation, rather than physical habitat, may govern ecological response. In other cases, the linkages between habitat and ecological response may not be well understood enough to support reliable analysis. Biotic responses are heavily influenced by water quality, channel-floodplain interactions, and hydrologic variations. Some or all of these factors may not be altered by the restoration project. Inclusion of biotic factors into risk analysis must often be simply qualitative.

## 9.2 PREPARATION OF SEDIMENT STUDIES PLAN

A sediment studies plan (Fig. 9-1) is a critical early component of a stream restoration project. A good plan will ensure that significant sediment problems are identified and that analysis of alternatives is satisfactory. The schematic

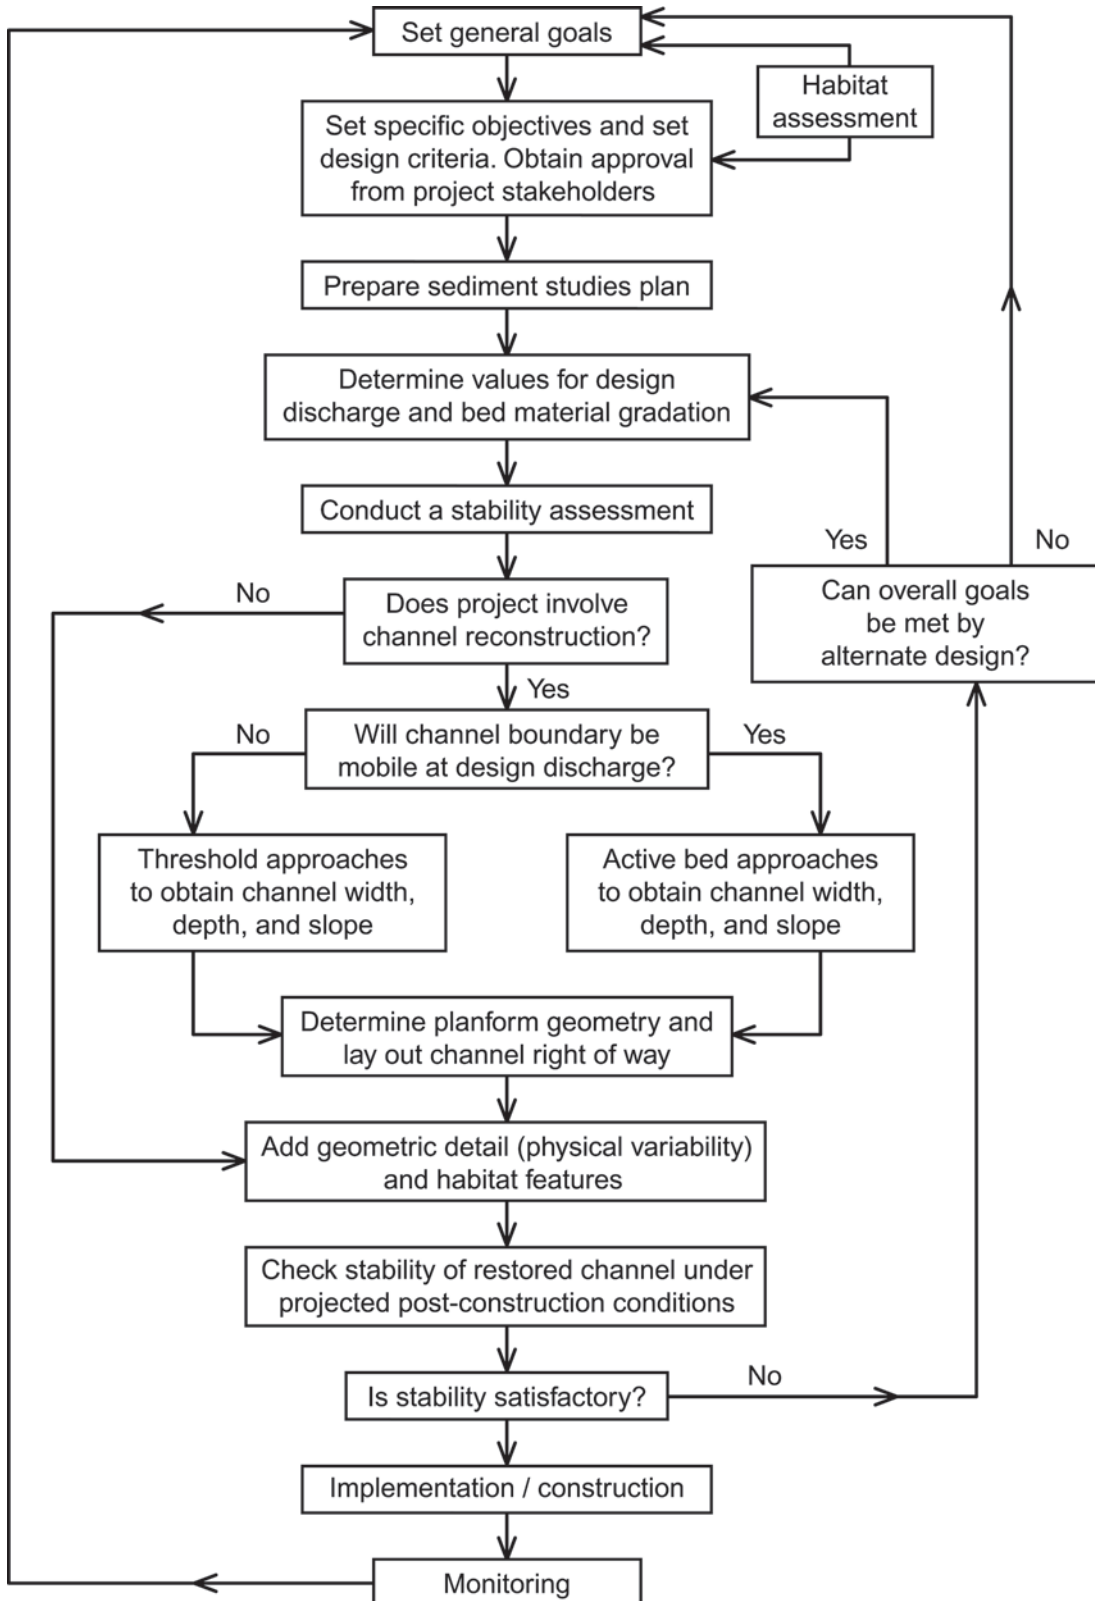

Fig. 9-1. Flow chart for sedimentation engineering aspects of stream restoration projects.

plan (Fig. 9-1) may be adjusted to fit a wide range of situations. For example, the stability assessment may be mainly qualitative for a simple project, but highly quantitative with multiple approaches to investigate the applicable variables for a complex project. As another example, the channel boundary may be constrained in urban areas, and therefore planform geometry will require little analysis.

### 9.2.1 Boundary of Study Area

The sediment studies plan should delineate the boundaries of the study area. Project impacts usually extend upstream and downstream beyond the project boundary. The region included in the assessment ideally should extend to major geomorphic boundaries such as watershed divides, reservoirs, or major confluences. However, resource limitations often dictate a smaller study area, and the engineer must exercise judgment in making tradeoffs between study quality and resource investment.

### 9.2.2 Stability Assessment

The sediment studies plan should include an assessment of historic and current system stability as described in Section 9.4.

### 9.2.3 Identification of Potential Problem Areas

The sediment studies plan should identify the potential problems in the study area. Sediment problems are most likely to occur in conjunction with the following project features:

- Expansions
- Bridge crossings or other constrictions
- Abrupt changes in channel slope
- Cutoffs and changes in channel alignment
- The upstream approach to the project reach
- The transition from the project reach to the existing channel downstream
- Appurtenant structures in the channel such as dikes and weirs
- Tributary junctions
- Lower reaches of tributaries
- Water diversions
- Upstream from reservoirs and grade control structures
- Downstream from dams and grade control structures.

### 9.2.4 Data Inventory

The plan should include a catalog of available geometric, hydrologic, hydraulic, sedimentary, and land use data. Potential future watershed land use changes should be identified using zoning maps, GIS, study of sequential air photographs, and other approaches. The previously established boundaries and problem area identification will guide selection of gauge sites and justify data requirements. Watershed

history and project life may be used to select time periods for trend evaluation.

### 9.2.5 Determination of Study Approach

The sediment studies plan should document the basis for the selection of methodology, such as time, cost, and data availability, as well as geomorphic factors. The current dynamism of the project reach and watershed should be considered, because the magnitude of sediment problems related to the restoration project will be in direct proportion to the scale of changes made to the channel geometry, boundary roughness, or discharge of a currently stable system. The level of study detail should ensure that major decisions about the project remain sound as more data become available during planning and design.

Sediment studies often include sediment budgets (Section 9.6.2) generated using various approaches. Because sediment budgets usually require extensive data sets (channel thalweg profile and cross sections, bed material gradations, flow duration curve, sediment inflows from upstream) and may involve substantial effort, an assessment based on the risk and consequences of project failure should be performed before a sediment budget analysis is launched. Many projects may require less elaborate analyses, but levels of uncertainty regarding project outcomes will be higher.

### 9.2.6 Data Collection

A data collection plan should be established and scheduled in the sediment studies plan if required data are not available. Standardized methods and equipment should be used to develop detailed and reliable sediment databases (e.g., Federal Interagency Sedimentation Project 2005). Chapter 5 in this volume and Edwards and Glysson (1988) describe approved samplers, standard sampling procedures, and laboratory analysis. Careful reduction and interpretation of the data is required in addition to the use of standardized data collection techniques. This is especially true when the data are collected over a relatively short time and at a relatively few sites within a large system. The engineer should advise the client regarding data collection needs and the levels of uncertainty that result from a lack of data.

### 9.2.7 Other Elements

The sediment studies plan should provide a reliable time and cost estimate for completion. A schedule of activities including preparation and review of end products should also be included. There should be a clear understanding among all participants in the planning and design processes about the scope of end products. An outline of the proposed final report may be helpful in this regard. A list of topics that may be included in such a report is provided in

**Table 9-4 Topics to Include in a Sediment Studies Report**

Topic	Remarks
Geography	Project and study area boundaries, current and projected future watershed land use
Data	Available data and sources Recommendations for data collection
History	Historic land use in the contributing watershed Hydrologic record Stream behavior in the study reach including aggrading and/or degrading trends, behavior of the system during flood events, and historical changes to and by the river system.
Bed and banks	Bed controls, bed material, bank heights, angles, vegetation, and stability
Channel stability	Existing channel and problems upstream and downstream from the proposed project area Knickpoints (headcuts) and knickzones
Physical habitat	Physical features that should be preserved or modified by a project
Project effects	Water-surface elevations and sediment transport capacity upstream of, within, and downstream of the project Tributaries (e.g., headcutting or induced deposition)
Recommendations	Project alternatives Future data collection and analyses to support design

Table 9-4. It should be clear how results of sediment studies will be used to affect decisions about overall project safety, efficiency, reliability, first cost, maintenance cost, environmental factors, social factors, and mitigation of adverse impacts resulting from sediment problems. Finally, the sediment studies plan and end products should be reviewed by scientists or engineers with expertise in sedimentation engineering and geomorphology to guard against costly oversights.

## 9.3 SELECTING VALUES FOR DESIGN DISCHARGE AND BED MATERIAL SIZE

### 9.3.1 Discharge

A representative discharge or discharge range is needed for many stability assessment tools (Section 9.4) and channel design (Section 9.5.1). The “channel-forming” or “dominant”

discharge is often used as this representative value. The channel-forming discharge concept is based on the idea that for a given alluvial channel geometry, there exists a single steady discharge that, given enough time, would produce width, depth, and slope equivalent to those produced by the natural hydrograph. Although the channel-forming discharge concept is not universally accepted, most river engineers and scientists agree that the concept has merit, at least for perennial nonincised streams, particularly coarse-bed snowmelt-dominated streams in the montane west. See Soar and Thorne (2001) and Biedenharn et al. (2000) for a review of relevant literature. Producing a single value for channel-forming discharge,  $Q_{cf}$ , has proven difficult in many cases. In attempts to provide quantitative expressions for discharge values that are believed to approximate  $Q_{cf}$ , the following terms have been suggested:

- The effective discharge, or the discharge that, over time, transports the most sediment ( $Q_{eff}$ ),
- The bank-full discharge ( $Q_{bf}$ ), and
- A discharge based on statistical return intervals ( $Q_r$ ).

Of the three quantitative approaches to  $Q_{cf}$ ,  $Q_{eff}$  generally requires the most data and effort (Table 9-5). Some workers have used sediment-discharge rating curves coupled with detailed geomorphic analysis to find  $Q_{eff}$  when historical hydrologic data were unavailable (Boyd et al. 1999). Additional comments dealing with ungauged sites are provided in Section 9.3.1.4.

#### 9.3.1.1 Effective Discharge, $Q_{eff}$

**9.3.1.1.1 Concept and Cautions** Although discharge varies continuously, it is usually represented by a time series of discrete values measured at daily or shorter intervals. These data may be used to construct a frequency histogram by breaking the observed range into a finite number of increments. The mass of sediment transported by each discharge increment may be computed using a sediment rating curve or sediment transport formula if hydraulic and bed-material parameters are available. The effective discharge,  $Q_{eff}$ , is the increment of discharge that transports the largest sediment load over a period of years (Andrews 1980) (Fig. 9-2). Thus  $Q_{eff}$  integrates the magnitude and frequency of flow events (Wolman and Miller 1960) and is the best basis for channel restoration design. However, there are several problems associated with  $Q_{eff}$ :

- Computed values of  $Q_{eff}$  are sensitive to the number of increments used to build the discharge histogram.
- Computation of  $Q_{eff}$  has the same drawback as other methods in identifying one flow rather than a range of flows for channel formation (see Section 9.3.1.1.2 for details).
- Care must be exercised in applying the effective discharge procedure, particularly in unstable channels and those that have experienced catastrophic events during the period of record, because flow-frequency and sediment-transport relations may have changed or be changing with time as the channel adjusts. Results

**Table 9-5 Quantitative Representations of Channel-Forming Discharge ( $Q_{cf}$ )**

Quantitative estimate of $Q_{dom}$	Data requirements	Recommended for	Limitations
Effective discharge ( $Q_{eff}$ )	Historical hydrology for flow duration curve (10 years or more recommended) or synthetic flow duration curve; channel survey; hydraulic analysis; sediment gradation; sediment transport analysis and model calibration (if possible)	Channel design	Requires large data set
Bank-full discharge ( $Q_{bf}$ )	Channel survey; hydraulic analysis and model calibration (if possible); identification of field indicators in a stable, alluvial reach.	Stability assessment; estimation of $Q_{eff}$ in stable channels	Can be very dynamic in unstable channels/watersheds; field indicators can be misleading
Return interval discharge ( $Q_{ri}$ )	Historical hydrology for flood frequency analysis, regional regression equations, or hydrologic model	First approximation of $Q_{eff}$ and/or $Q_{bf}$ in stable channels	No physical basis; relations to $Q_{eff}$ and $Q_{bf}$ inconsistent in literature

may therefore represent a transient average condition that does not accurately depict either the present flow and sediment-transport conditions or those prior to the event or disturbance.

The effective discharge is useful in comparing various channel geometries for competence to transport the incoming sediment load, facilitating study of project alternatives. Results of the effective discharge analysis are also useful when predicting the impact of alteration of watershed sediment loads (e.g., upstream dam removal) or hydrology (e.g., urbanization) on channel stability.

**9.3.1.1.2 Determining Effective Discharge** A three-phase process is involved in determining  $Q_{eff}$ :

1. Construct a frequency distribution (histogram) for discharge;
2. Construct a sediment-transport rating from either bed-material transport data or an analytical sediment transport relationship and reach hydraulics; and
3. Integrate the two relations by multiplying the sediment-transport rate for a specific discharge class by that discharge, with the maximum product being the effective discharge.

**Fig. 9-2.** Derivation of effective discharge by multiplying the discharge frequency histogram and the sediment rating curve to produce a collective sediment discharge histogram. Vertical axis represents frequency (percent of time), sediment discharge (mass per time), and collective sediment discharge (mass) for grey, white, and black bars, respectively.

The first phase involves selecting the type of discharge data to be used and a method for subdividing the observed range of discharge into classes to produce a frequency histogram. The period of record should be at least 10 to 15 years. In many cases, mean daily discharges are used because these data are readily available from the USGS and others. However, except for large rivers, mean daily flows tend to be underestimators of sediment transport because they mask the effects of short-duration peak flows. Discharges representing time periods shorter than a day, such as the 15-min data collected by the USGS, provide a more accurate means of establishing a sediment-transport rating relation. These data, although superior for a broader size range of streams and rivers, are not readily available, but may sometimes be obtained via special request.

There are no definite rules for selecting the most appropriate interval and number of classes (Thorne et al. 1998). The reader should note that the outcome of an effective discharge analysis is sensitive to the method used to derive the flow histogram. Yevjevich (1972) stated that the class interval should not be larger than 25% of the standard deviation of the sample. Hey (1997) found that 25 classes with equal arithmetic intervals produced a relatively continuous flow-frequency distribution and a smooth sediment load histogram with a well-defined peak, indicating an effective discharge that corresponded exactly with bank-full flow. Biedenharn et al. (2000) recommend setting the interval size equal to the discharge range (maximum observed discharge minus the minimum observed discharge) divided by 25. The first interval should begin at zero for suspended-load channels and at the critical discharge for initiation of bed load movement for gravel-bed rivers. Experience has shown that in some cases 25 classes produce unsatisfactory results, and a larger number of classes may be required. However, class size should be large enough so that some discharges occur in each class. In cases where the hydrologic response is extremely flashy, use of constant increments for the flow histogram may result in an extremely high relative frequency for the lowest interval, biasing  $Q_{\text{eff}}$  downward (Fig. 9-3). Soar and Thorne (2001) advocate using a continuous probability density function based on very small discharge intervals to avoid the problems associated with histogram development. If the frequency distribution is based on real data, it will exhibit a “noisy” appearance, but this may be addressed by using a moving average approach in phase 3, described below.

The second phase of the procedure involves developing a rating curve showing sediment concentration as a function of water discharge. Only sediment size classes that form the channel boundary should be used in the rating curve (Kuhnle et al. 2000). Typically, this range corresponds to the bed material sediment, but it may include finer sizes if significant material is being deposited on top of the banks (e.g., to form natural levees). The use of total-load transport data separated into suspended-, wash-, and bed-load components is ideal, but data in such detail are usually not available. Suspended sediment data are generally most readily available, and these data represent the sum of wash load and bed-material load moving

Figure 9.3a. 25 Equal arithmetic class intervals.

Figure 9.3b. 25 Logarithmic classes

**Fig. 9-3.** Effects of using (a) 25 equal (“arithmetic”) class intervals and (b) 25 “logarithmic” class intervals for developing the flow-frequency histogram. The large number of discharges in the first class interval may bias the resulting value of  $Q_{\text{eff}}$  downward.

in suspension. Bed material moving as bed load is usually not measured. The transport of bed material load can be classified as bed-load-dominant, mixed-load-dominant, or suspended-load-dominant on the basis of the ratio of shear velocity to fall velocity (Julien 1995). If sediment data are not available, bed-material load transport rates can be derived from a variety of transport functions, as described in Chapter 2 and elsewhere (Stevens and Yang 1989; Andrews and Nankervis 1995). Generally, sediment concentrations are plotted against discharge in log-log space and regressed to create a simple rating relation (Fig. 9-4a). However, power functions derived in this way are often inadequate to define the transport relation because they overestimate transport at high flows. In addition, transport can also be overestimated at low discharges because

**Fig. 9-4.** Sediment rating curve derivation. (A) Use of simple power function relation. (B) Use of two linear segments. Points inside rectangular box were regarded as anomalies and were not included in regression. (C) Use of three linear segments. Points inside rectangular box were regarded as anomalies and were not included in regression.

of the sensitivity of transport relations to bed-material gradations, which sometimes vary with discharge. This necessitates using two or three linear segments or a curved rating (Glysson 1987; Simon et al. 2004; Fig. 9-4b and c). In gravel-bed

streams, surface armoring and incipient motion flow requirements (Parker and Klingeman 1982) also suggest the use of more than one segment for the bed load relation.

Phase three of the procedure is accomplished by multiplying the frequency (in percent) of each discharge class by the sediment load corresponding to the discharge at the center of the class interval. The resulting values represent the average transport rate for each discharge class. The center of the class interval with the greatest transport rate is  $Q_{\text{eff}}$  (Andrews 1980) (see Fig. 9-2). In some cases, however, there may not be a single class interval representing a maximum. Instead, the peak average transport rate may spread across a range of classes, indicating that there is no single effective discharge but that significant geomorphic work is performed by a wide range of flows (e.g., Biedenharn and Thorne 1994). There is considerable support for this concept in the literature, and such a situation calls for considerable professional judgment in selecting design discharge capacity for the restored channel.

**9.3.1.2 Bank-Full Discharge,  $Q_{\text{bf}}$**  The bank-full discharge is the maximum discharge that a channel can convey without overflow. Theoretically,  $Q_{\text{bf}}$  and  $Q_{\text{eff}}$  are generally equivalent in channels that have remained stable for a period of time, thus allowing the channel morphology to adjust to the current hydrologic and sediment regime of the watershed (e.g., Andrews 1980). However, in an unstable channel that is adjusting its morphology to changes in the hydrologic or sediment regime,  $Q_{\text{bf}}$  can vary markedly from  $Q_{\text{eff}}$ . Therefore, the expression “bank-full discharge” should never be used to refer to  $Q_{\text{ri}}$  or  $Q_{\text{eff}}$ . The relationship of  $Q_{\text{bf}}$  to  $Q_{\text{ri}}$  and  $Q_{\text{eff}}$  is useful as an indicator of channel stability and sheds light on morphologic changes to be expected locally as well as up- and downstream (Schumm et al. 1984; Simon 1989; Thorne et al. 1996a). The  $Q_{\text{bf}}$  from “template” or “reference” reaches (stable reaches from similar reaches/watersheds) has been used as a guideline for relevant dimensions of the restored channel (Rosgen 1996). Three problems should be noted in regard to  $Q_{\text{bf}}$ :

- Identifying the relevant features in the field that define the stage associated with  $Q_{\text{bf}}$  can be problematic. Many field indicators have been proposed, but none appear to be universally applicable or free from subjectivity (Williams 1978). Similar statements hold for the methods developed for selecting appropriate ranges of  $Q_{\text{bf}}$  values based on these indicators (Johnson and Heil 1996). Field methods presented by Harrelson et al. (1994) should be considered in  $Q_{\text{bf}}$  determination.
- Channel restoration is most often (if not always) practiced in unstable channels (instability is often the reason for restoration), and hence, unstable watersheds. Other candidates for restoration include channels that have stable boundaries but that have been greatly enlarged for flood control. In such cases  $Q_{\text{bf}}$  can be highly dynamic and very different from  $Q_{\text{cf}}$  (Doyle et al. 1999) and should not be assumed to be the same as  $Q_{\text{cf}}$ .

- In certain instances, the current  $Q_{bf}$  may be a poor choice for future channel performance. For example, an apparently stable channel may overflow frequently due to upstream urbanization. Urbanization typically increases the amount of impervious area, decreasing infiltration and increasing runoff peaks and quantities. Urbanization has the greatest impact on small, frequent events (Hollis 1975), and there may be a threshold level of watershed imperviousness (approximately 15%) beyond which effects significantly increase (Moscrip and Montgomery 1997). As another example, streams in arid landscapes may adjust to large, infrequent events and have very large values for  $Q_{bf}$ . Additional discussion is provided in numerous references, including FISRWG (1998).

### 9.3.1.3 Discharge for a Specific Return Interval,

$Q_{ri}$  If gauge data are available, the discharge equivalent to the event with a given return interval is often assumed to be the channel-forming discharge; for example,  $Q_{cf} = Q_2$  (where  $Q_2$  is the two-year event). Similarities exist between certain recurrence interval discharges,  $Q_{eff}$ , and  $Q_{bf}$ . In general,  $Q_{bf}$  in stable channels corresponds to a flood recurrence interval of approximately 1 to 2.5 years in the partial duration series (Simon et al. 2004), although intervals outside this range are not uncommon. Recurrence interval relations for channels with flashy hydrology are intrinsically different from those for channels with less variable flows. Because of such discrepancies, many studies have concluded that recurrence interval approaches tend to generate poor estimates of  $Q_{bf}$  (Williams 1978) and of  $Q_{eff}$  (Pickup 1976; Doyle et al. 1999). Hence, assuming a priori that  $Q_{ri}$  is related to either  $Q_{bf}$  or  $Q_{eff}$  should be avoided in channel design, although it may be useful at times to take  $Q_{ri}$  as a first estimate of  $Q_{eff}$  and/or  $Q_{bf}$  in stable channels, particularly those with snowmelt hydrology (Doyle et al. 1999). Watershed urbanization typically causes greater runoff amounts and larger peak discharges for similar storms, increasing the frequency of higher discharges. Channel enlargement may result. This makes the recurrence interval approach tenuous, because it is commonly based on events that have occurred over the full historical record.

**9.3.1.4 Ungauged Sites** When gauge records are not available, estimates of  $Q_{ri}$  can be based on similar gauged watersheds or on regression formulas (Wharton et al. 1989; Jennings et al. 1994; Ries and Crouse 2002) developed using appropriate regional data sets. Calculation of  $Q_{eff}$  will require synthesis of a flow duration curve. Two methods are described by Biedenharn et al. (2000; 2001): the drainage area-flow duration curve method (Hey 1975) and the regionalized duration curve method. It should be noted that both methods simply provide an approximation to the true flow duration curve for the site because perfect hydrologic similarity never occurs. Accordingly, caution is advised.

**9.3.1.4.1 Drainage Area-Flow Duration Curve** Graphs of  $Q_{ri}$  versus drainage area are developed for a number of sites

on the same river or within hydrologically similar portions of the same drainage basin as the ungauged location. If data are reasonably homogenous, power functions may be fit using regression and used to generate a flow duration curve for the ungauged location.

**9.3.1.4.2 Regionalized Duration Curve** A nondimensional flow duration curve is developed for a hydrologically similar gauged site by dividing discharge by  $Q_{bf}$  or  $Q_2$ . Then  $Q_2$  is computed for the ungauged site using the aforementioned regression equations. Finally the flow duration curve for the ungauged site is derived by multiplying the dimensionless flows ( $Q/Q_2$ ) from the nondimensional curve by the site  $Q_2$ .

**9.3.1.5 Checking Computed and Estimated Channel-Forming Discharges** The quantities  $Q_{eff}$ ,  $Q_{bf}$ , and  $Q_{ri}$  are all hypothetical estimates of  $Q_{cf}$ . Their equivalence to the theoretical single discharge that would produce the same channel geometry as the natural runoff sequence is based on observations and judgment. For this reason it is important that more than one estimator for the channel-forming discharge be considered. Computed effective and bank-full discharges outside the range between the 1- and 3-year recurrence intervals should be questioned. The computed effective and recurrence interval discharges should be compared with field evidence to ascertain if these discharges have geomorphic significance.

**9.3.1.6 A Range of Discharges** The quantities  $Q_{eff}$ ,  $Q_{bf}$ , and  $Q_{ri}$  provide single values for a design discharge. However, inspection of a natural channel reveals the inherent variability present in natural fluvial systems. Hence, in designing channels that are intended to replicate natural channel features, but also remain stable over long periods of time, it is important to establish an acceptable range of design discharges. In addition, channel flow resistance may change appreciably with discharge, producing major effects on stage, sediment transport, and channel stability. Acceptable discharge capacity ranges may also be needed to guide channel sizing. For example, to incorporate natural variability, specifications could allow a range of channel widths and depths. If  $Q_{bf}$  is used for design discharge, then an appropriate range of discharges should be selected based on the range of  $Q_{bf}$  observed in the reference reaches. If  $Q_{eff}$  is used as the design tool, then the range of discharges should correspond to the effective discharge increment.

After a preliminary design is prepared, channel stability checks (Fig. 9-1 and Section 9.6) may include simulation of sediment transport either for selected hydrologic events or a flow duration curve. This type of analysis will indicate if the channel will experience unacceptable levels of scour or deposition during discharges above and below the design flow.

The discussion above deals with selection of discharges for channel design. Other types of stream restoration design problems may require selection of different discharges. For example, structural or vegetative bank treatments may be

designed to withstand events with a certain probability of annual occurrence. Riparian vegetation may require limited periods of inundation during certain seasons. Riffles and other zones with coarse bed material may be designed to allow disturbance for removal of fines ("flushing") at a certain frequency (see Section 9.5.4).

### 9.3.2 Bed Material Size Distribution

A description of the bed material size distribution that is planned or anticipated under project conditions is needed for stability assessment and restoration design. Supplemental information will also be needed on bank material characteristics, particularly if banks are noncohesive. Information about the stream-bed and banks may be gathered at the same time using suitable sampling methods (cores, bulk samples, or layer samples, as appropriate) and sample processing techniques (sieving or sedimentation tests, as appropriate) for the sizes of material present. Although the bed material and bank material sizes may be visually estimated for rough preliminary estimates, careful sampling is required for quantitative analyses.

Bed material is characteristically heterogeneous. Bed material sampling techniques should vary with the bed type and the purpose for sampling. For example, floodplain boring may be needed to determine bed sediment size when a new channel is to be excavated. In other cases, bed material may be sampled from the existing channel or from a reference reach that serves as a restoration template. The resulting data may be used for sediment transport and channel stability computations, habitat assessment, or design of habitat features (e.g., flow regimes for periodically flushing coarse beds; stability of aquatic habitat structures).

Bed material sampling should provide estimates of representative sizes as well as information regarding spatial variability in the channel. Coarse beds pose greater difficulties than sand beds. Techniques applicable to coarse-bed rivers have been described by Bunte and Abt (2001), whereas techniques for sands and smaller materials are described by USACE (1995), and Ferguson and Paola (1997). If a coarse bed is rarely mobilized, then a surface hand-sampling technique (e.g., a Wolman (1954) pebble-count procedure) may be sufficient. If sediment transport is expected at a coarse bed, then sieve analysis of bulk sample is needed to include smaller subsurface particles. Relationships between gradations of bulk samples representing surface and subsurface sediments are presented by Parker (1990).

The median particle size,  $D_{50}$  (the size for which 50% of the bed material by weight is smaller), is the parameter most commonly used in sediment transport calculations. Less common descriptors include  $D_{90}$ ,  $D_{84}$ ,  $D_{75}$ ,  $D_{65}$ ,  $D_{35}$ , and  $D_{16}$  (for use in bed load, incipient motion, and flow resistance equations) and  $D_{60}$ ,  $D_{25}$  and  $D_{10}$  (e.g., to describe particle sorting). For some types of aquatic habitat work (e.g., habitats for fish that spawn in gravel) it is also important to know the proportion of particles finer than gravel (<2 mm) found

within the coarse matrix. Some streams have beds composed of mixtures of sand and larger sediments that have bimodal particle size distributions. Bimodality can also have a major impact on incipient motion and sediment transport (Chapter 2 of this volume and Wilcock 1998). Specific gravity of bed material can be quite important if it departs from standard values between 2.6 and 2.7.

Streamwise and lateral variations in bed material sizes occur along point bars, at lateral bars, and between pools and riffles, as well as for straight reaches with little thalweg variability. Bed particles near an eroding bank containing gravel or coarser materials are likely to be similar in size to the coarse component of bank material, rather than to upriver bed material. Therefore, if a restoration project for a coarse-bed stream emphasizes benthic habitats, it will be necessary to consider the spatial variability of bed material in detail. But if the restoration project emphasizes sediment transport and continuity of sediment supply from upstream to downstream reaches, the bed material size available for transport is of greatest interest.

Clearly, site-specific factors should be considered. Bed material along a mid-channel bar or other obvious depositional surface indicates the size of sediment transported by recent events. However, care should be taken that long-term stable morphologic features are not assumed to be representative of short-term channel dynamics. For example, channels with relict glacial outwash material often have riffles that are not mobilized by any but extreme events. Material in such features is not representative of normal bed material load.

## 9.4 STABILITY ASSESSMENT

### 9.4.1 Purpose and Scope

Stability assessment and analysis are a key aspect of planning and design for restoration of dynamic stream corridors. River channels are often perturbed by imbalances in watershed sediment supply, transport, or storage (Sear 1996) triggered by large floods (Stevens et al. 1975), channelization (Schumm et al. 1984; Simon 1989), upstream reservoirs (Simons and Senturk 1976), urbanization (Hammer 1972; Moscrip and Montgomery 1997), or other watershed land use changes. Using results of a system stability assessment, the project manager can select an appropriate level of effort for sedimentation engineering aspects of predesign assessment, design, and postproject monitoring. In addition, because habitat degradation is often related to erosion or sedimentation, stability assessment is needed to develop restoration alternatives. Furthermore, the restoration project may itself affect channel stability (Table 9-3), and this possibility must be evaluated during design. More detailed guidance for performing stream channel stability assessments is provided by the U.S. Army Corps of Engineers (USACE 1994) and by Lagasse et al. (2001). A template for geomorphic investigations is provided in Chapter 6 of this volume.

A stability assessment consists of examination of a selected part of the fluvial system encompassing the restoration project to determine the direction and speed of morphologic changes. The assessment provides a foundation for design and predictions of how the system will respond to the restoration project. Inadequate assessment may result in a restoration design that is obliterated by erosion or deposition within a short period of time, or one that degrades stream corridor resources or endangers floodplain assets. If possible, the dominant geomorphic processes influencing the channel and their root causes should be identified. Relative magnitudes are emphasized rather than quantification during assessment. The nature of the existing hydrologic response and the likelihood of future shifts in discharge and sediment load due to land use changes (e.g., urbanization or afforestation) should be considered. Existing instabilities in the channel system should be identified (Kondolf and Sale 1985; Kondolf 1990).

If significant sedimentation problems are identified, more detailed engineering analysis will be required during design. Stream channel performance includes both conveyance and geometric stability, especially as they relate to long-term maintenance. Stability impacts are generally determined by comparing bed-material sediment transport for existing and anticipated project conditions. The stability assessment also provides an inventory of available data and may include recommendations for additional data collection programs and more detailed studies.

The first step in conducting the stability assessment is to determine the spatial domain for the investigation. Usually, this area will coincide with the project boundaries identified in the sediment studies plan (Section 9.2).

The second step is to formulate a statement describing acceptable rates of morphologic change. Current and projected channel stability may be assessed relative to these levels. From a strictly pragmatic standpoint, a reach is unstable when morphologic change (i.e., erosion or deposition) is rapid enough to generate public concern (Brice 1982). From a more scientific perspective, a stream is unstable only if it exhibits abrupt, episodic, or progressive changes in location, geometry, gradient, or pattern because of changes in water or sediment inputs or outputs (Rhoads 1995; Thorne et al. 1996b). In other words, a stream may be highly dynamic but considered geomorphically stable (i.e., in a state of dynamic equilibrium, Section 9.1.2.2) if its long-term temporal average properties (channel width and sediment input and output) are stationary. Such a stream may have relatively rapid rates of lateral migration and thus bank retreat. Thus the statement defining acceptable rates of change should provide a clear rationale.

The scale of observed instabilities should also be considered in setting criteria. Short segments of channels may be locally stable or unstable due to structures, vegetation, or geological conditions, but the reach or watershed that surrounds them may exhibit different patterns. For example,

reaches upstream of headcuts in incising channel networks are often quite stable, but downstream zones are extremely disturbed (Simon 1989). If headcuts migrate upstream, stable reaches may quickly shift to unstable. Local flow constrictions (e.g., bridge crossings) may produce serious local scour in an otherwise stable stream. An assessment should differentiate between local, reach, and systemwide instabilities. Clearly, systemic instability is most serious and is usually not amenable to purely local treatment. Spatial patterns of channel form and process are best understood when stability assessment results are placed on a watershed map or within a geographic information system.

## 9.4.2 Types of Stability Assessments

**9.4.2.1 Qualitative Stability Assessments** Qualitative assessments are simple efforts requiring less than 1 week of effort for one person, and consist mostly of visual inspection. This type of assessment can be powerful when performed by someone with a high level of expertise. Large areas can be inspected from low-flying aircraft, with follow-up on the ground. On-the-ground reconnaissance should include the project reach and adjoining upstream and downstream reaches. Spatial trends in channel conditions should be examined. If the downstream reach is degrading, it is possible that disturbance could move upstream into the project reach in the form of a headcut or knickzone. Instability upstream could increase sediment supply to the project reach.

Qualitative assessments should also include a review of the available information regarding the geological and physiographic setting for the project, as well as its temporal context. The engineer should develop a timeline or table showing major disturbances (e.g., large floods, avulsions, dam closure, channelization, deforestation) affecting the project reach. Review of historic maps and air photo coverage can be a powerful tool (Rhoads and Urban 1997). Sear (1996) provides an excellent overview of factors to be considered in qualitative stability assessments for river restoration projects. Additional guides are provided by Biedenharn et al. (1998) and USACE (1995, Appendix E).

**9.4.2.2 Quantitative Stability Assessments** Quantitative assessments vary in methodology, but have in common the collation of numerical data about the study area from a variety of sources to describe channel geometry, bed sediments, hydrology, and land use in the past and present. Five types of tools are commonly used in stability assessment: (1) Lane relations, (2) channel classification, (3) hydraulic geometry relationships, (4) relationships between sediment transport and hydraulic variables, and (5) bank stability. All five are easily misused, so professional judgment is required. These tools are discussed in the following section, and comments are made regarding tool selection.

### 9.4.3 Tools for Stability Assessment

**9.4.3.1 Lane Relations** The first group of tools is based on the Lane (1955a) relationship (also due to Gilbert 1914), which states that stream power is proportional to the product of sediment discharge ( $Q_s$ ) and bed material size ( $D_s$ ) in an alluvial stream in a state of dynamic equilibrium:

$$Q_w S \sim Q_s D_s$$

Note that  $Q_w S$ , the product of water discharge ( $Q_w$ ) and stream gradient ( $S$ ) is a reduced form of stream power, dimensionally corresponding to power per unit weight of fluid per unit length of channel. In this relationship and the others that follow the water discharge of interest is a fluvially significant (e.g., channel-forming) discharge. Other investigators have combined the original proportionality with others (e.g.,  $H$  = flow depth,  $B$  = channel width) to form a set of relationships useful for characterizing fluvial behavior:

$$S \sim BD_{50} / Q_w \quad (9-1)$$

$$B/H \sim Q_w Q_s \quad (9-2)$$

$$\text{Channel sinuosity} \sim 1/Q_s \quad (9-3)$$

Many other workers (e.g., Schumm 1969; Nunnally 1985; Sear 1996; Hooke 1997) have extended these relationships to predict fluvial response to disturbance. In the following relations, a superscript of + indicates increase, 0 indicates no change, - indicates decrease, and  $\pm$  indicates unpredictable shifts.

Increase of water discharge, for example, diversion of water into a reach:

$$Q_s^0 Q_w^+ \sim S^-, D_{50}^+, H^+, B^+ \quad (9-4)$$

Decrease of water discharge, for example, extraction of water from a reach resulting in a narrower channel:

$$Q_s^0 Q_w^- \sim S^+, D_{50}^-, H^-, B^- \quad (9-5)$$

Increased sediment supply, for example due to hydraulic mining:

$$Q_s^+ Q_w^0 \sim S^+, D_{50}^-, H^-, B^- \quad (9-6)$$

Decrease in bed material load as water discharge increases, for example in later stages of urbanization as paved area increases:

$$Q_s^- Q_w^+ \sim S^-, D_{50}^+, H^+, B^\pm \quad (9-7)$$

Decrease in bed material load and water discharge, following dam construction, for example:

$$Q_s^- Q_w^- \sim S^\pm, D_{50}^\pm, H^\pm, B^- \quad (9-8)$$

Bed material and water discharge both increase, but water discharge increases more. For example, in long-term urbanization, the frequency and magnitude of discharge increase, triggering channel erosion (increasing width and depth):

$$Q_s^+ Q_w^{++} \sim S^-, D_{50}^+, H^+, B^+ \quad (9-9)$$

Sediment supply and water discharge both increase, but sediment supply increases more. For example, when forest is converted to row crop production, gravel beds tend to change to sand, and channels become wider and shallower:

$$Q_s^{++} Q_w^+ \sim S^+, D_{50}^-, H^-, B^+ \quad (9-10)$$

Use of these and similar relations for stability assessment is discussed in standard texts (e.g., Chang 1988; USACE 1995, Appendix D). The engineer should be aware of important limitations:

- Anticipated adjustments may not occur because the system is currently responding to prior disturbance. Accordingly, a review of watershed history for events creating channel system disturbance is an important part of stability assessment.
- The channel system may not comply with the relation because it is not free to adjust. For example, the bed may contain bedrock controls that limit changes in slope, or bed material may not become coarser because gravel and cobble are not available for transport or because fine sediment contributions from eroding banks and tributaries overwhelm main channel processes. Slope is governed by channel pattern (straight, braided, meandering, etc.), but channel pattern changes are very difficult to predict and may be governed by discontinuous (threshold) relations rather than continuous relationships.
- Lane-type relations do not explicitly allow for complex response (Schumm 1977), in which fluvial systems exhibit unsteady, complex behaviors (e.g., a period of channel scour followed by aggradation or long lags in system response) in response to a single external influence.
- Lane-type relations allow prediction of the direction of a change, but not its magnitude.

Despite these limitations, the Lane-relation approach may be quite powerful when the history of disturbance is known. For example, a straightened stream experiencing accelerated bed and bank erosion may be responding to the increased

slope by increasing sediment load (e.g., Parker and Andres 1976).

The discharge-slope product  $QS$  that forms the left side of the Lane relation is one representation of stream power. Various workers have noted that stream channel pattern (straight, meandering, or braided) is reflective of the balance between stream power and sediment grain size. A review of the numerous resultant equations for planform prediction is provided by Thorne (1997). These relations may be useful in stability assessment, because systems that are near the threshold between meandering and braided may respond strongly to restoration actions. Further, the engineer should avoid designing a channel with a slope that is too small or too great for the selected planform. One of the more recent contributions is by van den Berg (1995), who proposes a relationship based on “potential” stream power, which is computed using the valley slope rather than the channel slope. A data set representing observations from 228 streams was used to produce a formula defining the threshold between single-thread meandering rivers with sinuosities greater than 1.5 and less-sinuuous braided rivers:

$$\omega_{vt} = 843 D_{50}^{0.41} \quad (9-11)$$

where

$\omega_{vt}$  = the specific stream power at the transition between meandering and braided planforms in  $W\ m^{-2}$ .

Specific stream power, or stream power per unit bed area, is defined by

$$\omega_v = CS_v Q_{bf}^{0.5} \quad (9-12)$$

where

$C = 2.1$  for sand-bed rivers and  $3.3$  for gravel-bed rivers, and

$S_v$  = valley (not channel) slope.

Channel width, which appears in the conventional definition of unit stream power ( $\omega = \gamma Q S/B$ , power per unit bed area), does not appear in the relationship because it is assumed to be a function of  $Q_{bf}$ . Streams with values of specific stream power greater than the threshold will braid, whereas those with lower values will meander, as shown in Fig. 9-5. Limits for the function are  $Q_{bf} > 10\ m^3\ s^{-1}$  and  $0.1\ mm < D_{50} < 100\ mm$ . Dade (2000) produced a more qualitative planform discriminator based on channel slope, median bed material size, and discharge.

**9.4.3.2 Channel Classification** Channel classification is a primarily qualitative approach for stability analysis in which the engineer divides the channel network in the study area into reaches and assigns each channel reach to a class or type based on visual inspection or measurement of key variables (Chapter 6). The quantity and quality of regional

**Fig. 9-5.** Planform prediction diagram developed by van den Berg (1995) after Thorne (1997).

experience of the engineer is the key determinant of the quality of channel stability assessment based upon qualitative reconnaissance. Ideally, results from reconnaissance should be verified using tools that examine recent trends such as specific gauge analyses, comparison of thalweg profiles, and comparison of channel width, depth, and bed elevation depicted on successive surveys of several cross sections through time (USACE 1994; Biedenharn et al. 1998). Examination of historical photographs (aerial and ground) and maps and interviews with landowners and other observers can also be particularly valuable.

Results of inspection and salient data can be recorded on a form for each reach and entered into a GIS or mapping software for synoptic visualization of ongoing processes throughout the system. It is critical to view results of classifications within the context of the entire watershed, because changes and modifications within a reach may be propagated through the system. Systemwide trends should be clearly identified. Presentation of classification results in map format can be extremely useful for communication with funding agencies or local landowners involved with or impacted by channel modifications.

Classification schemes generally fall into two broad groups, descriptive and process-based. Among the former is the scheme proposed by Rosgen (1994, 1996). Using this scheme, a reach can be assigned an alphanumeric taxonomic code based on its appearance and rough estimates of channel dimensions. For instance, a channel classified as “C4” is a single-thread meandering gravel-bed channel with a width-to-depth ratio greater than 1.4 and a slope less than 0.02, whereas a “D3” channel is a braided cobble-bed channel with a width-to-depth ratio greater than 40 and a slope less

than 0.02. Codes in this classification scheme range from A1 to G6 and ostensibly cover all river conditions. The widespread adoption of the Rosgen method is an indicator of its ease of use. However, simple descriptive classifications do not allow the user to infer what processes control channel form and future response. The Rosgen method has drawn severe criticism for its use beyond description and communication (Miller and Ritter 1996; Doyle and Harbor 2000).

In contrast to descriptive schemes, process-based classifications can be used as preliminary indicators of channel stability. However, because these schemes describe processes in addition to form, they require more expertise to use. In particular, process-based schemes require the user to relate processes occurring at the watershed scale to the reach of interest. For example, Schumm (1977) proposed placing of components of a fluvial system in one of three classes based on their current dominant geomorphic function: sediment sources, sediment transportation zones, or sediment sinks, and a similar approach was proposed by Montgomery (1999). Thorne et al. (1996b) suggested that all channels are either unstable (active morphological changes), dynamically stable (no characteristic change over engineering time scales), or "moribund" (unable to alter morphology due to the presence of geologic or engineering controls on geometry or discharge).

A specific example of application of the Schumm approach to disturbed fluvial systems involves the use of conceptual channel evolution models (CEMs) (Harvey and Watson 1986; Simon 1989). Though essentially qualitative, CEMs are powerful tools because they link channel forms to key geomorphic processes in a rational way that allows post-and prediction. However, their use is limited to channel systems experiencing adjustment by channel incision. Typically real-world watersheds do not follow the CEM models perfectly, but the absence of a distinct longitudinal progression in channel stages indicates that instabilities are the result of local phenomena rather than systemwide instability. In other words, classification systems can be used to indicate channel stability either directly or indirectly.

Simon and Downs (1995) and Thorne et al. (1996b) provide rough guidelines on inspecting key sites throughout a channel network in a given watershed to assess channel stability via reach classification. Inspection includes visually assessing key parameters such as bed material types, channel morphology, and bank stability. Measurements such as channel width and depth, thickness of sediment deposits, and bank height and angle may also be collected. Inspection of a single reach (6–12 channel widths long) can be done by an experienced person in 1 to 1.5 h (Simon and Downs 1995). These inspections should be conducted at key sites throughout the watershed. Selection of reaches to inspect is critical—sites must form a sufficiently dense network, and additional attention must be paid to the most dynamic reaches. Local influence of bridge crossings should be avoided by inspecting reaches several hundred meters upstream from, rather than at, bridges.

Johnson et al. (1999) reviewed and synthesized rapid stream channel stability assessment tools developed by Pfankuch (1978), the Federal Highway Administration (FHA 1995), and the previously noted work of Simon and Downs (1995) and Thorne et al. (1996b). A key component of the Johnson procedure is computation of the ratio of average boundary shear stress to critical shear stress. In gravel-bed rivers, as a rule of thumb, bed motion begins when this shear stress ratio exceeds 1. When the ratio exceeds about 2, most of the bed is in motion, and when it exceeds 3, the entire bed is in motion. However, Parker and Klingeman (1982) noted that bed shear stresses in gravel-bed streams rarely exceed more than two or three times the critical value even during severe floods. The Johnson procedure is not limited to use in watersheds experiencing incision, and it results in a qualitative stability rating (excellent, good, fair, or poor) rather than a CEM stage. The effort and experience required to use this assessment method are similar to that for the other methods. However, estimates of average boundary shear stress and critical shear stress are required, and the effort required to generate these estimates varies widely based upon the availability of existing data, the size of bed sediments, and the confidence level required. Average boundary shear stress should be computed for a range of discharges bounding the effective or design discharge. Johnson et al. (1999) suggest computing critical shear stress using the Shields (1936) equation,

$$\tau_c = \theta(\gamma_s - \gamma_w)D_{\text{critical}} \quad (9-13)$$

where

$\theta$  = dimensionless critical shear stress (Shields constant);

$\tau_c$  = critical shear stress for movement of material of size  $D_{\text{critical}}$ ; and

$\gamma_s$  and  $\gamma_w$  = specific weights for water and sediment.

Modification of  $\tau_c$  for the effects of sediment mixtures when bed sediments are mixtures of sand and gravel may be in order. Critical shear  $\tau_c$  may also be modified for the effect of gravity on bank slopes, if banks are comprised of granular, noncohesive sediments. See Chapter 2 in this volume for a full discussion of the Shields constant. A useful compilation of reported values for  $\theta$  is provided by Buffington and Montgomery (1997). A compilation of data from natural rivers showed that  $\theta$  exhibits modal values of approximately 10, 1, and 0.04 for rivers characterized by suspended-load, mixed-load, and bed-load regimes (Dade and Friend 1998).

In using this (Johnson et al. 1999) method, as well as other assessment methods, the user should bear in mind the conditions and purposes of the original tool. The Johnson method was developed specifically for road crossing stability and may require some modification for reach stability assessment. In particular, some of the indicators do not necessarily distinguish between local instability and natural channel processes

(Doyle et al. 2000). Both Johnson et al. (1999) and Pfankuch (1978) equate channel stability with channel uniformity, associating local erosion caused by flow obstructions like woody debris with channel instability. Although such features may be causes of instability at road crossings, they are common in natural channels and are critical for maintaining aquatic habitat and overall fluvial system stability. Hence, the method provides an estimate of stability, but each case should be treated individually due to local effects and inherent variability between sites.

**9.4.3.3 Hydraulic Geometry Relationships** The third type of stability assessment tool involves application of hydraulic geometry relations, which are empirical formulas that predict channel width, depth, slope, etc. as a function of a characteristic discharge,  $Q_{cf}$ ,  $Q_{bf}$ ,  $Q_{eff}$ , or  $Q_{ri}$ . Use of hydraulic geometry relations for restoration planning (Allen et al. 1994) and channel design (e.g., Shields 1996) is discussed elsewhere; here we focus on their use for stability assessment. These relationships are sometimes referred to as “downstream” hydraulic geometry formulas to differentiate them from formulas that describe how flow width and depth change at a given location as discharge increases (“at-a-station” formulas) (Leopold and Maddock 1953; Dunne and Leopold 1978). Surrogates for discharge, such as contributing drainage area, have been used in modified versions of these formulas, although this may introduce additional error. Hydraulic geometry relationships have also been applied to other dependent variables such as depth, slope, and velocity. Hydraulic geometry relations are sometimes stratified according to bed material size or other factors.

Hydraulic geometry relations can be developed for a specific river or watershed, or for streams with similar physiographic characteristics. River reaches that are judged to be in a state of dynamic equilibrium are selected for data collection. Use of field indicators rather than gauge data to determine channel-forming discharge is usually unwise (Williams 1978). Data scatter about the developed curves is expected even in the same river reach. The more dissimilar the stream and watershed characteristics are, the greater the expected data scatter. So-called “regional curves” would be expected to have data scatter across a full log cycle. It is important to recognize that this scatter represents a valid range of stable channel configurations due to variables such as geology, vegetation, land use, sediment load and gradation, and runoff characteristics. The composition of banks is very important in the determination of stable channel width. It has been shown that the percentage of cohesive material (Schumm 1977) and the type and amount of bank vegetation (Hey and Thorne 1986; Trimble 1997) significantly affect channel width.

The departure of a reach from a relationship based on data from adjacent lightly disturbed watersheds may be diagnostic of instability. For example, in their assessment of the Blackwater River in England, Thorne et al. (1996b) found that mean width and depth were 47% and 42% larger, and mean velocity 233% smaller, respectively, than values predicted using applicable hydraulic geometry relationships (Hey and

Thorne 1986). Although the computed stream power was 57% greater than predicted using the Hey and Thorne (1986) relationship, it remained low ( $\sim 13 \text{ W m}^{-2}$ ) relative to unstable, eroding channels in the United Kingdom and Denmark ( $\geq 35 \text{ W m}^{-2}$ ) (Brookes 1990). In contrast, meander wavelength and arc length were only 12% and 20% larger, respectively, than predicted. Using this information and the results of a qualitative reconnaissance of a larger area, they concluded that the reach in question had been enlarged, but not straightened. The reach was assessed to be geomorphically active, but recovering its natural size only slowly due to low stream power and limited sediment availability. This case study highlights the importance of professional judgment and field observations in interpreting results of stability analysis.

Hydraulic geometry formulas are easily and widely misused in river restoration. Like all empirical regressions, they are limited in their predictive capacity to the domain of independent variables used in their derivation. Extrapolation of formulas developed using data from England to the western United States or from the Rocky Mountains to the eastern seaboard leads to erroneous results. For example, Rinaldi and Johnson (1997) found that meander geometry equations developed by Leopold and Wolman (1960) overpredicted meander dimensions for small streams in central Maryland by average factors of 2.67, 2.22, and 2.48 for meander wavelength, amplitude, and radius of curvature, respectively. Because hydraulic geometry formulas are continuous, deterministic functions free of time dependence, they overlook threshold behaviors, indeterminacy (equifinality), and long-term dynamism, which are common in many fluvial systems (Schumm 1977). Analytical tools (discussed below) coupled with modern geomorphic analyses are required for more reliable assessments.

**9.4.3.4 Relationships between Sediment Transport and Hydraulic Variables** The fourth and largest suite of tools used in stability assessment are various types of relationships between sediment transport and hydraulic variables. These may be applied at the watershed level, or at a particular cross section.

**9.4.3.4.1 Slope-Drainage Area Relations** Data from reconnaissance surveys (described above) may be used to develop relationships between channel slope and channel-forming discharge for channel reaches 1 to 10 km long. Discharge is plotted against slope for each reach, and points are classified as representatives of stable or unstable reaches. Stability classification is based on subjective interpretation of field indicators of stability (Thorne et al. 1996a; 1996b), successive surveys and aerial photos, and specific gauge analyses. If discharge information is lacking, channel slope is plotted against contributing drainage area, and specific gauge analyses are omitted. For example, field reconnaissance and evaluation of the Yalobusha River Watershed, Mississippi, indicated that stable reaches could be plotted close to a line defined by

$$S = 0.0028A^{-0.433} \quad (9.14)$$

**Fig. 9-6.** Example of channel bed slope-drainage area relation used for reach stability assessment. Solid line represents the power function shown on the plot, which was obtained from regression of data from stable reaches (Simon and Thomas 2002). Unstable reaches generally plot above the line.

where

$S$  = slope of the energy gradient and

$A$  = upstream drainage area in  $\text{km}^2$

(Simon and Thomas 2002, Fig. 9-6). Steeper reaches tended to be unstable.

**9.4.3.4.2 Stream Power** Outputs from one-dimensional hydraulic models may be used to compute stream power or average boundary shear stress, and these values may be compared to those developed for nearby stable reaches. For example, the product of mean velocity and shear stress at channel-forming discharge, which is one form of the stream power per unit bed area, may be used as a criterion for stability in stream restoration projects (Brookes 1990). Unit stream power data are plotted as squares, triangles, and circles for initially straightened channels that were restored by meander reconstruction in Fig. 9-7. Based on experience with several restoration projects in Denmark and the United Kingdom with sandy banks, beds of glacial outwash sands, and a rather limited range of  $Q_{\text{bf}}$  ( $\sim 0.4$ – $2 \text{ m}^3 \text{ s}^{-1}$ ); a unit stream power value of  $35 \text{ W m}^{-2}$  discriminated well between stable and unstable re-meandered channels. Projects with unit stream powers less than about  $15 \text{ W m}^{-2}$  failed through deposition, whereas those with unit stream powers greater than about  $50 \text{ W m}^{-2}$  failed through erosion.

Because these criteria are based on observation of a limited number of sites in specific geographical areas and with small bed sediment sizes, application to different situations (e.g., cobble-bed rivers) should be avoided. However, similar criteria may be developed for basins of interest. For example, data points representing stable reaches in the Coldwater River watershed of northwestern Mississippi are shown in Fig. 9-7

**Fig. 9-7.** Stream power stability criteria (Brookes 1990). Squares, triangles, and circles represent straightened, re-meandered channels in Denmark and the United Kingdom with sandy banks and beds of glacial outwash sands. Stars represent stable reaches in the Coldwater River watershed of northwestern Mississippi. This watershed is characterized by incised, straight (channelized) sand-bed channels with cohesive banks. Slopes for stable reaches shown were measured in the field, and channel-forming discharges were assumed equal to  $Q_{2\text{yr}}$ , computed using a watershed model (HEC-1) (USACE 1993).

as x's. This watershed is characterized by incised straight (channelized) sand-bed channels with cohesive banks. Slopes for stable reaches shown were measured in the field, and 2-year discharges were computed using a watershed model (HEC-1) (USACE 1993). Downs (1995) developed stability criteria for channel reaches in the Thames Basin of the United Kingdom based entirely on slope: channels straightened during the twentieth century were depositional if slopes were less than 0.005, and erosional if slopes were greater.

**9.4.3.4.3 Incipient Motion** Fundamental principles regarding incipient motion of sediments on channel bed and banks are presented in Chapter 2 in this volume. Incipient motion analyses offer a quick check of bed stability in channels with beds coarser than sand (Pemberton and Lara 1984). These approaches indicate whether or not the bed will move when subjected to certain hydraulic conditions, but do not directly tell anything about channel stability. For example, shear stress may exceed the level needed to move a representative particle size, but because there is a supply of sediments from upstream, bed elevation may remain stable or even aggrade. Use of incipient motion relationships is further complicated by the fact that there is no true threshold condition where all the particles of a given size begin to move. Most critical shear stress relationships were developed by extrapolation of sediment transport rate versus shear stress curves to zero transport. This process results in critical shear stresses

**Fig. 9-8.** Allowable mean shear stress for channels with boundaries of noncohesive material smaller than 5 mm carrying negligible bed-material load (after Lane 1955b in USDA 1977). “Allowable” stresses may be tolerated without causing serious erosion or endangering channel stability. Average shear stress may be adjusted for trapezoidal channel side slopes and width-depth ratio. Details are provided by Chang (1988) and USDA (1977). Values are for straight channels, and should be reduced approximately 10%, 25%, and 40% for slightly, moderately, and very sinuous channels, respectively.

that may be significantly higher than those at which sediment actually begins to move (Gessler 1971; Paintal 1971).

Some incipient motion relations indicate that critical bed size in mm is about 20 times the average velocity in  $\text{m s}^{-1}$  or about 10,000 times the product of depth in meters and slope. Typically, the median grain size,  $D_{50}$ , is used for the critical bed size in assessing the stability of a particular slope-width-depth-discharge combination (Pemberton and Lara 1984). A guideline used by the U.S. Department of Agriculture (USDA 1977) is shown in Fig. 9-8. It should be noted that the curves in Fig. 9-8 were drawn based on observations from straight canals, which have much more steady, uniform flows than most natural streams. In addition, the original source (Lane 1955b) for these curves states that “where much sand is carried, this method of analysis is not applicable,” and “for crooked canals, lower values [of critical shear stress] must be used.”

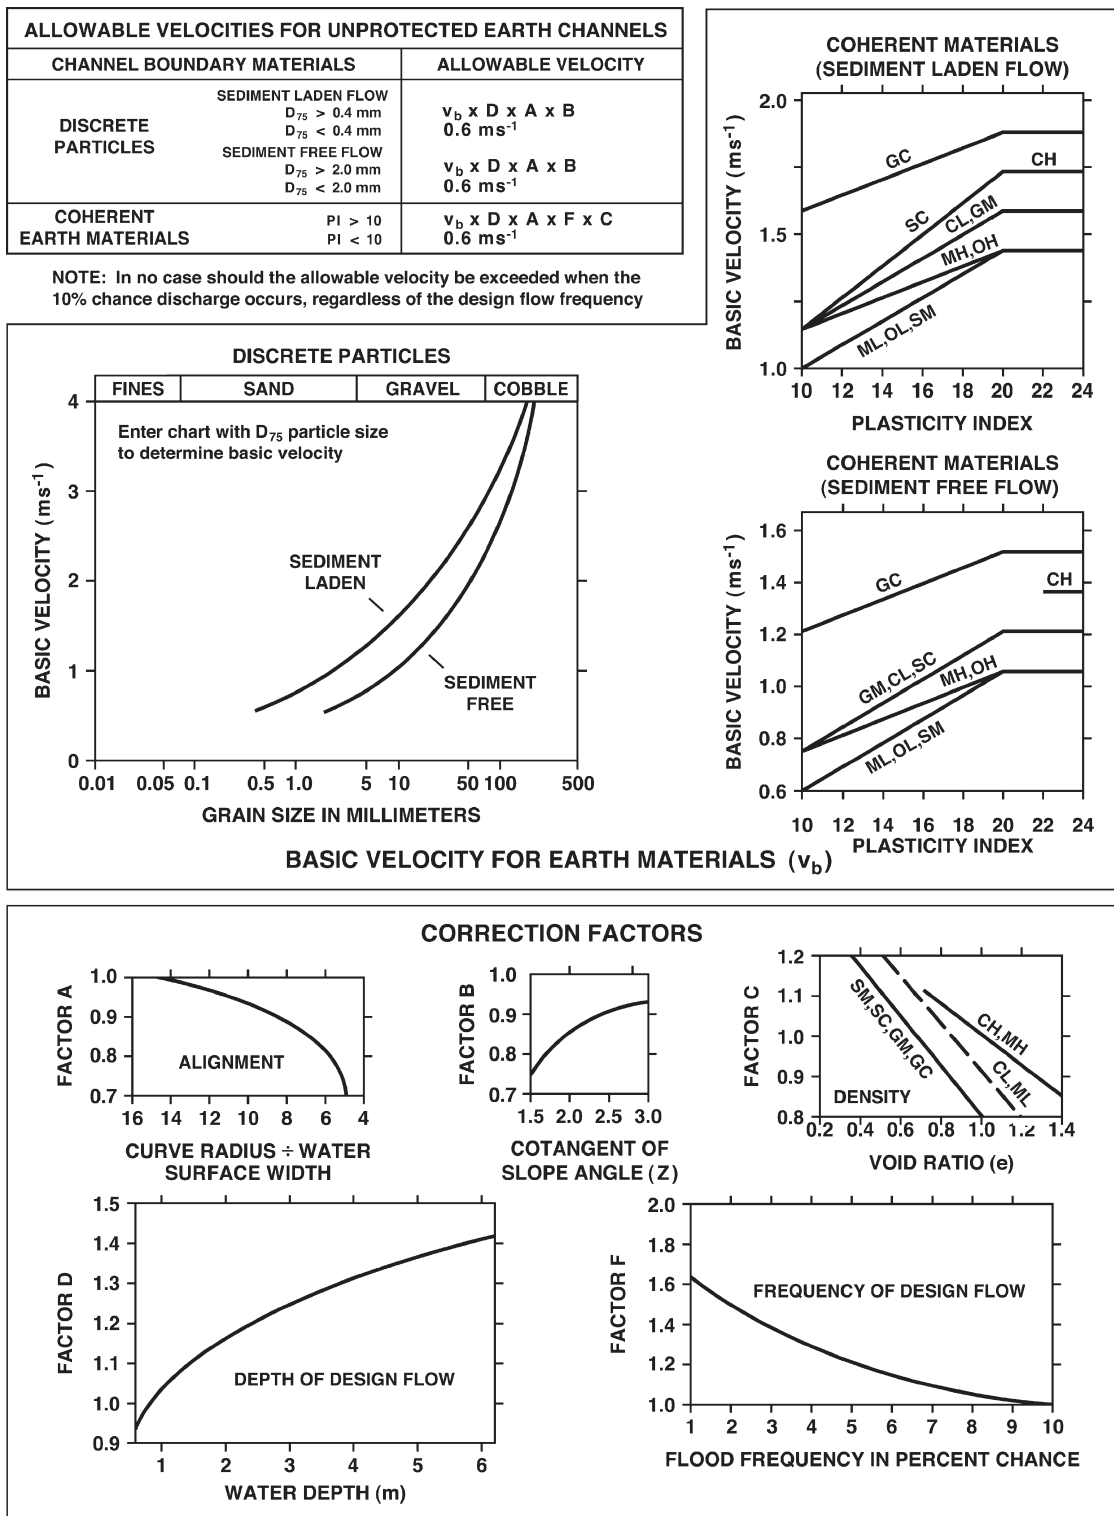

A list of five procedures useful for gravel or cobble beds is presented in Table 9-6. These five relationships predict a critical sediment size of 20 to 31 mm for a hypothetical example where  $Q = 14.2 \text{ m}^3 \text{ s}^{-1}$ , channel width = 18.3 m, mean depth = 1.2 m, mean velocity =  $1.0 \text{ m s}^{-1}$ , slope = 0.0021,  $D_{90} = 34 \text{ mm}$ , and Manning  $n$  based on bed material size = 0.03 (Pemberton and Lara 1984). Typically, the engineer computes the bed material sizes that are at the threshold of motion for the upper and lower bounds of the discharge range of interest, but the relationships in Table 9-6 may also be solved for slope or discharge given the other variables.

The relationships in Table 9-6 involve varying amounts of theory and empiricism, and the engineer should be familiar with the underlying assumptions before interpreting their results. However, for ease of use we have omitted the details and simply reduced the equations to simplest form to yield

**Table 9-6 Incipient Motion Stability Checks for Coarse, Noncohesive Beds Solved for Critical Bed Material Size,  $D_{\text{critical}}$  (from Pemberton and Lara 1984)**

Basic relationship	$D_{\text{critical}}$ (mm)	Remarks	Source
$D_{\text{critical}} = 20.2 V_m^2$	$20.2 V_m^2$	Based on assumption that velocity near bed is $0.7 V_m$ .	Mavis and Laushey (1949)
$V_m / V_f = 2.05$	$21.6 V_m^2 (D_{\text{critical}} > 2 \text{ mm})$	$V_f$ is the terminal fall velocity, approximated by the settling velocity formula of Rubey (1933)	Yang (1973)
$\tau_c = \gamma_w HS$	$13,000 HS (D_{\text{critical}} > 6 \text{ mm})$	Fig. 9-8 gives range of values for $\tau_c$	Lane (1955b)
$\theta = \tau_c / [(\gamma_s - \gamma_w) D_{\text{crit}}]$	$10,000 HS (D_{\text{critical}} > 1 \text{ mm})$	Assumes Shields constant = 0.06	Shields (1936)
$D_{\text{crit}} = HS / [0.058 (n_s / D_{90}^{1/6})^{3/2}]$	$17.2 HS D_{90}^{0.25} n_s^{-1.5}$	Reduces to form similar to Lane and Shields when Strickler equation is used for $n_s$	Meyer-Peter and Muller (1948)

Note:  $V_m$  = mean velocity,  $V_f$  = terminal fall velocity.

**Fig. 9-9.** USDA (1977) allowable-velocity charts for “unprotected earth channels.” “Allowable velocities” are the maximum cross-sectional average flow velocities that do not cause serious boundary erosion. Allowable velocity for a given channel is determined using the formula in the box at the top left. The basic velocity,  $v_b$ , is given by one of the group of three plots at the top of the figure, whereas correction factors A, B, C, D, and F are obtained from the five plots in the bottom group. The letters PI = plasticity index, and the abbreviations GC, SC, CH, CL, GM, MH, OH, ML, OL, SM, etc. refer to the type of boundary as classified using the Unified Soil Classification System.

**Table 9-7 Suggested Maximum Permissible Mean Channel Velocities (after USACE 1991)**

Channel material	Mean channel velocity $\text{m s}^{-1}$
Fine sand	0.6
Coarse sand	1.0
Fine gravel <sup>a</sup>	2.0
Earth	
Sandy silt	0.6
Silt clay	1.0
Clay	2.0
Grass-lined earth <sup>b</sup>	
Bermuda grass	
Sandy silt	2.0
Silt clay	2.0
Kentucky blue grass	
Sandy silt	2.0
Silt clay	2.0
Poor rock (usually sedimentary)	3.0
Soft sandstone	2.0
Soft shale	1.0
Good rock (usually igneous or hard metamorphic)	6.0

<sup>a</sup>For particles larger than about 20 mm.

<sup>b</sup>For slopes less than 5%. Keep velocities less than  $1.5 \text{ m s}^{-1}$  unless good cover and proper maintenance can be obtained.

bed material size in mm. It is important to note that incipient motion analyses are invalid for sand channels or gravel beds in motion at the discharge of interest because they presume zero transport of the critical bed size at the selected discharge.

Incipient motion approaches based on velocity rather than shear stress are also available. Because channels with identical average velocities can experience different bed shear stresses, correction factors for variation in flow depth, sediment load, channel curvature, and so forth have been developed (USDA 1977). A series of charts for determining allowable velocity is presented in Fig. 9-9, and a commonly used set of values based on experience is presented in Table 9-7. The allowable-velocity approach is not recommended for channels transporting a significant load of material larger than 1 mm.

**9.4.3.4.4 Silt and Clay Beds** For beds finer than sand, few tools exist and much uncertainty arises due to the complexity of cohesive bed erosion. However, the preceding discussion regarding critical values of stream power and slope

offers some guidance. Erosion of cohesive materials is affected by water quality, by material history (weathering and saturation), and by macroscale phenomena (e.g., zones of weakness between cohesive blocks). A review is provided in Chapter 4 of this volume. Current research emphasizes the importance of positive and negative pore water pressure in cohesive beds (Simon and Collison 2001) and banks (Simon et al. 2000). A field test for measuring cohesive bed erodibility is available, but many replications are required to characterize a channel reach, because of local variations (Hanson and Simon 2001).

At present, most guidance for stability of cohesive material is based on scattered observations. Neill (1973, in Pemberton and Lara 1984) published competent velocities for erosion of cohesive materials ranging from  $0.6$  to  $1.8 \text{ m s}^{-1}$  for flow depth of  $1.5 \text{ m}$ , and  $0.8$  to  $2.6 \text{ m s}^{-1}$  for flow depth of  $15 \text{ m}$ . Fortier and Scobey (1926, in French 1985) suggested a maximum permissible mean velocity of  $1.1 \text{ m s}^{-1}$  for alluvial silts and stiff clay and a value of  $1.8 \text{ m s}^{-1}$  for shales and hardpans. These values correspond to mean bed shear stresses of  $12$  and  $32 \text{ N m}^{-2}$ , respectively. Values are

**Fig. 9-10.** Allowable shear stresses for cohesive materials based on conversion by Chow (1959) of permissible velocities published by “The maximum” (1936) to boundary shear stresses. “Allowable” stresses may be tolerated without causing serious erosion or endangering channel stability. Curves represent the maximum allowable boundary shear stress for cohesive soils with void ratios as given on the x-axis and soil properties shown on the curve labels. Values are for straight channels, and should be reduced approximately 10%, 25%, and 40% for slightly, moderately, and very sinuous channels, respectively.

for “straight channels of small slope after aging” and depths of flow less than 0.9 m. The Fortier and Scobey values should be reduced 25% for sinuous channels, increased by  $0.15 \text{ m s}^{-1}$  when depth exceeds 0.9 m, and increased 0.3 to  $0.6 \text{ m s}^{-1}$  for streams carrying high sediment loads (French 1985). Data presented by Chow (1959) regarding allowable shear stresses for cohesive materials are shown in Fig. 9-10, and additional empirical data are presented by Julien (1995). Empirical data such as those shown in Fig. 9-10 should be used with extreme caution, because they represent a limited data set and do not allow for inclusion of macroscale phenomena that may be most important.

**9.4.3.4.5 Sediment Budgets** Sediment budgets for channel reaches are at the upper end of a continuous scale of complexity and effort for stability assessments, and at the lower end of the scale for design. The purpose of a sediment budget analysis is to determine if a specific channel reach has the capacity to transport the sediment load delivered to it by upstream channels. If significant differences are found between the inflowing sediment rating curve and a rating curve for the specific channel reach, then a condition of channel instability has been identified. Detailed computations must necessarily be postponed until the design stage, because project dimensions and boundaries may not yet be known. Nevertheless, assumed channel properties may be used to good effect within the bounds of normal sediment transport relationship accuracy. Sediment budgets are discussed in greater detail in Section 9.6.2.2.

**9.4.3.5 Bank Stability** Streambank erosion may be classified as fluvial erosion of material from a bank face (generally analyzed using incipient motion approaches described above) or collapse of large masses of bank material. These masses are removed from the bank toe (“basal cleanout”), resteeptening the bank profile and creating conditions conducive to another failure. Mass failure of steep, cohesive banks is related to bank height, bank angle, and soil properties (Simon et al. 2000). If bank heights are greater than about 3 m and angles greater than about  $45^\circ$ , a stability analysis may allow assessment of the severity of bank instability and the need for remedial measures. A stability chart may be prepared for a given set of bank soil properties, as described by Thorne (1999). Software packages may prove helpful in simulating effects of stage and groundwater table fluctuations on banks of various height and angle (e.g., Simon et al. 2000; 2003). If bank soil properties are not known, a tabulation of stable and unstable bank heights derived from the watershed qualitative reconnaissance may prove helpful, particularly when coupled with forecasts of future channel degradation or aggradation.

#### 9.4.4 Assessment Tool Selection

Normally a stability assessment proceeds by dividing the channel network into reaches displaying consistent fluvial properties and applying a set of assessment tools to each reach. A greatly simplified example is provided in Table 9-8.

**Table 9-8 Summary of Simplified Hypothetical Stability Assessment**

Assessment tool	Reach				Value required for stability	Reference
	1	2	3	4		
Bed slope from a slope-drainage area relationship <sup>a</sup>	0.002	0.00018	0.0022	0.0024	0.0006–0.0008	Simon and Thomas (2002)
Unit stream power, $\text{W m}^{-2}$	29	43	33	52	$<35$	Brookes (1990)
Potential specific unit stream power, $\text{W m}^{-2\text{b}}$	24	32	38	45	$\leq 30$ for meandering planform	Van den Berg (1995)
Channel evolution model	Stage V	Stage V	Stage IV	Stage II	Stage V or VI	Simon (1989), reconnaissance per Thorne et al. (1996b)
Average bed shear stress, $\text{N m}^{-2}$	24	26	30	29	20–25 <sup>c</sup>	Regional observations
Height of near-vertical banks, m	5.1	4.7	4.3	2.2	3.8	Bank stability analysis per Thorne (1999) and Simon et al. (2003)

Note: Consensus of assessment indicates incision (and instability) is proceeding upstream through reach 3 to reach 4. Reaches 1 and 2 are slightly aggradational, but accelerated lateral channel migration likely continues there.

<sup>a</sup> $S = 0.0028 A^{-0.33}$ .

<sup>b</sup> $2.1 S_v Q_{br}^{0.5} < 843 D_{50}^{0.41}$ .

<sup>c</sup>Larger than value based on incipient motion ( $12 \text{ N m}^{-2}$ ) due to significant bed material load.

Selection of a suite of tools for a particular project involves considerable judgment and is strongly influenced by the availability of existing data sets, the experience of responsible personnel, and economic factors. However, some generalizations can be made. Lane-type relations are good for quick preliminary assessments, particularly where system disturbance is dominated by a shift in one of the main variables. Process-based classification schemes are most highly developed for fluvial systems disturbed by influences leading to rapid incision or aggradation. Hydraulic geometry approaches are limited to projects located in regions with lightly perturbed alluvial channels in dynamic equilibrium for which extensive data sets are available. Incipient motion type analyses including Shields parameters are usually limited to channels with beds dominated by material coarser than sand, whereas sediment budgets are best for sand-bed streams prone to aggradation. Cohesive boundary channels are most difficult to analyze, and empirical tools such as slope-area relations, regional stream power indices, or shear stress thresholds are often applied. Channels with cohesive banks higher than about 3 m usually call for some type of bank stability analysis.

## 9.5 RIVER RESTORATION DESIGN

Following stability assessment, the restoration project enters the design phase (Fig. 9-1). Although not shown in Fig. 9-1, preliminary analyses may be performed for several alternatives, and detailed design may be reserved for subsequent iterations using the selected alternative. The complexity of design studies should be related to project scale, but an understanding of likely impacts on sediment transport and channel morphology is needed for all restoration projects. Techniques used for design borrow principles from the engineering topics of stable channel design and channel stability analyses and the science of fluvial geomorphology (Chapter 6).

The adaptive, dynamic quality of river systems gives them a certain capacity for recovery (self-restoration). Some stream ecosystems may respond more favorably to assisted recovery (e.g., creating conditions that allow natural revegetation of riparian zones) than strategies featuring aggressive intervention. Generally, strategies that involve the greatest structural modification hold potential for the greatest project-induced adverse environmental impacts, but may prove most beneficial in the long run. Reconstruction of a meandering or braided channel with appropriate width, depth, bed texture, and sinuosity may be necessary to restore a drastically altered stream.

### 9.5.1 Channel Design

**9.5.1.1 Channel Design for Restoration Projects** If the existing stream is stable (Thorne et al. 1996b), a good

rule of thumb is to modify the channel as little as possible. However, in some cases it may be necessary to modify a stable channel to meet overall project objectives (e.g., restoring some of the functional attributes of the ecosystem). When the existing stream is unstable, significant intervention may be necessary for restoration. In reach-scale projects consideration should be given to isolating the restored reach from the disturbed channel (e.g., through the use of grade controls or sediment traps).

Analytical equations are preferred for design over empirical formulas. Many empirical relations (e.g., hydraulic geometry formulas) are based on limited, regional data sets, and the influence of variables that become important in application may be hidden. For example, a relationship between discharge and velocity based only on data from streams with engineered bank protection would not be applicable to a natural stream with unprotected banks. When design variables are related to a single independent variable such as discharge, the reliability of the relationship is limited.

**9.5.1.1.1 Acceptable Levels of Dynamism** Conventional flood control, navigation, and channel stabilization projects have focused on increasing the stability of channel position, geometry, and flow conditions. A premium has been placed on high levels of certainty regarding performance and fluvial response. In contrast, restoration projects often seek to enhance the dynamic behavior of fluvial systems, often by relaxing constraints when past activities have led to highly regulated flows or uniform, fixed boundaries. System restoration may involve restoration of processes such as flooding, meander migration, channel avulsion, formation and destruction of large woody debris jams, and backwater sedimentation. For example, high flows may be ecologically beneficial in a number of ways: flushing fine sediments from coarse deposits and thus maintaining conditions that allow intra-gravel movement of water and oxygen, recharging floodplain water tables, depositing nutrient-laden silt on floodplain lands, and temporarily creating extensive “lakes” and feeding areas for migratory waterfowl, fish, and other organisms. Removing or changing the operational strategy for flood control structures may restore high-flow regimes. Experiments by the U.S. Bureau of Reclamation in 1996 and 2004 that produced artificial floods of preset magnitude and duration on the Colorado River in the Grand Canyon downstream from Glen Canyon Dam provide an example of flood restoration. The artificial floods were designed to restore beaches, bars, and wildlife habitat impacted by decades of reservoir operation. Immediate results of the 1996 event showed that morphologic response occurred rapidly—changes were observed after only a few days of high flow (Vaselaar 1997; Schmidt et al. 1998), but longer-term outcomes were less satisfactory, driving plans for the second experiment (Pennisi 2004).

Restoring natural fluvial processes present challenges to engineers because it requires changing streams from

an understood present condition to an uncertain, more dynamic future situation. Human systems tend to call for stability, reliability, and predictability; natural systems tend to be dynamic and unpredictable. The reluctance to venture into unknown outcomes may be addressed in at least three ways:

- Incorporating new physical controls into project design. For example, if meandering processes are to be restored or enhanced, then meander belt boundaries could be established. These may be geologic controls, existing structural controls, or new structural controls installed either during project construction or at a later date if and when needed. Similarly, longitudinal limits for re-meandering (e.g., at bridges) might be established at existing or constructed controls such as drop structures.
- Developing the restoration project in stages. If each stage is well conceived and fits into the ultimate restoration condition, this allows the uncertainties to be reduced with each stage and the dynamism and instabilities to be somewhat restricted.
- Providing sediment sinks or sources as needed to maintain sediment continuity and channel stability. These measures will generally require costly operation or maintenance programs.

Restoring a channel to a state of dynamic equilibrium may not be a socially acceptable outcome if the resulting situation poses threats to riparian resources or infrastructure. The need for a relatively high level of channel stability is often a driving factor in urban settings, where tolerance for channel adjustments is low. Clearly, human factors may force design tradeoffs that lead to less than full restoration of channel dynamics and dependent ecosystem attributes. Although these tradeoffs were common in historical river engineering projects, they usually reduce the value of restoration projects. Regardless of strategy, the consequences for channel stability of design alternatives under various scenarios may be evaluated using approaches described in Section 9.6.

**9.5.1.1.2 Channel Reconstruction** Design analyses should attempt to ensure that the reconstructed channel is not rapidly damaged or destroyed by erosion or sedimentation. The approaches described in Sections 9.5.1.2 and 9.5.1.3 may be used to select the channel width, depth, and slope required for an acceptable level of stability given water and sediment inflows anticipated for the future with-project condition. However, it should be noted that the analytical approaches described in these sections are applicable only to fluvial systems that, given enough time, develop characteristic forms (equilibrium morphologies) in response to an unchanging hydrologic regime. Usually these are perennial, moderate-to-low-energy, single-thread, meandering streams. In these systems, channel width, depth, slope, and bed material grain size eventually adjust to the

channel-forming discharge and the input bed-material sediment load. The restoration designer seeks to assist this adjustment by computing and selecting appropriate values for channel geometry. When the computed channel geometry is not feasible due to site or project constraints, the resulting maintenance requirements (erosion controls or sediment removal requirements) may be computed. However, it is important to understand that many fluvial systems are not responsive to a channel-forming discharge of a given average frequency (see Section 9.3.1). Special analyses (Section 9.5.2) may be appropriate when hydraulic structures or habitat enhancement features will be used within the channel, in adjacent backwaters, or on the floodplain.

**9.5.1.1.3 Design Variables and Approaches** The engineer must select average channel width, depth, slope, and hydraulic roughness and lay out a planform so that the channel will pass the incoming sediment load without significant degradation or aggradation. These design variables are functions of the independent variables of water discharge, sediment inflow, and streambed and stream bank characteristics. In some cases, channel dimensions may be based on a preexisting condition, but this set of dimensions may not be stable if watershed land use or climate has changed. The design process is most challenging when the project reach is unstable due to straightening, channelization, or changing hydrologic or sediment inflow conditions, as is the case in most urban areas. The effects of urbanization on hydrologic response (e.g., increasing flow quantities and peaks) can trigger rapid bed and bank erosion, particularly when these effects are coupled with declining watershed sediment yield as development proceeds.

Channel design approaches may be classified as threshold or active-bed methods. These approaches are discussed in the following sections. The engineer should select an approach based on boundary mobility at design discharge conditions (Fig. 9-1).

#### **9.5.1.2 Design Procedure for Threshold Channels**

##### **9.5.1.2.1 When to Use the Threshold Approach**

Threshold methods are appropriate in cases where bed-material inflow is negligible and the channel boundary is immobile even at high flows. For example, streambeds that are composed of very coarse material or that contain numerous bedrock controls may be immobile even during bank-full flows. Channels with bed material derived from events or processes not currently operative, such as glaciation, may also be candidates for threshold analyses. It should be noted, however, that unmodified channels generally transport significant quantities of material composing their boundaries. Because restoration projects usually are intended to promote natural processes and functions, use of threshold approaches is rarely appropriate. An example of an appropriate use of threshold methods is provided by Newbury and Gaboury (1993), who used tractive-force analysis to size stone used to construct permanent artificial spawning riffles in a channelized stream.

Threshold channels are designed so that a selected fraction of the bed material will be at the threshold of motion (see Section 2.4) at design discharge. Clearly, selection of the design bed material size is crucial. Guidance for sampling bed material is provided in Section 9.3.2. If fine material is moved as throughput over a pavement of coarser sediment, the pavement material should be used to determine the sediment size for design. However, an active-bed analysis may be necessary to ensure that the throughput transport rate is maintained. Threshold methods do not provide unique solutions for channel geometry, and geomorphic principles may be used to finalize selection of reasonable design variables.

#### 9.5.1.2.2 Allowable Velocity and Tractive Force

Threshold-of-motion channel design procedures have been widely used for many years (e.g., Lane 1955b). The allowable-velocity approach of USDA (1977) is reviewed in Section 9.4.3.4.3, and graphs are provided in Fig. 9-9. Allowable velocity values are based on experience and various observations. The tractive-force approach (also known as the tractive-stress approach) is a more scientific method based on an analysis of the forces acting on sediment particles on channel boundaries. The basic derivation of equations used in the tractive-force approach assumes that channel cross sections and slopes are uniform, beds are flat, and bed-material transport is negligible. These conditions are rarely found in nature, particularly in lightly degraded streams. Therefore this approach has limited applicability to restoration design.

**9.5.1.2.3 Step-by-Step Approach** Although design should include reiteration to refine values based on preliminary estimates, a threshold approach may proceed as follows:

- Determine design bed material gradation and water discharge as described above. Note that the use of  $Q_{\text{eff}}$  is inappropriate for most cases of threshold channel design, because the boundary of the channel will be immobile under design discharge conditions. The discharge selected for sizing a threshold channel should be less than the channel-forming discharge, which, by definition, “does the most work on the channel.” Accordingly, the discharge used for design will usually be  $Q_n$  or  $Q_{\text{bf}}$  and will be smaller than  $Q_{\text{eff}}$ , unless  $Q_{\text{eff}}$  is determined based on transport of sediments finer than the boundary materials.
- Use hydraulic geometry or regime formulas (see above) to compute a preliminary average flow width.
- Using the design bed material size gradation, estimate critical bed shear stress. The compilation of data presented by Buffington and Montgomery (1997) may prove helpful, because it includes many values from natural streams (as opposed to laboratory flumes) and extensive information regarding the collection and derivation of each value of dimensionless critical shear stress.

- Use bed material size, estimated channel sinuosity, bank vegetation, and flow depth to estimate a flow resistance coefficient. Normally resistance due to bars and bed forms will not be important in threshold channels flowing full, so formulas such as those proposed by Limerinos (1970) or Hey (1979) may be used to compute resistance coefficients. Bathurst (1997) provides a review of flow resistance equations and their proper application.
- Using the continuity equation and a uniform flow equation (e.g., Manning or Chezy), compute the average depth and bed slope needed to pass the design discharge. Sinuosity may be computed by dividing the valley slope by the bed slope. Adjustment of the flow resistance coefficient for sinuosity and reiteration may be required.

**9.5.1.2.4 Example** An example of a preliminary design developed using the above step-by-step process is provided in Table 9-9. The hydraulic geometry formula chosen for flow width corresponds to bank-full discharge in gravel-bed streams with armor layers and “5 to 50% tree and shrub cover” on the banks. A Shields constant of 0.042 was computed and used to define threshold conditions, but other approaches such as maximum permissible velocity or tractive stress could also be used. The value of the flow resistance coefficient (Darcy-Weisbach  $f$ ) computed using the formula by Hey (1979) was not modified to account for head losses due to bends, because bend losses would be a relatively small fraction of total loss in such a channel (Onishi et al. 1976). Bend losses are more important for channels with finer bed material and more pronounced bars and bed forms. Channel sinuosity, planform, and alignment were designed as described in Section 9.5.1.4.

**9.5.1.2.5 Refinements** Additional refinements to shear-stress-based threshold design approaches to allow for the effects of the angle of repose of noncohesive materials, channel side slopes, and bend flow are explained in textbooks (e.g., French 1985; Chang 1988; Julien 1995). For channels with bottom widths greater than twice the flow depth and with side slopes steeper than 1V:2H, the maximum boundary shear stress at a point on the bed or banks may be approximated by  $1.5 \gamma_w HS$  (Chang 1988). Information on the cross-sectional distribution of velocity and shear stress in bends is provided by the USACE (1991).

**9.5.1.3 Design Procedure for Active-Bed Channels** Active-bed approaches should be used for channels with beds that are mobilized during all high-flow events (at least several times a year). These systems are much more sensitive to relationships between channel geometry and sediment inflow than threshold channels, and design requires more attention. The method described here is applicable for hydraulic design of channels for single-thread streams with mobile beds. Design of braided channel networks is beyond the scope of this chapter. The active-bed design procedure is intended to produce a channel that will transport the sediment supplied to the reach from upstream. Selecting

**Table 9-9 Example of Preliminary Channel Design Using Threshold Approach**

Quantity	Relationship	Source	Value
Valley slope		Survey or topographic map	0.007
Downvalley distance, km		Survey or topographic map	1.5
D <sub>50</sub> of bed material, mm		Samples and sieve analysis	45
D <sub>84</sub> of bed material, mm		Samples and sieve analysis	60
Design discharge, m <sup>3</sup> s <sup>-1</sup>	Q <sub>1.5 yr</sub>	Flood-frequency curve	6.7
Width, B, m	2.73 Q <sup>0.5</sup>	Hey and Thorne (1986)	7.1
Shields constant, $\theta$	Appropriate value or relationship <sup>a</sup>	Buffington and Montgomery (1997)	0.042
Depth-slope product, RS, m <sup>b</sup>	1.65 D <sub>s</sub> $\theta$		0.0031
Variation in depth at a section	R/H <sub>max</sub>	Assumed based on reference reach	0.75
Channel shape coefficient, a	11.1 [R/H <sub>max</sub> ] <sup>-0.314</sup>	Hey (1979)	12.15
Darcy-Weisbach flow resistance coefficient, f <sup>c</sup>	$\frac{8}{\left[ 5.75 \log \left( \frac{aR}{3.5 D_{84}} \right) \right]^2}$	Hey (1979)	0.10
Hydraulic radius, R, m <sup>d</sup>	$\sqrt{\frac{fQ^2}{8gP^2(RS)}}$	Simultaneous solution of continuity and uniform flow equations for depth.	0.6
Bed slope, S	RS/R		0.005
Sinuosity	Valley slope/channel slope		1.3
Channel length, km	Sinuosity × downvalley distance		2.0

<sup>a</sup>Many of the relations tabulated by Buffington and Montgomery (1997) require an entire gradation curve for both surface (armor) and subsurface bed sediments.

<sup>b</sup>Assumes that average flow depth = hydraulic radius.

<sup>c</sup>Assume a trial value for R. Numerous other relationships are available. For example, the equation due to Limerinos (1970) leads to a Manning n of 0.032, which is equivalent to a Darcy-Weisbach f of 0.10.

<sup>d</sup>Assume wetted perimeter P = width, B. Check R computed with this formula against trial value assumed for computation of Darcy f. Iterate as needed.

channel geometry based on preexisting conditions or threshold approaches without regard to sediment continuity can produce channels that are competent to transport only a fraction of the supplied sediment (Shields 1997). Rapid sedimentation, instability, and high maintenance requirements may result.

The reader should note that the approach described below is based on one-dimensional models, and the highly three-dimensional nature of fluid motion in meanders, which is closely coupled with complex bed topography, is poorly represented. In most cases, two- and three-dimensional effects (e.g., bends) must be incorporated into design computations by professional judgment. The overall approach described

could be used with more sophisticated numerical models of flow and sediment movement, but input requirements are often prohibitive for application to smaller projects. Future advances in the state of the art of hydrodynamic modeling may address these issues.

**9.5.1.3.1 Width Determination** When channel width is not constrained by right-of-way limitations, design width may be determined using the analogy method, hydraulic geometry formulas, and analytical methods (in order of preference). Each is discussed briefly here.

**Analogy Method** The width may be set equal to the average of measured widths from a reference reach. The reference

reach must be in a state of dynamic equilibrium and have the same channel-forming discharge as the project reach. The reference reach may be in the project reach itself, upstream and/or downstream from the project reach, or in a physiographically similar watershed. Streambanks and streambeds in the project and reference reaches must be composed of similar material, and there should be no significant hydrologic, hydraulic, or sediment differences in the reaches.

**Hydraulic Geometry** Hydraulic geometry formulas (described in Section 9.4.3.3) for width generally display less scatter (residual error) than those for depth or slope. Appropriate formulas, wisely applied, can therefore be used to generate initial values for reach-average channel width.

**Analytical Methods** If a reliable width versus channel-forming discharge relationship cannot be determined from field data, or if there is significant sediment transport, analytical methods may be employed to obtain a range of feasible solutions, as described below.

**9.5.1.3.2 Average Slope and Depth** Depth and slope should be calculated using analytical techniques. Analytical techniques are based on physical laws and limited empiricism, and therefore are preferred to empirical hydraulic geometry relationships. In addition to depth and slope, analytical methods may also be used to calculate width in lieu of an empirical method. The design variables of width, slope, and depth may be calculated from the independent variables of water discharge, sediment inflow, and bed-material composition. Three equations are required for a unique solution of the three dependent variables. Flow resistance and sediment transport equations are readily available. Several investigators propose using the extremal hypothesis to supply the third equation (Chang 1980; White et al. 1982; Millar and Quick 1993). However, extensive field experience demonstrates that channels can be stable with widths, depths, and slopes different from extremal conditions.

The stable-channel design routine in the hydraulic design software SAM (Copeland 1994; Thomas et al. 1995; "SAM Hydraulic" 2005) and also found within HEC-RAS 3.1 and higher may be used to determine channel depth and slope. This method is based on a typical trapezoidal cross section and assumes steady uniform flow. The method is especially applicable to small streams because it accounts for sediment transport, bed form and grain roughness, and bank roughness. The first step in using an analytical method for channel dimensions is to determine the sediment inflow into the project reach. SAM requires that the user either provide the bed material discharge input to the design reach or specify the discharge, channel geometry, and bed sediment size for a "supply reach" upstream from the design reach. SAM computes sediment discharge for the supply reach assuming that it is transporting bed material at full capacity. Supply reach computations are important in restoration projects, because restoration almost never extends to the upper limits of disturbance. Therefore the

**Fig. 9-11.** Stable channel design chart showing family of solutions yielding a stable channel for a given design discharge.

designer must develop features (such as sediment traps) that allow a transition from the sediment supply typical of the disturbance regime to the regime provided by the restored reach. Many urban areas are built on alluvial fans or other aggradational features with channels supplied by relatively steep headwaters. Historically, the downstream reaches maintained equilibrium by periodically avulsing. However, once floodplains are developed, such channel changes are typically prevented, thus exacerbating channel aggradation (personal communication, D. Simons).

The second step in active-bed analytical channel design is to develop a family of slope-width solutions that satisfy the resistance and sediment transport equations. For each combination of slope and base width, a unique value of depth is calculated. The engineer may select any appropriate flow resistance and sediment transport relations to generate the family of slope-width solutions. Shiono et al. (1999) present a simple equation useful for computing flow resistance of a two-stage channel with a meandering low-flow channel, but the equation is based on data from a physical model with uniformly smooth floodplains and main channel. The stable channel design routine in SAM uses either resistance and sediment transport equations by Brownlie (1981; 1983) or a combination of the Meyer-Peter and Muller (1948) sediment transport equation and the Limerinos (1970) resistance equation to calculate bed resistance and sediment transport. The routine may also be used to assess the stability of an existing channel.

An example stability curve is shown in Fig. 9-11. Any combination of slope and base width from this curve will be stable for the prescribed stable channel design discharge. Using the width from a hydraulic geometry predictor or from a reference reach, a unique slope and depth are determined. Width could also be obtained from the minimum slope. Other possible stable channel width and slope combinations can be found from the stability curve. Depth is specified by

a given slope and width (or width by a given slope and depth). Constraints on this wide range of solutions may result from a maximum possible slope or a width constraint due to right-of-way. Maximum allowable depth could also be a constraint. With constraints, the range of solutions is reduced. Combinations of width, depth, and slope above the stability curve will result in degradation, and combinations below the curve will result in aggradation. The greater the distance from the curve, the more severe the instability will be. The relationship between sediment transport in the restoration project reach and in downstream reaches must also be investigated. The same general discussion applies, except that the restoration reach becomes the sediment supply reach and the downstream reach is evaluated for an imbalance between bed material transport capacity and sediment supply.

**9.5.1.3.3 Example** A preliminary design for a hypothetical channel reconstruction for rehabilitation of a sand-bed stream in an urban area with actively eroding banks was developed using the process described above (Table 9-10). Reaches upstream and downstream from the project are relatively stable, except for a few bend locations where bank failure is occurring.

The effective discharge was found by developing a flow-duration curve using data from a downstream gauge. The flow-duration curve was then integrated with a sediment-discharge-rating curve calculated using the Brownlie (1981) equation and channel geometry upstream from the project reach. An hydraulic geometry formula was developed for flow width using appropriate regional data (Table 9-10). Use of the inflowing sediment load to solve for depth and slope ensures that the restoration design will be competent to transport the supplied load.

**9.5.1.4 Design of Channel Alignment and Geometric Detail** Designing the reconstructed channel alignment involves selecting a channel right-of-way that produces appropriate bed slope and, for single-thread meandering channels, meander geometry. Procedures are similar for threshold and active-bed channel designs. In some cases, preexisting channel alignments determined from maps, aerial photos, or soil surveys may be used if the resulting channel slope is adequate. Channel alignment may be designed by arranging a curve of fixed length (=channel length) on a map of the site. The channel length is simply the down-valley distance times the reach sinuosity, which is the ratio of valley slope to channel slope. Reach sinuosity may be

**Table 9-10 Example of Preliminary Channel Design Using Active-Bed Approach**

Quantity	Relationship	Source	Value
Valley slope		Survey or topographic map	0.001
Downvalley distance, km		Survey or topographic map	10
Median bed material size, mm		Samples and sieve analysis	0.6
$D_{84}$ of bed material, mm		Samples and sieve analysis	1.0
Design discharge, $\text{m}^3 \text{s}^{-1}$		Effective discharge analysis	68
Sediment load at design discharge, $\text{kg s}^{-1}$	Sediment transport equation and channel geometry from upstream reach	Brownlie (1981)	25
Channel side slope		Assumed	1V:1.5H
Manning n value for side slopes		Estimated	0.05
Top width B, m	$3.6Q^{0.5}$	Developed from stable reaches within watershed	30
Depth, m and bed slope	Simultaneous solution of sediment transport and uniform flow equations	Brownlie (1983) for bed resistance	2.4 (depth) 0.00061 (slope)
	Bed resistance composited with assumed Manning n-value for side slopes	Equal-velocity approach (Chow 1959) for compositing	
Sinuosity	Valley slope/channel slope		1.6
Channel length, km	Sinuosity $\times$ downvalley distance		16

checked against values for reference reaches in nearby, similar watersheds.

Meander wavelengths resulting from channel right-of-way layout may be checked against values obtained from hydraulic geometry formulas (e.g., Leopold et al. 1964; Ackers and Charlton 1970) or analytical functions (Langbein and Leopold 1966), but care should be taken to ensure that the data sets used to generate the formulas are from geomorphically similar regions and streams (Rinaldi and Johnson 1997). In general, hydraulic geometry formulas that give wavelength as a function of width are preferred. Uniform geometries (e.g., constant bend length and radius) should not be used. Values derived from formulas may be taken as averages, but bend-to-bend variation should occur. Constant dimensions for channel width, depth, slope, and meander radius and wavelength should not be used for design. Instead, design should capture the spatial variability typical of lightly degraded systems. For example, meandering channels tend to be wider and shallower at riffles, which are often found at meander inflection points, and narrower and deeper at bend apices (Richards 1978; Hey and Thorne 1986). The dimensions computed as described in Sections 9.5.12 and 9.5.1.3 should be used only as averages. Excavation and fill are generally less effective than flow constriction and expansion in producing and maintaining bed features such as pools and riffles. Well-designed projects will develop higher levels of physical heterogeneity with time as vegetation develops, bed material is sorted, large woody debris is trapped, and patterns of local scour and deposition replace uniform dimensions with those typical of natural, lightly degraded streams. Physical response tends to be most favorable for sinuous channels.

As an example, the design outlined in Table 9-10 has a valley slope of 0.001 and a channel slope of 0.00061. Thus a channel sinuosity of 1.6 is feasible. Using a hydraulic geometry formula ( $L = 61.21 Q_{bf}^{0.467}$ ) curve for meander wavelength (Ackers and Charlton 1970), an approximate meander wavelength of 439 m was selected. Using GIS or mapping software, a mildly sinuous planform channel of fixed length was laid out on a digital topographic map of the project reach.

## 9.5.2 Habitat Structures

In addition to varying channel geometry, additional physical heterogeneity may be introduced into a reconstructed channel by constructing various types of in-channel habitat structures. Many river restoration projects consist entirely of placing habitat structures and planting riparian vegetation. In some cases, structures are intended to control erosion and enhance habitat (e.g., Shields et al. 1995a). Some workers have questioned the philosophy of using structures to restore habitat, reasoning that if natural fluvial forms and processes are restored, artificial structural elements will be unnecessary or even detrimental. In all types of aquatic habitat planning and design, it is best to

let natural processes guide choices for actions. Wherever natural conditions can be used to advantage, the actions are likely to become most compatible with the habitat needs in the ecosystem. Structures not in harmony with the geomorphic processes controlling channel form and physical aquatic habitat are at best a waste of resources, and may damage the stream corridor ecosystem. Conversely, when watershed and riparian conditions are restored to predisturbance status, there is generally little need for habitat structure (except to produce rapid change, which may be desired by stakeholders).

Many types of structural measures have been used for in-channel aquatic habitat improvement, but most fall into four categories (Shields 1983): sills, deflectors, random rocks, and covers. An overview of these categories is provided in Table 9-11. Some structures are essentially erosion control structures (e.g., irregularly shaped revetments and intermittently spaced spur dikes), whereas others are designed to cause bed or bank erosion. Materials used for construction may be natural or artificial, but materials occurring naturally in the stream corridor prior to degradation are preferred.

**9.5.2.1 Design of Habitat Structures** The design of aquatic habitat structures is a combination of hydraulic engineering concepts and experience. Care should be used to ensure that structures do not induce unwanted erosion or sedimentation that adversely impacts riparian structures. Shields (1983) provides a review of several habitat structure design case studies. Additional case studies of use of deflectors (Shields et al. 1995a) and sills (Shields et al. 1995b) in small sand- and gravel-bed streams are also available. Long-term case studies are provided by Thompson (2002b). Unfortunately, there have been many failures (Table 9-11). Gabion structures often fail because of poor anchorage or because abrasion from cobbles transported by large flows causes breaks in wire meshes and loss of fill material. Various structures have been damaged during floods by debris or by being moved out of position. Other structures have succeeded in providing the intended physical effects, but have not produced measurable biological responses. Given these difficulties, the designer must proceed with caution. A step-by-step approach is provided by Shields (1983) and FISRWG (1998). In addition to the design guides referenced in Table 9-11, information useful for designing large woody debris structures is given by Shields and Gippel (1995), Hilderbrand et al. (1998), D'Aoust and Millar (2000), and Shields et al. (2004).

**9.5.2.2 Spawning Gravel and Fish Passage** Habitat structures are used to provide pool habitat, cover, and overall physical heterogeneity in many types of stream ecosystems, but additional issues arise in streams that support gravel-spawners and migratory species.

**9.5.2.2.1 Spawning Gravel** Design of habitat measures to trap and hold gravel for fish spawning beds involves competing constraints: bed sediment stability is needed to protect eggs while incubating, but periodic sediment transport

**Table 9-11 Typical Characteristics of In-Channel Habitat Structures**

Structure type	Intended effects	Typical location	Materials	Common problems	Design guidance
Sills	Increase scour away from banks	Extending across channel from bank to bank	Stone, gabion, or log weirs with uniform, sloping, or notched crests	Flanking. Fish passage. Undermined by downstream scour hole. Erosion of crest. Abrasion and failure of gabion wire.	Klingeman et al. (1984). “Simple bed control structures,” in Biedenharn et al. (1998). Artificial riffles described by Newbury and Gaboury (1993)
Deflectors	Increase surface flow disturbance along banks; deflect flow away from banks	Along banks	Irregularly shaped revetments, intermittently spaced short spurs or groins, boulders, or root wads	Erosion of crest. Structure subsidence in fine-bed channels. Erosion of opposite bank. Scour holes too small. Covered by deposition.	Klingeman et al. (1984). “Dikes and retards,” in Biedenharn et al. (1998). Kuhnle et al. (1999b; 2002), Thompson (2002a)
		Extending out from river bank	Cabled (anchored) trees; longer spur dikes, groins, or jetties	Flanking.	
Random rocks	Induce scour, create zones of low velocity in wake	Isolated midchannel flow obstructions	Boulders, boulder clusters (groups), root wads, vanes, or sills detached from banks	Fall or roll into downstream scour hole.	
Covers	Little impact on flow or sediment; primarily intended to provide shade and hiding places	Along undercut banks	Lumber piers, trees, brush, rafts, and features that cause local turbulence and thus reduce water transparency	Habitat protected by cover may be eliminated by sedimentation.	

is needed to prevent fine sediment from depositing in the upper portions of the gravel matrix. Hydraulic analysis is required to select appropriate bed material gradations and flow regimes (Reiser et al. 1989; Reiser 1998; Wu and Chou 2003).

**9.5.2.2.2 Migratory Barrier Removal** Removal of passage blockages has been undertaken in many tributary streams in order to expand the range of habitat use for migratory fish. Blockages have also been removed on larger rivers, usually older dams or weirs or landslides that have blocked channels that once allowed fish to pass. A full discussion of the subject of dam removal is beyond the scope of this chapter (see HCSEE 2002), but recent studies have begun to document the physical (Doyle et al. 2003) and ecological (Stanley et al. 2002) changes associated with removing dams, and other studies provide specific guidance for dam decommissioning and removal (ASCE Task Committee 1997). Bedrock outcrops have been modified by drilling or blasting to carve steps or pools. Artificial structures have also been built to bypass blockages and older dams and weirs have been removed or rebuilt to provide passage. Large hydraulic structures have been constructed to allow fish passage past hydroelectric dams, and voluminous literature is available (e.g., Bell 1986; Jungwirth et al. 1998). Information is also available regarding fish passage over simple rock ramps or weirs (Harris et al. 1998).

### 9.5.3 Channel-Floodplain Connectivity

Past engineering activities have included placing stream-bank protection to control channel migration and constructing levees to eliminate floodplain inundation. These actions have often altered and degraded ecosystems. Because hydrologic interaction between the floodplain and channel is so ecologically important, reestablishment of floodplain functions is often a goal of river restoration projects.

**9.5.3.1 Floodplain Reconnection Issues** Floodplain reconnection may simply involve levee breaching to allow pastures or gravel pits to flood during high-water periods. More generally, reconnection is a major undertaking, particularly where extensive floodplain development has occurred. It involves full or partial restoration of large-scale flow and sediment transport conditions. It may be necessary to limit floodplain reconnection projects to elementary bank-line alterations that result in most of the water and all of the bed load remaining in the prerestoration channel and only minor diversions of water and suspended sediments. In other cases it may be possible to introduce major alterations that allow limited re-meandering between set-back levees or within a low-elevation floodplain.

Channel stability and flooding are primary concerns when floodplain reconnections are considered. Breaching or removing dikes and revetments may trigger channel destabilization. Hence, economic, physical, and environmental impacts of various levels of confinement of flow, sediment load, and meandering processes must be assessed. Hydrologic

conditions (river flows, floods, droughts) and physical space (channels, riparian zones, floodplains) are key elements for working with these concepts (Williamson et al. 1995a; 1995b; Bella et al. 1996).

**9.5.3.2 Longitudinal Variation in Floodplain Confinement** In projects where there is significant longitudinal variation in floodplain confinement, sediment transport continuity during high flows should be carefully considered. For example, when the project reach is located in a relatively broad valley just downstream from the mouth of a steep-walled canyon, deposition is likely in the project reach during flows that exceed bank-full in the project channel but remain confined to the upstream channel. A similar situation may occur in developed areas where the upstream floodplain has been encroached upon by levees. In such a situation, simulation of sediment transport for large single events or long-term flow records including such events will allow determination of the magnitude of the sediment transport imbalance. It may be necessary to increase the channel capacity in the project reach. Designs featuring excavation to lower berms or terraces, in order to increase the frequency of overbank flooding, may be especially vulnerable to aggradation in this type of situation (Fullerton and Baird 1999).

A contrasting situation occurs when the proposed restoration reach has incised, but upstream reaches have not. Because the incised channel is larger, high flows are generally confined to the channel, and sediment transport rates and erosive forces are elevated relative to the upstream reaches. Reestablishment of the hydraulic connectivity between the channel and floodplain is often desirable in such a situation. Two approaches are possible: the incised channel may be filled to preincision elevations, or a berm (an artificial floodplain) may be excavated along and adjacent to the incised channel (Shields et al. 1999). Filling may be done during construction or gradually by sedimentation in response to low weirs or roughness elements placed in the incised reach, thus accelerating natural incised channel evolution. Hydraulic and sediment transport analysis can assist in determining the most feasible approach and the appropriate geometry for the restored channel cross section. Impacts of incised channel filling on flooding may be important in some situations.

### 9.5.4 Channel Bottom Habitats

Sediment size and gradation are key aspects of riverine aquatic habitats. The ASCE Task Committee (1992) developed a bed-material-based stream-reach classification (Table 9-12) and reviewed literature dealing with biological functions of bed sediments within each stream type. Interstitial voids are an important component of habitat in gravel and cobble beds for some fish (e.g., salmonid reproduction) and many invertebrates. Some cobble- or gravel-bed streams are impaired due to deposition of fine sediments within the coarse matrix as a result of flow stabilization by

**Table 9-12 Bed-Material-Based Stream Reach Classification (after ASCE Task Committee 1992)**

Bed type	Particle size (mm)	Relative frequency of bed movement	Typical benthic macroinvertebrate density/diversity	Fish use of bed sediments
Boulder-cobble	$\geq 64$	Rare	High/high	Cover, spawning, feeding
Cobble-gravel	2–256	Rare to periodic	Moderate/moderate	Spawning, feeding
Sand	0.062–2	Continual	Low/low	Silt and clay bed deposits in off-channel backwaters are used for feeding
Fine material	$< 0.062$	Continual or rare	High/low	Feeding

upstream dams or sediment-producing watershed activities (Reiser 1998). Rehabilitation activities include control of sediment sources and techniques to mobilize the fine sediment trapped in the bed using mechanical flushing, scour-producing structures, and the release of “flushing flows” from upstream reservoirs. Design of a flushing flow regime requires considerable analysis (Reiser et al. 1989; Reiser 1998) to define flows adequate to winnow fines away from the matrix without destroying it.

### 9.5.5 Backwater Protection

River development activities have routinely led to closing secondary channels, sloughs, and other backwater zones (Gore and Shields 1995; Klingeman et al. 1998). They have been used for disposal of dredged or excavated material. In other cases they have been deepened to provide dock access or storage of vessels. Unaltered backwaters (e.g., secondary channels, sloughs, and floodplain lakes) support local ecosystems directly connected to the main channel on a continuous, perennial, or seasonal basis. For example, backwaters sustain organisms that would not otherwise survive or thrive in the stream because they provide low-velocity habitats and critical refuge zones, especially during floods. Because backwater areas are depositional zones, they are relatively transient features. Because many rivers have been stabilized, the creation of new backwaters by channel migration, avulsion and other processes has been slowed or eliminated. As a result, backwater habitats are declining along many rivers (ASCE Task Committee 1992). Backwater zones primarily receive suspended sediment through connecting channels that introduce flow from the mainstem or by flooding. During floods, coarse material may be swept into backwater channels from the tops of intervening bars. The mouths of connecting channels are susceptible to bed load deposition and eventual closure, thus degrading ecological and recreational values (Shields and Abt 1989).

True restoration would involve restoration of processes responsible for backwater creation (e.g., avulsions). Although this strategy is preferred, it is often not feasible, particularly along larger rivers. Instead, strategies intended to reverse or retard sedimentation in existing backwaters and to create new backwaters (e.g., dredging or excavation) are often pursued. Backwater projects include development of connecting channels and protection of existing backwaters using weirs, blocks, or river training structures. Effects of these measures may be short-lived without maintenance. Sedimentation in zones adjacent to river training dikes is complex, but appears to be inversely related to dike crest elevation relative to annual flood stage (Shields 1984 and 1995). Typical sediment transport calculations (e.g., one-dimensional models) may not replicate phenomena in the vicinity of channel margins where backwaters connect to the main channel. Backwater protection may require more elaborate sedimentation analyses (e.g., Barkdoll et al. 1999).

## 9.6 STABILITY CHECKS

Because of the uncertainties involved in channel design, a series of stability checks should be performed. Stability checks include simple approaches such as those discussed in Section 9.4 as well as more detailed analyses of bank stability and sediment transport capacity.

### 9.6.1 Bed and Bank Stability

Bank erosion is difficult to predict and simulate, and thus the outer banks of bends and other locations subjected to potentially erosive flows should be protected if the consequences of bank erosion are unacceptable. Mass failure of steep, cohesive banks is related to bank height, bank angle, and soil properties. Stability assessment analyses that incorporate

these variables are described in Thorne (1999) and numerical models (e.g., Simon et al. 2000; 2003) are available. In general, cohesive banks over 3 m high should be analyzed for slope stability. Because bank stability is sensitive to bank height, impacts of channel aggradation and degradation on bank stability should be considered. Bank protection of any type (vegetation or structure) is usually ineffective if bed erosion (degradation) is occurring. If the aim of the project is a partial return to a less disturbed stream condition, then usually some bank erosion is desirable because many ecosystems have key species that depend on habitats created by lateral channel migration.

Restoration projects often feature the use of vegetation to protect banks. A full discussion of vegetation for streambank protection is beyond the scope of this chapter, but engineers should bear in mind that bank erosion is often governed by erosion of the toe of the bank, which cannot be stabilized by vegetation in channels with perennial flow. With adequate structural toe protection, woody vegetation has been used to stabilize banks along channels experiencing mean velocities as great as  $2$  to  $3 \text{ m s}^{-1}$  (Nunnally and Sotir 1997). Limited information is available regarding critical levels of hydraulic loading for plant materials (e.g., Hoitsma and Payson 1998; Fischenich 2001). Newly constructed banks are more readily eroded than those that have become well vegetated, and may require protection with temporary measures such as biodegradable fabric during the period of plant establishment. The rate of the fabric degradation should be analyzed in tandem with the expected growth rate of the planted vegetation in order to ensure that the protection is not compromised through time. Miller and Skidmore (1998) describe a bank protection design featuring vegetation on the upper bank and toe protection with cobbles wrapped in a biodegradable fabric (coir). The fabric decays as plants become established, gradually leading to a well-vegetated, but deformable bank. Additional useful information regarding bed and bank stabilization is provided by Biedenharn et al. (1998), FISRWG (1998), and Gray and Sotir (1996), and science underpinning interactions between channels and vegetation is reviewed in Bennett and Simon (2004).

## 9.6.2 Sediment Budgets

A sediment budget is a tool for assessing the long-term stability of a restored reach and estimating maintenance requirements. Average annual bed-material yields of the design channel and either the existing channel (if it is stable) or the upstream reach (if the existing channel is unstable) are compared. Large differences in bed-material yields indicate potential channel instability. The level of confidence that can be assigned to the sediment budget is a function of the reliability of the available data. In many restoration projects, the absence of relevant flow data will require the

use of synthetic or extrapolated flow data, greatly reducing the confidence level.

**9.6.2.1 Tools** Effects of alternative designs with different reach-average widths, depths, and slopes on sediment continuity may be analyzed using spreadsheets, but the most reliable way to determine the long-term effects of changes in a complex mobile-bed channel system is to use a numerical model such as HEC-6 (e.g., Copeland 1986) or HEC-RAS, one-dimensional models based on a series of channel cross sections, which may vary in shape and are available at Hydrologic Engineering Center (2005). A simpler treatment is provided by SAM, which simulates steady, uniform flow at a single cross section. SAM is described in Section 9.5.1.3.2. The SAM approach is appropriate if longitudinal changes in cross-sectional shape and bed-material gradation are small, because it does not account for hydraulic sorting or bed armoring.

It should be noted that most numerical models suitable for design work do not simulate bank erosion, and few simulate washload transport or effects of unsteady flows. In addition, one- and two-dimensional models do not simulate flow phenomena that are three-dimensional. A full discussion of sediment transport models is provided in Chapters 14 and 15.

**9.6.2.2 Step-by-Step Approach** The following steps are recommended for conducting a sediment budget analysis:

- Calculate hydraulic parameters for a typical or average reach for a range of discharges. This range should extend from the average annual low flow to the peak of the design discharge. If restoration channel design is based on a single discharge value (e.g., the channel-forming discharge), sediment budget analysis for the entire range of discharges that will affect the stability of the project should be performed as a check on design.
- Select an appropriate sediment transport function for the study reach. This can be done by comparing calculated sediment transport to measured data, taking care to ensure that bed-material load is being compared. When no data are available, one may rely on experience with similar streams in choosing an equation.
- Calculate bed-material sediment transport rating curves for the existing channel in the project reach and upstream and downstream from the project reach. Sediment transport curves should also be calculated for the alternative project design channels. Pre- and post-project sediment transport rating curves should also be determined for tributaries that might be affected by the proposed design.
- Calculate bed-material yield for the existing and project channels using the flow duration sediment discharge rating curve method as described by USACE (1995, pp. 3-4 through 3-10). Average annual bed-material yield should be calculated using the flow duration curve. This provides an estimate of average annual deposition

or degradation. Performance of the project during a design flood event should be evaluated using the design flood hydrograph. If the project will affect the flow duration curve or the flood hydrograph, then this should be reflected in the analysis.

- Calculate trap efficiency by comparing the pre- and postproject bed-material yields. The reach trap efficiency,  $E$ , in percent is expressed by the equation

$$E = \frac{100(Y_{sin} - Y_{sout})}{Y_{sin}} \quad (9-15)$$

where

$Y_s$  = annual bed-material yield,

and subscripts “in” and “out” refer to inflow and outflow, respectively. Negative trap efficiency implies that bed material sediment will be eroded from the project reach. A positive value means that bed material sediment will be deposited in the project reach. Forecast stability is highest for trap efficiency of zero.

**9.6.2.3 Interpretation** Consider a reach that contains three-dimensional features and longitudinal differences that require repeated basic sediment transport calculations at successive cross sections along the length of the channel. Assuming that a reliable formula is used or that accurate field measurements are made, it is quite likely that bed-material yield at adjacent cross sections may be unequal. The engineer must resist the temptation to quickly dismiss differences in sediment transport at opposite ends of a reach as the product of formula limitations or measurement errors (or to immediately accept agreement in sediment transport at opposite ends of the reach). Local hydraulic conditions may well lead to local deposition or erosion. Hence the analysis must include consideration of spatial and temporal sources and sinks for sediment within the reach. Otherwise, a situation where sediment is placed into or removed from local storage may be treated as one where sediment merely passes through a reach. Given enough time or a large enough sediment transport event, the consequences could be surprising and damaging.

**9.6.2.4 Example** Using the example channel geometry described in Section 9.5.1.3.3 and Table 9-10, a new sediment-rating curve was developed and integrated with the flow duration curve to determine the effect of the new geometry on the sediment budget. By comparing the calculated annual design channel sediment transport with the bed-material yield from the supply reach, it was found that about 83% of the annual bed-material load would be transported through the reach. Higher levels of bed-material transport could be obtained by increasing the channel slope, but it was determined that decreasing sinuosity would adversely affect habitat quality. In order to retain sinuosity, the preliminary design planform was adopted for the final design, and plans for periodic sediment removal were included in the operation and maintenance plan.

## 9.7 IMPLEMENTATION AND CONSTRUCTION

In general, disturbance of a river and its riparian corridor should be minimized during construction. Standard practices for sediment and erosion control should be employed. These require design, careful installation, and repeated inspection and maintenance. Complicated projects may require sequenced measures, including site dewatering. Unexpected site conditions may require fit-in-field adjustments. Contingency plans should include scenarios involving extreme floods or droughts during and shortly after construction. Features involving live vegetation require special considerations for selecting, handling, installing, and caring for plant materials. FISRWG (1998) provides an introduction to these topics.

Projects involving only minor changes to channel systems with negligible sedimentation problems are good candidates for design-build contracts. In simple low-cost projects for which consequences of failure are acceptable, a low-level or conceptual design may be used with a higher-than-normal level of on-site construction oversight. With such conceptual designs, it is relatively easy to incorporate habitat variability and diversity, as adherence to specified dimensions may be relaxed. Detailed plans and specifications, which are necessary for complex projects, often feature strict adherence to design criteria, and the resulting habitat is too uniform. When possible, contract specifications should be written in terms of maximum and minimum values for key parameters (e.g., “channel top width shall be no less than 16 m and no greater than 18 m”), and because contractors will tend to employ the limit of tolerance to achieve lowest cost (e.g., a constant width = 16 m), construction oversight must be employed to provide suitable physical irregularity. Personnel assigned to oversee construction must have an understanding of fluvial systems and project objectives to effectively translate the design into reality.

## 9.8 MONITORING AND POSTCONSTRUCTION ADJUSTMENT

Fluvial system response to restoration projects cannot be precisely predicted, and dynamic watershed land use, extreme weather events, and changing project objectives add more uncertainty. Accordingly, project plans should provide for adaptive management after initial construction. Information from monitoring project performance is required for adaptive management decisions. Monitoring efforts are normally tightly constrained by economic factors. A standard suite of variables for monitoring includes stage, discharge, and sediment concentration and periodic determinations of bed material size and channel geometry. Evaluation of hydraulic performance may include determination of changes in flow resistance due to changes in bank and floodplain vegetation, bed material size, and channel planform. Because project objectives usually focus on

ecosystem response, it may be important to monitor water quality, biological populations, or social variables. Clearly, it is not possible to monitor every project fully. Even projects that have monitoring programs may produce little useful information if monitoring data are not combined into well-defined metrics reflective of overall system response. In addition, monitoring results must be disseminated so that future restoration projects are responsive to new knowledge gained. Feedback should be provided to project designers and to those charged with program management. Restoration projects should be viewed within a landscape context. Individual restoration projects should be viewed as staged components of overall, long-term ecosystem management schemes for the larger river system and watershed (Seal et al. 1999).

No simple rules exist for setting the length of a monitoring program, but several seasonal cycles should be included. Monitoring intensity may be greatest during the first two or three years, when greatest response is anticipated, and less frequent in subsequent years except after extreme events. The life cycles for key species should also be considered. The impact of physical habitat improvements on plant and animal communities may not become apparent rapidly. Vegetative growth and fluvial response take time. For example, it may take many years for riparian zone revegetation to supply large woody debris for instream recruitment. Furthermore, the physical recovery of degraded stream banks requires more time than is needed only for the recovery of plant community composition (Clary and Webster 1989). Similarly, structures may require high flows to produce the intended effects.

## 9.9 CONCLUSIONS

Stream restoration is a term often used to refer to stream corridor manipulation. True restoration, however, seeks to return the status of an ecosystem to a former, less degraded state with recovery of function and processes. Large-scale projects, though not always economically or socially feasible, offer the greatest potential for true restoration. All stream restoration projects require some level of sedimentation engineering to reduce the risk of undesirable outcomes. Often the basic task for the engineer is to formulate a sediment budget for the project and to determine how alternatives and various sequences of hydrologic events will impact the quantity and size of sediments within the reach. The outcome of this analysis provides a foundation for a projection of the sustainability of the project. Due to the unorthodox nature and relatively high level of uncertainty surrounding stream restoration projects, involvement of the sedimentation engineer should continue through the implementation phase, and a monitoring program should be included in project plans.

## ACKNOWLEDGMENTS

Meg Jonas, Bruce Rhoads, Peter Downs, and Darryl Simons read an earlier version of this paper and made many helpful comments, leading to substantial improvement. Chester Watson, Colin Thorne, Philip Soar, and David Biedenbarn provided useful insights in the discussion of channel-forming discharge. The authors also acknowledge contributions by other control and corresponding members of the Task Committee on River Restoration in the form of conference papers and oral discussions at committee meetings. Among these members are Rebecca Soileau, William Fullerton, Richard Hey, and Drew Baird.

## CHAPTER 10

### *Bridge Scour Evaluation*

*J. R. Richardson  
and E. V. Richardson*

#### 10.1 INTRODUCTION

Scour at highway bridges is the result of the erosive action of flowing water removing bed material from around the abutments and piers that support the bridge and erosion of stream bed and bank material which the bridge crosses. The latter results from stream migration and degradation. Both stream migration and degradation (stream instability) and scour at highway bridges can cause bridge failure.

Bridge failures cost millions of dollars each year as a result of both direct costs necessary to replace and restore bridges, and indirect costs related to disruption of transportation facilities. However, of even greater consequence is loss of life from bridge failures (Richardson et al. 1989). In the United States there are over 575,000 bridges in the National Bridge Inventory. These numbers include federal highway system, state, county, and city bridges. Approximately 84% of these bridges are over water. Erosion of the foundations of the bridges resulting from stream instability, long-term degradation, contraction scour, and local scour cause 60% of bridge failures. There have been 25 fatalities from bridge failures in the United States since 1987 (Richardson and Lagasse 1999).

Chang's study for the Federal Highway Administration (Chang 1973) indicated that about \$75 million was expended annually to repair flood damage to roads and bridges. Rhodes and Trent (1993) document that \$1.2 billion was expended for restoration of flood damaged highway facilities during the 1980s. They state that this amount is conservative because (1) they only include the amount funded by the U.S. government, which ranges from 75 to 100% of the total restoration costs, and (2) the funds were only for disasters that are very large and do not include the hundreds of smaller events that occur every year. These costs do not include the additional indirect costs to highway users for fuel and operating costs resulting from temporary closures and detours and to the

public for costs associated with higher tariffs, freight rates, additional labor costs, and time. Rhodes and Trent (1993) also demonstrate that the indirect cost (operating a vehicle over a detour and time lost traveling when a bridge fails) exceed by several times the direct cost of bridge replacement or repair.

Research efforts have developed a large body of knowledge on bridge scour, mostly from laboratory studies. This bridge scour research started in the early 1950s through Carl Izzard's efforts to have the U.S. Bureau of Public Roads (predecessor agency to the Federal Highway Administration) and the Iowa State Highway Department fund Emmett Laursen's research on bridge scour (Laursen and Toch 1956; Laursen 1958; 1960; 1963). However, field data and measurements of scour at bridges, which are necessary to better understand the problem of stream instability and scour and to evaluate analytical methods for scour prediction, are extremely limited. In addition, many of the problems of stream instability and bridge scour have not been studied in depth. Many analytical techniques are recommended for use simply because they are the best currently available, and are overly conservative. For example, many equations for determining local scour depths at bridge abutments use abutment and roadway approach length as a variable instead of the flow they intercept (Richardson and Richardson 1993; Richardson and Davis 2001). In the field case, this is a spurious correlation.

All material on the stream bed and banks at a bridge crossing will erode. It is just a matter of time. Some material, such as granite, may take hundreds of years. Whereas sand-bed streams will erode to the maximum depth of scour in hours. Sandstones, shales, and other sedimentary bed rock material do not erode in hours or days but will, over time, if subjected to the erosive force of water, erode to the extent that a bridge will be in danger unless the substructure is founded deep enough. Cohesive bed and bank material such as clays, silty clays, silts, and silty sand or material such as

glacial tills, which are cemented by chemical action or compression, will erode. The erosion of these materials is slower than that of sand-bed material, may take the erosive action of several major floods, but ultimately the scour hole will be equal to the depth with a noncohesive sand-bed material (Jackson et al. 1991; Briaud et al. 1999).

Scour at bridge crossings is a sediment transport process. Long-term degradation, contraction scour, and local scour at piers and abutments result from the fact that more sediment is removed from these areas than is transported into them. If there is no transport of bed material into the bridge crossing, *clear-water* scour exists. Transport of appreciable bed material into the crossing results in *live-bed* scour. In this latter case the transport of the bed material may limit scour depth. With clear-water scour the scour depths are limited by the critical velocity or critical shear stress of a dominant size in the bed material at the crossing.

Major floods tend to scour the material at a bridge crossing during the rising limb of the flood and refill the scour holes during the recession limb. Often the redeposited material in the scour hole is more easily eroded by subsequent floods. Postflood inspection of the bridge crossing may indicate that the material around the foundations is adequate when, in fact, the bridge is in jeopardy of failing during the next flood. This infilling also makes it difficult to obtain field measurements of scour depths because the measurements have to be made during a flood.

The magnitude of the scour depth depends on the flow variables of the stream (discharge, flow velocity and depth, angle of the flow to the bridge, etc.), bed and bank material characteristics (bed rock, alluvial or nonalluvial, cohesive or noncohesive, size distribution, etc.), and bridge characteristics (size and shape of the pier and abutments, elevation of the deck, etc.).

The magnitude of the flow variable depends on the selection of a design discharge. The design discharge selected for a bridge is based on the design life of the bridge, bridge importance, consequences of failure, etc. The design discharge for a divided highway with large average daily traffic (ADT) (interstate highway, autobahns, etc.) would be larger than that for a farm-to-market or logging road. Some engineers advocate a maximum possible flood for important bridges (Laursen 1998); others recommend risk analysis. Important bridges are those with large ADT, interstate highways, school bus and ambulance routes, etc.

For important highways the Federal Highway Administration in HEC 18 (Richardson and Davis 2001) recommends that bridges should be designed to resist the flood event(s) that are expected to produce the most severe scour conditions. HEC 18 recommends the 100-year flood or the overtopping flood when it is less than the 100-year flood. Overtopping refers to flow over the approach embankment(s), the bridge itself, or both. Also, investigate other flood events if there is evidence that such events would create deeper scour than the 100-year or overtopping floods. In addition, HEC 18 states, "Bridges

should be designed to withstand the effects of scour from a super-flood (a flood exceeding the 100-year flood) with little risk of failing. This requires careful evaluation of the hydraulic, structural, and geotechnical aspects of bridge foundation design. It is recommended that this super-flood or check flood be on the order of a 500-year event. "The bridge design for the 100 year or overtopping flood should be designed with the normal safety factors but checking the design for the super flood is made with safety factors of 1.0." Also, "The foundation should be designed by an interdisciplinary team of engineers with expertise in hydraulic, geotechnical, and structural design."

## 10.2 TOTAL SCOUR

Total scour at a highway crossing is composed of long-term degradation, general scour (contraction and other general scour), and local scour. The components are assumed to be additive. In addition, lateral shifting of a stream can cause or increase the scour of bridge foundations. Each of the three types of scour and stream instability are introduced separately below.

### 10.2.1 Long-Term Aggradation and Degradation

Aggradation is the deposition of sediment in the bridge reach of a stream, whereas, degradation is the erosion of the sediment in the bridge reach. The former causes the bed elevation to increase and the latter causes the bed elevation to decrease. These riverbed elevation changes are over long lengths and times due to natural or man-made changes. These changes can be in controls, such as dams or bed rock, in sediment discharge, and in river form, such as from a meandering to a braided stream. Long-term degradation is defined as long-term scour and is added to the other scour components to obtain total scour, but long-term aggradation is not usually considered because over time it could stop or change to degradation.

### 10.2.2 General Scour

General scour is a uniform or nonuniform lowering of the waterway bed as a result of the passage of high flow. It may result from contraction of the flow (contraction scour) or flow around a bend (other general scour).

- *Contraction scour* is erosion of the stream bed under a bridge that results from the acceleration of the flow due to either a natural or man-made contraction. It may occur during the passage of a flood, scouring during the rising stage and refilling on the falling limb of the runoff.
- *Other general scour* may result from flow around a bend, variable downstream control, or other stream changes that decrease the bed elevation.

- *General scour* is different from *long-term degradation* in that it may be cyclic and/or related to the passage of a flood.

### 10.2.3 Local Scour

Erosion of the stream bed around a pier or abutment as the result of the pier or abutment obstructing the flow is *local scour*. These obstructions accelerate the flow and create vortices that remove bed material around them.

### 10.2.4 Lateral Shifting of the Stream

In addition to the above, lateral shifting of a stream (stream instability) may erode the approach roadway and abutments of a bridge and/or change the angle of the flow to the piers and abutments (angle of attack). This latter can increase local scour at the piers or abutments.

## 10.3 CLEAR-WATER AND LIVE-BED SCOUR

There are two conditions for contraction and local scour. These are clear-water and live-bed scour. Clear-water scour occurs when there is no transport of bed material in the flow upstream of the bridge. Live-bed scour occurs when there is transport of bed material from upstream of and into the bridge cross-section. However, clear-water scour may occur if the material being transported in the upstream reach or floodplain is transported in suspension through the bridge cross-section.

Typical clear-water scour situations include (1) coarse bed material streams, (2) flat gradient streams during low flow, (3) local deposits of bed materials that are larger than the biggest fraction being transported by the flow (rock riprap is a special case of this situation), (4) armored stream beds where the only locations with tractive forces adequate to penetrate the armor layer are at piers and/or abutments, and (5) vegetated channels where, again, the only locations where, cover is penetrated are at piers and/or abutments.

During a flood event, bridges over streams with coarse bed material are often subjected to clear-water scour at low discharges, live-bed scour at the higher discharges, and then clear-water scour in the falling stages. Clear-water scour reaches its maximum over a longer period of time than live-bed scour (see Fig. 10-1). In fact, local clear-water scour may not reach a maximum until after several floods.

Equations given later for determining the velocity or shear stress associated with initiation of motion can be used as indicators for clear-water or live-bed scour. If the mean velocity ( $V$ ) or average shear stress ( $\tau_0$ ) in the upstream reach is less than the critical velocity ( $V_c$ ) or critical shear stress ( $\tau_c$ ) of the median diameter ( $D_{50}$ ) of the bed material, then contraction and local scour will be clear-water scour.

Fig. 10-1. Illustrative pier scour depth in a sand-bed stream as a function of time (not to scale) (Richardson and Davis 2001).

## 10.4 LONG-TERM BED ELEVATION CHANGES

Long-term bed elevation changes (aggradation or degradation) may be the natural trend of a stream or may be the result of some modification to the watershed condition of the stream. The stream bed may be aggrading, degrading, or not changing in the bridge crossing reach. When the bed of the stream is neither aggrading or degrading, it is considered to be in equilibrium with the sediment discharge supplied to the bridge reach. It is the long-term trends, not the cutting and filling of the bed of the stream that might occur with contraction scour, that must be determined. The engineer must assess the present state of the stream and watershed and determine future changes in the river system, and from this, determine the long-term stream bed elevation changes.

Factors that affect long-term bed elevation changes are dams and reservoirs upstream and downstream of a bridge, changes in watershed land use (urbanization, deforestation, etc.), channelization, cutoff of meander bends (natural or man-made), changes in the downstream base level (control) of the bridge reach, gravel mining from the stream bed, diversion of water into or out of the stream, natural lowering of the total system, movement of a bend, bridge location in reference to stream plan form, and stream movement in relation to the crossing (Keefer et al., 1980). Richardson et al. (1990; 2001) provide examples of long-term bed elevation changes.

Analysis of long-term stream bed elevation changes must be made using the principles of river mechanics in the context of a fluvial system analysis. Such an analysis of a fluvial system requires consideration of all influences upon the bridge crossing, i.e., runoff from the watershed to the channel (hydrology), sediment delivery to the channel (erosion), sediment transport capacity of the channel (hydraulics), and response of the channel to these factors (geomorphology and river mechanics). Many of the stream impacts are

from human activities, in either the past, present, or future. Analysis requires a study of the past history of the river and human activities on it; a study of present water and land use and stream control activities; and finally contacting all agencies involved with the river to determine future changes to the river system.

A method for organizing such an analysis is to use a three-level fluvial system approach. This method provides three levels of detail in an analysis, (1) qualitative determination based on general geomorphic and river mechanics relationships, (2) engineering geomorphic analysis using established qualitative and quantitative relationships to establish the probable behavior of the stream system in various scenarios of future conditions, and (3) quantifying the changes in bed elevation using available physical process mathematical models such as BRISTARS (Molinas 1993), HEC-6 (USACE 1993), or SAMwin (Ayres Associates 2003), extrapolation of present trends, and engineering judgment to assess the result of the changes in the stream and watershed. Recent FHWA reports, such as "Stream Channel Degradation and Aggradation: Analysis of Impacts to Highway Crossings" (Brown et al. 1980), "Stream Stability at Highway Structures" (Lagasse et al. 2001a), and "River Engineering for Highway Encroachments—Highways in the River Environment" (Richardson et al. 2001) discuss methodologies to determine long-term elevation trends. Vanoni (1975) discusses degradation and aggradation in Section 21, pp. 64 and 65. The general discussion of sediment transport in Vanoni (1975) is also very useful in understanding and determining long-term degradation.

## 10.5 GENERAL SCOUR

### 10.5.1 Contraction Scour

Contraction scour occurs when the flow area of a stream at flood stage is reduced, either by a natural contraction or by a bridge and/or its approach embankments. From continuity, a decrease in flow area results in an increase in average velocity and bed shear stress through the contraction. Hence, there is an increase in erosive forces in the contraction and more bed material is removed from the contracted reach than is transported into the reach. This increase in transport of bed material from the reach lowers the bed elevation. As the bed elevation is lowered, the flow area increases and, in the riverine situation, the velocity and shear stress decrease until relative equilibrium is reached. That is, either the quantity of bed material that is transported into the contraction is equal to that removed from the reach, *live-bed scour*, or the mean velocity ( $V$ ) or average shear stress ( $\tau_0$ ) in the contraction is less than the critical velocity ( $V_c$ ) or critical stress ( $\tau_c$ ) of the median diameter ( $D_{50}$ ) of the bed material, *clear-water scour*.

In coastal streams that are affected by tides, as the cross-sectional area increases the discharge from the ocean may increase and thus the velocity and shear stress may not

decrease. Consequently, relative equilibrium may not be reached. Thus, at tidal inlets that experience clear-water or live-bed scour, contraction scour may result in continual lowering of the bed (long-term degradation) (Richardson et al. 1993; 1995; Richardson and Davis 2001).

Live-bed contraction scour is typically cyclic. That is, the bed scours during the rising stage of a runoff event and fills in the falling stage. The contraction of flow due to a bridge can be caused either by a natural decrease in the flow area of the stream channel or by abutments projecting into the channel and/or the piers blocking a large portion of the flow area. Contraction can also be caused by the approaches to a bridge cutting off floodplain flow. This can cause clear-water scour on a setback portion of a bridge section and/or a relief bridge because the floodplain flow does not normally transport significant concentrations of bed material sediments.

Other factors that can cause contraction scour are (1) ice formation or jams, (2) natural berms along the banks due to sediment deposits, (3) island or bar formations upstream or downstream of the bridge opening, (4) debris, and (5) growth of vegetation in the channel or floodplain.

### 10.5.2 Other General Scour

In a natural channel, the depth of flow and the velocity are always greater on the outside of a bend. In fact there may well be deposition on the inner portion of the bend at the point bar. Other general scour at a bridge located on or close to a bend will be concentrated on the outer part of the bend. Also, in bends, the thalweg (the part of the stream where the flow is deepest and, typically, the velocity is the greatest) may shift toward the center of the stream as the flow increases. This can increase scour and the nonuniform distribution of the scour in the bridge opening (chute channel).

### 10.5.3 Contraction Scour Equations

Contraction scour equations are based on the principle of conservation of sediment transport. In the case of live-bed scour, this simply means that the fully developed scour in the bridge cross-section reaches equilibrium when sediment transported into the contracted section equals sediment transported out and the conditions for sediment continuity are in balance. For clear-water scour, the transport into the contracted section is essentially zero and maximum scour occurs when the shear stress reduces to the critical shear stress of the bed material.

To determine if the contraction scour at a bridge is *clear-water* or *live-bed*, determine if the critical velocity ( $V_c$ ) or critical shear stress ( $\tau_c$ ) of the median diameter ( $D_{50}$ ) of the bed material in the channel upstream from the bridge opening is greater than the average velocity or shear stress (clear-water scour) or smaller (live-bed scour). Or calculate the contraction scour using both equations and take the smaller scour depth (Richardson and Davis 2001).

### 10.5.4 Live-Bed Contraction Scour Equation

Laursen (1958,1962) derived the following equation for live-bed contraction scour. It is based on a simplified transport function (Laursen and Toch 1956) to obtain equilibrium sediment transport in a long contraction. In short contractions, such as at a bridge, it slightly overestimates the scour depth,

$$\frac{y_2}{y_1} = \left( \frac{Q_2}{Q_1} \right)^{6/7} \left( \frac{W_1}{W_2} \right)^{k_1} \left( \frac{n_2}{n_1} \right)^{k_2} \quad (10-1)$$

$$y_s = y_2 - y_0 = (\text{average scour depth, m, ft})$$

where

$y_1$  = average depth in the upstream main channel, m, ft;

$y_2$  = average depth in the contracted section, m, ft;

$y_0$  = average depth in the contracted section before contraction scour, m, ft;

$W_1$  = bottom width of the upstream main channel, m, ft;

$W_2$  = bottom width of main channel in the contracted section, m, ft;

$Q_1$  = flow in the upstream channel transporting sediment,  $\text{m}^3/\text{s}$ , cfs;

$Q_2$  = flow in the contracted channel,  $\text{m}^3/\text{s}$ , cfs (often this is equal to the total discharge unless the total flood flow is reduced by relief bridges or water overtopping the approach roadway);

$n_2$  = Mannings  $n$  for contracted section;

$n_1$  = Mannings  $n$  for upstream main channel;

$k_1, k_2$  = exponents determined depending on the mode of bed material transport;

$V_* = (gy_1 S_1)^{1/2}$  shear velocity in the upstream section,  $\text{m/s}$ ,  $\text{ft/s}$ ;

$\omega$  = median fall velocity of the bed material based on the  $D_{50}$  (see Fig. 10-2);

$g$  = acceleration of gravity ( $9.81 \text{ m/s}^2$ ,  $32.2 \text{ ft/s}^2$ );

$S_1$  = slope of energy grade line of main channel,  $\text{m/m}$ ,  $\text{ft/ft}$ ;

$D_{50}$  = median diameter of the bed material, m, ft.

$V_* / w$	$k_1$	$k_2$	Mode of Bed Material Transport
$<0.50$	0.59	0.066	Mostly contact bed material
$0.50-2.0$	0.64	0.21	Some suspended bed material discharge
$>2.0$	0.69	0.37	Mostly suspended bed material discharge

The value of  $y_0$  may be difficult to determine because of residual contraction scour from previous floods or other factors. Nevertheless,  $y_0$  must be determined. A reasonable value can be determined by a study of the channel using cross sections and longitudinal profiles from upstream, through the bridge, and downstream.

Richardson and Davis (2001) recommend that the Manning  $n$  ratio in Eq. (10-1) be eliminated. The Manning  $n$  ratio can be significant for a condition of dune bed in the main channel and a corresponding plane bed, washed out dunes or antidunes in the contracted channel. However, Laursen's equation does not correctly account for the increase in transport that will occur as the result of the bed planing out (which decreases resistance to flow and increases the velocity and the transport of bed material at the bridge). That is, Laursen's equation indicates a decrease in scour for this case, whereas in reality, there would be an increase in scour depth. In addition, in flood flows, a plane bedform will usually exist upstream and through the contracted waterway, and the values of Manning's  $n$  will be equal.

### 10.5.5 Clear-Water Contraction Scour Equations

Clear-water contraction scour occurs in a long contraction when (1) there is no significant bed material transport in the upstream reach into the downstream bridge reach or (2) the material being transported in the upstream reach is transported through the downstream bridge reach mostly in suspension. With clear-water contraction scour, the area of the contracted section increases until, in the limit, the velocity of the flow ( $V$ ) or the shear stress ( $\tau_0$ ) on the bed is equal to the critical velocity ( $V_c$ ) or the critical shear stress ( $\tau_c$ ) of a certain large size ( $D$ ) in the bed material. The width ( $W$ ) of the contracted section is constrained and the depth ( $y$ ) increases until the limiting conditions are reached.

Following a development proposed by Laursen (1963), Richardson and Davis (2001) developed the following equation for determining the clear-water contraction scour in a long contraction:

$$\tau_0 = \tau_c \quad (10-2)$$

Fig. 10-2. Fall velocity of sand-sized particles.

where

$\tau_0$  = average bed shear stress, contracted section,  
N/m<sup>2</sup>, lb/ft<sup>2</sup>

$\tau_c$  = critical bed shear stress at incipient motion,  
N/m<sup>2</sup>, lb/ft<sup>2</sup>.

The average bed shear stress using  $y$  for the hydraulic radius ( $R$ ) and the Manning equation to determine the slope ( $S_f$ ) can be expressed as

$$\tau_0 = \gamma y S_f = \frac{\rho g V^2 n^2}{y^{1/3}} \quad (10-3)$$

For noncohesive bed materials and for fully developed clear-water contraction scour, the critical shear stress can be determined using the Shields (Vanoni 1975) relation,

$$\tau_c = K_s (\rho_s - \rho) g D \quad (10-4)$$

The bed in a long contraction scours until  $\tau_0 = \tau_c$ , resulting in

$$\frac{\rho g n^2 V^2}{y^{1/3}} = K_s (\rho_s - \rho) g D \quad (10-5)$$

Solving for the depth ( $y$ ) in the contracted section gives

$$y = \left[ \frac{n^2 V^2}{K_s (S_s - 1) D} \right]^3 \quad (10-6)$$

In terms of discharge ( $Q$ ) the depth ( $y$ ) is

$$y = \left[ \frac{n^2 Q^2}{K_s (S_s - 1) D W^2} \right]^{3/7} \quad (10-7)$$

where

$V$  = average velocity in the contracted section, m/s,  
ft/s;

$Q$  = discharge, m<sup>3</sup>/s or cms, cfs;

$D$  = diameter of smallest nontransportable bed material particle, m, ft;

$\gamma$  = the unit weight of water (9,800 N/m<sup>3</sup> 62.4 lb/ft<sup>3</sup>);

$n$  = Manning roughness coefficient;

$K_s$  = Shield's coefficient;

$S_s$  = specific gravity (2.65 for quartz);

$\rho$  = density of water (999 kg/m<sup>3</sup>, 1.94 slugs/ft<sup>3</sup>);

$\rho_s$  = density of sediment (quartz-2,647 kg/m<sup>3</sup>, 5.14 slugs/ft<sup>3</sup>);

$g$  = acceleration of gravity (9.81 m/s<sup>2</sup>, ft/s<sup>2</sup>).

Equation (10-7) is the basic equation for the clear-water scoured depth ( $y$ ) in a long contraction. Laursen (1963), in English units, used a value of 4 for  $K_s (S_s - 1) \gamma$  in Eq. (10-4);  $D_{50}$  for the size ( $D$ ) of the smallest nonmoving particle in the bed material, and Strickler's approximation for Manning's  $n$  ( $n = 0.034 D_{50}^{-1/6}$ ). Laursen's value for Shield's coefficient,  $K_s$  is 0.039. Froehlich (1995) gives equations for Manning's

$n$  and Shield's coefficient, taking into account size distribution of the bed material and the fact that the bed material increases in size as the section scours.

Shield's coefficient for initiation of motion ranges from 0.03 to 0.1 (Vanoni 1975). Strickler's equation for  $n$  given by Laursen, in metric units, is  $n = 0.041 D^{1/6}$ . Research discussed in Richardson et al. (1990; 2001) recommends the use of the effective mean bed material size ( $D_m$ ) in place of the  $D_{50}$  size. The use of  $D_m$  would also be in accordance with the work of Froehlich (1995).  $D_m$  is approximately 1.25  $D_{50}$ . Using Laursen's value for Shield's coefficient  $K_s$  of 0.039,  $n = 0.04 D_m^{1/6}$ , and  $S_s = 2.65$  in Eq. (10.7) results in

$$y = \left[ \frac{0.025 Q^2}{D_m^{2/3} W^2} \right]^{3/7} \quad (10-8)$$

$$y_s = y - y_0 \text{ (average scour depth)} \quad (10-9)$$

where

$D_m$  = effective mean diameter of the bed material (1.25  $D_{50}$ ) in the contracted section, m;

$y_s$  = depth of scour in the contracted section, m;

$y_0$  = original depth in the contracted section before scour, m;

other variables are as previously defined.

Clear-water contraction scour equations assume homogeneous bed materials. However, with clear-water scour in stratified materials, assuming the layer with the finest  $D_{50}$  would result in the most conservative estimate of contraction scour. Alternatively, the clear-water contraction scour equations could be used sequentially for stratified bed materials.

Both the live-bed and clear-water contraction scour equations are the best that are available and should be regarded as a first level of analysis. If a more detailed analysis is warranted, a sediment transport model such as BRI-STARS (Molinas 1993) or HEC 6 (USACE 1993) could be used.

## 10.6 CRITICAL VELOCITY FOR MOVEMENT OF BED MATERIAL

The velocity and depth given in Eq. (10-6) are associated with initiation of motion of the indicated size ( $D$ ). Rearranging Eq. (10-6) to give the critical velocity for the beginning of motion of bed material of size  $D$  results in

$$V_c = \frac{K_s^{1/2} (S_s - 1)^{1/2} D^{1/2} y^{1/6}}{n} \quad (10-10)$$

Using  $K_s = 0.039$ ,  $S_s = 1.65$ , and  $n = 0.041 D^{1/6}$ ,

$$V_c = K u y^{1/6} D^{1/3} \quad (10-11)$$

where

$V_c$  = critical velocity above which bed material of size  $D$  and smaller will be transported, m/s, ft/s;

$K_s$  = Shield's parameter;  
 $S_s$  = specific gravity of the bed material;  
 $D$  = size of bed material, m, ft;  
 $y$  = depth of flow, m, ft;  
 $n$  = Manning's roughness coefficient;  
 $Ku$  = 6.19 SI units and 11.17 English units.

Additional discussion of beginning of motion is given in Vanoni (1975, pp. 91–107 for noncohesive sediments and 107–114 for cohesive sediments).

## 10.7 LOCAL SCOUR

The basic mechanism causing local scour at piers or abutments is the formation of vortices at their bases (known as the horseshoe vortex at a pier, Fig. 10-3, and horizontal vortex at an abutment, Fig. 10-4). The horseshoe vortex results from the pileup of water on the upstream surface of the obstruction and subsequent acceleration of the flow around the nose of the pier or embankment. The action of the vortex removes bed material from around the base of the obstruction. The transport rate of sediment away from the base region is greater than the transport rate into the region, and, consequently, a scour hole develops. As the depth of scour increases, the strength of the horseshoe vortex is reduced, thereby reducing the transport rate from the base region. Eventually, for live-bed local scour, equilibrium is re-established and scouring ceases. For clear-water scour, scouring ceases when the shear stress caused by the horseshoe vortex equals the critical shear stress of the sediment particles at the bottom of the scour hole.

In addition to the horseshoe vortex around the base of a pier, there are vertical vortices downstream of the pier, called the wake vortex (Fig. 10-3). Both the horseshoe and

wake vortices remove material from the pier base region. However, the intensity of wake vortices diminishes rapidly as the distance downstream of the pier increases. Therefore, immediately downstream of a long pier there is often deposition of material.

At abutments, in addition to the horizontal vortex that forms around and erodes their bases there is a vertical vortex that results from flow separation at the downstream side of the abutment (Fig. 10-4). This vortex erodes the approach embankment and the abutment foundations on the downstream corner and side. Thus, there are two scour problems at abutments, (1) a scour hole at the abutment base resulting from the horizontal vortex and (2) erosion of the downstream approach embankment and abutment foundation by the vertical vortex caused by the flow separation.

Factors that affect the magnitude of local scour at piers are (1) width of the pier; (2) length of the pier if skewed to flow; (3) depth and (4) velocity of the approach flow upstream of the pier; (5) size and gradation of bed material; (6) angle of attack of the approach flow; (7) shape; (8) bed configuration; (9) ice formation or jams; and (10) debris. The scour results from free surface flow unless the bridge is submerged or overtopped; then the scour results from pressure flow. The shape of many piers is complex. The piers may rest on footings or pile caps on piles. The footings or pile caps may be in the flow or at the mean water elevation by design or erosion.

Factors that affect the magnitude of local scour at abutments are (1) discharge intercepted by the abutment and returned to the main channel at the abutment (in laboratory flumes this discharge is a function of projected length of an abutment and approach roadway into the flow); (2) depth of flow; (3) velocity of flow at the upstream and downstream ends of the abutment; (4) size and gradation of bed material; (5) angle of attack of the approach flow; (6) shape;

Fig. 10-3. Schematic representation of scour at a cylindrical pier (Richardson and Davis 2001).

Fig. 10-6. Nondimensional local scour depth as a function of nondimensional velocity and bed material size (Melville 1984).

during plain bed and antidune flow conditions some of the sediment in transport washes through the scour hole. At high values of  $V/V_c$  the scour condition is similar to clear-water scour. That is, the bed material that is being transported upstream of the pier is swept through the scour hole and takes no part in the scouring process.

Chang (Richardson and Davis 2001) noted that in all the data he studied, there were no values of the ratio of scour depth to pier width ( $y_s/a$ ) larger than 2.3. Melville and Sutherland (1988) reported 2.4 as an upper limit ratio for cylindrical piers. In these studies, the Froude number was less than 1.0. Values of  $y_s/a$  around 3.0 were obtained by Jain and Fischer (1979) for chute-and-pool flows with Froude numbers as high as 1.5. Their largest value of  $y_s/a$  for antidune flow was 2.5 with a Froude number of 1.2. These upper limits were derived for circular piers and were uncorrected for pier shape and for skew. Also, pressure flow or debris can increase the ratio.

From the above discussion, the ratio of  $y_s/a$  can be as large as 3 at large Froude numbers. Therefore, Richardson and Davis (2001) recommended that the maximum value of the ratio be taken as 2.4 for Froude numbers less than or equal to 0.8 and as 3.0 for larger Froude numbers. These limiting ratio values apply only to round nose piers that are aligned with the flow.

Over 30 equations have been developed for pier scour (Jones 1983; McIntosh 1989; Landers and Mueller 1996). In the following, three of the equations given in the literature are presented.

## 10.9 HEC 18 PIER SCOUR EQUATION

To determine pier scour, an equation based on the CSU equation (Richardson et al. 1990; 2001) was recommended by

the Federal Highway Administration in HEC 18 (Richardson and Davis 2001) for both live-bed and clear-water pier scour. A study of 22 scour equations using field data presented by Landers et al. (1996) indicated that the HEC 18 equation was good for design because it rarely underpredicted measured scour depth, but frequently grossly overpredicted the observed scour (Mueller 1996). The data contained 384 measurements of scour at 56 bridges. The Landers and Mueller data are also given by Richardson and Lagasse (1999). The HEC 18 equation slightly underpredicted 6 of the 384 scour measurements. The maximum deviation was 3 ft when the scour depth was 25 ft (7.62m). The HEC 18 equation overestimated scour in coarse bed streams because of restrictions placed on a correction factor  $K_4$  for coarse bed material. A  $K_4$  factor for coarse bed material developed by Mueller (1996) decreased the overprediction without altering the underprediction.

The HEC 18 pier scour equation is

$$\frac{y_s}{y_1} = 2.0 K_1 K_2 K_3 K_4 K_w \left( \frac{a}{y_1} \right)^{0.65} F_1^{0.43} \quad (10-12)$$

In terms of  $y_s/a$ , Eq. (10-12) is

$$\frac{y_s}{a} = 2.0 K_1 K_2 K_3 K_4 K_w \left( \frac{y_1}{a} \right)^{0.35} F_1^{0.43} \quad (10-13)$$

$$\begin{aligned} y_s &\leq 2.4 a & F < 0.8 \\ y_s &\leq 3.0 a & F > 0.8 \end{aligned} \quad (10-14)$$

where

- $y_s$  = scour depth, m, ft;
- $y_1$  = flow depth directly upstream of the pier, m, ft;
- $K_1$  = correction factor for pier nose shape from Fig. 10-7 and Table 10-1;
- $K_2$  = correction factor for angle of attack of flow from Eq. (10-15) or Table 10-2;
- $K_3$  = correction factor for bed condition from Table 10-3;
- $K_4$  = correction factor for size of bed material;
- $K_w$  = correction factor for very wide, piers;
- $a$  = pier width, m, ft;
- $L$  = length of pier, m, ft;
- $F_1$  = Froude number =  $V_1 / (gy_1)^{1/2}$ ;
- $V_1$  = mean velocity of flow directly upstream of the pier, m/s, ft/s.

The correction factor for angle of attack of the flow  $K_2$  given in table 10-2 can be calculated using the equation:

$$K_2 = (\cos \theta + L/a \sin \theta)^{0.65} \quad (10-15)$$

If  $L/a$  is larger than 12, use  $L/a = 12$  as a maximum in Eq. (10-15).

Fig 10-7. Common pier shapes (Richardson, and Davis 2001).

### 10.9.1 Mueller (1996) $K_4$ Correction Coefficient

Mueller (1996) developed a  $K_4$  correction coefficient from a study of 384 field measurements of scour at 56 bridges. It is as follows:

$$\begin{aligned} K_4 &= 1 \text{ if } D_{50} < 2 \text{ mm or } D_{95} < 20 \text{ mm} \\ K_4 &= 0.4(K_5)^{0.15} \text{ if } \\ D_{50} &\geq 2 \text{ mm and } D_{95} \geq 20 \text{ mm} \end{aligned} \quad (10-16)$$

where

$$K_5 = \frac{V_1 - V_{icD_{50}}}{V_{cD_{50}} - V_{icD_{95}}} > 0 \quad (10-17)$$

$V_{icD_x}$  = the approach velocity corresponding to critical velocity for incipient scour in the accelerated flow region at the pier for the grain size  $D_x$ , m/s;

$$V_{icD_x} = 0.645 \left( \frac{D_x}{a} \right)^{0.053} V_{cD_x} \quad (10-18)$$

$V_{cD_x}$  = the critical velocity for incipient motion for the grain size  $D_x$ , m/s, ft/s.

Mueller (1996) used a variable Shield's parameter to define the critical velocity for incipient motion. However, for the coarser size of bed material to which  $K_4$  is applicable, it can be determined using Eq. (10-11). It is as follows:

$$V_{cD_x} = Ku y_1^{1/6} D_x^{1/3} \quad (10-19)$$

$y_1$  = depth of flow just upstream of the pier, excluding local scour, m, ft;

$V_1$  = velocity of the approach flow just upstream of the pier, m/s, ft/s;

$D_x$  = grain size for which x% of the bed material is finer, m, ft;

$Ku$  = 6.19 SI units and 11.17 English units.

Although this  $K_4$  provides a good fit to the field data the velocity ratio terms are so formed that if  $D_{50}$  is held constant and  $D_{95}$  increases the value of  $K_4$  increases rather than decreases (Mueller and Jones 1999). For field data an increase in  $D_{95}$  was always accompanied by an increase in  $D_{50}$ . A minimum value for  $K_4$  is 0.4.

### 10.9.2 Correction Factor for Very Wide Piers

Field and flume studies of scour depths at wide piers in shallow flows indicate that existing scour equations over estimate scour depths. Johnson and Torrico (1994) suggest the following equations for a  $K_w$  to correct for wide piers in shallow flows.

The correction factor should be used when the ratio of depth of flow to pier width is less than 0.8; the ratio of the pier width to the median diameter of the bed material is greater than 50; and the Froude number of the flow is subcritical:

$$K_w = 2.58 (y/a)^{0.34} F^{0.65} \text{ for } V/V_c < 1 \quad (10-20)$$

$$K_w = 1.0 (y/a)^{0.13} F^{0.25} \text{ for } V/V_c \geq 1 \quad (10-21)$$

Engineering judgment should be used in applying  $K_w$  because it is based on limited data.

### 10.9.3 Scour for Complex Pier Foundations

**10.9.3.1 Introduction** The piers of many bridges may not be solid single shafts as shown in Figs. 10-3 and 10-7 but may be composed of a combination of elements. In the general case, the flow could be obstructed by three

**Table 10-1 Correction Factor  $K_1$  for Pier Nose Shape**

Shape of pier nose	$K_1$
(a) Square nose	1.1
(b) Round nose	1.0
(c) Circular cylinder	1.0
(d) Sharp nose	0.9
(e) Group of cylinders	1.0

**Table 10-2 Correction for Angle of Attack  $\theta$  of the Flow**

Angle	$L/a=4$	$L/a=8$	$L/a=12$
0	1.0	1.0	1.0
15	1.5	2.0	2.5
30	2.0	2.75	3.5
45	2.3	3.3	4.3
90	2.5	3.9	5.0

Note:  $\theta$  = Angle = skew angle of flow;  $L$  = length of pier, m, ft.

**Table 10-3 Increase in Equilibrium Pier Scour Depths ( $K_3$ ) for Bed Condition**

Bed condition	Dune height, m	$K_3$
Clear-water scour	N/A	1.1
Plane bed and antidune flow	N/A	1.1
Small dunes	$3 > H > 0.6$	1.1
Medium dunes	$9 > H > 3$	1.1 to 1.2
Large dunes	$H > 9$	1.3

Note: The correction factor  $K_1$  for pier nose shape should be determined using Table 9-2 for angles of attack up to  $5^\circ$ . For greater angles,  $K_2$  dominates and  $K_1$  should be considered as 1.0. If  $L/a$  is larger than 12, use the values  $L/a = 12$  as a maximum. The correction factor  $K_3$  results from the fact that for plane-bed conditions, which are typical of most bridge sites for the flood frequencies employed in scour design, the maximum scour may be 10% greater than computed with the CSU equation (Richardson et al. 1990). In the unusual situation where a dune bed configuration with large dunes exists at a site during flood flow, the maximum pier scour may be 30% greater than the predicted value. This may occur on very large rivers, such as the Mississippi. For smaller streams that have a dune bed configuration at flood flow, the dunes will be smaller and the maximum scour may be only 10 to 20%, greater than equilibrium scour. For antidune bed configuration the maximum scour depth may be 10% greater than the computed equilibrium pier scour depth.

substructural elements, which include the pier stem, the pile cap or footing, and the pile group. The three types of exposure to the flow may be by design or by scour (long-term degradation, general (contraction) scour, and local scour, in addition to stream migration).

Ongoing research has determined methods and equations to determine scour depths for complex pier foundations (Jones 1989; Salim and Jones 1995; 1996; 1999; Jones and Sheppard 2000). The results of this research are given in HEC 18 (Richardson and Davis 2001) and are given in the following sections. Physical model studies are still recommended for complex piers with unusual features such as staggered or unevenly spaced piles or for major bridges where conservative scour estimates are not economically acceptable (Richardson et al. 1987). However, the methods presented in this section provide a good estimate of scour for a variety of complex pier situations.

The following steps are recommended for determining the depth of scour for any combination of the three substructural elements exposed to the flow. However, engineering judgment is an essential element in applying the design graphs and equations presented in this section, as well as in deciding when a more rigorous level of evaluation is warranted. Engineering judgment should take into consideration the volume of traffic, type of traffic (school bus, ambulance, fire trucks, local road, interstate, etc.), importance of the highway, cost of a failure (potential loss of life and dollars), and increase in cost that would occur if the most conservative scour depth were used. The stability of the foundation should be checked for the following:

Determine the scour depths for the 100-year flood or smaller discharge if it causes deeper scour and the superflood, i.e., the 500-year flood, as recommended in this manual.

If needed, use computer programs such as HEC-RAS (USACE 2001), FESWMS (Froehlich 1996), or RMA2 (USACE 1997) to compute the hydraulic variables.

Determine total scour depth by separating the scour-producing components, determining the scour depth for each component and adding the results. The method is called "superposition of the scour components."

Analyze the complex pile configuration to determine the components of the pier that are exposed to the flow or will be exposed to the flow, which will cause scour.

Determine the scour depths for each component exposed to the flow using the equations and methods presented in the following sections.

Add the components to determine the total scour depths.

Plot the scour depths and analyze the results using an interdisciplinary team to determine their reliability and adequacy for the bridge, flow and site conditions, and safety and costs.

Conduct a physical model study if engineering judgment determines that it will reduce uncertainty, increase the safety of the design, and/or reduce cost.

**10.9.3.2 Superposition of Scour Components Method of Analysis** The components of a complex pier are illustrated in Fig. 10-8. Note that the pile cap can be above the water surface, at the water surface, in the water, or on the bed. The location of the pile cap may result from design or from long-term degradation and/or contraction scour. The pile group, as illustrated, is in uniform (lined up) rows and columns. This may not always be the case. The support for the bridge in many flow fields and designs may require a more complex arrangement of the pile group. In more complex pile group arrangements, this methods of analysis may give smaller or larger scour depths.

The variables illustrated in Fig. 10-8 and others used in computations are as follows:

- $f$  = distance between front edge of pile cap or footing and pier, m (ft);
- $h_0$  = height of the pile cap above bed at beginning of computation, m (ft);
- $h_1 = h_0 + T$  = height of the pier stem above the bed before scour, m (ft);
- $h_2 = h_0 + y_{s \text{ pier}} / 2$  = height of pile cap after pier stem scour component has been computed, m (ft);
- $h_3 = h_0 + y_{s \text{ pier}} / 2 + y_{s \text{ pc}} / 2$  = height of pile group after the pier stem and pile cap scour components have been computed, m (ft);
- $S$  = spacing between columns of piles, pile center to pile center, m (ft);
- $T$  = thickness of pile cap or footing, m (ft);
- $V_1$  = approach velocity used at the beginning of computations, m/s (ft/s);
- $V_2 = V_1(y_1 / y_2)$  = adjusted velocity for pile cap computations, m/s (ft/s);

Fig. 10-8. Definition sketch for scour components for a complex pier (Richardson and Davis 2001).

$V_3 = V_1(y_1 / y_3)$  = adjusted velocity for pile group computations, m/s (ft/s).

$y_1$  = approach flow depth at the beginning of computations, m (ft);

$y_2 = y_1 + y_{s \text{ pier}} / 2$  = adjusted flow depth for pile cap computations, m (ft);

$y_3 = y_1 + y_{s \text{ pier}} / 2 + y_{s \text{ pc}} / 2$  = adjusted flow depth for pile group computations, m (ft)

Total scour from superposition of components is given by

$$Y_s = Y_{s \text{ pier}} + Y_{s \text{ pc}} + Y_{s \text{ pg}} \quad (10-22)$$

where

$y_s$  = total complex pier scour depth, m (ft);

$y_{s \text{ pier}}$  = scour component for the pier stem in the flow, m (ft);

$y_{s \text{ pc}}$  = scour component for the pier cap or footing in the flow, m (ft);

$y_{s \text{ pg}}$  = scour component for the piles exposed to the flow, m (ft).

Each of the scour components is computed from the basic pier scour by Eq. (10.12) using an equivalent-sized pier to represent the irregular pier components, adjusted flow depths, and velocities as described in the list of variables for Fig. 10-8 and height adjustments for the pier stem and pile group. The height adjustment is included in the equivalent pier size for the pile cap. In the following sections, guidance for calculating each of the components is given.

**10.9.3.3. Determination of the Pier Stem Scour Depth Component** The need to compute the pier stem scour depth component occurs when the pier cap or the footing is in the flow and the pier stem is subjected to sufficient flow depth and velocity to cause scour. The first computation is the scour estimate,  $y_{s \text{ pier}}$ , for a full-depth pier that has the width and length of the pier stem using the basic pier equation

(Eq. (10-12)). In Eq. (10-12),  $a_{\text{pier}}$  is the pier width and other variables in the equation are as defined previously. This base scour estimate is multiplied by  $K_{h \text{ pier}}$ , given in Fig. 10-9 as a function of  $h_1/a_{\text{pier}}$  and  $f/a_{\text{pier}}$ , to yield the pier stem scour component

$$\frac{y_{s \text{ pier}}}{y_1} = K_{h \text{ pier}} \left[ 2.0 K_1 K_2 K_3 K_4 K_w \times \left( \frac{a_{\text{pier}}}{y_1} \right)^{0.65} \left( \frac{V_1}{\sqrt{g y_1}} \right)^{0.43} \right] \quad (10-23)$$

where

$K_{h \text{ pier}}$  = coefficient to account for the height of the pier stem above the bed and the shielding effect by the pile cap overhang distance  $f$  in front of the pier stem (from Fig. 10-9).

The quantity in the square brackets in Eq. (10-23) is the basic pier scour ratio as if the pier stem were full depth and extended below the scour.

**10.9.3.4 Determination of the Pile Cap (Footing) Scour Depth Component** The need to compute the pile cap or footing scour depth component occurs when the pile cap is in the flow by design, or as the result of long-term degradation, contraction scour, and/or by local scour attributed to the pier stem above it. As described below, there are two cases

to consider in estimating the scour caused by the pile cap (or footing). Eq. (10-12) is used to estimate the scour component in both cases, but the conceptual strategy for determining the variables to be used in the equation is different (partly due to limitations in the research that has been done to date). In both cases the wide pier factor,  $K_w$ , may be applicable for this computation.

**Case 1:** The bottom of the pile cap is above the bed and in the flow, either by design or after the bed has been lowered by scour caused by the pier stem component. The strategy is to reduce the pile cap width,  $a_{\text{pc}}$ , to an equivalent full depth solid pier width,  $a_{\text{pc}}^*$ , using Fig. 10-10. The equivalent pier width, an adjusted flow depth,  $y_2$ , and an adjusted flow velocity,  $V_2$ , are then used in Eq. (10-12) to estimate the scour component.

**Case 2:** The bottom of the pile cap or footing is on or below the bed. The strategy is to treat the pile cap or exposed footing like a short pier in a shallow stream of depth equal to the height to the top of the footing above the bed. The portion of the flow that goes over the top of the pile cap or footing is ignored. Then, the full pile cap width,  $a_{\text{pc}}$ , is used in the computations, but the exposed footing height,  $y_f$  (in lieu of the flow depth), and the average velocity,  $V_f$ , in the portion of the profile approaching the footing are used in Eq. (10-12) to estimate the scour component.

An inherent assumption in this second case is that the footing is deeper than the scour depth, so it is *not necessary*

Fig. 10-9. Suspended pier scour ratio (Jones and Sheppard 2000; Richardson and Davis 2001).

to add the pile group scour as a third component in this case. If the bottom of the pile cap happened to be right on the bed, either the case 1 or case 2 method could be applied, but they would not necessarily give the same answers. If both methods are tried, then engineering judgment should dictate which one to accept.

Details for determining the pile cap or footing scour component for these two cases are described in the following paragraphs.

#### 10.9.3.4.1 Case 1. Bottom of the Pile Cap (Footing) in the Flow above the Bed

$T$  = thickness of the pile cap exposed to the flow, m (ft);

$h_2 = h_0 + y_{s \text{ pier}} / 2$ , m (ft);

$y_2 = y_1 + y_{s \text{ pier}} / 2$ , = adjusted flow depth, m (ft);

$V_2 = V_1(y_1 / y_2)$  = adjusted flow velocity, m/s (ft/s),

where

$h_0$  = original height of the pile cap above the bed, m (ft);

$y_1$  = original flow depth at the beginning of the computations before scour, m (ft);

$y_{s \text{ pier}}$  = pier stem scour depth component, m (ft);

$V_1$  = original approach velocity at the beginning of the computations, m/s (ft/s).

Determine  $a_{pc}^* / a_{pc}$  from Fig. 10-10 as a function of  $h_2 / y_2$  and  $T / y_2$  (note that the maximum value of  $y_2 = 3.5 a_{pc}$ ).

Compute  $a_{pc}^* = (a_{pc}^* / a_{pc}) a_{pc}$  where  $a_{pc}^*$  is the width of the equivalent pier to be used in Eq. (10-12) and  $a_{pc}$  is the width of the original pile cap. Compute the pile cap

scour component,  $y_{s \text{ pc}}$ , from Eq. (10-12) using  $a_{pc}^*$ ,  $y_2$ , and  $V_2$  as the pier width, flow depth, and velocity parameters, respectively. The rationale for using the adjusted velocity for this computation is that the near-bottom velocities are the primary currents that produce scour and they tend to be reduced in the local scour hole from the overlying component. For skewed flow use the  $L/a$  for the original pile cap as the  $L/a$  for the equivalent pier to determine  $K_2$ . Apply the wide pier correction factor,  $K_w$ , if (1) the total depth  $y_2 < 0.8 a_{pc}^*$ , (2) the Froude number  $V_2 / (g y_2)^{1/2} < 1$ , and (3)  $a_{pc}^* > 50 D_{50}$ . The scour component equation for the case 1 pile cap can then be written

$$\frac{y_{s \text{ pc}}}{y_2} = 2.0 K_1 K_2 K_3 K_4 K_w \left( \frac{a_{pc}^*}{y_2} \right)^{0.65} \left( \frac{V_2}{\sqrt{g y_2}} \right)^{0.43} \quad (10-24)$$

Next, the pile group scour component should be computed. This is discussed later.

**10.9.3.4.2 Case 2. Bottom of the Pile Cap (Footing) Located on or below the Bed** One limitation of the procedure described above is that the design chart in Fig. 10-10 has not been developed for the case of the bottom of the pile cap or footing being below the bed (i.e., negative values of  $h_2$ ).

As for case 1,

$y_2 = y_1 + y_{s \text{ pier}} / 2$ , m (ft);

$V_2 = V_1(y_1 / y_2)$ , m/s (ft/s).

The average velocity of flow at the exposed footing ( $V_f$ ) is determined using the following equation

Fig. 10-10. Pile cap (footing) equivalent width (Jones and Sheppard 2000; Richardson and Davis 2001).

$$\frac{V_f}{V_2} = \frac{\ln\left(10.93 \frac{y_f}{k_s} + 1\right)}{\ln\left(10.93 \frac{y_2}{k_s} + 1\right)} \quad (10-25)$$

where

- $V_f$  = average velocity in the flow zone below the top of the footing, m/s (ft/s);
- $V_2$  = average adjusted velocity in the vertical of flow approaching the pier, m/s (ft/s);
- $\ln$  = log to the base  $e$  (natural log);
- $y_f$  =  $h_1 + y_{s \text{ pier}}/2$  = distance from the bed (after degradation, contraction scour, and pier stem scour) to the top of the footing, m (ft);
- $k_s$  = grain roughness of the bed (normally taken as  $D_{84}$  for sand-size bed material and  $3.5 D_{84}$  for gravel and coarser bed material), m (ft);
- $y_2$  = adjusted depth of flow upstream of the pier, including degradation, contraction scour, and half the pier stem scour, m (ft).

See Fig. 10-11 for an illustration of variables.

Compute the pile cap scour depth component  $y_{s \text{ pc}}$  from Eq. (10-12) using the full pile cap width  $a_{\text{pc}}$ ,  $y_f$ , and  $V_f$  as the width, flow depth, and velocity parameters, respectively. The wide pier factor  $K_w$  should be used in this computation if (1) the total depth  $y_2 < 0.8 a_{\text{pc}}$ , (2) the Froude number  $V_2 / (gy_2)^{1/2} < 1$ , and (3)  $a_{\text{pc}} > 50 D_{50}$ . Use  $y_2 / a_{\text{pc}}$  to compute the  $K_w$  factor if it is applicable. The scour component equation for the case 2 pile cap or footing can then be written

$$\frac{y_{s \text{ pc}}}{y_f} = 2.0 K_1 K_2 K_3 K_4 K_w \left( \frac{a_{\text{pc}}}{y_f} \right)^{0.65} \left( \frac{V_f}{\sqrt{gy_f}} \right)^{0.43} \quad (10-26)$$

In this case assume the pile cap scour component includes the pile group scour and compute the total scour depth as

$$y_s = y_{s \text{ pier}} + y_{s \text{ pc}} \quad (\text{for case 2 only}) \quad (10-27)$$

**10.9.3.5 Determination of the Pile Group Scour Depth Component** Research by Salim and Jones (1995; 1996; 1999) and by Smith (1999) has provided a basis for determining pile group scour depth by taking into consideration the spacing between piles, the number of pile rows, and a height factor to account for the pile length exposed to the flow. Guidelines are given for analyzing the following typical cases:

Piles aligned with each other and with the flow. No angle of attack.

Pile group skewed to the flow, with an angle of attack, or pile groups with staggered rows of piles.

The strategy for estimating the pile group scour component is the same for both cases, but the technique for determining the projected width of piles is simpler for the special case of aligned piles. The strategy is as follows:

Project the width of the piles onto a plane normal to the flow.

Fig. 10-11. Definition sketch for velocity and depth on exposed footing (Richardson and Davis 2001).

Determine the effective width of an equivalent pier that would produce the same scour if the pile group penetrated the water surface.

Adjust the flow depth, velocity, and exposed height of the pile group to account for the pier stem and pile cap scour components previously calculated.

Determine the pile group height factor based on the exposed height of the pile group above the bed.

Compute the pile group scour component using a modified version of Eq. (10-12).

**10.9.3.5.1 Projected Width of Piles** For piles aligned with the flow, the projected width,  $a_{proj}$ , onto a plane normal to the flow is simply the width of the collapsed pile group as illustrated in Fig. 10-12.

Pile groups not aligned to the flow are represented by an equivalent solid pier that has an effective width,  $a_{pg}^*$ , equal to a spacing factor multiplied by the sum of the nonoverlapping projected widths of the piles onto a plane normal to the flow direction (Smith 1999). The projected width can be determined by sketching the pile group to scale and projecting the outside edges of each pile onto a projection plane as illustrated in Fig. 10-13 or by systematically calculating coordinates of the

**Fig. 10-12.** Projected width of piles for flow aligned with the piles (Richardson and Davis 2001).

edges of each pile along the projection plane. The coordinates are sorted in ascending order to facilitate inspection to eliminate double counting of overlapping areas. Additional experiments are being conducted at the FHWA hydraulics laboratory to test simpler techniques for estimating the effective width, but currently Smith's summation technique is a logical choice.

Smith attempted to derive weighting factors to adjust the impact of piles according to their distance from the projection plane, but concluded that there were not enough data and the procedure would become very cumbersome with weighting factors. A reasonable alternative to using weighting factors is to exclude piles other than the two rows and one column closest to the plane of projection, as illustrated in Fig 10-13.

**10.9.3.5.2 Effective Width of an Equivalent Full Depth Pier** The effective width for an equivalent full depth pier is the product of the projected width of piles multiplied by a spacing factor and a number of aligned rows factor (used for the special case of aligned piles only),

$$a_{pg}^* = a_{proj} K_{sp} K_m \quad (10-28)$$

where

$a_{proj}$  = sum of nonoverlapping projected widths of piles (see Figs 10-12 and 10-13);

$K_{sp}$  = coefficient for pile spacing (Fig 10-14)

$K_m$  = coefficient for number of aligned rows,  $m$ , (Figure 10-15 — note that  $K_m$  is constant for all  $S/a$  values when there are more than six rows of piles)

$K_m = 1.0$  for skewed or staggered pile groups.

**Fig. 10-13.** Projected width of piles for skewed flow (Richardson and Davis 2001).

The number of rows factor,  $K_m$ , is 1.0 for the general case of skewed or staggered rows of piles because the projection technique for skewed flow accounts for the number of rows and is already conservative for staggered rows.

**10.9.3.5.3 Adjusted Flow Depth and Velocity** The adjusted flow depth and velocity to be used in the pier scour equation are as follows:

$$y_3 = y_1 + y_{s \text{ pier}} / 2 + y_{s \text{ pc}} / 2, \text{ m (ft)} \quad (10-29)$$

$$V_3 = V_1 (y_1 / y_3), \text{ m/s (ft/s)} \quad (10-30)$$

The scour equation for a pile group can then be written as

$$\frac{y_{s \text{ pg}}}{y_3} = K_{h \text{ pg}} \left[ 2.0 K_{10} K_3 K_4 K_w \left( \frac{a_{\text{pg}}^*}{y_3} \right)^{0.65} \left( \frac{V_3}{\sqrt{g y_3}} \right)^{0.43} \right] \quad (10-31)$$

where

$K_{h \text{ pg}}$  = pile group height factor given in Fig 10-16 as a function of  $h_3 / y_3$  (note that the maximum value of  $y_3 = 3.5 a_{\text{pg}}^*$ );

$h_3 = h_0 + y_{s \text{ pier}} / 2 + y_{s \text{ pc}} / 2$  = height of pile group above the lowered stream bed after pier and pile cap scour components have been computed, m (ft).

$K_2$  from Eq. (10-12) has been omitted because pile widths are projected onto a plane that is normal to the flow. The

quantity in the square brackets is the scour ratio for a solid pier of width  $a_{\text{pg}}^*$ , if it extended to the water surface. This is the scour ratio for a full depth pile group.

In many complex piers, the pile groups have different numbers of piles in rows or columns, the spacing between piles is not uniform, and the widths of the piles may not all be the same. An estimate of the scour depth can be obtained using the methods and equations in this section. However, again it is recommended that a physical model study be conducted to arrive at the final design and to determine the scour depths.

Engineering judgment must be used if debris is considered a factor, in which case it would be logical to treat the pile group and debris as a vertical extension of the pile cap and to compute scour using the case 2 pile cap procedure described previously.

In cases of complex pile configurations where costs are a major concern or where significant savings are anticipated, and/or for major bridge crossings, physical model studies are still the best guide. Nevertheless, the equations and methods described in this section provide a good calculation of the scour depth.

#### 10.9.4 Multiple Columns Skewed to the Flow

Scour depth for multiple columns skewed to the flow (as illustrated as a group of cylinders in Fig. 10-7) depends on the spacing between the columns. The correction factor for angle of attack would be smaller than that for a solid pier. How much smaller is not known. Raudkivi (1986), in discussing effects of alignment, states that “the use of cylindrical

**Fig. 10-14.** Pile spacing factor (D.M. Sheppard, unpublished design procedure, University of Florida, 2001).

Fig. 10-15. Adjustment factor for number of aligned rows of piles (D.M. Sheppard, unpublished design procedure, university of Florida, 2001).

Fig. 10-16. Pile group height adjustment factor (D.M. Sheppard, unpublished design procedure, University of Florida, 2001).

columns would produce a shallower scour; for example, with five-diameter spacing between columns the local scour can be limited to about 1.2 times the local scour at a single cylinder." Thus for multiple columns spaced five diameters or more apart and at an angle, Richardson and Davis (2001) recommend that the local scour depth can be taken as 1.2 times the local scour depth at a single column.

For multiple columns spaced less than five pier diameters apart, the pier width "a" is the total projected width of all the columns in a single row, normal to the flow angle of attack. This composite pier width would be used in Eq. (10-12) to determine depth of pier scour. The correction factor  $K_1$  would be 1.0 regardless of column shape. The coefficient  $K_2$  would also be equal to 1.0 because the effect of skew would be accounted for by the projected area of the piers normal to the flow (Richardson and Davis 2001).

The depth of scour for a multiple column bent will be analyzed in this manner except in addressing the effect of debris lodged between columns. If debris is evaluated, it would be logical to consider the multiple columns and debris as a solid elongated pier.

Additional laboratory studies are necessary to provide guidance on the limiting flow angles of attack for a given distance between multiple columns, beyond which multiple columns can be expected to function as solitary members with minimal influence from adjacent columns.

### 10.9.5 Pressure Flow Scour

Pressure flow, which is also denoted as orifice flow, occurs when the water surface at the upstream face of the bridge is greater than or equal to the low chord of the bridge superstructure and the water is in significant contact with the bridge deck. At higher approach flow depths, the bridge can be entirely submerged, with the resulting flow being a complex combination of plunging flow under the bridge (orifice flow) and flow over the bridge (weir flow). In many cases, when a bridge is submerged, flow will also overtop adjacent approach embankments. Hence, for any overtopping situation, the total weir flow can be subdivided into weir flow over the bridge and weir flow over the approach. Weir flow over approach embankments and the bridge reduces the discharge that passes under the bridge.

With pressure flow, the local scour depths at a pier or abutment may be larger than those for free surface flow with similar depths and approach velocities. The increase in local scour at a pier subjected to pressure flow results from vertical contraction scour and local pier scour caused by the horseshoe vortex (Jones et al. 1993). However, sometimes when a bridge becomes submerged, the average velocity under the bridge is reduced due to a combination of additional backwater caused by the bridge superstructure impeding the flow, and a reduction of the discharge that passes under the bridge due to weir flow over the bridge

and approach embankments. As a consequence scour depths are reduced.

Abed (Abed 1991; Abed et al. 1991), from a limited clear-water flume study at Colorado State University, stated that pressure flow could increase pier scour depths by 2.3 to 10 times. These results were obtained by comparison of scour depths for free surface and pressure flow simulations with similar hydraulic characteristics.

Jones (Jones et al. 1993; 1996; Richardson and Lagasse 1999, p. 288), in clear-water pressure flow studies at FHWA's Turner-Fairbank Research Center, found that (1) local pier scour with pressure flow has two components; (2) one component is vertical contraction scour caused by the bridge superstructure and the other is local pier scour caused by the pier obstructing the flow; (3) the magnitude of the local pier scour with pressure flow is approximately the same as for free surface flow; and (4) the two components are additive.

Arneson (1997; Arneson and Abt 1998), in a comprehensive live-bed flume study of pressure flow scour sponsored by the FHWA, verified Jones's findings. Equation (10-12) is used to determine the local pier scour component caused by the pier obstructing the flow. For the vertical contraction pier scour component additional research is needed.

## 10.10 SCOUR DEPTHS WITH DEBRIS ON PIERS

Debris lodged on a pier usually increases local scour at the pier. The debris may increase pier width, and local velocity and deflect the flow downward. This increases the transport of sediment out of the scour hole. When floating debris is lodged on the pier, the scour depth is estimated by assuming that the pier width is larger than the actual width. The problem is in determining the increase in pier width to use in the pier scour equation. Furthermore, at large depths, the effect of the debris on the scour depths should diminish. Also, debris lodged on piers and abutments can deflect the flow against another pier or abutment, resulting in very large angles of attack and larger velocities. This may be worse than the scour at the pier or abutment with the debris.

As with estimating local scour depths with pressure flow, only limited research has been done on local scour with debris. Melville and Dongol (1992) have conducted a limited quantitative study of the effect of debris on local pier scour and have made some recommendations. However, additional laboratory studies will be necessary to better define the influence of debris on local scour.

## 10.11 JAIN AND FISHER'S EQUATION

Jain and Fisher (1979) studied local pier scour at large Froude numbers in the laboratory. They found that live-bed scour at a circular pier first slightly decreased and then increased with the increase in the Froude number. Live-bed scour depths at

high Froude numbers are larger than the maximum clear-water scour. The contribution of bed-form scour to the total scour depth in the upper flow regime becomes significant with higher flow velocities. They developed the following two equations:

For live-bed scour ( $F - F_c > 0.2$ ),

$$y_s/a = 2.0(F - F_c)^{0.25}(y_1/a)^{0.5}. \quad (10-32)$$

For clear-water scour, ( $F - F_c \leq 0.2$ ),

$$y_s/a = 1.84(F_c)^{0.25}(y_1/a)^{0.3} \quad (10-33)$$

where

$F_c$  = Froude number for beginning of motion,  $V_c/(gy_1)^{1/2}$  of the  $D_{50}$  size of the bed material.

The other variables are as defined previously.

They determined the critical velocity for the beginning of motion using a procedure based on Einstein's (1950) logarithmic velocity equations. His equations are given by Richardson et al, (1990) as follows:

1. Determine the median diameter,  $D_{50}$ , of the bed material, m, ft;
2. Determine  $\tau_c$  from Shield's relation,  $N/m^2$ ,  $lb/ft^2$ ;
3. Compute  $U_{*c} = (\tau_c/\rho)^{0.5}$ , m/s, ft/s;
4. Compute  $V_c = U_{*c} \cdot c [(2.5 \ln (12.27 y X/D_{65}))]$ , m/s, ft/s;
5. Assume  $\chi$  is 1.0, i.e., hydraulically rough flow;
6. Compute  $F_c = V_c / (gy_1)^{0.5}$ .

The equation given in Section 10.6 can also be used to determine the critical velocity.

They also recommended that the scour depth for  $0 < (F - F_c) < 0.2$  can be assumed equal to the larger of the two values of scour obtained from Eqs. 10-29 and 10-30. For shapes different from circular piers and pier alignment other than parallel with the flow direction, multiply the results given by Jain and Fisher's equations by the coefficients given in Tables 10-1 and 10-2.

## 10.12 MELVILLE'S EQUATION

Mellville (1997) gave the following equation for computing local scour depths at piers

$$y_s = K_1 K_2 K_{ya} K_i K_D \quad (10-34)$$

where

$y_s$  = depth of scour, m;  
 $K_1$  = correction for pier nose shape from Figure 10-7 and Table 10-1;

$K_2$  = correction for flow angle of attack from Eq. (10-15);  
 $K_{ya}$  = flow depth-pier size expression

$$K_{ya} = 2.4a, \text{ if } y/a < 0.7$$

$$K_{ya} = 2\sqrt{y_1 a}, \text{ if } 0.7 < \frac{a}{y_1} < 5 \quad (10-35)$$

$$K_{ya} = 4.5y_1, \text{ if } \frac{a}{y_1} > 5$$

$K_i$  = flow intensity factor

$$K_i = \frac{V_1 - (V_a - V_c)}{V_c}, \text{ if } \frac{V_1(V_a - V_c)}{V_c} < 1$$

$$K_i = 1, \text{ if } \frac{V_1 - (V_a - V_c)}{V_c} \geq 1 \quad (10-36)$$

$K_D$  = sediment size factor

$$K_D = 1.0, \text{ if } a/D_{50} > 25$$

$$K_D = 0.57 \log(2.24a/D_{50}), \text{ if } a/D_{50} \leq 25 \quad (10-37)$$

$V_1$  = mean approach velocity, m/s;  
 $V_a$  = mean approach velocity at the armor peak =  $0.8 V_{ca}$ , m/s;  
 $V_c$  = critical velocity at beginning of motion, m/s.

Mellville gives the equation

$$\frac{V_c}{V_{*c}} = 57.5 \log \left( 5.53 \frac{y_1}{D_{50}} \right) \quad (10-38)$$

where

$V_{ca}$  = maximum mean approach velocity for armoring of the channel bed to occur, m/s.

Mellville gives the equation

$$\frac{V_{ca}}{V_{*ca}} = 57.5 \log \left( 5.53 \frac{y_1}{D_{50a}} \right) \quad (10-39)$$

where

$V_{*c}$  = critical shear velocity for the  $D_{50}$  defined by the Shield's relation, m/s;  
 $V_{*ca}$  = critical shear velocity for the  $D_{50a}$  defined by the Shield's relation, m/s;  
 $D_{50a}$  = median armor size, m, where  $D_{50a} = D_{\max}/1.8$ ;  
 $D_{\max}$  = maximum bed material size, m.

Melville gives as an approximation to the Shield's diagram for quartz sediment in water at 20°C the following,

$$V_{*c} = 0.0115 + 0.0125D^{1.4}, 1\text{mm} < D < \phi 0.1\text{mm} \quad (10-40)$$

$$V_{*c} = 0.305D^{0.5} - 0.0065D^{-1}, 1\text{mm} < D < 100\text{mm}$$

where  $V_{*c}$  or  $(V_{*ca})$  is in m/s and  $D = D_{50}$  or  $D_{50a}$  in mm.

### 10.13 OTHER PIER SCOUR EQUATIONS

Other pier scour equations and data sets are given by Jones (1983); Froehlich (1988); Johnson and Torrico (1994); Landers and Mueller (1996); Landers, et al. (1996); Mueller (1996); and Richardson and Lagasse (1999). Vanoni (1975) discusses pier scour and gives Laursen's equation.

### 10.14 TOP WIDTH OF PIER SCOUR HOLES

The top width of a scour hole in cohesionless bed material from one side of a pier or footing can be estimated from the equation (Richardson and Abed 1993; Richardson and Lagasse 1999; Richardson and Davis 2001)

$$W = y_s (K + \cot \theta) \quad (10-41)$$

where

- $W$  = top width of the scour hole from each side of the pier or footing, m, ft;
- $y_s$  = scour depth, m, ft;
- $K$  = bottom width of the scour hole as a fraction of scour depth;
- $\theta$  = angle of repose of the bed material which ranges from about 30° to 44°.

If the bottom width of the scour hole is equal to the depth of scour  $y_s$  ( $K = 1$ ), the top width in cohesionless sand will vary from 2.07 to 2.80  $y_s$ . At the other extreme, if  $K = 0$ , the top width will vary from 1.07 to 1.8  $y_s$ . Thus, the top width could range from 1.0 to 2.8  $y_s$  and would depend on the bottom width of the scour hole and the composition of the bed material. In general, the deeper the scour hole, the smaller the bottom width. A top width of 2.0  $y_s$  is suggested for practical application.

### 10.15 LOCAL SCOUR AT ABUTMENTS

Local scour at abutments has two components (see Fig. 10-4). One component is caused by a horizontal vortex that forms at the upstream end of the abutment and runs along the abutment toe. The other component is a vertical vortex that forms at the

downstream end of the abutment when the flow separates and starts to expand. This vertical vortex erodes the downstream corner of the abutment and the downstream approach roadway. There are no equations available to determine the erosion caused by this downstream vortex. The abutment is protected from erosion caused by this vertical vortex by riprap or a short guidebank (Lagasse et al. 2001). The available equations are for the scour caused by the horizontal vortex.

Equations for predicting local scour depths at abutments are almost all based entirely on laboratory data. For example, equations by Laursen and Toch (1956), Liu et al. (1961), Laursen (1980), Froehlich (1989; 1989b), and Melville (1992; 1997) are based entirely on laboratory data. The problem is that few field data on abutment scour exist. Liu et al.'s equations were developed by dimensional analysis of the variables with a best-fit line drawn through the laboratory data. Laursen's equations are based on inductive reasoning on the change in transport relations due to the acceleration of the flow caused by the abutment. Froehlich's equation was derived from dimensional analysis and regression analysis of the available laboratory data. Melville's equations were derived from dimensional analysis and development of relations between dimensionless parameters using best-fit lines through laboratory data.

All equations in the literature, prior to 1993, were developed using the abutment and roadway approach length ( $L$ ) as one of the variables and result in excessively conservative estimates of scour depth. As Richardson and Richardson (1992) and Richardson and Richardson (1998) point out in a discussion of Melville's (1992; 1997) papers and in a 1993 paper, the reason the equations in the literature predict excessively conservative abutment scour depths for the field situation is that, in the laboratory flume, the discharge intercepted by the abutment is directly related to the abutment length; whereas, in the field, this is rarely the case.

Figure 10-17 illustrates the difference. Thus, using the abutment length in the equations instead of the discharge returning to the main channel at the abutment results in a spurious correlation between abutment lengths and scour depth at the abutment end.

Abutment scour depends on the interaction of the flow obstructed by the abutment and roadway approach and the flow in the main channel at the abutment. Also, abutment scour depth depends on abutment shape, sediment characteristics, cross-sectional shape of the main channel at the abutment (especially the depth of flow in the main channel and the depth of the overbank flow at the abutment), velocity in the main channel and in the flow returning to the main channel at the abutment, and alignment. In addition, field conditions may have tree-lined or vegetated banks, low velocities, and shallow depths upstream of the abutment. Much of the research up to 1993 failed to replicate these field conditions. However, since 1993, research by Sturm et al., Young et al., Kouchakzadeh and Townsend, Chang and Davis, and Molinas et al. (Richardson and Lagasse

**Flow Distribution for Laboratory**

**Flow Distribution at Typical Bridges**

**Fig. 10-17.** Comparison of laboratory flow characteristics to field conditions (Richardson and Richardson 1998).

1999) has addressed the problem of using abutment length as the primary variable for the discharge intercepted by the abutment.

Therefore, engineering judgment is required in designing foundations for abutments. In many cases, foundations can be designed with shallower depths than predicted by the equations when the foundations are protected with rock riprap placed below the streambed and/or a guide bank placed upstream of the abutment (Richardson and Davis 2001). The design of guide banks is given by Lagasse et al. (2001).

#### 10.15.1 Abutment Site Conditions

Abutments can be at the channel bank, be set back from the natural stream bank, or project into the channel. They can have various shapes and can be set at varying angles to the flow. Scour at abutments can be live-bed or clear-water scour. Finally, there can be varying amounts of overbank flow intercepted by the approaches to the bridge and returned to the stream at the abutment. More severe abutment scour will occur when the majority of overbank flow returns to the bridge opening directly upstream of the bridge crossing. Less severe abutment scour will occur when overbank flows gradually return to the main channel upstream of the bridge crossing.

#### 10.15.2 Abutment Shape

There are three general shapes for abutments: (1) spill-through abutments, (2) vertical-wall abutments with wing walls, and (3) vertical walls without wing walls (Fig. 10-18). Depth of scour is approximately double for vertical-wall abutments as compared with spill-through abutments. In Table 10-4 coefficients for correcting scour equations for abutment shape (Froehlich, 1989) is given. However, recent research by Sturm (1999) on abutment scour in compound

channels demonstrated that abutment shape is important for shorter abutments but detected no abutment shape effects as abutments increased in length and caused more contraction with encroachment on the main channel.

#### 10.15.3 Skew Adjustment of Abutment Scour Depths

Figure 10-19 shows the effect of flow angle of attack on abutment scour (Ahmad 1953). As shown, an abutment or spur angled downstream decreases scour depth, whereas an abutment angled upstream into the flow increases scour depth.

#### 10.15.4 Design for Scour at Abutments

The lack of adequate abutment scour equations (some equations are fundamentally wrong and/or overconservative) lead the Federal Highway Administration to recommend that in setting abutment foundation depths the potential for lateral migration, long-term degradation, and contraction scour should be considered. It is recommended that foundation depths for abutments be set at least 1.8 m below the stream bed, including long-term degradation and contraction scour, and rock riprap and/or guide banks should be used to protect the abutment. As a check on the potential scour depth they gave two equations to aid in design and placement of rock riprap (Richardson and Davis 2001).

In the following sections four equations are given. These equations are the result of recent research that properly uses the discharge obstructed by the abutment rather than abutment length. These are

- The Chang and Davis equation (Richardson and Lagasse 1999), which is based on the Laursen live-bed contraction scour equation.
- The Sturm (1999) equation for abutments in compound channels with variable setbacks from the main channel.

Fig. 10-18. Abutment shape.

- The Richardson and Trivino (1999) equation, based on momentum exchange.
- The Richardson et al. (1990) equation, based on Corps of Engineers data on scour at the end of spur dikes in the Mississippi River. It is recommended for use when abutment length divide by flow depth is greater than 25 ( $L/y > 25$ ).

equations and methods are given for live-bed and clear-water scour. The equations are adjustments to live-bed and clear-water contraction scour for the increase in local scour caused by the horizontal vortex at the abutment. Both equations are nondimensional and can be used for either English or SI units. In the process a computer program titled ABSCOUR was developed. Their equations are given in the following.

## 10.16 CHANG AND DAVIS ABUTMENT SCOUR EQUATION

Chang and Davis (Richardson and Davis 2001) present methods for computing local scour at abutments, developed for the Maryland Department of Transportation. Different

### 10.16.1 Live-Bed Abutment Scour

The equation is

$$\frac{y_{2a}}{y_1} = k_f \left( \frac{k_v q_2}{q_1} \right)^{K_2} \quad (10-42)$$

where

$y_{2a}$  = total flow depth in the abutment scour hole after scour has occurred, measured from the water surface to the bottom of the scour hole, m (ft);

$y_1$  = approach flow depth, m (ft);

**Table 10-4 Abutment Shape Coefficients (Froehlich 1989)**

Description	$K_1$
Vertical-wall abutment	1.00
Vertical-wall abutment with wing walls	0.82
Spill-through abutment	0.55

**Fig. 10-19.** Adjustment of abutment scour estimate for skew (Ahmad 1953).

- $q_1$  = flow rate per unit width in the approach section,  $\text{m}^3/\text{s}/\text{m}$  ( $\text{ft}^3/\text{s}/\text{ft}$ );  
 $q_2$  = flow rate per unit width in contracted section,  $\text{m}^3/\text{s}/\text{m}$  ( $\text{ft}^3/\text{s}/\text{ft}$ ) (determination of  $q_1$  and  $q_2$  is explained in a section);  
 $k_v = 0.8 (q_1 / q_2)^{1.5} + 1$ ;  
 $k_f = 0.1 + 4.5 F_1$  for clear-water scour;  
 $k_f = 0.35 + 3.2 F_1$  for live-bed scour.

Equation (10-42) applies to live-bed scour. It can be used for clear-water scour only for the condition where the shear stress in the approach section (Section 1) is at the critical value.

Values of  $k_v$  should range from 1.0 to 1.8. If the calculated value is smaller or larger than this range, use the limiting value.

Values of  $k_f$  should range from 1.0 to 3.3. If the calculated value is smaller or larger than this range, use the limiting value.

The Froude number in the approach section, Section 1,  $F_1 = V_1 / (gy_1)^{0.5}$ , where  $V_1$  = average flow velocity in the approach floodplain or channel section ( $\text{m}/\text{s}$  or  $\text{ft}/\text{s}$ ) and  $y_1$  = average flow depth in the approach floodplain or channel section ( $\text{m}$  or  $\text{ft}$ ).

Laursen's sediment transport function for  $K_2$  is

$$K_2 = 0.11 (\tau_c / \tau_1 + 0.4)^{2.2} + 0.623 \quad (10-43)$$

where

- $\tau_c$  = critical shear stress of soil,  $\text{N}/\text{m}^2$  ( $\text{lb}/\text{ft}^2$ );  
 $\tau_1$  = shear stress at approach section, Section 1,  $\text{N}/\text{m}^2$  ( $\text{lb}/\text{ft}^2$ ),  $\tau_1 < \tau_c$ . The value of  $K_2$  varies from 0.637 to 0.857.  $\tau_c \geq \tau_1$ , select a value of  $K_2$  equal to 0.857.

Chang (personal communication 2000) determined that, although  $K_2$  in Eq. (10-35) is based on a concept similar to  $K_1$  in the table accompanying the live-bed contraction scour equation, (10-1), the values of these coefficients are derived in different ways and cannot be mathematically correlated.

### 10.16.2 Clear-Water Abutment Scour

Clear-water scour occurs if the shear stress in the approach section, Section 1, is less than critical, or if the approach section is armored. The clear-water abutment scour equation is

$$y_{2a} = k_f (k_v)^{0.857} y_{2c} \quad (10-44)$$

where

- $y_{2a}$  = total depth of flow at the abutment, measured from the water surface down to the bottom of the abutment scour hole,  $\text{m}$  ( $\text{ft}$ );

- $y_{2c}$  = clear-water contraction scour depth in the channel or on the floodplain (beyond the abutment scour hole) at critical velocity  $y_{2c} = q_2 / V_c$ ,  $\text{m}$  ( $\text{ft}$ ) (Eq. 10-11) or similar equations can be used to compute  $V_c$ . Another approach would be to compute  $y_{2c}$ , the clear-water contraction scour, from Eq. (10-7) or (10-8);

- $k_f$  and  $k_v$  = dimensionless coefficients as defined in the discussion of live-bed scour.

## 10.17 STURM ABUTMENT SCOUR EQUATION

Sturm (1999) evaluated abutment scour using a flume with a compound channel. He determined that a discharge distribution factor ( $M$ ) is a better measure of the effect of abutment length on the flow redistribution and abutment scour. His research resulted in an equation for clear-water scour around setback and bankline abutments and for live-bed scour around bankline abutments. His equations are given in the following discussions.

### 10.17.1 Clear-Water Scour

Sturm's clear-water abutment scour equation is

$$y_s / y_{fo} = 8.14 K_{st} (q_{fl} / MV_{xc} y_{fo} - 0.47) + \text{FS} \quad (10-45)$$

where

- $y_s$  = depth of scour at the abutment,  $\text{m}$ ;  
 $y_{fo}$  = average depth of flow on the floodplain at the approach section for existing conditions based on normal flow conditions in the river without backwater from the proposed bridge,  $\text{m}$ ;  
 $K_{st}$  = abutment shape factor given below;  
 $q_{fl}$  = unit flow rate on the approach floodplain section that will be blocked by the embankment at Section 2 (The conditions are based on the proposed structure in place and creating backwater effects at the approach section),  $\text{m}^3/\text{s}/\text{m}$ ;  
 $M$  = discharge distribution factor  $= (Q_{1/2 \text{ channel}} + Q_{\text{floodplain}} - Q_{\text{blocked flow}}) / (Q_{1/2 \text{ channel}} + Q_{\text{floodplain}})$  —  $Q_{1/2 \text{ channel}}$  is the discharge from the centerline to the bank of the main channel in the approach section,  $Q_{\text{floodplain}}$  is the floodplain discharge in the approach section, and  $Q_{\text{blocked flow}}$  is the floodplain discharge blocked by the embankment in the approach section;  
 $V_{xc}$  = critical velocity at the approach floodplain section for existing conditions based on normal flow conditions in the river without backwater from the

proposed bridge, m/s (use Eq. (10-10) or (10-11) and the  $D_{50}$  of the bed material);

FS = factor of safety, with a recommended value of 1.0;

$K_{st}$  = 1.0 for vertical wall abutments.

For spillthrough abutments  $K_{st}$  is as follows:

$$K_{st} = 1.52 (K_a - 0.67) / (K_a - 0.40) \text{ where } 0.67 \leq K_a \leq 1.2$$

$$1.0 \text{ where } K_a > 1.2$$

$$0.0 \text{ where } K_a < 0.67$$

$$K_a = q_{fl} / (M \times V_{xc} \times y_{f0}) \quad (10-46)$$

### 10.17.2 Live-Bed Scour around Bankline Abutments

Sturm's live-bed abutment scour equation around bankline abutments is

$$y_s / y_{f0} = 2.0 K_{st} [q_{ml} / (M V_{m0c} y_{f0}) - 0.47] + \text{FS} \quad (10-47)$$

where

$y_s$  = depth of scour at the abutment, m (ft);

$y_{f0}$  = average depth of flow on the floodplain (Step 5), m (ft);

$K_{st}$  = 1.0;

$q_{ml}$  = unit flow rate in the main channel at the approach section 1 for the approach critical velocity, i.e., ( $V_{m1c} \times y_{m1}$ ), m<sup>3</sup>/s/m (cfs/ft);

$M$  = discharge distribution factor as defined above;

$V_{m0c}$  = critical velocity in the main channel for unconstricted flow at depth  $y_{m0}$ , m/s (ft/s);

FS = factor of safety, with a recommended value of 1.0.

Note that Eq. (10-47) is based on experimental results for clear-water scour around bankline abutments. Its extension to the live-bed case by assuming threshold live-bed scour is tentative at this time.

## 10.18 RICHARDSON AND TRIVINO ABUTMENT SCOUR EQUATION

Using a regression technique developed by Box and Tidwell (1962), Richardson and Trivino (1999) regressed approximately 160 clear-water scour data compiled by Froehlich (1989); Lim (1993; 1997); and a field measurement of abutment scour obtained during the 1993 Missouri–Mississippi River flood. The last was an 18.3-m (60-ft)-deep abutment scour hole near the right abutment of the 1-70 Bridge over the Missouri River, near Columbia, MO (Brian Hefner, Hydraulic Section, Missouri Department of Transportation, Bridge Inspection File for Interstate 70 near Rocheport; Missouri, personal communication, 1999). A hydraulic study by Greble (1999) noted that the 2,060-m (6,760-ft)-long approach embankment cut off nearly 80% of the

estimated 9,900 m<sup>3</sup>/s (349,700 cfs) floodplain discharge. The equation is

$$\frac{y_s}{y_1} = 0.02 K_1^{-6.81} + 7.47 F^{1.60} + 1.68 \left( \frac{L}{y_1} \right)^{0.41}$$

$$- 3.32 \left( \frac{M_1}{M_2} \right)^{2.46} - 335 \left( \frac{D_{50}}{y_1} \right)^{1.66} - 1.41 \quad (10-48)$$

where

$y_s$  = the depth of abutment scour, m (ft);

$y_1$  = the unscored average flow depth on the overbank (near the abutment end), m (ft);

$K_1$  = the coefficient for abutment shape (as previously defined), m (ft);

$F$  = the Froude number of the approach flow unobstructed by the abutment;

$L$  = the length the approach embankment projects into the floodplain, m (ft);

$D_{50}$  = the median grain size of the bed material, m (ft);

$M_1$  = the momentum of the flow intercepted by the abutment and approach (Eq. (10-48));

$M_2$  = the momentum of the flow in the bridge opening (Eq. (10-49)).

$M_1/M_2$  is the momentum ratio of the flow that is mixed near the abutment end, which causes the horizontal vortex and abutment scour:

$$M_1 = \rho Q_1 V_1 \quad (10-49)$$

$$M_2 = \rho Q_2 V_2 \quad (10-50)$$

Where

$\rho$  = mass density of water;

$Q_1$  = overbank discharge cutoff by the abutment and approach one bridge length upstream, m<sup>3</sup>/s (cfs);

$Q_2$  = discharge in the constricted section (bridge section), m<sup>3</sup>/s (cfs)—for an abutment set back from the main channel it is the discharge between the end of the abutment and the channel bank, whereas for abutments at the channel bank or projecting into the main channel it is the total discharge in the bridge section;

$V_1$  = average overbank velocity of the flow cutoff by the abutment and approach embankment one bridge length upstream of the bridge (corresponding to  $Q_1$ ), m/s (ft/s);

$V_2$  = average velocity of the flow in the constricted (bridge section corresponding to  $Q_2$ ), m/s (ft/s).

Equation (10-48), for Froehlich's and Lim's data set, has a computed  $R^2$  equal to 0.895. The standard error,  $S_e$ , of estimating  $d_s/d_1$  was 0.48. In comparison, the  $S_e$  was computed to be 1.12 and 1.98 for Froehlich's and Lim's equation when applied to the same data set. It accurately predicted the actual  $y_s/y_1$  of 3.9 for the I-70 scour hole. This contrasts with  $y_s/y_1$  values of 6.4 and 17.8 using Froehlich's and Lim's equation respectively. When Eq. (10-47) was applied to a set of 37 complex laboratory channel data documented by Sturm (1998) and Sturm and Janjua (1994), the standard error of estimate ( $S_e$ ) was 0.89.  $S_e$  was likely greater due to the relatively small sample size. Considering all of the data, the  $S_e$  was only slightly higher ( $S_e = 0.56$ ).

A separate Box-Tidwell regression without the  $L/d_1$  term produced good agreement with the Missouri River data, but the correlation with the flume data was poor. This was not surprising because the flume experiments were performed using the approach and abutment length as the primary variable, not the momentum or discharge ratios. Also, at small laboratory scales the momentum ratio is small and has a minimal influence on the resulting dependent variable. At larger scales, the influence of the momentum ratio,  $M_1/M_2$  is more important than the  $L/y_1$ . Because of its importance in the data set, the  $L/y_1$  was retained in the formulation. The sensitivity of the dependent variable ( $y_s/y_1$ ) to  $L/y_1$  is significantly less than for other formulations involving the ratio of abutment length to flow depth.

Due to the manner in which the equation was formulated, Eq. (10-48) is applicable to conditions in which the abutment is set back from the main channel. All of the data used to develop the equation was for approach embankments normal to the average flow direction, and therefore no correction for abutments angled to the flow is incorporated into the equation. However, for abutments at an angle to the flow, the length  $L$  should be adjusted to its normal length and Fig. 10-19 used to correct the scour depths. As with all other existing abutment scour equations, the equation has not been thoroughly verified for field conditions.

### 10.19 RICHARDSON ET AL. EQUATION FOR $L/y > 25$

Richardson et al. (1990, 2001) give an equation developed using Corps of Engineers field data on scour at the end of spurs in the Mississippi River. This field situation closely resembles the laboratory experiments for abutment scour in that the discharge intercepted by the spurs was a function of the spur length. This is recommended when the ratio of projected abutment length ( $L$ ) to flow depth ( $y_1$ ) is greater than 25. This equation can be used to estimate scour depth ( $y_s$ ) at an abutment where conditions are similar to the field conditions from which the equation was derived,

$$\frac{y_s}{y_1} = 4F_1^{0.33} \frac{K_1}{0.55} \quad (10-51)$$

where

$y_s$  = scour depth, m, ft;

$y_1$  = depth of flow at the abutment, on the overbank or in the main channel, m, ft;

$F_1$  = Froude number based on the velocity and depth adjacent to and upstream of the abutment;

$K_1$  = abutment shape coefficient, from Table 10-6.

To correct Eq. (10-51) for abutments skewed to the stream use Fig. 10-19.

## 10.20 COMPUTER MODELS

The hydraulic routines of computer models WSPRO (Shearman 1987) or HEC-RAS (USACE 2001), can determine the one-dimensional flow variable for use in the determination of scour depths at a bridge. These models determine average flow depths and velocities over a roadway and bridge, as well as average velocities and depths approaching and under the bridge.

## 10.21 STREAM INSTABILITY

Streams are dynamic. Areas of flow concentration continually shift bank lines. In meandering streams having an S-shaped planform, the channel moves both laterally and downstream. A braided stream has numerous channels that are continually changing. In a braided stream, the deepest natural scour occurs when two channels come together or when the flow comes together downstream of an island or bar. This scour depth has been observed to be one to two times the average flow depth (Northwest Hydraulic Consultants Ltd., personal communication, 1973; Richardson and Davis 2001).

A bridge is static. It fixes a stream at one place in time and space. A meandering stream whose channel moves laterally and downstream into the bridge reach can erode the approach embankment and affect contraction and local scour because of changes in flow direction. A braided stream can shift under a bridge and have two channels come together at a pier or abutment, increasing scour. Descriptions of stream morphology are given by Schumm (1977), Lagasse et al., (2001), and Richardson et al. (2001), among others.

Factors that affect lateral shifting of a stream and the stability of a bridge are the geology and geomorphology of the stream, the location of the crossing on the stream, flood characteristics, the characteristics of the bed and bank material, and wash load.

It is difficult to anticipate when a change in planform may occur. It may be gradual with time or the result of a major flood. Also, the direction and magnitude of the movement of the stream are not easily determined. It is difficult to evaluate the vulnerability of a bridge properly due to changes in

planform. It is important to incorporate potential planform changes into the design of new bridges and design of countermeasures for existing bridges.

Countermeasures for lateral shifting and instability of a stream may include changes in the bridge design, construction of river control works, protection of the foundations with riprap, or careful monitoring of the river in a bridge inspection program. Richardson and Davis (2001) recommend that foundations of piers and abutments located on floodplains be placed at elevations approximating those for piers located in the main channel.

To control lateral shifting requires river training works, bank stabilization by riprap, and/or guide banks. Design methods are given in publications of the Federal Highway Administration, U.S. Army Corps of Engineers, and American Association of State Highway and Transportation Officials (AASHTO). Of particular importance are "Spurs and Guide Banks" (Richardson and Simons 1974); "The Design of Spurs for River Training" (Richardson et al. 1975); "The Streambank Erosion Control Evaluation and Demonstration Act of 1974" (USACE 1981); "Streambank Protection Guidelines for Landowners and Local Governments" (USACE 1983); "Use of Spurs and Guidebanks for Highway Crossings" (Richardson and Simons, 1984); "Streambank Stabilization Measures for Highway Stream Crossings" (Brown 1985); "Highways in the River Environment" (Richardson et al. 1990); "Hydraulic Analysis for the Location and Design of Bridges," Volume VII, Highway Drainage Guidelines (AASHTO 1992); "Bridge Scour and Stream Instability Countermeasures" (Lagasse et al. 2001a); "Stream Stability at Highway Structures" (Lagasse et al. 2001b); "River Engineering for Highway Encroachments" (Richardson et al. 2001).

## 10.22 SCOUR IN TIDE-AFFECTED WATERWAYS

Scour (erosion) of the foundations of bridges over tidal waterways in the coastal region that are subjected to the effects of astronomical tides and storm surges is a combination of long-term degradation, contraction scour, local scour, and waterway instability (Richardson et al. 1993; 1995; Richardson and Lagasse 1999; Richardson and Davis 2001). These are the same scour mechanisms that affect nontidal (riverine) streams. Although many of the flow conditions are different in tidal waterways, the equations used to determine riverine scour are applicable if the hydraulic forces are carefully evaluated.

Bridge scour in the coastal region results from the unsteady diurnal and semidiurnal flows resulting from astronomical tides, large flows that can result from storm surges (hurricanes, nor'easters, and tsunami), and the combination of riverine and tidal flows. Also, the small size of the bed material (normally fine sand) as well as silts and clays with

cohesion and littoral drift (transport of beach sand along the coast resulting from wave action) affect the magnitude of bridge scour. In addition, tidal flows are subject to mass density stratification and water salinity, but these have only a minor effect on bridge scour. The hydraulic variables (discharge, velocity, and depth) and bridge scour in the coastal region can be determined with as much precision as riverine flows. These determinations are conservative and research is needed to improve scour determinations in both cases. Determining the magnitude of the combined flows can be accomplished by simply adding riverine flood flow to the maximum tidal flow or routing the design riverine flows to the crossing and adding them to the storm surge flows.

Some of the similarities and differences between tidal and riverine flows are as follow:

- Tidal flows are unsteady with short-duration peak flows. Riverine flows are also unsteady and many have short-duration peak flows. Existing scour equations predict scour depths for these short-duration peak riverine flows. Also, waterways in the coastal zone are composed of fine sand that erodes easily. Therefore, riverine scour equations will predict scour depths in short-duration tidal flows.
- Astronomical tides, with their daily or twice-daily in- and outflows, can and do cause long-term degradation if there is no source of sediment except at the crossing. This has resulted in long-term degradation of several feet per year with no indication of stopping (Butler and Lillycrop 1993; Vincent et al. 1993). Existing scour equations can predict the magnitude of this scour, but not the time history (Richardson et al. 1993).
- Mass density stratification (saltwater wedges), which can result when denser, more saline ocean water enters an estuary or tidal inlet with significant freshwater inflow, can result in larger velocities near the bottom than the average velocity in the vertical (Sheppard 1993). However, with careful evaluation, the correct velocity for use in the scour equations can be determined. With storm surges, mass density stratification will not normally occur. The density difference between salt and fresh water, except when it causes saltwater wedges, is not significant enough to affect scour equations. Density and viscosity differences between fresh and sediment-laden water can be much larger in riverine flows than the differences between salt and fresh water. Salinity can affect the transport of silts and clays by causing them to flocculate and possibly deposit, which may affect stream stability and must be evaluated. Salinity may affect the erodibility of cohesive sediments, but this will only affect the rate of scour, not ultimate scour.
- Littoral drift is a source of sediment to a tidal waterway (Sheppard 1993) and its availability can decrease contraction and possible local scour and may result in a stable or aggrading waterway. The lack of sediment

from littoral drift can increase long-term degradation, contraction scour, and local scour. Evaluating the effect of littoral drift is a sediment transport problem involving historical information, future plans (dredging, jetties, etc.) for the waterway and/or the coast, sources of sediment, and other factors.

- *There is one major difference between riverine scour at highway structures and scour resulting from tidal forces.* In determining scour depths for riverine conditions, a design discharge is used (discharge associated with a 50-, 100-, or 500-year return period). For tidal conditions, a design storm surge elevation is used (elevation for the 50-, 100-, or 500-year storm surge return period), and from the storm surge elevation, the discharge is determined. That is, for the riverine case, the discharge is fixed, whereas, for the tidal case, the discharge may not be. In the riverine case, as the area of the stream increases, the velocity and shear stress on the bed decrease because of the fixed discharge. In the tidal case, as the area of the waterway increases, the discharge may also increase and the velocity and shear stress on the bed may not decrease appreciably. Thus, long-term degradation and contraction scour can continue until sediment inflow equals sediment outflow or the discharge driving force (difference in elevation across a highway crossing an inlet, estuary, or channel between islands or islands and the mainland) reduces to a value that the discharge no longer increases (Richardson et al. 1993; Richardson and Davis 2001).

The reason the design discharge for the same return periods for tidal waterways may increase is that the discharge is dependent on the design storm surge elevation, the volume of water in the tidal prism upstream of the bridge, and the area of the waterway under the bridge at mean tide. If there is erosion of the waterway from the constant daily flow from the astronomical tides or from the storm surge, the discharge may increase as the waterway area increases.

### 10.22.1 Design Discharge

The design discharge for tidal waterways is determined from the 50-, 100-, and 500-year storm surge return period elevation. From this elevation, tidal prism volume, and waterway area, the design discharge is determined. If the waterway area increases the design discharge may increase. This is a major difference between the tidal and riverine design discharge (see discussion above) (Richardson et al. 1993; Richardson and Davis 2001). Models are available to generate synthetic storm surge hydrographs combined with different periods of the daily tides (Zevenbergen et al. 1997a, b).

Determination of the design discharge for scour analysis for bridges in tidal waterways consists of a three-level approach. First is preliminary qualitative evaluation of the stability of a tidal waterway, estimation of the magnitude of

the tides, storm surges, littoral drift, and flow in the tidal waterway, and determination of whether the hydraulic analysis depends on tidal or river conditions or both. Next an engineering analysis is used to obtain the velocity, depths, and discharge for tidal waterways to be used in determining long-term aggradation or degradation, contraction scour, and local scour using existing scour equations. Finally, if necessary for complex tidal situations, one- or two-dimensional computer models or even physical models must be used.

## 10.23 SCOUR CALCULATIONS FOR TIDAL WATERWAYS

Long-term degradation, contraction scour, and local scour can be determined in tidally affected waterways using methods and equations given previously for riverine flows (Richardson and Davis 2001). A brief summary for long-term degradation and contraction scour follows.

### 10.23.1 Long-Term Degradation

To determine if long-term degradation is occurring, site conditions, fluvial geomorphology, historical data on changes in waterway bed elevation, and potential future changes in the tidal waterway or coastal conditions must be studied to determine if the waterway is aggrading or degrading. If the waterway is degrading, an estimate of the amount of degradation that will occur in the future is made and added to the other scour components. Historical data sources could be maps, soundings, tide gauge records, and bridge inspection reports for the site and in the area. Determine if there are plans to construct jetties or breakwaters, dredge the channel, construct piers, etc., which could affect waterway stability. Also, determine changes in the riverine environment, such as dams, which could change flow conditions.

In tidal conditions long-term degradation can occur from the daily tides if there is little or no sediment supply to an inlet or estuary or it is decreased (Butler and Lillycrop 1993; Richardson et al. 1993; Vincent 1993). The potential magnitude but not the time of this long-term degradation can be determined using the clear-water contraction scour equation given previously. Richardson and Davis (2001) present an example of the use of the clear-water contraction scour equation to estimate potential long-term degradation.

### 10.23.2 Contraction Scour

Contraction scour can occur at a tidal inlet, estuary, or passage between islands or islands and the mainland. It may be live-bed or clear-water scour. It would be considered live-bed scour if there were a substantial quantity of bed material transport in contact with the bed. Equations given previously can be used to determine contraction scour from the daily

tidal or storm surge flows. Because the discharge in a contracted tidal waterway depends on the area of the waterway for a given tidal or storm surge amplitude and tidal prism, the discharge will need to be recalculated after the area has increased from contraction scour.

### 10.23.3 Local Scour

The equations and method given previously for local scour at piers and abutments are used for tidal waterways.

## 10.24 OVERVIEW OF TIDAL PROCESSES

### 10.24.1 Glossary of Terms

- Bay: A body of water connected to the ocean by an inlet.
- Estuary: Tidal reach at the mouth of a river.
- Flood or flood tide: Flow of water from the ocean into the bay or estuary.
- Ebb or ebb tide: Flow of water from the bay or estuary to the ocean.
- Littoral drift: Transport of beach material along a shoreline by wave action.
- Run-up: Height to which water rises above still-water level when waves meet a beach or wall.
- Storm surge: Tidelike phenomenon resulting from wind and barometric pressure changes. Hurricane surge, storm tide.
- Tidal amplitude: Generally, half of tidal range.
- Tidal cycle: One complete rise and fall of the tide.
- Tidal inlet: A channel connecting a bay or estuary to the ocean.
- Tidal passage: A tidal channel connected with the ocean at both ends.
- Tidal period: Duration of one complete tidal cycle.
- Tidal prism: Volume of water contained in a tidal bay, inlet, or estuary between low and high tide levels.
- Tidal range: Vertical distance between specified low and high tide levels.
- Tidal waterways: A generic term that includes tidal inlets, estuaries, bridge crossings to islands or between islands, crossings between bays, tidally affected streams, etc.
- Tides, astronomical: Rhythmic diurnal or semidiurnal variations in sea level that result from gravitational attraction of the moon and sun and other astronomical bodies acting on the rotating earth.
- Tsunami: Long-period ocean wave resulting from an earthquake, or other seismic disturbance, or a submarine landslide.
- Waterway opening: Width or area of bridge opening at a specific elevation, measured normal to principal direction of flow.
- Wave period: Time interval between arrivals of successive wave crests at a point.

### 10.24.2 Definition of Tidal and Coastal Processes

Typical bridge crossings of tidal waterways are diagrammed in Fig. 10-20. Tidal flows are defined as being between the ocean and a bay (or lagoon), from the ocean into an estuary, or through passages between islands or between islands and the mainland. Idealized astronomical tidal conditions and tidal terms are illustrated in Fig. 10-21.

The forces that drive tidal fluctuations are, primarily, the result of the gravitational attraction of the sun and moon on the rotating earth (astronomical tides), wind and storm setup or seiching (storm surges), and geologic disturbances (tsunami). As illustrated in Fig. 10-21, the maximum discharge ( $Q_{\max}$ ) at the flood or ebb tide occurs often (but not always) at the crossing from high to low or low to high tide. The continuous rise and fall of astronomical tides will usually influence long-term trends of aggradation and degradation. Conversely, when storm surges or tsunami occur, the short-term contraction and local scour can be significant. Storm surges and tsunami are single-event phenomena that, due to their magnitude, can cause significant scour at a bridge crossing.

Although the hydraulics of flow for tidal waterways is complicated by the presence of two-directional flow, the basic concept of sediment continuity is valid. Consequently, a clear understanding of the principle of sediment continuity is essential for evaluating scour at bridges spanning waterways influenced by tidal fluctuations. The sediment continuity concept states that the sediment inflow minus the sediment outflow equals the time rate of change of sediment volume in a given reach.

In addition to sediments from upland areas, littoral drift (Figs. 10-20 and 10-22) is a source of sediment supply to an inlet, bay estuary, or tidal passage. During flood tide, sediments can be transported and deposited into the bay or estuary. During ebb tide, sediments can be remobilized and transported out of the inlet or estuary and either deposited on shoals or moved further down the coast as littoral drift.

Sediment transported to a bay or estuary from an upland river system can also be deposited in the bay or estuary during flood tide and remobilized and transported through the inlet or estuary during the ebb tide. However, if the bay or estuary is large, sediments derived from the upland river system can be deposited in the bay or estuary in areas where the velocities are low and may not contribute to the supply of sediment to the bridge crossing. The result is clear-water scour unless sediment transported on the flood tide (ocean shoals, littoral drift) is available on the ebb. Sediments transported from upland rivers into an estuary may be stored there on the floor and transported out during ebb tide. This would produce live-bed scour conditions unless the sediment source in the estuary were disrupted. Dredging, jetties, or other coastal engineering activities can limit sediment supply to a reach and influence live-bed and clear-water scour conditions.

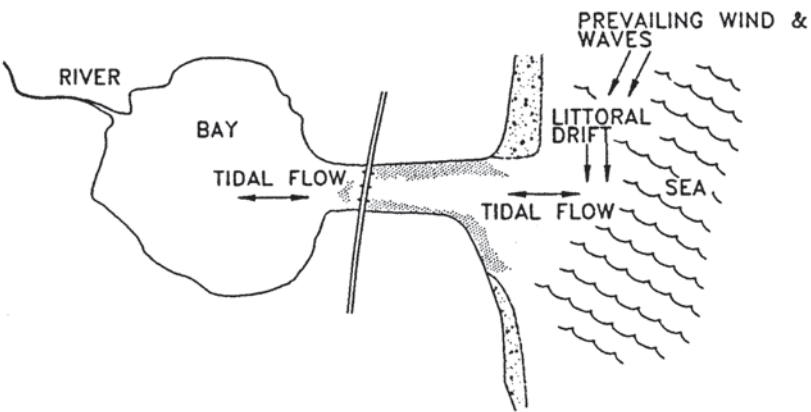

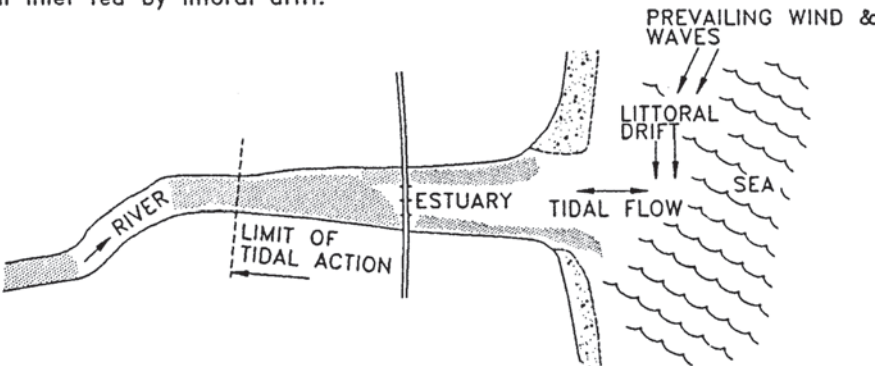

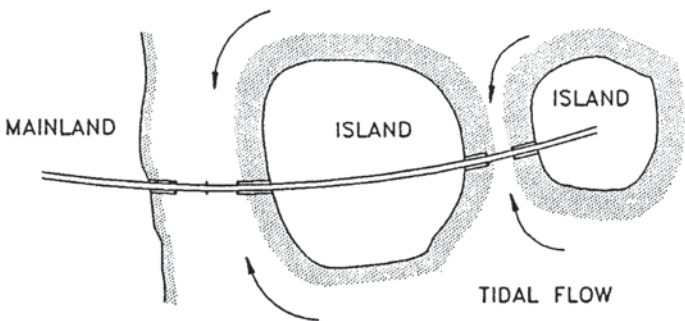

- 
1. Inlets between the open sea and an enclosed lagoon or bay, where most of the discharge results from tidal flows. Tidal inlet fed by littoral drift.
- 
2. River estuaries where the net discharge comprises river flow as well as tidal flow components
- 
3. Passages between islands, or between an island and the mainland, where a route to the open sea exists in both directions.

Fig.10-20. Types of tidal waterway crossings (after Neill 1973).

## 10.25 PRELIMINARY ANALYSIS

As a preliminary analysis it is necessary to determine (1) classification of the tidal crossing, (2) tidal characteristics, (3) lateral, vertical, and overall stability of the waterway and bridge foundations, and (4) characteristics of the riverine and tidal flows. In such a design, plans, boring logs, inspection and maintenance reports, fluvial geomorphology,

historical flood, scour and tidal information, 100- and 500-year return period storm surge elevations, riverine flows, etc. are collected and analyzed. In addition, field reconnaissance and contact with agencies such as the Federal Emergency Management Agency (FEMA), National Oceanic and Atmospheric Administration (NOAA), U.S. Geological Survey (USGS), U.S. Coast Guard (USCG), U.S. Corps of Engineers (USCOE), state agencies, etc. are used.

Fig. 10-21. Principal tidal terms (after Neill 1973).

The crossing is classified as an inlet, bay, estuary, or passage between islands or islands and the mainland (Fig. 10-20). The crossing may be tidally affected or tidally controlled. Tidally affected crossings do not have flow reversal, but the tides act as a downstream control. Tidally controlled crossings have flow reversal. The limiting case for a tidally affected crossing is when the magnitude of

the tide is large enough to reduce the discharge through the bridge to zero.

The objectives of the preliminary analysis are to determine the magnitude of the tidal effects on the crossing, the overall long-term vertical and lateral stability of the waterway and bridge crossing, and the potential for waterway and crossing to change.

Fig. 10-22. Sediment transport in tidal inlets (after Sheppard 1993).

## 10.26 DETERMINATION OF HYDRAULIC VARIABLES

The general procedure is to determine (1) design flows (100- and 500-year storm tides and riverine floods), and (2) hydraulic variables of discharge, velocity, and depths. These variables are then used to determine the scour components (depths of degradation, contraction scour, pier scour, and

abutment scour) using the equations and methods given previously, followed by (3) evaluation of the results.

### 10.26.1 Design Flows and Hydraulic Variables

The riverine 100- and 500-year return period storm discharge is determined by standard hydrology frequency analysis procedures. The magnitude of the 100- and 500-year return

period discharges for a tidal surge depends on the elevation of the surge at the crossing, the volume of water in the tidal prism above the crossing, the area of the bridge waterway at the water surface elevation between high and low tide (ebb) or low and high tide (flood), and the tidal period (time between successive high or low tides).

The elevation of the 100- and 500-year storm surge, tidal period, and surge hydrographs for storm surges can be obtained from FEMA, NOAA, and USCOE. From this information, the volume of the tidal prism above the crossing, the area of the waterway at the bridge and the elevation of the crossing between high and low tide, the design storm surge discharges, and hydraulic variables for use in the scour equations can be determined for an unconfined waterway by a method given by Neill (1973) and for a constricted waterway by a method given by Chang et al. (1994).

### 10.27.2 Hydraulic Variables for Unconfined Waterways

Richardson and Davis (2001) present Neill's (1973) method as follows:

1. Determine and plot the net waterway area at the crossing as a function of elevation. Net area is the gross waterway area between abutments minus area of the piers.
2. Determine and plot tidal prism volumes as a function of elevation. The tidal prism is the volume of water between low and high tide levels or between the high tide elevation and the bottom of the tidal waterway.
3. Determine the elevation versus time relation for the 100- and 500-year storm tides. The relation can be approximated by a sine curve, which starts at mean water level or a cosine curve which starts at the maximum tide level. The cosine equation is

$$y = A \cos \theta + Z \quad (10-52)$$

where

- $y$  = amplitude or elevation of the tide above mean water level, time  $t$ ;  
 $A$  = maximum amplitude of the tide or storm surge, m, ft, defined as half the tidal range or half the height of the storm surge;  
 $\theta$  = angle in degrees subdividing the tidal cycle where one tidal cycle is equal to  $360^\circ$ ,

$$\theta = 360 \left( \frac{t}{T} \right) \quad (10-53)$$

- $t$  = time in minutes from beginning of total cycle;  
 $T$  = total time for one complete tidal cycle, min;  
 $Z$  = vertical offset to datum, m, ft.

To determine the elevation versus time relation for the 100- and 500-year storm tides, the tidal range and period must be known. The FEMA, USCOE, NOAA, and other federal or state agencies compile records that can be used to estimate the 100- and 500-year storm surge elevation, mean sea level elevation, low tide elevation, and time period.

Tides, and in particular storm tides, may have different periods than astronomical semidiurnal and diurnal tides, which have periods of approximately 12.5 and 25 h, respectively. This is because storm tides are influenced by factors other than the gravitational forces of the sun, moon, and other celestial bodies. Factors such as the wind, path of the hurricane or storm creating the storm tide, freshwater inflow, shape of the bay or estuary, etc. influence the storm tide amplitude and period.

4. Determine the discharge, velocities, and depth. The maximum discharge, in an ideal tidal estuary, may be approximated by the equation (Neill 1975)

$$Q_{\max} = \frac{3.14 \text{ VOL}}{T} \quad (10-54)$$

where

- $Q_{\max}$  = maximum discharge in the tidal cycle, cms, cfs;  
 VOL = volume of water in the tidal prism between high and low tide levels,  $\text{m}^3$ ,  $\text{ft}^3$ ;  
 $T$  = tidal period between successive high or low tides, s.

In the idealized case,  $Q_{\max}$  occurs in the estuary or bay at mean water elevation and at a time midway between high and low tides when the slope of the tidal energy gradient is steepest (Fig. 10-21). In many field cases,  $Q_{\max}$  occurs 1 or 2 h before or after the crossing, but any error caused by this is diminutive.

The corresponding maximum average velocity in the waterway is

$$V_{\max} = \frac{Q_{\max}}{A'} \quad (10-55)$$

where

- $V_{\max}$  = maximum average velocity in the cross section at  $Q_{\max}$ , m/s, ft/s;  
 $A'$  = cross-sectional area of the waterway at mean tide elevation, halfway between high and low tide,  $\text{m}^2$ ,  $\text{ft}^2$ .

The average velocity must be adjusted to determine velocities at individual piers to account for nonuniformity of velocity in the cross section. As for inland rivers, local velocities can range from 0.9 to approximately 1.7 times the average velocity depending on whether the location in the cross section is near the bank or near the flow thalweg. The calculated velocities should be compared with any measured

velocities for the bridge site or adjacent tidal waterways to evaluate the reasonableness of the results.

The discharge at any time  $t$  in the tidal cycle, ( $Q_t$ ) is given by:

$$Q_t = Q_{\max} \sin \left( 360 \frac{t}{T} \right) \quad (10-56)$$

5. Include any riverine flows. This may range from simply neglecting the riverine flow into a bay (which is so large that the riverine flow is insignificant in comparison to the tidal flows), to routing the riverine flow through the crossing.
6. Evaluate the discharge, velocities and depths that were determined in Steps 4 and 5.
7. Determine scour depths for the bridge using the values of the discharge, velocity and depths determined from the above analysis.

### 10.26.3 Hydraulic Variables for Constricted Waterways

To determine the hydraulic variables at a constricted waterway (constricted either by the bridge or the channel), the tidal flow may be treated as orifice flow and the following equation taken from van de Kreeke (1967) and Bruun (1990) reported by Richardson and Davis (2001) can be used:

$$V_{\max} = C_d (2g\Delta H)^{1/2} \quad (10-57)$$

$$Q_{\max} = A'V \quad (10-58)$$

where

- $V_{\max}$  = maximum velocity in the inlet, m/s, ft/s;  
 $Q_{\max}$  = maximum discharge in the inlet, cms, csf;  
 $C_d$  = coefficient of discharge ( $C_d < 1.0$ );  
 $g$  = acceleration due to gravity, 9.81 m/s<sup>2</sup>, 32.2 ft/s<sup>2</sup>;  
 $\Delta H$  = difference in water surface elevation between the up- and downstream sides of a crossing or channel for the 100- and 500-return period storm surges as well as for the normal astronomical average tides. —this latter is used to determine the average normal discharge on a daily basis to determine potential long-term degradation at the crossing of a tidal waterway if it becomes unstable (3), m, ft;  
 $A'$  = net cross-sectional area at the crossing, at mean water surface elevation, m<sup>2</sup>, ft<sup>2</sup>.

The coefficient of discharge ( $C_d$ ) is:

$$C_d = \left( \frac{1}{R} \right)^{1/2} \quad (10-59)$$

where

$$R = K_u + K_d + \frac{2g n^2 L_c}{1.49^2 h_c^{4/3}} \quad (10-60)$$

and

- $R$  = coefficient of resistance;  
 $K_d$  = velocity head loss coefficient on downstream side of the waterway;  
 $K_u$  = velocity head loss coefficient on upstream side of the waterway;  
 $n$  = Manning's roughness coefficient;  
 $L_c$  = length of the waterway or bridge opening, m, ft;  
 $h_c$  = average depth of flow at the bridge at mean water elevation, m, ft.

If  $\Delta H$  is not known, the following method, developed by Chang et al. (1994), which combines the orifice equation with the continuity equation, can be used. The total flow approaching the bridge crossing at any time ( $t$ ) is the sum of the riverine flow ( $Q$ ) and tidal flow. The tidal flow is calculated by multiplying the surface area of the upstream tidal basin ( $A_s$ ) by the drop in elevation ( $H_s$ ) over the specified time ( $Q_{\text{tide}} = A_s dH_s/dt$ ). This total flow approaching the bridge is set equal to the flow calculated from the orifice equation,

$$Q + A_s \frac{dH_s}{dt} = C_d A_c \sqrt{2g\Delta H} \quad (10-61)$$

where

$A_c$  = bridge waterway cross-sectional area, m<sup>2</sup>, ft<sup>2</sup>.

The other variables have been defined previously.

Equation (10-52) may be rearranged into the form of Eq. (10-53) for the time interval,  $\Delta t = t_2 - t_1$ , subscripts 2 and 1 representing the end and beginning of the time interval, respectively. Then

$$\begin{aligned} & \frac{Q_1 + Q_2}{2} + \frac{A_{s1} + A_{s2}}{2} \frac{H_{s1} - H_{s2}}{\Delta t} \\ &= C_d \left( \frac{A_{c1} + A_{c2}}{2} \right) \sqrt{2g \left( \frac{H_{s1} + H_{s2}}{2} - \frac{H_{t1} + H_{t2}}{2} \right)} \end{aligned} \quad (10-62)$$

For a given initial condition,  $t_1$ , all terms with subscript 1 are known. For  $t = t_2$ , the downstream tidal elevation ( $H_{t2}$ ), riverine discharge ( $Q_2$ ), and waterway cross-sectional area ( $A_{c2}$ ) are also known or can be calculated from the tidal elevation. Only the water-surface elevation ( $H_{s2}$ ) and the surface area ( $A_{s2}$ ) of the upstream tidal basin remain to be determined. Because surface area of the tidal basin is a function of the water-surface elevation, the elevation of the tidal basin at time  $t_2$  ( $H_{s2}$ ) is the only unknown term in Eq. (10-62), which can be determined by trial and error to balance the values on the right and left sides.

Chang et al. (1994) suggest the following for computing the discharge:

1. Determine the period and amplitude of the design tide(s) to establish the time rate of change of the water surface on the downstream side of the bridge.

2. Determine the surface area of the tidal basin upstream of the bridge as a function of elevation by planimetry successive contour intervals and plotting the surface area versus elevation.
3. Plot bridge waterway area versus elevation.
4. Determine the quantity of riverine flow that is expected to occur during passage of the storm tide through the bridge.
5. Route the flows through the contracted waterway using Eq. 10-62 and determine the maximum velocity of flow.

Chang et al. (1994) give an example problem using a spreadsheet and have developed a computer program to aid in using this method. Richardson and Davis (1995) also give the sample problem and list the computer progress.

### 10.26.4 Hydraulic Variables Using Computer Programs

A Federal Highway Administration Pooled Fund study funded by the Connecticut, Florida, Georgia, Louisiana, Maine, Maryland, Mississippi, New Jersey, New York, North Carolina, South Carolina, and Virginia Departments of Transportation of computer models to analyze tidal stream hydraulic conditions at highway structures recommended a one-dimensional unsteady flow model entitled UNET (Burkau 1993; USACE 1996) and a two-dimensional unsteady flow model entitled FESWMS (Froehlich 1996). The studies were carried out by Ayres Associates, Inc., and Edge & Associates, Inc, with William H. Hulbert, North Carolina DOT, as project manager (Ayres Associates 1994; Zevenbergen et al. 1997a; 1997b). The use of FESWMS was enhanced by the FHWA-supported development of a graphical user interface called the Surface Water Modeling System (SMS) (Brigham Young University 1997). The interface develops two-dimensional model networks, run control, variable assignment, and output analysis for FESWMS. Both models proved themselves under a wide range of field tidal conditions.

Methods for predicting storm surge hydrographs using peak storm surge elevation and hurricane characteristics (radius of maximum winds and forward speed) for the 50-, 100-, and 500-year hurricanes are included. Zevenbergen et al. (1997a, b) contain methods and procedures for using UNET, FESWMS, and SMS and developing of storm surge hydrographs.

## CHAPTER 11

### ***Bridge-Scour Prevention and Countermeasures***

*Bruce W. Melville, Arthur C. Parola, and Stephen E. Coleman*

#### **11.1 INTRODUCTION**

Bridge-scour countermeasures are methods to protect bridges from scour and channel instability. Countermeasures include specific protection for piers and abutments, such as riprap, gabions, and other alternatives to riprap, the construction of guide banks at the ends of approach embankments encroaching on wide floodplains, grade control structures such as rock weirs, channel bank protection such as groins, and channel improvements such as channel straightening at the bridge site. The various bridge-scour countermeasures are described and categorized by scour type in Table 11-1. Design information for rock riprap is included in Appendix B.

The need for countermeasures can be avoided or reduced by appropriate bridge design. Good design practice comprises both the selection of a crossing site to reduce the likelihood of excessive scour and the design of the foundations and bridge superstructure to minimize the total depth of scour at the chosen site.

The results of a survey of bridge authorities in the United States conducted in 1995 (Parker et al. 1998) are shown in Table 11-2. The survey included more than 220,000 bridges and revealed that scour countermeasures were employed at 36,432 sites. Monitoring of scour depths was included as a form of countermeasure. Excluding monitoring, rock riprap is the most common countermeasure. Other commonly used countermeasures are rock gabions, extended footings, concrete pavement, grout-filled bags, and spurs. Table 11-2 lists a number of nonstructural countermeasures, including monitoring of scour depths, bridge closure, use of alarms, and imposing restrictions on vehicle use.

This chapter principally addresses countermeasures for local scour at bridge abutments and bridge piers, as well as countermeasures for general scour or channel degradation. The discussion is focused on commonly encountered countermeasures, especially riprap.

#### **11.2 SCOUR PROCESSES**

##### **11.2.1 Mechanisms of Local Scour around Piers**

The mechanics of flow at bridge piers is driven by strong pressure gradients caused by the stagnation of the flow on the upstream side of the pier, coupled with the nonuniform velocity distribution of the approaching flow, edge effects on the sides of piers, and flow expansion on the downstream side of the pier. The nonuniform velocities and pressures create flow separations and several three-dimensional vortex systems, which are scour-producing features that can fluctuate dramatically in size and intensity. Figure 11-1 shows a schematic representation of the dominant flow features at a rectangular pier.

The strong pressure gradient induced by the pier and the vertical velocity gradient causes a three-dimensional boundary-layer separation upstream and a system of three-dimensional vortices known as the horseshoe vortex system (Dargahi 1987; 1989). The nonuniform stagnation pressure zone on the upstream side of the pier forces high-velocity surface flow downward, where it impinges on the streambed at the base of the pier and rolls up into a horseshoe vortex system that is eventually carried to the pier sides. Under many flow conditions, the deepest scour has been observed to form under the area of flow impingement beneath the horseshoe vortex system (Melville and Coleman 2000).

A feature similar to the horseshoe vortex forms on the water surface upstream of the pier. The momentum gradient caused by the reduction in density at the air/water interface, in combination with the adverse pressure gradient of the pier, forms a flow reversal near the water surface. The general rotation in the surface roller is opposite to the rotation of the horseshoe vortex system. In addition, the deformation of the free surface by the roller instigates a wave that emanates from the pier nose. For relatively shallow flows, a weakening of the horseshoe vortex at the base of the pier has been attributed to the interaction of the surface roller.

**Table 11-1 Bridge-Scour Countermeasures**

Scour type	Measures	Purposes	Examples	Description
Channel instability – bank erosion	Armoring devices (revetment)	Prevention of erosion to the channel bank in the vicinity of the bridge; stabilization of channel alignment	Rock riprap	Dumped or placed broken rock
			Artificial riprap	Alternatives to rock riprap, including tetrapods, toskanes, akmons, and dolos
			Gabions and Reno mattresses	Wire-mesh baskets and mattresses filled with loose stone
			Precast concrete blocks	Concrete blocks of a cellular shape, possibly interlocking
			Cable-tied blocks	Concrete blocks or slabs interconnected with steel cables
			Grout-filled bags	Fabric bags filled with concrete
			Vegetation	Trees, shrubs, grasses
			Used tires	Used tires placed as a mattress or stacked against a bank
			Grouted riprap, concrete apron, grout-filled mats	Rigid revetments, grout-filled mats (fabric bags filled with concrete), and grouted riprap
	Flow-retarding devices	Reduction of flow velocity near the channel bank and inducement of deposition of sediment	Timber piles, sheet piles, Jack or tetrahedron fields	Permeable structures in a channel, generally placed parallel to the bank
			Vegetation planting	Trees planted to control bank erosion
	Flow-training devices	Reduction of flow velocity near the channel bank and inducement of deposition of sediment; stabilization of channel alignment	Groins (also known as spurs, dikes, jetties, wing dams, or deflectors)	Permeable or impermeable structures, projecting into the flow
			Hardpoints	Small spur-like structure of stone fill spaced along an eroding bank line
			Bendway weirs	Small spur-like structures, typically submerged at normal water levels, spaced along an eroding bank line
			Iowa vanes	Vertical plates installed in a streambed designed to break up secondary flow and mitigate the tendency to lateral migration of banks
Degradation and contraction scour	Check dams	Control of channel grade	Low dams or rock weirs	Constructed across the channel width
	Channel lining	Control of vertical erosion	Concrete or bituminous-concrete pavement	Reinforced-concrete or bituminous-concrete pavement covering channel bed and banks
			Boundary-armoring measures above	For contraction scour and not degradation

*(Continued)*

**Table 11-1 Bridge-Scour Countermeasures (Continued)**

Degradation and contraction scour	Bridge waterway area	Increase of bridge opening size or efficiency	Channel widening, relief bridges, or guide banks	
Aggradation	Channel improvement	Increased sediment transport to reduce sediment deposition at bridge crossing	Dredging, clearing of channel Formation of a cutoff Flow-control structures	
	Controlled mining	Reduction in sediment input at bridge site	Mining of bed sediment Bar mining	
	Debris basin	Reduction in sediment input at bridge site	Debris basin	Constructed to trap sediment
Local scour	Armoring devices	Reduced local scour	Rock riprap	Dumped or placed broken rock
			Artificial riprap	Alternatives to rock, including tetrapods, toskanes, and akmons
			Gabions and Reno mattresses	Wire mesh baskets and mattresses filled with loose stone
			Cable-tied blocks	Concrete blocks or slabs interconnected with steel cables
			Grout-filled bags	Fabric bags filled with concrete
			Grouted riprap, concrete apron, grout-filled mats	Rigid revetments
	Flow-altering devices	Reduced local scour at piers	Sacrificial piles	Piles or vanes placed upstream of bridge pier(s) to deflect flow away from the piers
			Iowa vanes	
			Horizontal collars	Thin horizontal plates attached to the base of the pier, to deflect flow away from the sediment bed
	Foundation modification	Reduced local scour	Underpinning Extended footing	Extending bridge foundations to lower levels Slab footing to piers, which can inhibit local scour
	Guide banks	Improved flow alignment at bridge crossing; reduction in local scour at abutments		Straight or outward-curving structure, extending upstream from the end(s) of the approach embankment

**Table 11-2 Distribution of Types of Scour Countermeasure in a 1995 U.S. Survey (after Parker et al. 1998)**

Countermeasure	Number	Percentage
Dumped riprap	5,913	16.23
Self-launching riprap	72	0.20
Rock gabions	567	1.56
Other flexible revetment	37	0.10
Pavement	253	0.69
Grout-filled bags	97	0.27
Concrete-grouted riprap	27	0.07
Concrete-filled mat	51	0.14
Tetrapods	1	0.003
Extended footings	778	2.14
Cable-tied blocks	6	0.02
Vanes (pier or bed)	1	0.003
Sacrificial piles	22	0.06
Flow-direction plates	6	0.02
Jetties	43	0.12
Spurs	420	1.15
Retards	35	0.10
Check dams	83	0.23
Rock bank protection	79	0.22
Soil cement	7	0.02
Increase bridge span	2	0.005
Brace piles in transverse direction	5	0.01
Monitoring	27,770	76.22
Alarms	22	0.06
Bridge closure	111	0.30
Vehicle restriction	0	0.00
Other	24	0.07
Total	36,432	100.0

Three-dimensional spiral-edge vortices form downstream of flow separation lines on the corners of rectangular piers, on the sides of cylindrical piers, and at the upstream and downstream edges of round-nosed piers skewed to the flow direction. The vertically oriented vortices remain attached to the streambed just downstream of the separation from pier corners. These tornado-like flow structures transfer flow and sediment from the streambed upward and may be a primary mechanism of removal of dislodged sediment from scour holes. For clear-water scour conditions, Hjorth (1975), Parola (1993), and others reported that the primary mechanism of initial failure of armor protection was related to the

flow at the edge separation points on rectangular piers, where conditions have been reported to be as much as an order of magnitude higher than those of the approaching flow.

Wake vortices form in response to the adverse pressure gradient of flow expansion, along with the highly nonuniform flow that is created along the shear flow zone on the pier sides. These vortices dominate the flow structure downstream of piers.

The pressure gradient that causes formation of the horseshoe vortex also deflects flow to the pier sides. The vertical nonuniformity of the boundary-layer flow approaching the pier in the presence of the stagnation pressure gradient causes a secondary flow throughout the flow depth as flow passes around the sides of the pier. Where the stagnation pressure gradient is relatively weak (wide piers in shallow flows), the vortical flow developed from flow curvature may be the most important feature in the formation of scour holes.

These large-scale vortical flow structures combine to increase the sediment entrainment and transport capacity by increasing near-bed flow velocity, turbulence levels, vorticity, and seepage gradients. In locations where surface water impinges on the streambed, near-bed streamlines and the sediment carried along them are deflected away from the region of the pier. Protection placed in this environment must resist the forces generated by these mechanisms and undermining by seepage and winnowing.

### 11.2.2 Mechanisms of Local Scour around Abutments

Although conceptually the pressure gradients and vertical nonuniformity that create the vortical flow at piers are also present at abutments, many factors associated with the generally large lateral extent of the flow field disturbed by abutments become important. In particular, the lateral extent of the flow disturbance is typically much larger than the flow depth. In contrast to the relatively uniform approach flow at piers, floodplain and main-channel geometry and roughness cause flow nonuniformity. The nonuniform lateral velocity distribution and extensive upstream adverse pressure gradients create upstream horizontal flow separation and recirculation zones. In laboratory experiments, where relatively low-roughness floodplains have typically been simulated, large separation regions called dead-water zones have been reported to form. Although the extent of the pressure gradients is larger, they are general much weaker than at piers. As a consequence, the dominant large-scale vortical structures include

- the flow curvature upstream that causes the primary vortex (see below) to form,
- the spiral edge vortices that form at flow separation from the edges, and
- the wake vortex systems.

Where abutments extend into the main channel or where bends force high-velocity flows against abutments, strong pressure gradients similar to those at piers may develop.

Fig. 11-1. Flow structures at a rectangular pier (modified from Parola 1995).

The pressure gradients caused by the flow at abutments force flow to contract toward the bridge opening. For short abutments that project into high-velocity flow, strong pressure gradients, similar to those at piers, cause a vortex to form that is similar to the horseshoe vortex. For relatively long abutments in relatively shallow flows, pressure gradients may be weaker; therefore, long vortices with their axes in the stream-wise direction develop. The strongest of these vortices has been called the primary vortex (Kwan 1984). Although the pressure gradients induced by abutments are typically not as severe as those at piers, the effects of the pressure gradients are more extensive, causing flow curvature that extends far upstream of a bridge crossing. The flow curvature causes the formation of longitudinal vortex systems. Spiral-edge vortices, similar to those created at piers, form along the vertical edges of vertical-wall abutments and along spillthrough abutments at the point of flow separation. Initial scour-hole formation frequently is initiated at these locations. The initial movement of rock protection has been reported to occur at these locations in model studies by Pagan-Ortiz (1991).

### 11.2.3 Effects of River Morphology Development and Channel Contraction on Bridge Scour

Bridge-scour processes occur over a range of scales, from the local-scour scale around individual foundations described

above, to the catchment scale extending to the limits of the catchment of the flow through the bridge section. In addition to local scour arising directly from the presence of individual bridge foundations, scour at a bridge site can arise due to contraction of flow width for the waterway section associated with the bridge structure (contraction scour), and also general river processes (general scour), including the respective processes of aggradation; degradation; scour in channel bends and channel confluences; scour due to the movement of both the channel thalweg and waves in the channel bed sediments; and lateral erosion arising from general bank erosion, channel widening, and channel migration processes. The total scour at a bridge site is given by the combination of the relevant components of general, contraction, and local scour.

Contraction scour can occur wherever the waterway section is laterally contracted by either natural channel morphology, such as a narrow neck in the river (a common bridge location), or imposed structures such as bridge foundations and associated road approach embankments. The width reduction causes increased flow velocities and bed shear stresses through the section, potentially increasing scour across the site as a whole. Analogously to local scour occurring at a bridge abutment, additional localized scour also typically occurs along boundaries at the entrance to a contraction where the flow is nonuniform. In practice,

contraction scour and local scour can occur together and it may be difficult to distinguish between them.

Aggradation, involving the building up of bed levels, can be ascribed to sediment supply generally exceeding sediment transport capacity or to a raising of the base level. Degradation, the lowering of bed levels over a region larger than the immediate vicinity of the bridge site, is conversely the result of sediment transport capacity generally exceeding sediment supply or a lowering of the channel base level. With sediment supply for a reach provided by erosion of the catchment and waterway, and sediment transport capacity a function of sediment size, channel size and discharge, degradation and aggradation are strongly influenced by changes in hydraulic regimes, geomorphic channel controls, and also catchment land uses, including changes in mining, deforestation, agricultural, urbanization, and river management practices within the catchment. Both aggradation and degradation can proceed in upstream or downstream directions, and both can induce associated lateral channel instability. It is important to recognize that cyclic aggradation and degradation responses of bed levels can follow from a disturbance to a channel system.

For most flows inducing general sediment motion at a bridge site, sediment waves will be migrating through the site. Waves in sand beds are commonly classified as ripples, dunes, antidunes, or chutes, and pools. In gravel-bed rivers, waves occur mostly as gravel bars moving down the river. With heights of migrating dunes and bars in natural alluvial channels potentially up to the order of the mean flow depth (Melville and Coleman 2000), the passage of these waves can potentially influence bridge scour significantly with wave troughs temporally and locally lowering bed elevations as the waves propagate through a site. Bed roughnesses determined by these waves also significantly affect stage-discharge relationships during the passage of floods.

Lateral movement of the channel thalweg (the line of lowest bed elevation along the channel) is a natural process that alters local bed elevations, inducing scour, and can change the point and/or angle of attack for a flow at a bridge site. Bridges need therefore to be designed for the potential influence of the thalweg occurring in the vicinity of each foundation.

At a confluence of river channels, the individual streams typically meet toward the centerline of the confluence, plunge to the channel bed, and then return to the water surface along the sides of the confluence. The induced helicoidal secondary currents, similar to such currents formed in river bends, result in a deep scour hole with steep sides. Channel confluences can form randomly in time and space for braided reaches, with the resulting scour holes potentially reaching depths below the surrounding bed of up to five times the mean flow depth in the converging channels. Such scour holes have been noted to be contributing factors in a number of bridge failures (Coleman et al. 2000; Coleman and Melville 2001).

For flow around a curved reach or bend, the interaction between the vertical gradient of streamwise velocity and the curvature of the primary flow generally produces secondary currents leading to greater flow depths, velocities, and shear stresses at the outside of the bend. These result in channel deepening at the outside of the bend (bend scour) and, in conjunction with concurrent undermining of the outside stream bank, increased lateral erosion at the outside of the bend.

Lateral erosion, reflecting the dynamic nature of channel planform, can have significant consequences if not allowed for in the design of static bridge structures. In addition to being associated with bend scour, lateral erosion can be in the form of general channel-bank erosion, channel widening, or channel shift for meandering and braided rivers. The relative importance of lateral erosion processes is reflected by the conclusion of Simon (1994; 1995) that width adjustment processes may represent the dominant mode of morphology adjustment for rivers. Certainly, Parola et al. (1996) indicate lateral channel instability to be one of the most common factors underlying excessive bridge and abutment scour and approach endangerment.

General channel-bank erosion can result from weathering mechanisms such as freeze-thaw and desiccation, seepage effects, surface runoff, erosion by current flow, the action of waves, the sediment-transport capacities of flows exceeding the potential supply of sediment from the channel bed, and mass failure mechanisms for banks, including sliding along a deep failure surface, shallow slips, and block failures.

Channel widening can accompany aggradation as flows seek to increase in width when the bed aggrades and flow depths decrease. Degradation can also result in channel widening, owing to the removal of toe support for the river banks, or resulting from increased excess pore pressures on the declining limbs of flood hydrographs causing bank failure.

For meandering and braided (including anabranching) rivers, incremental channel shift is inherent. Meander migration is typically directed outward and downstream and is typically a relatively slow and somewhat methodical process. For braided reaches, dramatic channel avulsion can occur in the course of a single flood, particularly for rivers with little vegetation within the floodplain. Incremental channel shift can be exacerbated by human activities such as land-use practices, gravel mining (Coleman and Melville 2001), and the removal of riparian vegetation.

Where bank erosion is a significant source of floating debris, lateral erosion can also lead to increased floating debris loading on bridges in the river, exacerbating any local scour at bridge foundations.

In regard to the overall assessment of potential scour magnitudes for a bridge, analyses of case studies of scour-induced bridge failure (Coleman and Melville 2001) indicate that ranges of combinations of potential scour components need to be considered—for example, solely pier scour, or pier scour combined with bend and contraction scours. Floods on the order of bank-full flows should be considered to assess

channel lateral migration and the influence of countermeasures on long-term lateral and vertical stream stability. Countermeasures should be designed to provide transport of sediment and debris through the bridge during bank-full events that is similar to that of the upstream and downstream reaches to prevent degradation or aggradation and lateral shift within the bridge opening. Case studies of scour-induced bridge failure (Coleman and Melville 2001) highlight, however, that both bridge-scour vulnerability and countermeasure design also need to be assessed for the occurrence of minor floods made more critical by present or potential river morphology at the bridge site.

### 11.3 PROTECTION AGAINST GENERAL SCOUR AND CONTRACTION SCOUR

#### 11.3.1 Site Selection

The characteristics of a river can change considerably over short distances. Where multiple choices of bridge site are available, the following factors should be considered, although economic considerations may dictate selection of the shortest crossing point. Generally, sites exhibiting evidence of channel instability including degradation and aggradation, lateral movement and bank erosion, and hydraulic problems at other bridges in the area need to be assessed carefully.

**11.3.1.1 Catchment Influences** In bridge site selection, the potential influence on the site of changes within the catchment should be assessed, including history and patterns of water levels, flood magnitudes, earth flows, landslides, volcanic or earthquake activity, channel bars, channel confluence location, channel morphological controls, bank erosion, degradation, aggradation, and lateral channel instability. In particular, changes in human activities within a catchment can potentially influence vertical and lateral channel stability for the catchment. Such activities include agriculture, vegetation clearing, forestation, strip mining, urbanization, dam construction or removal, stream-bed mining or dredging, channel clearing, and channel realignment or containment.

**11.3.1.2 Alluvial Fans** Alluvial fans are inherently unstable, channels on the fan being potentially subject to rapid aggradation, degradation, and shift in channel location. Thus, bridges located on alluvial fans may be subject to continual problems due to channel instability. It is normally better to select a location at the apex of the fan where the channel is relatively more stable.

**11.3.1.3 Influence of Channel Curvature** Potential variation in river planform needs to be allowed for in the design of bridge foundations. Bridge locations on stable straight reaches or gentle bends, or at positions of geologically stabilized morphology, are often preferable. In meandering rivers, the choice is between a location at a bend or at a crossover point, although in some cases, the ideal location of a nodal point may exist, where the river has been flowing permanently irrespective of past river alignment changes.

At a crossover the channel is wider, but may be more stable laterally than at a bend, where the channel is typically narrower and deeper. Bridge locations at stable bends necessitate designing the piers on the outside of the bend for the deepest channel scour, whereas the piers on the inside of the bend can be designed for less scour. If the bend can migrate, then all foundations need to be designed for the maximum scour in the bend. In straight reaches, the point of deepest scour can shift from side to side so that all piers need to be designed for the maximum scour. Foundations in the floodplain of a river need to be placed at the same level as those in the main channel if analyses indicate that the main channel can potentially move across the present floodplain.

#### 11.3.2 Bridge Waterway Area

Wide, unimpeded bridge waterways are preferable. Constricted waterways induce contraction scour. The constriction can be lateral, due to the bridge foundations, or vertical, due to the bridge superstructure becoming submerged. It is important to ensure that the bridge is designed with adequate clearance between the maximum water level and the lowest level of the superstructure (including allowance for potential debris accumulations) to avoid superstructure submergence. In addition, it may be desirable to have the approach roadways at a lower level than the underside of the bridge superstructure, this allowing floodwater to overtop the approaches without intercepting the superstructure. The consequences of flow contraction can also be relieved by the construction of auxiliary (relief) bridges for floodplain flow.

In the design of new and replacement bridges where river morphology or existing structures severely contract flow, additional floodplain spans and relief structures should be considered. In the design of a replacement for a bridge structure that may be providing grade control, any increase in the bank-full flow capacity of the bridge opening may initiate degradation upstream and may thereby warrant the installation of appropriate grade control structures at the site to prevent such progressive degradation.

#### 11.3.3 River Training Works

The cost of river training works at bridge sites can be significant. Training works are not normally required in relatively straight and stable reaches, where sites having the narrowest main channels and the smallest proportion of floodplain flow are preferable. In less stable rivers, sites requiring a minimum of river training are often preferable. For example, sites may be found where rock outcrops or other controls effectively limit lateral movement of the river channel.

#### 11.3.4 Bank Protection

Lateral instability through general channel-bank erosion, bend scour, channel widening, or channel shift can result in

erosion of abutments, breaching of bridge approaches leading to the bridge being outflanked, and scour of bridge foundations located outside of the main channel. Where bank failure is by rotational slip, lateral pressures on bridge foundations within the slip zone can further result in displacement or cracking of the foundations.

Lagasse et al. (2001) indicate that impermeable longitudinal stone dikes parallel to the bank line, or smaller rock toe-dikes, provide the most effective toe protection of all bank stabilization measures studied for very dynamic and/or actively degrading channels, the authors presenting design procedures for these dikes. Aside from such bank stabilization measures, measures to counter lateral erosion act to armor the boundary or retard or train the flow. Flow training measures include groins, hardpoints, bendway weirs, and Iowa vanes. The following focuses on countermeasures that are more commonly encountered or that hold potential.

#### 11.3.4.1 General Comments on Armoring Measures

Armoring measures, also known as revetments, are channel linings used to provide erosion-resistant surfaces. They can be flexible or rigid. Flexible revetments include rock riprap, artificial riprap (including akmons, dolos, and tetrapods), broken concrete, used tires, grout-filled bags, precast blocks, cable-tied blocks, gabions and Reno mattresses, and vegetation. Rigid revetments used include concrete pavement, grouted riprap, concrete-filled fabric mat, and cement-stabilized soil. Flexible revetments have the advantage of being able to adjust to local displacement of underlying materials without complete failure of the installation, although such deformations tend to be limited for mattresses of used tires or precast blocks. All revetment types must be designed to protect against

- slumping due to over-steepened slopes,
- undermining due to inadequate toe protection, and
- outflanking due to inadequate lateral coverage.

Any hardening of the outer bank of a bend to counter lateral erosion can potentially exacerbate vertical erosion in the bend by preventing the supply of sediment from bank erosion. There is evidence, however (Harvey and Sing 1989; Thorne et al. 1995), that hardening of the outer bank has no effect on maximum flow depth in the bend.

**11.3.4.2 Rock Riprap and Broken Concrete** Rock riprap is the measure most commonly used to protect banks from erosion. Guidelines and principles for the use of riprap as bank protection are given in Appendix B. Broken concrete has been used as an alternative to rock riprap in emergencies where rock of suitable sizes and quality has not been readily available.

**11.3.4.3 Artificial Riprap, Grout-Filled Bags, Precast (including Cable-Tied) Blocks, and Used Tires** Artificial riprap, typically fabricated of reinforced concrete in the form of standard units, may become cost-effective where rock riprap of a required size and quality is not readily available. Prefabricated units such as dolos, tetrapods, tetrahedrons,

Fig. 11-2. Example of flexible armoring measures.

and toskanes (Fig. 11-2) are designed to give maximum interlocking, and thereby maximum protection of the underlying surface, using a minimum amount of material. Artificial riprap is widely used in the coastal environment and for river-bank protection. The most common mode of failure of these armor units is edge failure. Each form of armor unit will have unique design criteria, and reference should be made to the unit manufacturer. Specifications for tetrapods and toskanes are given in USACE (1984). Filter layers or bedding material may be required to achieve the desired hydraulic performance.

Stacked grout-filled bags form a flexible armoring countermeasure. These bags, however, provide little interlocking, with or without a geotextile, and are thereby subject to sliding and dispersion, leading to failure of the armoring measure, in the presence of degradation or a dune field. Lagasse et al. (2001) observe that grout-filled bags are installed only where rock of suitable size and quality has not been readily available. They comment that engineering judgment is typically used to select a bag size that will not be moved by channel flows. Installation practices critical to the success of grout-filled bag systems are discussed in Lagasse et al. (2001). Bags filled with sand instead of grout may offer additional advantages, including increased countermeasure flexibility, and possibly better interlocking.

Cable-tied blocks are flexible mats of interconnected smaller units (Fig. 11-2), typically concrete blocks or slabs interconnected with steel cables. The flexibility of the mat enables settlement of the mat edges, facilitating self-anchoring of mats in sand-bed streams. The blocks can be constructed in units with a preattached geotextile. The interconnected nature of the blocks allows stable scour protection to consist of smaller block units than for loose riprap. Failure modes for cable-tied blocks are found to include overturning and rolling up of unsecured leading edges and uplift of inner mats at higher velocities.

Lagasse et al. (2001) cite favorable reports of the performance of precast concrete blocks, where vegetation growing between the blocks can improve the appearance and stability of the countermeasure. They observe that each form of pre-formed block unit, including those that interlock and those held together by steel rods or cables, will have unique design criteria that should be available from the block manufacturer, these criteria having been formulated to ensure that intimate contact between the revetment and the protected subgrade is maintained under the desired hydraulic conditions. Lagasse et al. (2001) note that the significant influence of block protrusion into the flow on block stability necessitates construction inspection to ensure that blocks are installed within design tolerances.

Revetments of used tires in lieu of rock riprap have been successfully used for flow velocities up to 3 m/s on mild bends. These revetments can accommodate minor bank subsidence, but are somewhat unsightly and vandalism-prone and are typically expensive, owing to construction being labor-intensive. To aid revetment stability, tires should typically be tied together, with the revetment edges tied to the bank. They can also be packed with rock. In addition, the tires should fit together well; they can be assisted by vegetation planted in the tires (also aiding aesthetics); and they should resist uplift by being anchored to the bank at intervals and by having the sidewalls pierced to prevent flotation.

**11.3.4.4 Concrete-Grouted Riprap, Concrete Pavement, and Grout-Filled Mats** Concrete-grouted riprap is relatively cost-effective, making possible the use of rock of smaller sizes and wider gradings, although it scores poorly in terms of aesthetics and environmental acceptability. The decreased countermeasure flexibility negates the natural benefit of riprap being able to deform and armor developing scour, caused by toe undermining or bank settlement, for example. The reduced permeability of the armor layer arising from the grouting, although decreasing the need for filter layers beneath the countermeasure, is disadvantageous in that uplift from turbulence and confined groundwater can lead to failure of the rigid riprap layer in entirety.

Concrete pavement is similarly subject to problems of aesthetics, environmental acceptability, and susceptibility to uplift pressures. Weep holes can be used for relief of hydrostatic pressures for both concrete-grouted riprap and concrete pavement. Partially grouted riprap (in conjunction with underlying filter layers) can be used as a compromise measure, the grout acting to increase the stability of riprap installations without sacrificing all of the flexibility or pore-pressure-drainage advantages of loose riprap.

Grout-filled mats are continuous layers of fabric with pockets or cells that are filled with concrete. These mats, typically strengthened with cables, form a monolithic armor-ing countermeasure that is taken to be rigid in action. Grout-filled mats face the same problems as concrete-grouted riprap and concrete pavements, although porous mats may act to relieve hydrostatic pressures. Lagasse et al. (2001) present

analyses of the hydraulic stability of these mats that make possible determination of mat thickness for a desired factor of safety against sliding of the unanchored mat.

In addition to potential failure due to uplift, these rigid revetments are subject to undermining by both hydraulic action (at the toe, the upstream and downstream edges, and also the upper edge if overtopped) and channel degradation. Grout-filled mats can also fail by overturning and rolling up of an unsecured leading edge, or uplift of the inner mat at higher velocities.

**11.3.4.5 Gabions and Reno Mattresses** Rock-and-wire gabions and mattresses comprise wire-mesh baskets and mattresses filled with loose stone, often connected together and often anchored to the channel boundary.

In comparison to more solid countermeasures, gabions are less susceptible to uplift forces, owing to the porous nature of the loose-rock fill material. In addition, should the countermeasure installation become unstable, the flexibility of the wire mesh enables gabions to mould themselves somewhat to restore stability of the installation. Gabions and Reno mattresses further allow the use of smaller rock than used for standard riprap protection (Simons et al. 1984), and can be used to protect steeper slopes, although gabions and mattresses are more expensive.

Damage to the wire mesh is a major reliability problem for gabions and Reno mattresses, potentially resulting in failure of individual gabions or even complete failure of the countermeasure installation as a whole. Wire damage may be from long-term corrosion or from abrasion due to the movement of either contained rock in highly turbulent flows or passing sediments in floods.

Design criteria for gabions can be determined from the unified formula (Table 11-3) of Pilarczyk (1995); this formula combines various design formulae for armoring countermeasure options. Alternatively, for stream slopes less than 2%, Maynard (1995) proposes use of the U.S. Army Corps of Engineers equation of B.11, where riprap size of which 30% by weight is finer,  $D_{30}$ , is replaced with the average filling rock diameter,  $D_m$ , which in turn is taken to be equivalent to half of a minimum gabion-basket thickness,  $D_{mmin}$ ; that is,  $D_{30} \rightarrow D_m = D_{mmin}/2$ . For this procedure, a blanket thickness coefficient of  $C_T = 1$  is adopted, and the stability coefficient  $C_s$  is taken to be  $C_s = 0.1$ . For additional detailed guidelines in regard to the materials and construction of gabions and Reno mattresses, the reader is referred to Parker et al. (1998).

**11.3.4.6 Vegetation** Through root action, dissipation of flow energy, and encouragement of sediment deposition, grasses and woody plants (trees and shrubs) act to armor surfaces to counter erosion and stabilize banks. Grasses can be used to protect upper banks that are subject to erosion due to rainfall, overland flow, and minor wave action. Woody plants offer better erosion protection owing to more extensive root systems. The U.S. Department of Agriculture (USDA 1996) provides U.S. guidelines for the use of vegetation as a method

**Table 11-3 Unified Formula for Armoring Countermeasure Options (after Pilarczyk, 1995)**

Factor		Relation
Unified formula	$\Delta D_n = \phi_c K_t \frac{0.035}{\theta_c} \frac{K_h}{K_{sl}} \frac{V^2}{2g} \quad (11-6)$	
	$V$ = depth-averaged mean velocity	
Relative density, $\Delta$	$\Delta = (S_s - 1)$ $\Delta = (1 - n)(S_s - 1)$ $n$ = porosity of stones $S_s$ = specific gravity of stones	Rock riprap, Blocks, Blockmats Gabions, Mattresses
Unit size, $D_n$	$D_n = 0.84 D_{r50}$ $D_n$ = block thickness $D_n$ = basket thickness $D_{r50}$ = median size of riprap	Rock riprap Blocks Gabions, Mattresses
Stability factor, $\phi_c$	$\phi_c = 1.0 \rightarrow 1.5$ $\phi_c = 0.50 \rightarrow 0.75$ $\phi_c = 0.75$	Exposed edges Continuous protection Common value for rock
Turbulence factor, $K_t$	$K_t = 1.0$ $K_t = 1.5$  $K_t = 2.0$ $r$ = bend radius $W$ = channel width	Normal turbulence (rivers) Nonuniform flow with increased turbulence, Outer bends ( $r/W > 2$ ) High turbulence, e.g. sharp outer bends, ( $r/W \leq 2$ )
Critical shear stress, $\theta_c$	$\theta_c = 0.035$ $\theta_c = 0.05$ $\theta_c = 0.05 \rightarrow 0.07$ $\theta_c \leq 0.10$	Rock Free blocks Blockmats, Mattresses Rock-fill in gabions, Mattresses
Velocity profile factor, $K_h$	$K_h = \frac{2}{\log^2 \left( 1 + 12 \frac{H}{D_n} \right)}$ $K_h = \left( 1 + \frac{H}{D_n} \right)^{-0.2}$ $H$ = flow depth	For a fully-developed log velocity profile  For a not-fully-developed velocity profile
Bank slope factor, $K_{sl}$	$K_{sl} = \left( 1 - \frac{\sin^2 \alpha}{\sin^2 \theta} \right)^{0.5}$ $\alpha$ = slope angle $\theta$ = angle of repose

of streambank protection, including descriptions of principles, practice characteristics, design, construction materials, and appropriate techniques for streams, lakes, and estuaries. Willow trees have been successfully used in New Zealand (Acheson 1968) for protection of lower banks, where they establish quickly, withstand inundation, and are sufficiently dense to promote deposition of sediment. In terms of using vegetation as a countermeasure for bridge scour, care must be taken to ensure that any introduced vegetation does not adversely reduce channel capacity. In addition, Lagasse et al. (2001) recommend that vegetation not be seriously considered as a countermeasure against severe bank erosion where a highway facility is at risk.

**11.3.4.7 Flow-Retarding Measures** Flow-retarding measures (retards) are typically permeable structures, generally installed parallel to the bank and placed at the toe of the bank. They are thus best suited to protecting low banks or the lower portions of stream banks. They are designed to reduce flow velocity and control flow alignment, and thereby induce sediment deposition and prevent lateral erosion, creating an environment suitable for the establishment of vegetation. Retards include piles (typically timber or steel), fences, vegetation planting, and fields of jacks or tetrahedrons (with individual units possibly tied together using cables).

Key factors in the design of these measures include the availability of adequate floating debris and bed material to facilitate development of flow resistance and sediment deposition and the potential for bank revegetation to aid bank stability. The required permeability of retards is inversely proportional to the radius of curvature of the bend being protected, sharper bends requiring less permeable retards. Retards must be designed to withstand local scour processes and the potential impact of debris on structural loads and local-scour magnitudes.

Brown et al. (1981) conclude that retards are most successful for channels of widths less than about 100 m, flow velocities not frequently exceeding 1.5 to 1.8 m/s, and beds of sands with relatively large bed and suspended loads.

**11.3.4.8 Groins and Bendway Weirs** Groins (also referred to as spurs, dikes, wing dams, jetties, or deflectors) are structures that project from the bank into the channel (Fig. 11-3). Commonly constructed using rock, they may be permeable or impermeable and submerged or unsubmerged. They are designed to control flow alignment and reduce flow velocities near scour-threatened boundaries, thereby preventing lateral erosion, and possibly also inducing sediment deposition in the scour-threatened zone. They act through a combination of diverting flow around the structure, reducing flow along the bank as it passes through the structure, and redirecting flow passing over the weir. Groins are typically used to control meander migration. They can also be used to align wide, poorly defined streams into well-defined channels, reducing required lengths for any planned bridge crossings.

Fig. 11-3. Aspects of the design of a field of 7 groins.

The specification of standardized procedures for the design of groin fields is inappropriate owing to any given design being inherently site-specific. Some general principles, including published guidelines for groin spacing, are summarized in Table 11-4. Bendway weirs, also referred to as stream barbs, bank barbs, and reverse sills, essentially act as upstream-pointing submerged groins. Alternative guidelines (in terms of lengths, orientations, spacings, locations and numbers, heights, cross-sections, and construction) for these structures, particularly for larger structures or larger rivers, are given in Lagasse et al. (2001).

**11.3.4.9 Hardpoints** Hardpoints are small groin-like structures of stone fill placed along an eroding bank line. They are distinguished from groins because they protrude only short distances into the channel, typically acting individually to provide localized protection against scour. Lagasse et al. (2001) indicate that hardpoints are most effective where streamlines and bank lines are approximately parallel and velocities within 15 m of the bank line are less than approximately 3 m/s. These structures can be effective where bank erosion is mainly caused by a wandering thalweg, but close spacings required by the short lengths typically render these structures uneconomic for protection of meander bends.

**11.3.4.10 Submerged (Iowa) Vanes** Iowa vanes are submerged vertical plates installed in the streambed to deflect flow and control sediment deposition and erosion (Odgaard and Wang 1987). These vanes have been successfully used to control erosion in river bends (Odgaard and Kennedy 1983), ameliorate shoaling problems in rivers (Odgaard and Spoljaric 1986), and control sediment at lateral diversions (Barkdoll et al. 1999). The reader is referred to these papers, and particularly Odgaard and Wang (1991a; 1991b), for design guidelines and principles for the use of Iowa vanes in these situations.

### 11.3.5 Degradation, Contraction, Thalweg, and Sediment-Wave Effects

Each process of degradation, contraction scour, thalweg effects, or sediment-wave effects can lead to undermining

**Table 11-4 Principles and Guidelines for the Design of Groin Fields (see Fig. 11-3)**

Factor	Design criteria		
Groin length, $L_g$ (normal to flow or bank)	Where the bank is irregular, groin length should be adjusted to provide even curvature of the thalweg Generally, $L_{ge} < 0.15W$ ( $W$ = channel width) for impermeable groins, and $L_{ge} < 0.25W$ for permeable groins, where $L_{ge}$ = effective groin length = distance between arcs describing the toe of the groin field and the desired bank line		
Groin orientation	Orientation affects groin spacing, scour depth at the tip of the groin, and degree of flow control achieved Groins oriented normal to the flow are most economical because they provide maximum protrusion for a given groin length The first (upstream) groin should be angled downstream		
Groin spacing, $S_g$	$S_g = L_{ge} \cot \theta$ ; where $\theta$ is the flow expansion angle downstream of the groin tips ( $\approx 17^\circ$ for impermeable groins, and increasing with permeability greater than 35%, Lagasse et al. 2001)		
	<i>Reference</i>	$S_g/L_g$	<i>Applicability</i>
	Acheson (1968)	3–4	Depends on curvature and channel slope
	Ahmad (1951)	4.3	Straight channels
		5	Curved channels
	Copeland (1983)	2–3	Concave banks
	Grant (1948)	3	Concave banks
	Maza Alvarez (1989)	5.1–6.3	Straight channels
		2.5–4	Curved channels
	Neill (1973)	4	General practice
	Richardson et al. (1988)	2–6	Depends on flow and groin characteristics
	Strom (1962)	3–5	General practice
	Suzuki et al. (1987)	<4	Straight channels
	United Nations (1953)	1	Concave banks
		2–2.5	Convex banks
Groin plan shape	Straight groins are preferred Top widths of impermeable groins should be at least 1 m		
Longitudinal extent of groin field	Field and aerial surveys of the extent of scour are a good basis for determination of the necessary extent of a groin field Protection downstream of a bend is especially important because meander bends propagate downstream		
Groin height	To avoid bank overtopping, impermeable groins generally do not exceed bank height Similarly, a sloping crest height (downward away from the bank line) is advantageous for impermeable groins Permeable groins should allow floating debris to pass over, unless the design requires trapping of light debris		
Groin side slopes	Side slopes should be 2:1 ( $H:V$ ) or flatter		
Groin permeability	Permeability up to about 35% does not affect the length of channel bank protected Impermeable groins give better flow control, but induce greater end scour and, if submerged, can induce bank erosion High-permeability groins are preferred for mild bends and regions requiring small flow velocity reductions		
Bed and bank contact	Adequate bed contact is necessary to avoid undermining of the groin, especially at the toe, where a launching apron is advantageous Adequate bank contact is necessary to avoid outflanking of the groin		
Erosion protection	Riprap protection to the upstream and downstream faces and the end of the groin is recommended (possibly aided by filter layers)		

of flow- and grade-control structures and bank protection, a need for bridge relocation, and bridge failure due to undermining of the foundations. Successful protection of piers and abutments involves providing adequate foundation depths, by underpinning of existing foundations if necessary, and allowing adequate setback of abutments from slumping banks where appropriate. Aside from such considerations of foundation design or modification, the countermeasures for these vertical-erosion processes act either to maintain stable bed levels through the bridge site or to ease the passage of flows past the bridge.

**11.3.5.1 Check Dams** Check dams are low dams or weirs constructed across the entire width of a channel. These dams act to establish a fixed grade point, maintaining bed levels at the bridge site and controlling any upstream migration of degradation. The structures are usually constructed of rock riprap (rock weirs), timber piles, gabions, concrete, or sheet piles, the first two materials being more for lower dams and channel widths less than 30 m. Typically, check dams are installed immediately downstream of the bridge they protect, although they can extend through the bridge site. For severe cases of degradation, two or more check dams in succession can be used, where a single higher dam may inhibit fish movement or cause severe scour downstream. Figure 11-4 shows the degradation protection for the Oreti River road bridge in New Zealand, the protection consisting of a rock weir downstream of the bridge and rock mattresses installed through the bridge site. Check dams are widely used in New Zealand to maintain bed levels through a bridge site, although increased focus on possible adverse ecosystem impacts is hindering the ready use of this countermeasure at present.

The dam height (relative to the bridge foundations) required to protect a bridge will depend on the identified causes of degradation and the morphology and hydrology of the river at both bridge and catchment scales. To be successful, check dams must not be undermined by piping or seepage around or beneath the dam or erosion upstream or downstream of the structure. In this regard, Parker et al. (1998) observe that

the degree of degradation that such structures can withstand before they fail (Fig. 11-5) remains to be determined. Check dams can also initiate erosion of the banks and bed downstream of the structure. Such erosion, which can potentially undermine the dam, or lead to the river outflanking the dam, can be countered by energy dissipation measures for flows over the dam, including stilling basins (Lagasse et al. 2001). Alternatively, several lower weirs, a constructed artificial rapid, or an armored riverbed can be used. Any bank erosion caused by check dams can be controlled by the bank protection measures discussed above. Means of calculating potential scour depths downstream of check dams are discussed in Melville and Coleman (2000) and Lagasse et al. (2001). Breusers and Raudkivi (1991) recommend, however, that predictions of scour downstream of low weirs be derived from specific model tests, owing to possibly significant variations in the predictions of currently available analytical expressions.

**11.3.5.2 Channel Lining (Paving)** Parker et al. (1998) note that pavements and asphalt paving are limited in application to ephemeral rivers in arid environments. In general, riprap or concrete channel lining (paving) in the vicinity of a bridge has proved unsuccessful at stopping degradation, the lining being subject to undermining. A check dam may be used to protect such a lining, in which case the lining essentially becomes redundant. Channel-lining armoring measures for contraction, thalweg, and sediment-wave effects are discussed further in Sections 11.3.4.1 to 11.3.4.6.

**11.3.5.3 Channel Widening, Relief Bridges, and Guide Banks** Relief flow paths and widening of the bridge opening and the channel in the vicinity of a bridge can act to alleviate contraction-scour lowering of bed levels at the bridge site (Section 11.3.2). Guide banks (Section 11.5.4) and measures acting to retard flows along upstream floodplains (Section 11.3.4.7) can also be used to reduce flow contraction effects and resulting scour by improving the alignment and efficiency of flows through the bridge opening (Lagasse et al. 2001). Where appropriate, use of streamlined and solid

**Fig. 11-4.** The rock weir and rock mattresses protecting the Oreti River road bridge (looking downstream).

**Fig. 11-5.** An undermined and failed concrete check dam designed to control degradation on a Taiwanese river (looking upstream).

foundations can also ease potential debris accumulations and contraction effects.

### 11.3.6 Aggradation

Potential consequences of aggradation range from bridges being buried by sediment, to a need for bridge relocation, to increased loading on bridge structures (particularly during flooding), to increased likelihood of bridge overtopping and flooding of surrounding areas (with possible associated erosion) owing to a reduced waterway. Associated channel widening and lateral instability can also lead to bridge failure or erosion of bridge approaches, and can result in greater volumes of in-stream floating debris, increasing the potential for blocked waterways and for increased hydraulic loads and scour at bridges downstream.

If aggradation threatening a site is a temporary phenomenon, which in time will dissipate or pass downstream, then the sediment pulse can be dredged or simply allowed to migrate through the site if it is judged that the pulse will not endanger the infrastructure.

For longer-term aggradation, ideally the cause of the aggradation can be remedied, although typically the required measures prove to be complex, extensive, and very costly. Alternatively, and in lieu of diverting the river to accommodate or redesigning the bridge and bridge approaches, the river morphology resulting from the aggradation, active countermeasures are adopted. These countermeasures aim to increase sediment-transport capacity in the vicinity of the bridge site through the use of bridge or channel modifications, or reduce the volume of sediment supplied to the site through the use of structures to trap sediment upstream of the bridge, channel-bed mining or bar removal to control the bed level at the bridge, or general channel maintenance. Any countermeasure method adopted needs to be appropriate to the cause of the associated problem; otherwise it may not be successful.

Ongoing in-channel dredging and removal of channel vegetation can be used to increase flow capacity and consequent sediment-transport capacity. The frequency of such measures will be dictated by comparison of monitored rates of aggradation with tolerable rates determined for the bridge site. Any such measures will require assessments of possible associated pollution and ecosystem impacts.

Alternative control structures reducing the width of the channel can give increased flow velocities and sediment-transport rates.

Construction of a cutoff downstream of a bridge will increase channel slope, inducing higher sediment-transport rates upstream of the cutoff, thereby moderating aggradation at the bridge while the river adjusts to the changed alignment. Cutoffs must be designed with considerable study to correctly assess the magnitudes and locations of potential degradation, aggradation, and lateral erosion. The viability of such a channel realignment solution essentially depends

upon the volume of the source aggradation material and the hydraulics and sediment-storage potential of possible alternative channel realignments.

Sediment traps and dams in the catchment upstream of the bridge can be used to reduce the supply of sediment to the bridge site, thereby moderating aggradation at the site. The performance of any in-channel trap must ensure that potential degradation downstream of the trap does not endanger the bridge structure. Sediment traps and dams can be expected to require some degree of ongoing maintenance. Johnson et al. (2001) observe that design of any sediment trap must consider

- appropriate width and depth to enable sediment to settle out of the flow and deposit,
- location facilitating ease of access for sediment-removal equipment,
- location enabling collection of sediments otherwise causing aggradation at the bridge site, and
- environmental impacts, including possible pollution and ecosystem impacts caused by trap maintenance procedures.

Channel-bed mining and bar removal provide very effective means of controlling aggradation or even inducing degradation at a bridge site, although such measures must continue as long as aggradation is occurring. The rate of sediment removal must be monitored to ensure that adverse degradation does not result at the bridge site.

In terms of a general channel-maintenance solution, equipment retained at the bridge site can be used to train the aggrading channel, pushing deposited material across to form terraced riverbanks. This maintenance process must continue as long as aggradation is occurring, and can result in the potentially dangerous situation of large channel levees of ungraded material containing flows over a channel bed elevated above the surrounding countryside. Such a scenario in the South Island of New Zealand has resulted in the Franz Josef community being threatened by the potential of flows being released by flood-induced breaching of the levees elevated above the township. Other measures must then be considered to alleviate the aggradation problem.

In general, any potentially adverse influence of the hydraulic and morphologic impacts of these countermeasure solutions on the bridge site and the general river system must be considered before the countermeasure can be adopted. A useful reference analysis of the potential benefits, disadvantages and costs of aggradation countermeasure options for a bridge in northern Pennsylvania, is presented by Johnson et al. (2001).

### 11.3.7 Bend and Confluence Scour

Vertical erosion arising from either bend scour or confluence scour can lead to undermining of flow- and grade-control

structures and bank protection, a need for bridge relocation, and bridge failure due to undermining of the foundations.

Channel lining (paving) at the outside of the bend using armoring measures discussed above (Sections 11.3.4.1–11.3.4.6) can be used as a countermeasure for vertical erosion arising from bend scour. Flow training measures discussed above (Sections 11.3.4.8–11.3.4.10) can alternatively be used to redirect flow through the bend, although it must be ensured that such measures do not simply relocate any adverse scour to a foundation away from the outside of the bend.

In the absence of foundation designs allowing for confluence scour magnitudes (Melville and Coleman 2000), foundations can be protected by maintenance of bed levels using check dams running through the bridge site and encompassing the foundations. Use of check dams extending across the entire width of the channel reflects the variable nature of confluence locations for braided rivers. Where constructing a check dam would prove prohibitively expensive for a wide braided river, monitoring of river planform development could alternatively be adopted as a form of countermeasure (Coleman et al. 2000). Protection measures at an individual foundation would then only be instigated when observed patterns of channel development indicate the possibility of a confluence scour hole impacting the foundation. Protection measures adopted for individual foundations could include armoring or flow training measures discussed above (Section 11.3.4).

### 11.3.8 Debris and Ice Jams

The accumulation of debris at bridge foundations typically increases the scour. Streamlined pier shapes are less likely to cause debris to accumulate, whereas pile bents are particularly prone to debris accumulation. Similarly, ice jams can exacerbate scour. At locations where ice jams and debris accumulations are expected, relief structures and roadway overtopping can be used effectively to reduce flooding as well as scour.

Piers and low-elevation superstructure may disrupt the flow of debris and ice through bridge openings. Velocities near the bridge may be significantly higher than those estimated when ice or debris accumulates on piers and superstructures blocking large areas of flow. Consequently, estimates of the potential impact of debris and ice blockage and their effect on flow direction and velocity should be considered when determining the type and size of countermeasures necessary to protect a bridge. Diehl (1997) provides a method for assessing the potential for debris accumulation on bridge elements that may be adapted for design of countermeasures at locations where debris is likely to be a problem. Bridges located on actively incising or widening streams are highly susceptible to blockage by debris because of the high input and transport of trees delivered through bank erosion (Diehl 1997; Parola et al. 1998).

## 11.4 COUNTERMEASURES FOR LOCAL SCOUR AT BRIDGE PIERS

### 11.4.1 Introduction

There are two categories of methods of protection of bridge piers against scour: armoring devices, such as riprap and alternatives to riprap, and flow-altering devices, such as sacrificial piles, horizontal collars, and deflector vanes. Alternatives to riprap include artificial riprap, such as toskanes and dolos, cable-tied blocks, grout-filled bags, and foundation extensions such as extended footings. The last can be effective in reducing local scour if the top level of the footing is at or below the undisturbed bed level, but can increase scour if the footing is at a higher level.

### 11.4.2 Pier Shape Design

The local scour at circular bridge piers is unaffected by changes in flow direction, rendering circular piers preferable to all other shapes where changes in flow alignment are likely. For piled foundations, the scour increases with the number and closeness of the piles. Therefore, it is better to develop bearing capacity using fewer and deeper piles. The local scour at piers with slab footings, pile bents, and piers founded on caissons may be exacerbated if the footing, pile cap, or caisson is at or above the undisturbed bed level. For piled foundations, it is preferable to construct pile caps above normal water level to minimize their influence on scouring.

### 11.4.3 Riprap Protection at Piers

The most commonly employed method of protecting bridge piers against scour is the use of a layer of riprap around the piers. Figure 11-6 shows riprap protection at a model-scale bridge pier (diameter 200 mm) prior to testing. The model riprap is crushed rock with median diameter 50 mm. The principle behind this technique is that large stones that are heavier than the bed sediment are able to withstand the higher shear stresses that occur around a bridge pier. A number of studies and reports dealing with riprap protection at bridge piers have been published, including Engels (1929); Gales (1938); Sousa Pinto (1959); Maza Alvarez (1968); Bonasoundas (1973); Neill (1973); Quazi and Peterson (1973); Posey (1974); Hjorth (1975); Breusers et al. (1977); Dargahi (1982); Farraday and Charlton (1983); Worman (1987); CBIP (1989); Parola and Jones (1989); Worman (1989); Breusers and Raudkivi (1991); Parola (1991, 1993); Austroads (1994); Chiew (1995); Parola (1995); Richardson and Davis (1995); Croad (1997); Lim and Chiew (1997); Parker et al. (1998); Lauchlan (1999); and Melville and Coleman (2000).

**11.4.3.1 Failure Mechanisms for Riprap Placed at Bridge Piers** The following four failure mechanisms of riprap layers at bridge piers were observed during laboratory

Fig. 11-6. Riprap protection at a model-scale bridge pier prior to testing (after Lauchlan 1999).

studies, including those of Parola (1993), Chiew (1995), and Lauchlan (1999):

- *Shear failure.* Shear failure occurs where the riprap stones are entrained by the flow, because they are unable to resist the hydrodynamic forces induced by the flow.
- *Winnowing failure.* The action of turbulence and seepage flows erodes the underlying bed material through voids between the riprap stones, a process that is more likely to occur in sand-bed rivers than in coarser bed materials. A filter is often recommended to resist winnowing failure.
- *Edge failure.* Scouring at the periphery of the riprap layer undermines the riprap stones. Riprap is vulnerable to edge failure in conditions where there is insufficient lateral extent of the protective layer.
- *Bed-form undermining.* The migration past the pier of the troughs of large dunes undermines the riprap layer, which settles as a consequence. Bed-form undermining is the controlling failure mechanism at bridge piers founded in riverbeds subject to migration of dunes, especially sand-bed rivers, according to Lim and Chiew (1997), Parker et al. (1998), and Lauchlan (1999). Figure 11-7 is a schematic diagram showing the failure mechanisms for a dune bed for riprap placed at the bed surface and riprap placed below the bed surface, respectively.

**11.4.3.2 Riprap Design for Pier Protection** Riprap design for pier protection against scour involves consideration of the following characteristics of the riprap layer, as illustrated in Fig. 11-8:

- Median size ( $D_{r50}$ ) and gradation of the riprap material;
- Vertical thickness ( $t_r$ ) of the riprap layer;
- Plan layout and horizontal coverage of the riprap layer,  $B_r$  and  $L_r$ ;

Fig. 11-7. Failure mechanisms for riprap protection at bridge piers (after Melville and Coleman 2000).

- Placement depth ( $Y_r$ ) of the surface of the riprap layer below the sediment bed level; and
- Need for, and design of, a filter layer beneath the riprap.

**11.4.3.3 Riprap Size** Some of the equations that have been suggested for sizing riprap at bridge piers are given in Table 11-5. Most of these equations can be expressed in the form

$$\frac{D_{r50}}{H} = \frac{C}{(S_s - 1)^x} F^y \quad (11-1)$$

where

$$F = U/(gH)^{0.5};$$

$H$  = flow depth;

$U$  = mean flow velocity;

and  $C$ ,  $x$ , and  $y$  are coefficients,  $y$  typically varying between 2 and 3. It is apparent that riprap stone size depends strongly on flow velocity, but is less dependent on flow depth. In using these equations,  $U$  and  $H$  can be taken to be the depth-averaged velocity and the depth of the flow approaching the pier under consideration.

Melville and Coleman (2000) show that the riprap size equations predict widely varying stone sizes. Several of the

Fig. 11-8. Definition diagram for placement of riprap protection at bridge piers.

equations are based on laboratory data, whereas others have not been validated with data. Significant among the former group are the equations derived from the laboratory studies of Parola (1990)—see Parola and Jones (1989); Parola (1993; 1995); and Richardson and Davis (1995)—and those of Quazi and Peterson (1973) and Lauchlan (1999). Parola (1990) investigated the stability of riprap layers around circular and rectangular piers under clear-water conditions. The riprap was either placed flush with the bed or mounded above the bed. The failure criterion was related to the exposure of any part of the second layer of a three-stone thick layer. Parola (1993) presented an equation for cylindrical piers ( $N_{sc} = 1.4$ ) and three equations for rectangular piers, depending on the riprap size relative to the pier width. Comparison of the former equation with standard riprap size relations (see Appendix B) indicates that riprap placed at a bridge pier needs to be about 2 to 3.6 times larger than the size required for stability in uniform undisturbed flow for the same flow conditions (Parola et al. 1995). Lauchlan (1999) examined the stability of riprap layers at circular and rectangular piers under live-bed conditions, finding no significant difference in riprap stability for the two pier shapes. The riprap was adjudged to have failed if the scour depth exceeded 20% of that at an unprotected pier under the same conditions. Lauchlan (1999) also investigated the effect of placing riprap below the sediment bed surface as a means of counteracting the influence of bed-form undermining. Quazi and Peterson (1973) formed a sediment

bed of riprap stones and determined the flow velocity at which the stones were just stable for a round-nosed pier. Richardson and Davis (1995) recommend the Parola and Jones (1989) equation with an additional factor ( $f_2$ ) for pier location in the channel. This equation is also suggested for use by Parker et al. (1998). The equations based on laboratory data, discussed above, are compared in Fig. 11-9 over the range  $F = 0$  to  $0.6$  and for specific gravity of riprap  $S_s = 2.65$ .

Given the different experimental methods and, in particular, diverse failure criteria among these methods, the riprap size predictions of these equations are acceptably consistent and give reasonable estimates of stone size for design. A conservative combination of the rock size estimates given by the plotted equations is obtained by using the upper envelope generated by the Lauchlan (1999) relation together with the appropriate Parola relation.

**11.4.3.4 Riprap Gradation** Although the exact size distribution of riprap is not critical, it is important that the riprap should be well graded. Richardson and Davis (1995) state that the maximum rock size should not exceed twice the median size of the riprap; that is,  $D_{rmax} \leq 2D_{r50}$ . Croad (1997) gives an additional criterion,  $D_{r50} \leq 2D_{r15}$ . The grading curve envelope (upper and lower limits) shown in Fig. 11-10 encompasses most of the recommended gradings (Gregorius 1985).

**11.4.3.5 Lateral Extent** Recommendations for the areal extent of riprap protection at bridge piers, based on

**Table 11-5 Equations for Sizing Riprap at Bridge Piers**

Reference	Equation	Symbols
Bonasoundas (1973)	$D_{r50} \text{ (cm)} = 6 - 3.3U + 4U^2 \quad (11-7)$	$D_{r50}$ = riprap stone size for which 50% are finer by weight The equation applies to stones with $S_s = 2.65$ $U$ = mean approach flow velocity (m/s)
Quazi and Peterson (1973)	$N_{sc} = 1.14 \left( \frac{D_{r50}}{H} \right)^{-0.2} \quad (11-8)$	$N_{sc}$ = Critical Stability Number = $U^2/[g(S_s-1)D_{r50}]$ $F$ = Froude number of the approach flow = $U/(gH)^{0.5}$ $H$ = mean approach flow depth
Breusers et al. (1977)	$U \leq 0.42[2g(S_s-1)D_{r50}]^{0.5} \quad (11-9)$	$S_s$ = specific gravity of riprap stones
Farraday and Charlton (1983)	$\frac{D_{r50}}{H} = 0.547 F^3 \quad (11-10)$	
Parola and Jones (1989)	$\frac{D_{r50}}{H} = \frac{0.346 f_1^2}{(S_s-1)} F^2 \quad (11-11)$	$f_1$ = factor for pier shape: $f_1 = 1.5$ (round-nose), 1.7 (rectangular)
Breusers and Raudkivi (1991)	$U = 4.8(S_s-1)^{0.5} D_{r50}^{1/3} H^{1/6} \quad (11-12)$	
Austroroads (1994)	$\frac{D_{r50}}{H} = \frac{0.58 K_p K_v}{(S_s-1)} F^2 \quad (11-13)$	$K_p$ = factor for pier shape: $K_p = 2.25$ (round-nose), 2.89 (rectangular) $K_v$ = velocity factor, varying from 0.81 for a pier near the bank of a straight channel to 2.89 for a pier at the outside of a bend in the main channel
Richardson and Davis (1995)	$D_{r50} = \frac{0.692 (f_1 f_2 V)^2}{(S_s-1) 2g} \quad (11-14)$	$f_2$ = factor ranging from 0.9 for a pier near the bank in a straight reach to 1.7 for a pier in the main current at a bend
Chiew (1995)	$D_{r50} = \frac{0.168}{\sqrt{H}} \left( \frac{U}{U_* \sqrt{(S_s-1)g}} \right)^3$ $U_* = \frac{0.3}{K_D K_H} \quad (11-15)$	$K_H$ = flow depth factor $K_H = 0.783 \left( \frac{H}{b} \right)^{0.322} - 0.106 \quad 0 \leq \left( \frac{H}{b} \right) < 3$ $K_H = 1 \quad \left( \frac{H}{b} \right) \geq 3$ $K_D$ = sediment size factor $K_D = 0.398 \ln \left( \frac{b}{D_{r50}} \right) - 0.034 \left[ \ln \left( \frac{b}{D_{r50}} \right) \right]^2 \quad 1 \leq \left( \frac{b}{D_{r50}} \right) < 50$ $K_D = 1 \quad \left( \frac{b}{D_{r50}} \right) \geq 50$
Parola (1993; 1995)	Rectangular: $N_{sc} = 0.8 \quad 20 < (b_p / D_{r50}) < 33$ $N_{sc} = 1.0 \quad 7 < (b_p / D_{r50}) < 14$ $N_{sc} = 1.2 \quad 4 < (b_p / D_{r50}) < 7$ Aligned Round-nose: $N_{sc} = 1.4 \quad (11-16)$	$b_p$ = projected width of pier
Croad (1997)	$\frac{U}{A \sqrt{(S_s-1)g D_{r50}}} = 1.16 \left( \frac{H}{D_{r50}} - 2 \right)^{1/6}$ $D_{r50} = 17 D_{b50} \quad (11-17)$	$A$ = acceleration factor: $A = 0.45$ (circular and slab piers), $A = 0.35$ (square and sharp-edged piers) $D_{b50}$ = median size of bed material Equation given for factor of safety = 1.25, as recommended by Croad (1997)
Lauchlan (1999)	$\frac{D_{r50}}{H} = 0.3 S_f \left( 1 - \frac{Y_r}{H} \right)^{2.75} F^{1.2} \quad (11-18)$	$S_f$ = safety factor, with a minimum recommended value = 1.1 $Y_r$ = placement depth below bed level

Fig. 11-9. Comparison of equations for sizing riprap at bridge piers.

laboratory testing, have been made by Sousa Pinto (1959); Maza Alvarez (1968); Bonasoundas (1973); Ruff and Nickelson (1993); Chiew (1995); Parola (1995); Croad (1997); Parker et al. (1998); and Lauchlan (1999), among others. These recommendations range from placing riprap only at the nose of the pier to completely surrounding the pier with a riprap layer extending up to  $3b$  (where  $b$  is pier width) from the pier face in all directions. For rectangular piers, Parker et al. (1998) suggest the equation

$$B_r = L_r = \frac{1.5b}{\cos\theta} \quad (11-2)$$

where:

$\theta$  = angle of attack of the flow (see Fig. 11-8).

Oblong-shaped piers can be treated similarly. An equivalent coverage for a circular pier is to use a circular stone mat of diameter  $4b$ , where  $b$  is the pier diameter.

**11.4.3.6 Layer Thickness** A range of recommendations for riprap layer thickness ( $t_r$ ), typically from  $t_r = 2D_{r50}$  to  $3D_{r50}$ , have been made. Thicker riprap layers impede the winnowing process and are able to resist disintegration through rearmoring. Chiew (1995) showed that thicker layers resist higher flow velocities, whereas laboratory testing by Lauchlan (1999) indicated an approximate 70% reduction in local scour pertaining to an increase in thickness from  $1D_{r50}$  to  $3D_{r50}$ .

**11.4.3.7 Placement Level** Richardson and Davis (1995) and others propose that the surface of the riprap

layer be placed at the streambed level. Neill (1973) and Breusers et al. (1977) recommend placing the riprap below the expected general scour level. Lauchlan (1999) found that placing riprap at some depth within the bed significantly improved the performance of the layer under live-bed conditions in sand-bed streams. The term  $(1-Y_r/H)^{2.75}$  in her equation (Table 11-5) reflects this advantage, as shown in Fig. 11-11. Riprap placed deeper is inherently more stable, especially in sand-bed rivers, because the stones

Fig. 11-10. Riprap grading curve envelope (after Gregorius 1985).

Fig. 11-11. Pier riprap size according to Lauchlan (1999) (modified from Melville and Coleman 2000).

are more resistant to bed-form undermining; see Fig. 11-8. Conversely, Parola (1991; 1993) observed enhanced stability for riprap mounded around the pier under clear-water conditions compared to that for riprap placed in preformed scour holes. Mounded riprap has construction advantages, and the mound may provide a source for replenishment of riprap material in the event of loss of riprap stones during a flood. Richardson and Davis (1995) warn that “it is a disadvantage to bury riprap so that the top of the mat is below the streambed because inspectors have difficulty determining if some or all of the riprap has been removed.” Also, Parker et al. (1998) found that riprap dumped over a geotextile placed on an unexcavated bed performed almost as well as riprap placed with prior excavation.

**11.4.3.8 Filters** To combat winnowing effects at the pier face and to improve general stability of riprap layers, the use of a filter layer beneath the riprap stones has been proposed. Filters can be either granular filters, which make use of the filtering effect of graded sediments, or synthetic filters, commonly known as geotextiles. Filters must prevent the passage of the finer bed sediment, but also have adequate permeability to prevent build-up of water pressure in the underlying sediment. The well-known Terzaghi and Peck filter criteria (see Appendix B) have been proposed to select suitable granular filter media, although Posey (1974) found that a single filter layer was sufficient and Worman (1989) found that a thick single layer of riprap was an adequate alternative to the conventional Swedish practice of using multilayered riprap (incorporating a granular filter layer). The use of granular filters in the highly turbulent flow region at the base of a bridge pier is questionable. For example, Escameia and May (1992) concluded from an experimental study that sand complying with the Terzaghi-based requirements performs poorly in highly turbulent environments.

An advantage of using geotextiles is fabric flexibility, which allows the geotextile to deform and remain intact, as well as to be reasonably resistant to tension and tearing. Important parameters in geotextile selection are appropriate pore size to retain finer sediments without clogging, adequate permeability to release pore pressures without causing uplift of the fabric under flood conditions, ultraviolet light resistance, puncture resistance, and shear strength. The lateral extent of the synthetic filter should be limited to about 75% of the lateral extent of the riprap. The reduced coverage of the synthetic filter ensures that edge stones in the riprap layer are able to protect the synthetic filter from being rolled up by the flow (Parker et al. 1998). It is important that the geotextile be adequately sealed to the pier face to prevent sediment from leaching at the pier/geotextile interface. Parker et al. (1998) offer suggestions for underwater installation of geotextiles at bridge piers.

On the basis of a detailed, large-scale laboratory study of riprap protection at bridge piers, with and without geotextiles, Parker et al. (1998) found “that under flood conditions in sand-bed streams with developed bed forms, the leaching of sand from the interstices of any armoring countermeasure may ultimately result in failure of the countermeasure. With this in mind, and in light of the positive results of experimental testing, it is suggested that such an armoring countermeasure be underlain by an appropriately selected geotextile.” They also suggest that geotextiles not be used for gravel bed streams, due to the abrasive nature of gravel and its low potential for leaching. In addition, geotextiles should not be used at sites where significant degradation is likely, because the scour may leave the geotextile and riprap perched during floods, possibly leading to the loss of both (see below). At bridge piers on the floodplain where clear-water scour conditions typically pertain, this potential disadvantage of the use of geotextiles is less likely to exist.

**11.4.3.9 Riprap Tolerance to Degradation** Degradation occurs in rivers when the outflow of sediment exceeds the inflow, leading to a net loss of sediment in the reach. Lauchlan (1999) investigated the effect of a degrading bed on riprap protective layers at bridge piers. Laboratory experiments indicated that riprap layers are capable of providing a reasonably high degree of protection for bridge piers for high rates of degradation and high flow rates. However, the results also imply that in a degrading bed situation, riprap protective layers would eventually fail. As the bed surrounding the riprap degrades, the stones subside and can move outward. Long-term degradation causes the majority of the stones to move outward from the pier, which reduces the thickness of the riprap layer and its ability to protect the pier. However, if lack of sediment input is merely a short-term problem, the layer is likely to be able to withstand the attack.

Because subsidence of the riprap layer with the degrading bed is important in maintaining stability of the layer, filters should not be employed where significant degradation is anticipated. A geotextile or granular filter would prevent

winnowing from occurring at the pier face, and winnowing is essential if the riprap is to subside. The implication is that the riprap would not subside if coupled with a filter, leading to increased exposure of the stones, disintegration of the riprap, and loss of protection against scour. At sites where degradation is anticipated, it is preferable to increase riprap layer thickness rather than use a filter.

#### 11.4.4 Alternatives to Riprap

Alternatives to rock riprap include other armoring measures, overviewed in Section 11.3.4, and flow-altering measures. Aside from these active countermeasures to prevent scour, bridges can also be structurally modified through underpinning or foundation extension. Examples of flow-altering measures that have been used or suggested to protect piers against local scour include sacrificial piles placed upstream of the pier, Iowa vanes, and flow deflectors attached to the pier such as collars. Field experience of flow-altering devices is limited.

**11.4.4.1 Artificial Riprap** Each form of artificial armor unit (Section 11.3.4.3) will have unique design criteria that should be available from the unit manufacturer. In terms of common forms of artificial riprap, Parker et al. (1998) consider guidelines for implementation at bridge piers to be complete, the work of Ruff and Fotherby (1995) being noteworthy.

Despite the detailed design criteria available, there are few examples of the use of artificial riprap as a scour countermeasure at bridge piers. Studies to date indicate that artificial riprap does not offer significant advantages over rock riprap for scour protection at piers. Ruff and Fotherby (1995) conclude this in terms of toskanes. Fotherby (1992) and Bertoldi et al. (1996) both suggest that the use of tetrapods at bridge piers offers little advantage over riprap in terms of stability of the armoring units. An additional disadvantage of artificial riprap in comparison to rock riprap is a possible lengthy installation time to achieve the required interlocking nature of the units.

If artificial riprap is to be utilized at a bridge pier, the reader is referred to Fotherby and Ruff (1996) and Parker et al. (1998) for design guidelines and principles, along with comments on construction and maintenance for this scour countermeasure. In addition, Lagasse et al. (2001) provide summaries of design procedures and present design examples for bridge-pier protection using toskanes (Fotherby and Ruff, 1996) and modules of A-Jacks (Armortec Inc., Bowling Green, Kentucky).

**11.4.4.2 Cable-Tied Blocks** A few examples of the use of cable-tied blocks (Section 11.3.4.3) currently exist at piers in the United States. More such installations may follow; cable-tied blocks have recently been shown (Jones et al. 1995; Bertoldi et al. 1996; University of Minnesota 1996; 1997; Parker et al. 1998) to provide a useful alternative to riprap at bridge piers over a wide range of conditions

and over successive flow events. The performance of this countermeasure is aided by the blocks being underlain by an appropriately sized geotextile filter, and also by the geotextile being sealed to the pier. Design guidelines given by Parker et al. (1998) are summarized in Table 11-6.

**11.4.4.3 Gabions and Reno Mattresses** Gabions (Section 11.3.4.5) have experienced significant use in the field as a countermeasure for bridge scour, although a recent evaluation of their field use in New York State is rather pessimistic, following the failure of many installations. Design guidelines given by Parker et al. (1998) for the use of gabions and Reno mattresses (Section 11.3.4.5) at bridge piers are summarized in Table 11-7. Additional detailed guidelines for the materials and construction of gabions and Reno mattresses are also given in Parker et al. (1998).

**11.4.4.4 Grout-Filled Bags or Mats** Grout-filled bags (sacks) or mats constitute fabric shells filled with concrete. These measures can be deployed rapidly and provide an economical alternative to rock riprap where this is not readily available. A particular advantage is that shells filled with dry concrete can be placed directly at bridge foundations, with hydration occurring naturally.

With regard to their potential to slide and disperse (Section 11.3.4.3), Parker et al. (1998) recommend avoiding grout-filled bags, concluding that riprap and cable-tied blocks are generally more effective as countermeasures for pier scour. In the event that grout-filled bags are nevertheless to be utilized, design guidelines given by Parker et al. (1998) are summarized in Table 11-8. Installation practices at bridge foundations, critical to the success of grout-filled bag systems, are also discussed in Lagasse et al. (2001).

Fotherby (1992), Jones et al. (1995), and Bertoldi et al. (1996) report studies of the use of concrete-filled mats (Section 11.3.4.4) for pier protection. These studies show that mats need to be bound to and sealed with the pier (although they recognize potential increased pier loadings) and recommend that mats be installed with their top surfaces flush with the bed, this reducing or eliminating the need for any anchoring to prevent uplift failure. Failure likely involves replacement of the entire unit; failure modes include undermining, overturning and rolling up of an unsecured leading edge, and uplift of the inner mat at higher velocities. Guidelines for mattress areal extent, thickness, and anchoring remain to be determined, including a lift criterion to size grout mattresses to prevent failure by rollop.

**11.4.4.5 Concrete Apron and Grouted Riprap** Concrete pavements and asphalt paving are best suited to applications in ephemeral rivers in arid environments (Parker et al. 1998). In general, bridge designers doubt the durability of in-stream pavements and anticipate turbulence-induced and confined-groundwater uplift stresses generated during flood events to cause failure of the impermeable pavement. Pavement edges are also prone to undermining, possibly leading to destabilization of the pavement.

**Table 11-6 Principles and Guidelines for the Design of Cable-Tied Blocks (Fig. 11-2) for Pier-scour Protection**

Factor	Design criteria
Feasibility	<p>Suitable for sand-bed and gravel-bed rivers</p> <p>Not suitable for pile bents or complex pier shapes</p> <p>Not suitable for rivers with large cobbles or rocks</p> <p>Not suitable for corrosive water quality, such as saline (including estuarine) or acidic environments</p> <p>Favorable characteristics for ephemeral, flashy, and moderate hydrograph streams, as well as floodplain installations</p> <p>May become cost-effective where rock riprap of a required size and quality is not readily available</p>
Block shape, spacing, and size	<p>Block shape to facilitate mat flexibility</p> <p>Spacing between blocks to facilitate mat flexibility</p> $\zeta = a_{cb} \left( \frac{\rho_{cb}}{\rho_{cb} - \rho} \right) \rho U^2 \quad \text{and} \quad \zeta = \rho_{cb} g H_{cb} (1 - p)$ <p>where:</p> <p><math>\zeta</math> = weight per unit mat area (N/m<sup>2</sup>) (required for mat stability)</p> <p><math>H_{cb}</math> = block height (m)</p> <p><math>p</math> = volume fraction pore space of the mat</p> <p><math>\rho</math> = water density = 1000 kg/m<sup>3</sup></p> <p><math>\rho_{cb}</math> = density of the block material for the mat (kg/m<sup>3</sup>)</p> <p><math>a_{cb} = 0.20</math></p> <p><math>U</math> = depth-averaged flow velocity (m/s)</p>
Mat installation	<p>Preexcavation of the upstream edge is required, and for gravel-bed streams, all edges must be anchored (requiring preexcavation)</p> <p>General prior excavation is not required unless <math>4H_{cb} &gt;</math> design approach flow depth</p> <p>Mat (centered on the pier) is to be of width <math>(4D/\cos\beta)</math> and length in the direction of flow <math>[L + (3D/\cos\beta)]</math> where:</p> <p><math>\beta</math> = angle of flow attack (<math>\beta = 0^\circ</math> giving the flow aligned with the pier)</p> <p><math>D</math> = pier diameter for cylindrical pier, and pier width for rectangular pier</p> <p><math>L</math> = pier length (= <math>D</math> for cylindrical pier)</p>
Cable location and quality	<p>Cables to be located near the center of each block to allow maximum mat flexibility</p> <p>Cables to be sufficiently flexible to allow mat deformation, but sufficiently durable to survive at least 20 years in situ</p> <p>Stainless steel to be used for harsh environments</p>
Geotextile filter	<p>Resists leaching of bed material from between blocks</p> <p>To be fastened firmly to the base of a mat for a sand-bed river</p> <p>Not to be used for a gravel-bed river</p> <p>Not to extend to the mat edges, but (approximately extending 2/3 of the distance from each pier face to the mat edge) to be of width <math>(3D/\cos\beta)</math> and length in the direction of flow <math>[L + (2D/\cos\beta)]</math></p> <p>Not to be replaced with a granular filter layer</p> <p>In some cases, local grouting is recommended wherever there is danger of abrasion of the geotextile</p>
Pier seal	<p>Mat (and geotextile filter) to be fastened and sealed to the pier (recognizing potential increased pier loadings), aided by a granular filter zone if required</p>

**Table 11-7 Principles and Guidelines for the Design of Gabions and Reno Mattresses for Pier-scour Protection**

Factor	Design criteria
Feasibility	<p>Potential abrasion of casing materials by passing sediments of sand-size and larger needs to be recognized and addressed where possible by material selection</p> <p>Gabions are not recommended for gravel-bed streams owing to bed-load abrasion wearing out the casing causing gabion rupture</p> <p>Well suited to ephemeral streams, but potentially difficult to place in deeper channels</p> <p>Not suitable for corrosive water quality, such as saline or acidic environments</p> <p>Potentially difficult to implement for nonuniform riverbed or pier geometries</p> <p>Useful where rock riprap of a large required size is not readily available</p>
Basket size and shape	$V_{\min} = 0.069 \left[ \frac{U^6 K^6}{(S_{sr} - 1)^3 g^3} \right], \text{ where:}$ <p><math>V_{\min}</math> = minimum basket volume for individual unconnected baskets (<math>\text{m}^3</math>)</p> <p><math>U</math> = depth-averaged flow velocity (m/s)</p> <p><math>K</math> = pier-shape factor (round-nosed piers, <math>K = 1.5</math>; square-nosed piers, <math>K = 1.7</math>)</p> <p><math>S_{sr} = \rho_r / \rho</math> = rock specific gravity</p> <p><math>\rho_r</math> = rock density (<math>\text{kg}/\text{m}^3</math>)</p> <p><math>\rho</math> = water density = <math>1000 \text{ kg}/\text{m}^3</math></p> <p><math>g</math> = gravitational acceleration, <math>g = 9.81 \text{ m}/\text{s}^2</math></p> <p>Basket volumes larger than <math>V_{\min}</math> may be appropriate</p> <p>Baskets to be kept relatively low in height to reduce cross-sectional blockage and resist uplift, with basket heights to exceed a minimum of 0.15 m</p> <p>Standard gabions are of nominal heights of 0.3, 0.45, or 0.9 m; nominal lengths of 1.8, 2.7, or 3.6 m; and a nominal width of 0.9 m</p> <p>Standard Reno mattresses are of nominal heights of 0.15 or 0.225 m; nominal lengths of 2.7 or 3.6 m; and a nominal width of 1.8 m</p>
Gabion-field installation	<p>Riverbed to be smoothed and existing scour holes filled with stones before gabions are installed, preexcavation to give the top of the gabion installation flush with the bed being advantageous</p> <p>The gabion-field coverage (centered on the pier) is to be of width (<math>5D/\cos\beta</math>) and length in the direction of flow [<math>L + (4D/\cos\beta)</math>], where:</p> <p><math>\beta</math> = angle of flow attack (<math>\beta = 0^\circ</math> giving the flow aligned with the pier)</p> <p><math>D</math> = pier diameter for cylindrical pier, and pier width for rectangular pier</p> <p><math>L</math> = pier length (= <math>D</math> for cylindrical pier)</p> <p>Gabions are readily stacked in stable configurations and mould themselves in response to instabilities</p> <p>Adjacent baskets to be joined using the same wire used to lace the baskets</p> <p>Completed gabions lifted into place, or empty baskets joined to gabions already in position, then stretched and correctly aligned before being filled</p> <p>Hand work helps to minimize the percentage of voids in baskets</p>
Basket materials	<p>Minimum rock size to be at least 25% larger than the minimum basket opening</p> <p>Maximum rock size not to exceed 2/3 of the minimum basket dimension</p> <p>Casing materials must be durable and also facilitate basket flexibility, ideally single-strand galvanized or PVC-coated wiring that resists corrosion (and with the wire recommended to be like a chain-link fence, i.e., formed with a double twist to prevent unraveling)</p> <p>Basket sidewalls to be reinforced with wires of diameter larger than that used for the basket mesh in order to provide sidewall stiffness</p>
Geotextile filter	<p>Resists leaching of bed material from beneath the gabions</p> <p>To be used underneath the gabion field for a sand-bed river</p> <p>Not to extend to the edges of the basket field</p> <p>Can be replaced with a granular filter layer if the geotextile is not available</p>
Pier seal	<p>Geotextile filter to be fastened and sealed to the pier (in recognition of potential increased pier loadings), aided by a granular filter zone if required</p>

**Table 11-8 Principles and Guidelines for the Design of Grout-Filled Bags for Pier-scour Protection**

Factor	Design criteria
Feasibility	Potentially applicable only to small streams, or where bag width ( $\sim 1$ m) > pier width (bags then being large relative to any local scour hole) Not suitable for gravel-bed streams, or sand-bed streams with developed dunes Can be aesthetically unacceptable Useful where rock riprap of a required size and quality is not readily available
Bag size and shape	Design as for riprap, with $D_{r50}$ = bag height, and with the following amendments: In calculations, use the material density $\rho_r$ pertaining to the grout Increasing the bag size $D_{r50}$ by a factor of 1.2 is recommended to aid bag stability Bags are not to be of sizes or shapes that hinder flexibility of the installed countermeasure Shorter bags heights are desirable An example bag size is $3 \times 0.9 \times 0.3$ m
Bag-field installation	The bag-field coverage (centered on the pier) is to be of width $(5D/\cos\beta)$ and length in the direction of flow $[L + (4D/\cos\beta)]$ , where $\beta$ = angle of flow attack ( $\beta = 0^\circ$ giving the flow aligned with the pier) $D$ = pier diameter for cylindrical pier, and pier width for rectangular pier $L$ = pier length (= $D$ for cylindrical pier) Upstream bags are to overlap downstream bags to aid stability Fotherby (1992) indicates that properly sized bags are more effective if used to extend a single layer of protection laterally, rather than if they are stacked Imbricated (shingled) stacking can potentially enhance interlocking and aid stability
Bag materials	If possible, the surface of the bag should be rendered angular and rough Grout quality should ensure that the grout does not degrade and break or crumble
Geotextile filter	Resists leaching of bed material from between bags To be used underneath the bag field for a sand-bed river Not to be used for a gravel-bed river Not to extend to the edges of the bag field, but to be of width $(3D/\cos\beta)$ and length in the direction of flow $[L + (2D/\cos\beta)]$ Can be replaced with a granular filter layer if the geotextile is not available
Pier seal	Geotextile filter to be fastened and sealed to the pier (recognizing potential increased pier loadings), aided by a granular filter zone if required

Parker et al. (1998) indicate concrete-grouted riprap to be relatively cost-effective, although it scores poorly in terms of aesthetics and environmental acceptability, as well as on feasibility for use with finer sediments such as silt. The reduced permeability arising from the grouting is disadvantageous because uplift can cause failure of the riprap layer in entirety. The decreased countermeasure flexibility also negates the natural benefit of riprap being able to deform and armor a developing scour hole.

**11.4.4.6 Sacrificial Piles** Sacrificial piles are piles placed upstream of a pier to deflect high-velocity flow from impacting the pier, with the pier located in the wake region behind the piles (Fig. 11-12). The piles can be arranged in a variety of plan configurations, with varying pile sizes

and numbers, and with the piles submerged or extending over the full depth of flow. A triangular pile configuration, with the apex pointing upstream, has been shown to be one of the better configurations in terms of protecting the pier (Fig. 11-12). Sacrificial piles have the benefit of being relatively quick to implement. They are, however, not suited to riverbeds of bedrock or boulders, and they can be unacceptable on aesthetic grounds. Chang and Karim (1972) and Paice and Hey (1993) report laboratory studies and field experience of the use of sacrificial piles for pier-scour protection. Further laboratory studies are reported by Chabert and Engeldinger (1956); Levi and Luna (1961); Shen et al. (1966); Wang (1994); Singh et al. (1995); and Melville and Hadfield (1999).

Fig. 11-12. Example configurations of five sacrificial piles.

The effectiveness of sacrificial piles for pier-scour protection is found to be particularly dependent on the approach flow angle  $\beta$  (Fig. 11-12) and flow intensity  $V/V_c$ , where  $V$  is depth-averaged flow velocity, and  $V_c$  is this velocity at the threshold condition for sediment movement. For aligned ( $\beta = 0^\circ$ ) clear-water ( $V/V_c < 1$ ) flows, sacrificial pile configurations can give up to 40 to 50% reduction in scour at the protected pier, with reduced effectiveness under live-bed conditions of  $V/V_c > 1$  (Melville and Hadfield 1999) due to the passage of bed forms. Parker et al. (1998) conclude that sacrificial piles are an ineffective way to suppress scour under mobile-bed conditions. A significant consideration is that variation in flow alignment  $\beta$  typically reduces the effectiveness of the pile configuration in protecting the pier. Large flow skewness ( $\beta > 20^\circ$ ) may result in the piles actually exacerbating scour at the pier.

In general, sacrificial piles are not recommended unless the flow remains aligned ( $\beta = 0^\circ$ ) and the flow intensity is relatively low. Under such conditions, submerged and full-depth piles give similar reductions in scour. If sacrificial piles are to be utilized for such conditions, model testing to determine the optimum pile configuration is recommended, with the piles themselves needing to be designed against

Fig. 11-13. The use of Iowa vanes as a pier-scour countermeasure.

scour undermining. The effects of debris contamination on the performance of the piles also need to be considered, as do any effects of the piles on navigation.

**11.4.4.7 Iowa Vanes** As a countermeasure for pier scour, Iowa vanes (Section 11.3.4.10) are installed just upstream of the pier and angled inward, looking downstream (Fig. 11-13), with the vane configuration designed both to induce secondary currents that interfere with the horseshoe vortex and also to encourage sediment deposition in the region of local scour at the pier. Potential disadvantages of a field of vanes include the potential to collect debris, the potential for damage by sediment in motion, and possible decreased performance for skewed flows. Parker et al. (1998) conclude, however, that of flow-altering countermeasures, only Iowa vanes show enough promise to warrant further study. Comments on construction and maintenance of Iowa vanes are given in Parker et al. (1998).

By varying vane height  $H_v$  (and thereby submergence  $T$  for constant flow depth), vane angle of attack  $\beta$ , vane spacings  $z$  and  $e$ , vane length  $L$ , and longitudinal extent of vane field  $X$  for two flow velocities (Fig. 11-13), Lauchlan (1999) investigated the performance of vane configurations in terms of countering clear-water and live-bed scour at a cylindrical pier. The results of the tests indicate the angle of attack  $\beta$  and the streamwise spacing  $e$  to be principal parameters affecting the performance of vane configurations. The testing, although indicating potential scour reductions through use of the vanes, is not comprehensive, and further tests remain to

**Fig. 11-14.** The influence of horizontal-collar location and size on equilibrium scour depth  $d_s$  for a cylindrical pier (modified from Melville and Coleman 2000).

determine the degree of usefulness of Iowa vanes for control of pier scour.

**11.4.4.8 Horizontal Collars** Horizontal collars (Fig. 11-14) are designed to protect piers against scour by shielding the sediment bed from the downflow and horseshoe-vortex flow structures (Fig. 11-1) in the vicinity of the pier. These collars are thin in vertical section in order not to exacerbate scour. They have the potential disadvantage, however, of encouraging debris accumulation. The concept of using collars as scour countermeasures has been investigated by Schneible (1951); Chabert and Engeldinger (1956); Tanaka and Yano (1967); Thomas (1967); Ettema (1980); Dargahi (1990); Chiew (1992); and Fotherby (1992).

To date, collars have not been tested under live-bed conditions, and so they should not be considered for use other than in low sediment-transport conditions, such as may exist on floodplains or in vegetated channels.

For clear-water conditions, Fig. 11-14 summarizes the trends of available data on the influence of collar diameter  $D_c$  and location  $Y$  above the surrounding bed on scour reduction. The data indicate that a collar can reduce scour depth significantly. For maximum scour protection, the collar should be placed beneath the surrounding bed level. Scour depth for a circular pier can thereby be halved for a collar diameter twice that of the pier. Despite these encouraging results, Parker et al. (1998) do not consider horizontal collars to warrant further study or the development of user guidelines.

## 11.5 ABUTMENT PROTECTION

### 11.5.1 Introduction

Protection of bridge abutments from scour includes countermeasures that alter flow and scour patterns and those that armor the bed, bank, floodplain, and embankment slopes. Armor

protection frequently includes the coverage of susceptible portions of embankment slopes. Many design guidance documents recommend that an apron be constructed around the toe of the embankment slope. Armor aprons can protect vertical-wall abutments founded on spread footings. Filters have been recommended below the protection to prevent piping of soils through the armor layers. The filters also may be beneficial to prevent winnowing of soils from beneath aprons, especially where the armor layer is used to protect embankments under live-bed conditions. There is evidence that fabric filters may be detrimental to the performance of armor protection where settlement and movement of the armor layer is necessary for the armor layer to conform to general bed degradation or scour hole formation.

Based on extensive field observations of flood-damaged bridges, Parola et al. (1998) suggest that under many circumstances where abutments are founded on piles of sufficient depth, prevention of progressive failure of spillthrough embankments may be detrimental to the protection of the bridge from scour. At many locations, failures of the approach embankments increase flow area substantially, reducing flow velocity and preventing the formation of deep abutment scour holes. This relief mechanism may greatly reduce the depth of scour at piers and the location of the abutment pile bents. This method may be acceptable at locations where such failures would pose no risk to bridge users and would have limited effect on the transportation network.

### 11.5.2 Failure Mechanisms

Lewis (1972), Macky (1986), Kwan (1988), Croad (1989), Kandasamy (1989), and Eve (1999) ran exploratory experiments on bridge abutments that showed the primary failure mechanism of spillthrough embankments to be the formation of scour holes along the toe of the embankment with subsequent mass failure of the embankment into the scour hole. Progressive failure of the abutment slope into the scour holes eventually leads to failure of the embankment and supported roadway. Observations of flood-damaged bridges confirm the laboratory observations (Parola et al. 1998). Bridge abutments supported on piles frequently are not damaged although sections of approach embankments and portions of roadway may be destroyed.

In a laboratory study of abutment scour protection methods typically used in practice, Macky (1986) found that scour and undermining of the slope protection was initiated at the upstream toe of the embankment. Pagan-Ortiz (1991) observed a critical zone where riprap failure was initiated on the apron at the point of flow separation from the upstream edge for vertical-wall abutments and along a separation line downstream of the spillthrough abutments. Both reports present observations that show a critical point for apron failure and initial undermining of the slope protection at or near the slope toe. Both experiments showed

**Fig. 11-15.** Photograph showing laboratory study of riprap protection at an abutment (after Eve 1999).

subsequent failure of the embankment to be governed by mass movements such as translational slides of the granular fill materials used. Eve (1999) conducted clear-water scour experiments and a limited number of live-bed experiments on the failure conditions of slope and toe protection that included filters beneath the riprap. She found that failure under clear-water conditions was progressive, with failure of the protection being initiated at three different locations. These initial failure mechanisms were failure of the edge of the protection where the protection rolled into a scour hole, entrainment of pieces of riprap along the toe of the abutment, and entrainment on the upstream edge of the embankment slope. Undermining of the protection occurred as slope materials mass-failed toward the slope toe. Fig. 11-15 shows a downstream scour hole and the dispersal of riprap within the scour hole. Under live-bed conditions without a filter, winnowing of the particles beneath the riprap caused rapid failure of the protection.

### 11.5.3 Abutment Shape Design

For abutments that are sited near the edge of a channel, considerable reductions in local scour depth are associated with streamlined abutment shapes. The local scour at spillthrough abutments can be as much as 50% less than that at the same-sized vertical-wall abutment, for example. On the other hand, waterway contraction effects for a given bridge span are greater at a bridge founded on spillthrough abutments.

### 11.5.4 Guide Banks

Guide banks are curved embankments that extend upstream and, in some cases, downstream from and perpendicular to the abutment end. The use of guide banks was first introduced in 1888 for the construction of a bridge on the Chenab River,

**Fig. 11-16.** Guide banks at Interstate 70 highway bridge embankment, bridge over Missouri River near Rocheport, Missouri, after 1993 flood.

Pakistan (CBIP 1989). Guide banks extending upstream from the end of bridge embankments have been used to

- confine flow in braided rivers to the bridge opening;
- improve flow distribution and alignment through bridge openings;
- alter flow in bends that impinge on abutments; and
- transfer the point of highest flow curvature and deepest scour upstream of the bridge away from the abutment.

An illustration of the benefits of guide banks is presented in Fig. 11-16, which shows the Interstate 70 highway bridge embankment after the 1993 Midwestern U.S. flooding of the Missouri River near Rocheport, Missouri. Guide banks upstream and downstream of the Interstate 70 embankment transferred the formation of a deep scour hole upstream of the bridge. Although this scour hole was in excess of 17 m deep and caused the failure of the tip of the guide bank, the embankment slopes, including the toe of the highway embankments, were not damaged. The scour hole extended beneath the structure; however, the maximum scour depth under the structure was less than 8 m.

Guidance for the design of guide banks is presented in Neill (1973); Bradley (1978); Ministry of Works and Development (MWD 1979); CBIP (1989); and Lagasse et al. (1995). Lagasse et al. (1995) present detailed guidance that is based on the laboratory research of Karaki (1959; 1961), procedures developed by Bradley (1978), and experience of many U.S. state highway agencies. The main features of guide banks are their orientation with respect to the abutment face and embankment, plan view shape, upstream and downstream length, cross-section shape, and crest elevation. The recommended shape is a quarter of an ellipse with upstream length ( $L_s$ ) equal to 2.5 times the offset length; see Fig. 11-17. The alignment of the guide bank should be parallel to the face of the abutment in the

Fig. 11-17. Typical guide bank details (modified from Lagasse et al. 1995).

bridge opening. The plan view coordinates for the crest can be determined from

$$\frac{x^2}{L_s^2} + \frac{y^2}{(0.4L_s)^2} = 1 \quad (11-3)$$

The length,  $L_s$ , is determined from the nomograph in Fig. 11-18 developed from the studies of Karaki (1959; 1961) and Neeley (unpublished report, U.S. Geological Survey, 1966). In the nomograph,  $Q$  is total discharge of the stream;  $Q_f$  is lateral or floodplain discharge of either floodplain;  $Q_{33}$  is discharge in a 33-m width of stream adjacent to the abutment;  $A_{n2}$  is cross-sectional flow area at the bridge opening during normal stage;  $V_{n2} = Q / A_{n2}$  is average velocity through the bridge opening (m/s);  $Q_f / Q_{33}$  is guide bank discharge ratio; and  $L_s$  is projected length of guide bank (m).

The use of the nomograph should be limited to a minimum length of 16 m and a maximum length of 82 m. Lagasse et al. (1995) recommend that guide banks should

not be shorter than 16 m or longer than 250 m. Experience indicates that a standard length of 50 m has performed well. Shorter lengths have been used successfully when the upstream end of the guide bank was extended to a tree line where the roughness of the trees reduced velocities at the tip of the guide bank.

The crest of the guide bank should be placed at least 0.6 m above the design flood elevation to prevent flows over the guide banks that may be damaging to the bridge. A downstream guide bank of length 16 m is used to prevent rapid expansion of flow in some U.S. states. Riprap protection is recommended for the channel side of the protection and the upstream tip of the guide bank. Rock protection may not be necessary at locations where vegetation will reliably protect guide banks.

### 11.5.5 Design Criteria for Riprap Protection

Model studies have shown and field observations have confirmed that failure of spillthrough abutments is progressive, in contrast to piers, which can fail catastrophically. The

**Fig. 11-18.** Nomograph for selecting the length of guide banks at bridge crossings (modified from Lagasse et al. 1995).

design of countermeasures may require that partial failure of the armor protection be acceptable. For extreme event design and where abutment foundations are supported on piled foundations, complete erosion and failure of the embankment and supported roadway may be acceptable as long as the piles have sufficient depth to resist failure of the embankment.

Research on the performance of riprap protection on abutment slopes and aprons was conducted by a number of researchers including Simons and Lewis (1971); Lewis (1972); Macky (1986); Croad (1989); Simons et al. (1989); Pagan-Ortiz (1991); and Eve (1999). These laboratory studies were conducted under clear-water conditions. Design guidance is presented by the Ministry of Works and Development (MWD 1979); Gregorius (1985); Harris (1988); Richardson et al. (1988); Brown and Clyde (1989); Central Board of Irrigation and Power (1989); Austroads (1994); Richardson and Davis (1995); and Lagasse et al. (1997).

**11.5.5.1 Riprap Size** Simons and Lewis (1971), using the research of Lewis (1972), developed a method for predicting the stability of rock based on detailed velocity measurements around and on the slopes of spillthrough abutments. The method requires the use of a two-dimensional numerical model and the determination of the velocity one rock diameter above the streambed. Croad (1989), based on a limited number of small-scale model tests and velocity measurements, developed an equation to predict the critical conditions for initial failure of riprap protection at the toe of the spillthrough abutment. Croad's method requires a depth-averaged velocity measured over the critical failure point at the abutment toe. He recommended that the depth-averaged velocity over the critical failure point be estimated as 1.5 times the average approach flow velocity.

Pagan-Ortiz (1991) conducted fixed-bed small-scale experiments on the stability of riprap on a spillthrough abutment with side slopes of 2H:1V and on vertical-wall abutments. Flow conditions were adjusted until failure conditions were observed near the abutment. Critical failure zones were found on the streambed protection at or near points of flow separation from the upstream end of the rectangular abutments and downstream of the flow separation point on the spillthrough abutment. Prediction equations for the critical conditions were developed based on the average contracted flow velocity measured in the experiments.

A. T. Atayee (Unpublished TRB paper No. 931021, 1993) extended the research of Pagan-Ortiz (1991) to include compound channel geometry. Critical failure zones similar to those described in Pagan-Ortiz (1991) were observed. The data of both Pagan-Ortiz (1991) and Atayee were used to develop two equations that are based on the contracted flow velocity on the floodplain portion of the bridge opening (Atayee et al. 1993). They recommend that a two-dimensional depth-averaged numerical model be used for determining the average contracted flow velocity on the floodplain. The method presented in Atayee et al. (1993) is recommended as design guidance by Richardson and Davis (1995), although ad hoc recommendations were added to allow for prediction of contracted flow velocity on the floodplain based on cross-section averaged contracted flow velocity and the width of the floodplain in the contracted bridge opening.

A list of the riprap sizing equations for abutment protection is provided in Table 11-9. The equations of Simons and Lewis (1971), Croad (1989), and Atayee et al. (1993) for  $F < 0.8$  can be arranged into the form

$$\frac{D_r}{H} = \frac{C}{(S_s - 1)} F^2 \quad (11-4)$$

where  $C$  is a coefficient. For  $F < 0.8$  and flat-bed conditions, the Simons and Lewis (1971) relation at the critical location of failure can be considered identical to that of Atayee et al. (1993) if the local velocity one rock diameter over the bed is 1.15 times the average contracted flow velocity on the floodplain. For the same flow range and conditions, the Croad (1989) equation can be considered identical to that of Atayee et al. (1993) if the depth-averaged velocity at the critical point of failure is 1.48 times the average contracted flow velocity on the floodplain.

Simon and Lewis (1971) and Croad (1989) both recommend that down-slope gravitational force should be considered in determining the size of rock on the abutment slope. They recommend increasing the rock size according to the relation provided by Lane (1955). The studies by Ulrich (1987) and Maynard (1995; 1996), as described in Appendix B, indicate that the theoretical slope adjustment factors used by Lane (1955) may be as much as 35% larger

**Table 11-9 Equations for Sizing Riprap at Abutments**

Reference	Applicability	Equation	Symbols
Simons and Lewis (1971)	Spillthrough abutments	$\eta = \frac{0.4 U_r^2}{(S_s - 1) g D_r} \quad (11-19)$	$D_r$ = riprap stone size $U_r$ = velocity at a level of one rock diameter above the bed $H$ = approach flow depth $S_s$ = specific gravity of rock $\eta$ = stability factor = 0.595, for flow over a horizontal bed
Croad (1989)	Spillthrough abutments	$D_{r50} = 0.025 U_b^2 K_{sl}^{-1}$ $K_{sl} = \sqrt{1 - \frac{\sin^2 \phi}{\sin^2 \theta}} \quad (11-20)$	$U_b$ = velocity at abutment end $K_{sl}$ = embankment slope factor $\phi$ = slope angle $\theta$ = angle of repose $F$ = Froude number of approach flow = $U/(gH)^{0.5}$
Brown and Clyde (1989)		$D_{r50} = \frac{0.006 U^3}{H^{0.5} K_{sl}^{1.5}} \left( \frac{S_f}{1.2} \right)^{1.5} \quad (11-21)$	$S_f$ = stability factor varying from 1.6 to 2.0 for abutment protection
Pagan-Ortiz (1991)	Vertical-wall abutment	$D_{r50} = \left( \frac{1.064 U_2^2 H_2^{0.23}}{(S_s - 1) g} \right)^{0.81} \quad (11-22)$	$U_2$ = mean velocity in contracted (bridge) section $H_2$ = flow depth in contracted section
	Spillthrough abutment	$D_{r50} = \frac{0.535 U_2^2}{(S_s - 1) g} \quad (11-23)$	
Austrroads (1994)		$\frac{D_{r50}}{H} = \frac{1.026}{(S_s - 1)} F^2 \quad (11-24)$	
Atayee et al. (1993) and Richardson and Davis (1995)	$F_2 \leq 0.8$	$\frac{D_{r50}}{H_2} = \frac{K_s}{(S_s - 1)} F_2^2 \quad (11-25)$	$K_s$ = shape factor = 0.89 for spillthrough abutments = 1.02 for vertical-wall abutments
	$F_2 > 0.8$	$\frac{D_{r50}}{H_2} = \frac{K_s}{(S_s - 1)} F_2^{0.14} \quad (11-26)$	$F_2$ = Froude number in the contracted section $K_s$ = 0.61 for spillthrough abutments = 0.69 for vertical-wall abutments

than data would indicate. If the rock protection on the slope is sized according to Atayee et al. (1993), then consideration should be given to use of slope correction factors by Ulrich (1987) and Maynard (1995; 1996).

**11.5.5.2 Extent of Rock Protection** Under clear-water conditions, Pagan-Ortiz (1991) found that an apron that extended along the toe of the abutment from the point of tangency on the upstream side of the abutment to the point of tangency on the downstream side of the abutment and extended a distance equal to two times the flow depth away from the toe of the abutment was adequate. Atayee et al. (1993) recommended that the width of the apron not exceed 7.5 m.

Eve (1999) conducted riprap tests with approach flow conditions at 90% of the approach shear stress required to mobilize the approach sand bed. Based on her observations of progressive failure of the abutment embankments, she developed the following relation for determining the extent of protection,

$$\frac{W}{H} \left( \frac{0.5W + r}{H + r} \right) = \left( 0.5 - 1.82 \frac{D_{r50}}{H} \right) \left( \frac{B}{B - L} \right) \left( \frac{180}{180 - (\theta + \phi)} \right) \quad (11-5)$$

**Fig. 11-19.** Definition diagram for placement of a riprap launching apron at a spillthrough abutment (after Eve 1999).

where

- $H$  = approach flow depth;
- $B$  = upstream width of the flume;
- $L$  = abutment length;
- $r$  is the radius of the spillthrough abutment toe;
- and  $W$ ,  $\theta$ , and  $\phi$  are defined in Fig. 11-19.

Macky (1986) examined typical New Zealand practice, rather than recommended practices, in small-scale model studies in which the protection on the slope was extended only slightly below the previously existing bed level and no apron was provided. He reported that riprap failed into scour holes that formed around the abutment; however, the slumped riprap armored part of the scour hole. Additionally, the remaining slope angle decreased and was armored by riprap that translated down slope. The tested abutment was substantially undamaged. Macky also found that for aligned flows, the downstream side of the abutment required only nominal protection.

Riparian and floodplain vegetation may provide adequate protection where shading beneath the structure does not prevent its growth. Although insufficient data are available for reliance on vegetation at the critical failure points, vegetation may provide reliable protection on the upper slope areas and at locations upstream and downstream of the bridge. Substantial reduction in the extent of armor protection may be possible. In practice, sufficient protection has been provided to bridges by armoring the area beneath the bridge superstructure. Unfortunately, laboratory studies have not modeled the effects of vegetation under similar conditions. Armor protection should be considered at all critical locations where unraveling of the vegetal cover may be initiated, such as on the toe of the abutment and around piers located within the high-velocity flow of the abutment and any areas where shading may prevent the growth of erosion-resistant vegetal covers. Use of two-dimensional numerical models to determine the extent of armor protection required and the appropriate locations for vegetation should be considered.

**11.5.5.3 Thickness of Riprap** Although specific tests on the thickness of riprap protection on abutment slopes and aprons have not been conducted, information on the thickness of riprap revetments for stream banks and streambeds is provided by Maynard (1995; 1996) and is given in Appendix B. Where riprap is placed in water, on fine-grained sediment without a filter, or where extensive scour holes are anticipated at the edges of the protection, increased riprap thickness may be warranted. Lagasse et al. (1997) suggest that the thickness should not be less than the larger of either  $1.5 D_{r50}$  or  $D_{r100}$  and should be increased by 50% when it is placed underwater to provide for uncertainties associated with underwater placement methods.

**11.5.5.4 Filter Requirements** An exploratory study by Eve (1999) showed the need for filters at abutments under live-bed conditions. In a very limited number of live-bed experiments, complete failure of approach embankments, initiated by bed-form undermining and winnowing of the bed material beneath the riprap, was observed on the apron as well as on the slope. On the other hand, Macky (1986) and Eve (1999) reported stable riprap configurations in several clear-water experiments in which filters were not used. Other factors such as groundwater flows from such sources as surface runoff may necessitate the use of filters on slopes. Additional research is needed to determine the benefit of placing riprap under the apron and on the slope, especially where riprap is designed to conform to adjacent scour holes or bed-form undermining.

### 11.5.6 Alternatives for Protection of Abutments

Where riprap of adequate size is unavailable or where environmental or geometric constraints preclude use of riprap, alternatives to riprap are necessary. Lagasse et al. (1997) describe several armoring alternatives for abutment slopes, including articulated concrete block (Section 11.3.4.3), articulated grout-filled mattresses (Section 11.3.4.4), soil cement, wire-enclosed mattresses, interlocking armor units (toskanes, Section 11.3.4.3), and cement-filled bags (Section 11.3.4.3).

As part of the study was completed to evaluate the performance of typical rather than recommended methods of protecting spillthrough abutments, Macky (1986) examined the performance of several alternatives to riprap including: interlocking concrete armor units (akmons), concrete mattresses (Section 11.3.4.4), gabions (Section 11.3.4.5) laid on the embankment slopes, gabions stacked horizontally and staggered up the slope, and boulder-filled wire baskets laid on the bed beneath the stacked gabions. Although a very limited number of tests were conducted, several important aspects of abutment protection were revealed. Although the interlocking armor units behaved similarly to riprap, their interlocking capabilities appeared to hinder dispersal on the slope after toe scour undermined the protection. Tests on riprap showed that dispersal of the rock is a key factor in the

ability of the protection to adjust and conform to scour holes and subsequent slope failures. Consequently, large areas of the slope were left unprotected after slope failures occurred. Macky (1986) recommended that noninterlocking shapes be considered. Concrete mattresses, gabions, and wire-filled baskets generally performed poorly, because of their inability to adjust and conform to scour holes and slope failures. As the experience of U.S. state highway agencies has shown, use of rigid concrete pavements (Section 11.3.4.4) on abutment slopes suffers from the same problems. Preexcavation of the scour hole at the toe of the slope and extension of the slope protection to the depth of scour were recommended as a possible way to improve the performance of mattress- and gabion-type countermeasures. An apron using these techniques may also improve the performance of these techniques.

The work on riprap protection on abutments, coupled with the work by Macky (1986), clearly shows that design of spillthrough abutment protection should either extend to a depth near to the scour depth, provide an extensive apron, or conform to progressive scour hole formation and slope failure.

## 11.6 ENVIRONMENTAL CONSIDERATIONS

Countermeasures for bridges should be constructed so that they enhance aquatic habitat and bridge-crossing aesthetics rather than degrading them. Selection of the size distribution of rock for armor protection should satisfy requirements for stream stability and habitat. Grade control structure drops should be selected to provide for fish migration. Consideration should also be given to countermeasure placement methods and their impact on aquatic habitat.

Although the full spectrum of potential flows at bridges should be considered, the countermeasure should be designed to protect the bridge for design flood events (500, 100, and/or overtopping event), maintain channel stability at bank-full levels, and enhance stream habitat at average annual and lower flow levels. Stream restoration concepts and habitat objectives given in Chapter 9 should be incorporated into the countermeasure designs at the bridge; however, highway right-of-way limits and cost may be apparent barriers to extensive modification of stream channels as part of bridge-scour countermeasures. Use of structures such as spur dikes, barbs, and bendway weirs provide nonuniformity to flow and topography through the bridge opening, which generally improve habitat; conversely, use of uniform rock revetments and other uniform topography and material configurations will tend to degrade habitat. Vegetation, especially riparian trees, should be used to protect streambanks where safety of the bridge is not compromised.

## CHAPTER 12

### *Reservoir Sedimentation*

*Gregory L. Morris, George Annandale, and Rollin Hotchkiss*

#### 12.1 INTRODUCTION

*Manual 54* was originally published in 1975, toward the end of a period of intensive dam building worldwide. Sedimentation investigations at that time focused primarily on computing rates of sediment inflow, predicting sediment-induced shifts in the stage-storage curve over time, sizing dead pools typically equivalent to 50 or 100 years of sediment storage, and determining the “life of the reservoir.” Today an increasing number of dams are reaching the end of their “design life,” and their operation is increasingly affected by long-term sedimentation issues ignored at the time of construction.

Dams represent a unique category of engineered infrastructure because their eventual obsolescence is determined by the geologic processes of erosion and sedimentation rather than by engineered works themselves, which can be continually rehabilitated. When sedimentation is controlled, dams can have useful lives greatly exceeding any other type of engineered infrastructure. For example, Schnitter (1994) lists 12 ancient dams that had operational periods exceeding 2,000 years. Four of these are still in operation, five have been rehabilitated and are operating again, and only three are no longer operational. However, absent sediment control, today’s dams represent an unsustainable pattern of water resource development.

There are over 75,000 dams in the United States, of which over 7,000 are classified as large dams having a height of at least 15 m. Most U.S. rivers have been essentially fully developed with respect to dams, and the rate of dam construction in the U.S. and worldwide has decreased dramatically since the 1970s (Fig. 12-1).

Dam sites are limited, and the best sites, which were developed first, are accumulating sediment. New dams can replace silted reservoirs in some cases but not others, with the largest and most important reservoirs being virtually irreplaceable. Siting obstacles to new reservoirs are formidable,

and even when technically feasible alternative dam sites exist, they may not be feasible from the economic, social, political, or environmental standpoint. This leaves today’s owners and engineers facing long-term sedimentation issues ignored in the original project concept.

In 1946, Brown recognized that major reservoirs are irreplaceable, and at the brink of the most active period of dam construction in U.S. history, he wrote,

If the contemplated public and private reservoir construction programs are carried out, we shall have utilized by the end of this generation a very substantial portion of all the major reservoir sites. . . . We cannot discover new reserves, as we will of oil. Nor can we grow new resources, as we can of forests. To whatever degree we conserve the capacity of the reservoirs built on these sites, to just that degree shall we conserve this indispensable base of our national strength and prosperity.

Whereas the twentieth century focused on dam construction, the twenty-first will focus on sustaining the function of existing infrastructure as it becomes increasingly affected by sedimentation.

Most natural river reaches are approximately balanced with respect to sediment inflow and outflow. Dam construction dramatically upsets this balance by creating a quiescent reach that accumulates sediment until the balance between sediment inflow and outflow is again reestablished. The objective of sediment management is to manipulate the river-reservoir system to achieve sediment balance while retaining as much beneficial storage as possible and minimizing environmental impacts and socioeconomic costs.

In addition to determining the rate of storage loss, sedimentation issues today are becoming increasingly focused on issues such as (1) continuation of reservoir operation beyond the original design life despite sediment accumulation,

Fig. 12-1. Rate of large dam construction in the United States (data from USCOLD 1994).

(2) modification of existing structures and operating rules to minimize sedimentation impacts, (3) design and management of new reservoirs to minimize sediment accumulation, (4) dredging and other sediment removal techniques, (5) sediment impacts associated with dam decommissioning and removal, and (6) sediment management to minimize or mitigate environmental impacts. Environmental issues associated with reservoir sedimentation include the consequences of altered sediment supply and regulated flows on the morphology and ecology of downstream channels. Sediment management is also a primary environmental issue associated with the decommissioning of dams because dam removal will expose deposits to scour and can potentially release large volumes of sediment and any included contaminants to the downstream channel.

There are three basic themes in this chapter. First, basic sustainable use concepts pertinent to dams and reservoirs are introduced. Second, concepts of sediment delivery processes and sampling are introduced. This topic is presented because sediment management for sustainable use requires a more detailed understanding of sediment delivery processes than the traditional approach of simply determining long-term yield to compute the rate of sediment accumulation. The third theme describes basic sediment management strategies applicable to reservoirs.

This chapter presents only a summary introduction to this complex topic, and additional resources should be consulted. The following references represent a useful starting point. Morris and Fan (1998) provide a comprehensive treatise

on sediment management in reservoirs and regulated river systems, including background descriptions of measurement, monitoring and modeling techniques, case studies, and an extensive bibliography. The World Bank's emerging approach to Reservoir Conservation (RESCON) is described by Palmieri et al. (2003) and Kawashima et al. (2003). An overview of reservoir-flushing techniques is provided by Atkinson (1996) and White (2001). Strand and Pemberton (1987) present a summary of reservoir sedimentation techniques used by the U.S. Bureau of Reclamation, and Corps of Engineers procedures are outlined by the U.S. Army Corps of Engineers (1989). Additional information is provided by Annandale (1987).

## 12.2 SEDIMENTATION RATES

### 12.2.1 Sedimentation Rates Worldwide

Sedimentation rate may be expressed as of the percentage of total original reservoir volume lost each year. Crowder (1987) estimated the rate of storage loss in the coterminous 48 states in the United States at 0.22% per year. Data on U.S. reservoirs compiled by Dendy et al. (1973) showed that storage loss tends to be more rapid in smaller reservoirs than in larger ones due to generally higher capacity: inflow ratios and lower specific sediment yields in the latter. The rate of storage loss in other parts of the world is generally higher than in the United States, and Mahmood (1987) estimated that storage capacity worldwide is being lost at an annual rate of 1%,

**Table 12-1 Worldwide Rates of Reservoir Sedimentation**

Region	Inventoried large dams	Storage (km <sup>3</sup> )	Annual percent storage loss by sedimentation
China	22,000	510	2.3
Asia excluding China	7,230	861	0.3–1.0
North America	7,205	1,845	0.2
Europe	5,497	1,083	0.17–0.2
South and Central America	1,498	1,039	0.1
North Africa	280	188	0.08–1.5
Sub-Sahara Africa	966	575	0.23
Middle East	<u>895</u>	<u>224</u>	<u>1.5</u>
Worldwide	45,571	6,325	0.5–1.0

Source: Adapted from White (2001).

and estimates compiled by White (2001) are summarized in Table 12-1. The world is now losing reservoir capacity much faster than new capacity is being constructed.

Within a given geographic region, there are wide variations in the rate of storage loss. For example, Gogus and Yalcinkaya (1992) examined data from 16 reservoirs in Turkey and computed a mean annual rate of storage loss of 1.2%, but the rates for individual reservoirs ranged from 0.2% to 2.4%. In India, Morris (1995) estimated an annual rate of storage loss of 0.5%, meaning that about half of India's total reservoir capacity will be lost during the twenty-first century. However, the least affected 20% of the reservoirs will not lose half their capacity until after the year 2500. Thus, the problem is highly site specific, and new reservoir construction at a geographically distant location will not solve a local water supply problem stemming from sedimentation. Only in the case of hydropower can a distant new site offset local problems because, unlike water, electricity can be transported for long distances at low cost.

### 12.2.2 Reservoir Half-Life

Common practice has been to compute "reservoir life" by dividing total reservoir volume by annual sedimentation volume during the early years of impoundment, thereby estimating the number of years to completely fill the reservoir. However, in most reservoirs, sediment will seriously interfere with design functions by the time half the storage pool is lost (Dendy et al. 1973; Murthy 1977). *Reservoir half-life*, the time required to lose half the original capacity to sedimentation, is thus a much better approximation of when sedimentation problems will become truly serious. At many sites,

sediments will seriously interfere with reservoir function when much less than half the original capacity has been lost. For example, Loehlein (1999) describes problems including hindered floodgate operation and clogging of hydropower and water supply intakes due to sedimentation at several Corps of Engineers flood control reservoirs in Pennsylvania, with only 6% storage loss.

### 12.2.3 Reservoir Life

Reservoir life has traditionally been conceptualized based on the continuous filling of the usable storage pool, presumably followed by abandonment of the structure. However, the "life" of a reservoir is better described based on the three distinct stages:

**Stage 1: *Continuous sediment trapping.*** During the first stage of reservoir life, continuous sediment trapping occurs during all inflowing flood events. A cross section perpendicular to the axis of the reservoir in continuously impounded areas will reveal a depositional sequence that fills the deepest part of the cross section first, eventually producing sediment deposits that are essentially flat (Fig. 12-2).

**Stage 2: *Partial sediment balance.*** During the second stage, the reservoir transitions from a continuously depositional environment to a mixed regime of deposition and removal. If sedimentation is allowed to proceed uninterrupted, the reservoir at this stage will become largely filled with sediment, and a channel-floodplain configuration will develop in the former pool area. The inflow and discharge of fine sediment may be nearly balanced, but coarse bed material continues to accumulate. Sediment management techniques, such as drawdown to pass sediment-laden flood flows through the impounded reach or periodic flushing, can produce a partial sediment balance to help preserve useful reservoir capacity.

**Stage 3: *Full sediment balance.*** A long-term balance between sediment inflow and outflow is achieved when both the fine and the coarse portions of the inflowing load can be transported beyond the dam or artificially removed on a sustainable basis. However, sediment movement through the impounded reach is not necessarily the same as the preimpoundment condition because sediment may accumulate during smaller events and be washed out during large floods or may be removed at intervals by dredging or flushing.

Most reservoirs worldwide are in Stage 1, continuously trapping sediment. Only a handful of reservoirs worldwide have been designed to achieve sediment balance. A notable example is the large (more than 600 km long) Three Gorges reservoir on China's Yangtze River, designed to reach full sediment balance after about 100 years.

Fig. 12-2. Successive cross sections of Lake Francis Case on Missouri River above Ft. Randall Dam, showing the deposition of sediment in flat beds (Stanley Consultants 1989).

#### 12.2.4 Capacity-History Curves

Reservoir volumetric capacity will steadily diminish in a reservoir that is continuously impounded, although the rate of storage loss will tend to decrease as the reservoir's hydrologic size and trap efficiency diminish (Brune 1953). Sediment management can retard or reverse this trend, and storage capacity can increase over time as sediment is removed. Capacity-history curves may be drawn to illustrate historical and anticipated changes in usable storage volume under different management options.

Illustrative capacity-history curves are given in Fig. 12-3, illustrating the case where sediment management is initiated when half the reservoir capacity has been lost. This example compares dredging alone versus dredging in combination with pass-through routing of major sediment-producing floods. The rate of sediment accumulation eventually decreases under the do-nothing alternative because of the declining capacity to inflow ratio (Brune, 1953). Similar curves may be constructed for other types of sediment management operations and can be useful in visualizing the impacts of alternative strategies on the long-term evolution of the reservoir.

### 12.3 SUSTAINABILITY

#### 12.3.1 Sustainability and Economic Analysis

The underlying concept of sustainable development is that the welfare of future generations (including our own children and grandchildren) should logically figure into the project

decision-making process. This concept arose from the recognition that many development and resource utilization patterns could not be sustained in the long term, coupled with the failure of conventional economic analysis to formally consider impacts over periods as short as a single human life span. Reservoirs arguably represent today's most important class of nonsustainable infrastructure.

Definitions of sustainable development have proliferated, but the following basic concepts are most relevant from the standpoint of water resource infrastructure: (1) Today's patterns of infrastructure development should not compromise the ability of future generations to access these same resources. (2) Maintain biological diversity and environmental integrity. (3) Minimize the potential for catastrophic disasters resulting from infrastructure failure or obsolescence. (4) Avoid activities that create a legacy of environmental restoration or infrastructure rehabilitation obligations that fall disproportionately on future generations.

Hotchkiss and Bollman (1996) have emphasized the need to assess project configurations on the basis of long-term parameters rather than relying solely on limited-horizon economic performance. Project economic analysis is based on benefit-cost techniques in which the future streams of benefits and costs are time discounted. Using a discount rate of 7%, for example, the present value of a \$100 benefit 50 years in the future is only \$5.83, and end-of-project decommissioning costs are typically ignored. Traditional discounting procedures discourage additional construction costs aimed at sustaining long-term function, such as large low-level flushing outlets that do not produce quantifiable

**Fig. 12-3.** Alternative storage history curves to conceptually illustrate sediment management alternatives, dredging only versus sediment-pass through with less frequent dredging.

economic benefits during the initial decades of reservoir life. Despite the logic behind sustainability considerations and the technical feasibility of a variety of preventive sediment management options, there is usually little economic incentive for an owner to invest today in strategies that reduce future sedimentation problems.

Cairns (1993) concluded that short-term economic gain overrides long-term sustainability or ecological considerations. He observed that historical development in the United States has followed this policy and that the same

policy is definitely being pursued in developing countries. Weiss (1993) points out that market conditions also tend to be evaluated within the context of the present generation, and the needs of future generations are not explicitly represented. In addition to the problem posed by limited planning horizons, the benefit-cost analysis is not always appropriate for two other reasons: (1) incomplete information and improper valuation of impacts and (2) uncertainties in future markets. Most secondary impacts of reservoir sedimentation are not included in benefit-cost analysis. O'Neil

(1997) concluded that uncertain futures, both economic and technological, make the use of benefit-cost analysis for far-distant project impacts questionable.

Requiring a reservoir life measured in terms of generations instead of decades will demand new methods of analyzing costs and benefits. Palmieri et al. (1998) demonstrate that “for a very wide range of realistic parameter values, sustainable management of reservoirs is economically more desirable than the prevailing practice of forcing a finite reservoir life through excessive sediment accumulation.” They reach such a conclusion after comparing the salvage value of projects to the cost of continuing dam operation. They suggest that an annual contribution to a “retirement fund” or to an “insurance policy” will affect future salvage value and may extend the economic life of a reservoir indefinitely.

### 12.3.2 The RESCON Approach

The RESCON (REServoir CONservation) approach to sustainable reservoir management developed under the auspices of the World Bank is described by Palmieri et al. (2003), and its technical details are outlined by Kawashima et al. (2003). The methodology proceeds in three stages: (1) determine which methods of sediment management are technically feasible; (2) determine which alternatives are more desirable based on an economic analysis; and (3) incorporate environmental and social factors to select the best course of action for sediment management.

The RESCON methodology can be applied to proposed or existing dams and reservoirs to make a preliminary assessment of sustainable management alternatives, and to compare them to the nonsustainable alternative of allowing the reservoir to silt up and implement decommissioning procedures at the end of a dam’s physical life. Should the latter choice be identified as the only feasible alternative, a sinking fund to pay for decommissioning should be established to ensure intergenerational equity?

The RESCON approach accounts for all major benefits and costs over the complete project life-cycle and, in particular, acknowledges the need for intergenerational equity. This is achieved by maximizing the algebraic sum of net benefits, capital cost, and salvage value, that is,

$$\text{Maximize } \sum_{t=0}^T NB_t \cdot d^t - C_2 + V \cdot d^T,$$

subject to

$$S_{t+1} = S_t - M + X_t,$$

given the initial capacity  $S_0$  and other physical and technical constraints, and where:  $NB_t$  = net benefit in year  $t$ ;  $d$  = discount rate factor defined as  $1/(1 + r)$ , where  $r$  = discount

rate;  $C_2$  = initial capital cost of construction (= 0 for existing facilities);  $V$  = salvage value;  $T$  = terminal year;  $S_t$  = remaining reservoir capacity (volume) in year  $t$ ;  $M$  = trapped annual incoming sediment; and  $X_t$  = sediment removed in year  $t$ .

In the case of reservoirs, the salvage value  $V$  is usually negative as it represents the cost of decommissioning at terminal year  $T$ , should this prove the most economical solution. Allowance for intergenerational equity is made by creating a sinking fund that will create a large enough retirement fund to decommission the facility, if required. The annual investment,  $k$ , into the sinking fund is calculated as

$$k = -m \cdot V / [(1 + r)^T - 1]$$

where  $m$  = interest rate (which can differ from the discount rate  $r$ ). When assessing the economic feasibility of a decommissioning option,  $k$  is subtracted from the net benefits on an annual basis.

### 12.3.3 Regulatory and Legal Aspects

Important sustainability criteria are already established by regulation or law rather than economic analysis, such as the requirements for environmental protection and dam safety. From the owner’s standpoint, these may be viewed as onerous and uneconomic measures, and it is precisely this difference in perception between the owner and society in general that has given rise to socially protective regulations and engineering standards. From this standpoint, it may be logical for the engineering community to develop minimum standards for considering long-term sustainability in future design and management activity related to reservoir sedimentation.

A logical starting point would be to formally evaluate and incorporate to the extent possible measures to sustain long-term capacity in all designs for new reservoirs, or significant modifications to existing ones. These measures are not necessarily costly. For example, in a new reservoir having crest gates and where sediment pass-through may eventually be feasible, this future option is facilitated by the specification of bottom-opening gates, as opposed to bascule gates which are unsuited to passing sediment. Similarly, outlets for river diversion during construction might be closed, but not filled with concrete, to facilitate the installation of bottom gates at some point in the future.

Legal and liability considerations will also have impacts on sediment management activities. In addressing this issue, Thimmes et al. (2005) have pointed out that the dam owner may be liable for the accumulation of sediment within

the reservoir that causes upstream flooding, as well as for impacts of sediment release downstream.

## 12.4 SEDIMENTATION IMPACTS

Sedimentation impacts not only the impoundment but also areas extending far downstream and short distances upstream of the design pool. Typical impacts are outlined in Table 12-2. Fig. 12-4 presents a highly simplified longitudinal profile along a reservoir, illustrating the various patterns of sediment deposition and associated impacts.

The primary sedimentation impact within a reservoir is storage loss that impairs water supply, hydropower, flood control, and both commercial and recreational navigation. The impacts of storage loss on water supply yield may be quantified as a gradual reduction in firm yield based on the storage–yield relationship for the site or as the increased risk (increased frequency) of water shortage with time when attempting to maintain a stated rate of withdrawal.

Coarse sediments (>0.6 mm diameter) can abrade hydro-mechanical equipment, and sediment deposits against the dam may increase the static loading on the structure. The presence of contaminants in sediments (Chapter 21) can greatly hinder any procedure that would release these sediments, such as dredging, flushing, or dam removal (Chapter 23).

Deltas can form where the main or side tributaries discharge into a reservoir, and these deltas will create back-water and bed aggradation above the normal pool level (Chapter 2). This deposition can create problems such as increased frequency and depth of flooding, decreased navigational clearance at bridge crossings, and sedimentation of upstream water intakes. Streambed aggradation will increase groundwater levels, which in turn can saturate vegetative root zones and waterlog riparian agricultural soils, increase soil salinity, and alter ecological habitats.

Below a dam, the river will adjust to both reduced sediment inputs and the altered stream flows produced by reservoir releases. Dams are highly efficient bed-load traps, and even reservoirs operated for sediment release may trap most of the inflowing bed material. Reservoir trapping of bed material encourages channel incision along the river reach below the dam, lowering the base level of the river. This can trigger processes much the opposite of those upstream: degradation of tributaries, destabilization and undercutting of streambanks, undermining of bridge piers and river training works, and sediment starvation of river bars and beaches important for both environmental and recreational benefits. Sediment starvation will also reduce aggregate supplies in the stream channel and contribute to coastal erosion.

Also, as the base level in the river incises in response to sediment trapping by the reservoir, channel degradation

**Table 12-2 Sedimentation Impacts**

Impact location and type	Impact description
Within-reservoir impacts:	
Storage loss	Reduced firm yield, hydropower, and flood-control benefits.
Reservoir operations	Sediment can clog intakes, interfere with gate operation, and abrade hydromechanical equipment.
Organic sediments	Oxygen demand can make bottom waters anaerobic.
Turbidity	Reduced euphotic zone and decreased primary productivity. Aesthetically unpleasant for recreation.
Navigation	Sedimentation of marinas and navigation channels. Interferes with recreational use and sport fisheries.
Air pollution	During drawdown, fine sediment exposed to air can dry out and be carried by wind.
Above-reservoir impacts:	
Delta deposition	Higher river levels flooding and reduce navigational clearance beneath bridges. Groundwater levels can rise causing soil waterlogging, salinization, and increased evaporation from vegetated deltas.
Below-reservoir impacts:	
Reduced bed-material load	Streambed incision and accelerated bank erosion. Bed may become too coarse for spawning. Structures such as bridges, intakes, and training works may be undermined. Cutoff of sand supply contributes to coastal erosion. Reduced supply of aggregate materials.
Reduced fine sediment load	Reduced nutrient delivery to downstream ecosystems. Increased water clarity will alter ecological conditions and benefit recreational use.

Fig. 12-4. Deposition patterns in reservoirs and classes of sediment-related impacts imposed by the dam.

can proceed upstream along tributaries and thereby affect stream reaches not themselves directly below the dam and thus unaffected by reservoir hydrology. Lower groundwater levels can result in loss of riparian vegetation and dewatering of wetlands. Fish habitats may degrade as a smaller fraction of the bed material is washed downstream, leaving behind an armored bed too coarse for fish spawning.

Dams reduce downstream flood peaks even in reservoirs not operated for flood control. This reduces the energy available to mobilize bed material, allowing an armor layer to form with smaller material than in the predam river channel (Chapter 3). This peak flow reduction and armoring will limit channel degradation below the dam, but without periodic mobilization of the armor layer and flushing of fines from the riverbed sediment, the immobilized bed can become useless for spawning and habitat. Although streambed degradation and bed-material coarsening below dams tend to occur in the first decades after construction, the process occurs erratically rather than as a uniform progression (Williams and Wolman 1984).

Channels below dams do not always degrade. When the dam significantly reduces downstream flows and sediment transport capacity yet below-dam tributaries continue to deliver large sediment loads to the river, the channel may aggrade, as in the case of Río Grande at Presidio, Texas, below Elephant Butte reservoir (Collier et al. 1995).

There is growing appreciation that the long-term impacts of dams on river systems have often been underestimated or even ignored, that dams can cause unnecessary environmental damage, and that the wise development and utilization of environmental resources is incompatible with the destruction of biological habitats. However, with proper management, these impacts can be greatly diminished. Environmental and related impacts of dams have been reviewed by Goldsmith and Hildyard (1984, 1985), McCully (1996), and Petts (1984).

River channels are maintained by periodic flood events, and the channel-forming event typically has a return interval of about 1.5 years (Leopold et al. 1964; Simon and Heins 2005). When downstream flood releases are reduced,

the channel can no longer maintain its original size and is encroached on by vegetation, as shown in the example pictured in Fig. 12-5. Ligon et al. (1995) described impacts on the McKenzie River in Oregon by flow regulation in two Corps of Engineer dams that reduced peak discharges by over 50%. Reduced flows allowed channel simplification, channel stabilization, and vegetative encroachment, substantially reducing the areas of gravel suitable for salmon spawning. They also reduced the area of sloughs, backwaters, and traces of former channels created by meander cutoffs, habitat required for rearing juveniles.

The increased resistance of public and environmental organizations to new reservoir construction is a logical reaction to the extensive reservoir building that has already occurred and to the impacts of dams on free-flowing rivers, including impacts not necessarily understood by their original designers. By 1990, a total of 965,000 km of rivers had been submerged by dams in the United States, versus only 15,000 km protected under the Wild and Scenic Rivers Act (Graf 1993). Much of the “wild and scenic” river mileage is itself downstream of or sandwiched between dams.

**Fig. 12-5.** Encroachment of vegetation into channels of North Canadian River 0.8 km below Canton Dam, Oklahoma, due to reduction in channel-maintaining flows. Photos taken in (A) 1938 and (B) 1980 (Williams and Wolman 1984).

## 12.5 SEDIMENT DELIVERY TO RESERVOIRS

Sediment yields vary remarkably over time and space, and this variability must be understood to properly interpret data, to predict sediment yields, and to successfully implement strategies for reducing sediment inflow or passing sediment-laden flows around or through the storage pool. This section outlines basic concepts of variability in sediment yield and delivery to reservoirs. The discussion focuses on suspended load because it is responsible for most sediment discharge worldwide, but basic concepts are generally applicable to the bed load as well.

### 12.5.1 Erosion and Sediment Yield

*Erosion* is the process of detaching particles from the soil matrix and initiating their transport away from the point of detachment. Erosion rates are measured using small plots, and the distance that a particle must travel before being counted as having been “eroded” may be a few meters or less. Erosion rates from farms and watersheds are computed by empirical models, such as the Universal Soil Loss Equation (USLE) and its variants (MUSLE, RUSLE), or the more complex physically based detachment and transport models, such as AGNPS, ANSWERS, CREAMS, SEDIMONT, and WEPP.

*Sediment yield* is the amount of sediment transported beyond or delivered to a specified point in the drainage network over a specified time period. It is always less than and typically much less than the amount of sediment eroded within a watershed due to redeposition prior to reaching stream channels or reservoirs. Watershed sediment yield is also addressed in Chapter 17.

*Sediment delivery ratio* is ratio of eroded sediment to delivered sediment. Because erosion rates are computed rather than measured, the sediment delivery ratio is actually the ratio of computed erosion to measured yield. Sediment yield estimates derived from erosion estimates are typically more sensitive to errors in estimating the sediment delivery ratio than to errors in erosion rate. For example, with a sediment delivery ratio equal to 10% of erosion, a 1% error in estimating sediment delivery ratio would have the same impact on computed sediment yields as a 10% error in the erosion estimate. For a good review of the problems associated with estimating sediment delivery ratio, see Walling (1983).

### 12.5.2 Spatial Variation in Sediment Yield

Sediment yield is highly variable over space, and a small part of the landscape unit will contribute a disproportionate amount of the total sediment yield. Dividing total sediment discharge by total basin area to obtain the average yield can be grossly misleading by masking the underlying variability in sediment yield (Campbell 1985). Variations in specific sediment yield, the sediment yield per unit of land area, can be particularly

**Table 12-3 Sediment Yield from Gauge Stations Worldwide**

Yield Class (tn/km <sup>2</sup> /year)	Number of Gauge Stations	Gauged Land Area (%)	Total Gauged Sediment Load (%)
0–10	230	21.3	0.3
11–50	285	25.6	1.8
51–100	172	11.9	2.1
101–500	426	25.6	14.7
501–1,000	145	6.9	12.0
>1000	179	8.8	69.1

Source: Jansson (1988).

dramatic in watersheds subject to disturbance. For example, Megahan (1975) showed that, compared to natural conditions, logging increased specific sediment yield by a factor of 1.6 on forest soils subjected to tree felling and skidding but by a factor of 550 on logging roads subject to mass erosion. For this reason, erosion control on forestlands focuses foremost on logging roads. On a larger scale, Jansson (1988) analyzed data from 1,358 gauge stations worldwide with tributary watersheds between 350 and 100,000 km<sup>2</sup>. These data, summarized in Table 12-3, show that only 9% of the land area accounts for 69% of the sediment load. Effectively targeting erosion-control efforts requires that the landscape units and land use practices responsible for most sediment delivery be identified.

Sediment yield is particularly sensitive to vegetative cover. Thus, in selecting data sets for use in the estimation of sediment yield at an ungauged site or to confirm the reasonableness of an available data set, data should be compared within ecoregion. Background material and GIS mapping products for North American ecoregions can be found on several sites by Internet search. The Holdridge life zone system of ecological classification, more widely used in tropical areas, may represent another suitable landscape classification method.

An example of suspended sediment variability in the United States is presented by Simon and Heins (2005). They examined suspended sediment characteristics of the effective discharge, defined as the discharge or range of discharges that transport the largest proportion of the annual suspended sediment load over the long term (Wolman and Miller 1960). The 1.5-year discharge ( $Q_{1.5}$ ) approximates the effective discharge. The range of median concentration and daily load values corresponding to the  $Q_{1.5}$  discharge for representative ecoregions are illustrated in Table 12-4. Although the highest concentrations occur in the semiarid Arizona–New Mexico area, the highest yield occurs in a moist environment with erodible soils.

The size of the area analyzed can have a significant impact on both delivery ratio and sediment yield. The long-term delivery ratio decreases as watershed area increases because the opportunity for sediment trapping increases as a

**Table 12-4 Median Suspended Sediment Characteristics of 1.5-year Discharge at USGS Gauge Stations, Selected U.S. Ecoregions**

Ecoregion	Number of Stations	Concentration (mg/L)	Specific Yield (tn/d/km <sup>2</sup> )
Northern Rockies	13	30.13	0.05
Arizona—New Mexico Plateau	40	4143	6.5
Middle Atlantic Coastal Plain	22	22.1	0.16
Mississippi Valley Loess Plains	33	2175	173

Source: Data from Simon and Heins (2005).

function of the distance from the erosion source. As a result, both delivery ratio and sediment yield tend to vary as a log-log function of drainage area (Fig. 12-6), although this trend may not be evident in all data sets.

### 12.5.3 Temporal Variation in Sediment Yield

Suspended sediment concentration typically increases as a function of discharge, making sediment yield more concentrated in time than the discharge of water (Chapter 2). In their review of data from stream gauges in the United States, Meade and Parker (1984) found that 50% of the annual sediment load is discharged on 1% of the days. Extreme storms or cycles of wet and dry years can dramatically influence annual yield, and it is not unusual for a single large storm event to deliver more sediment than an entire year of average flows. Uncertainty parameters affecting annual sedimentation rates have been analyzed by Salas and Shin (1999).

That most sediment yield is high focused in time implies that large sediment reduction benefits can be achieved from control methods focused on these highest-discharge days. In hydrologically small reservoirs having a capacity–inflow ratio less than about 0.2, it may not be necessary to capture every runoff event; large but infrequent sediment-producing events may be passed around or through the storage pool.

Sediment yield is also heavily influenced by land use changes such as deforestation or reforestation, changes in grazing intensity, and urbanization and by climatic variation. For example, analysis of sediment cores covering 110 years of impounding at Fairfield Lake, North Carolina, revealed a several-fold increase in the rate of sediment deposition following relatively limited urban development activities in its 7.3-km<sup>2</sup> watershed.

Techniques for evaluating long-term sediment yield have been summarized by Strand and Pemberton (1987) and MacArthur et al. (1995). They are also considered in Chapter 17. Long-term trends can be visualized by constructing a cumulative mass curve for water and sediment,

**Fig. 12-6.** Average annual sediment yield versus drainage area for semiarid areas of the United States (Strand and Pemberton 1987).

as in Fig. 12-7. This format gives a better idea of trends than a timewise plot since it helps compensate for runoff variability. Lacking site-specific data, long-term sediment yield can be estimated by data from similar watersheds within the ecoregion. Sediment yield data from various sources may be plotted on a log-log graph of yield versus drainage area for verification. Plotting yield data from several regional sources (Fig. 12-8) can help arrive at a better sediment yield estimate when site-specific data are sparse or are collected over a short time period (Burns and MacArthur, 1996).

In applying regional curves to a particular study site, take care to consider local features such as upstream reservoirs, a history of fire, and land use, topographic, or geological conditions that may depart from regional norms. Departures from average regional conditions by one or two orders of magnitude may be anticipated in heavily disturbed areas.

With long service lives, reservoirs will be affected by very long-term trends in sediment yield plus the years of lag time that may occur between changed erosion rates in the watershed and sediment delivery to the reservoir. As an example, consider the long-term changes in the erosion rates and sediment yield from the Piedmont area of the eastern United States from 1700 to 1970 documented by Trimble (1974, 1977). Deforestation for agricultural use began in the late 1700s, and the area was completely deforested by

**Fig. 12-7.** Cumulative mass curve of water and sediment showing a long-term trend of declining sediment yield, Río Puerco, New Mexico (after Gellis 1991).

the mid-1800s, greatly accelerating erosion rates and sediment yield. Erosion rates declined after the 1920s as hillside farms were abandoned and revegetated naturally and soil conservation methods were developed and implemented on the remaining farms. Despite the erosion of 1 mm/year of soil over a 150-year period, export by rivers accounted for less than 0.053 mm/year (a sediment delivery ratio of

Fig. 12-8. Regional values of sediment yield versus drainage area, Jennings Randolph Reservoir (Burns and MacArthur 1996).

only 5.3%) because eroded sediment was redeposited further downslope in downstream channels and on floodplains. Debris filled streams and covered floodplains, and stream aggradation frequently swamped adjacent bottomlands, making them unfit for agriculture. Today, with low rates of erosion, the aggrading stream reaches are now incising.

Long-term sediment yield may also decline as the watershed degrades and the supply of readily erodible sediment is progressively exhausted (Sutherland and Bryan 1988; Rooseboom 1992). Long-term variations in sediment yield from rivers in the semiarid southwestern United States appear to be cyclic and attributable to a complex interaction of variables including climate (sequence of drought years and floods) and grazing pressure (Gellis et al. 1991). Sediment yield data from Río Puerco exhibits a long-term trend due to these effects (Fig. 12-7). Fire can cause a temporary increase in sediment yield. In areas subject to urban development, sediment yield is typically low in the predevelopment period, increases dramatically during development because of earth movement activity, and declines to lower levels after all soils in the catchment are stabilized with pavement and landscaping (Livesey 1975). Long-term yield can also be reduced by construction a large upstream reservoirs or by thousands of small stock watering ponds across the watershed (Chapter 17).

There has been a tendency to underestimate long-term sediment yield, particularly in developing areas where increasing population pressure results in the deforestation of sloping soils. In a comparison of predicted sedimentation rates with actual performance at 21 reservoirs in India, Tejwani (1984) found that sediment yield was less than predicted at one site, but from 40% to 2,166% higher than predicted at the other 20 sites. Lagwankar et al. (1995) found sediment delivery 1.5 to 3 times higher than predicted in 24 of 27 Indian reservoirs. Major factors contributing to underprediction of sediment inflows are watershed degradation and the lack of accurate long-term records.

## 12.6 QUANTIFYING SEDIMENT YIELD

### 12.6.1 Estimating Sediment Yield by Reservoir Survey

There are two basic strategies for measuring sediment yield: (1) by the volume of sediment deposited in reservoirs and (2) continuous monitoring of fluvial sediment discharge. Reservoir resurvey data are generally more accurate because reservoirs collect sediment from all events since their construction, eliminating problems of missed or underreported events at fluvial gauge stations. They also reveal patterns of sediment deposition critical to evaluating remedial actions.

As a disadvantage, reservoir data do not reveal the spatial or temporal patterns of sediment delivery needed to analyze some sediment management alternatives.

**12.6.1.1 Bathymetric Survey** Bathymetric data from successive reservoir surveys are used to track volume depletion and revise elevation–capacity curves; to predict the type, magnitude, and time horizon for sedimentation problems; to calibrate mathematical models of sedimentation; and to help develop and monitor the effectiveness of sediment management practices. For modeling of sedimentation processes, bathymetric mapping should be complemented with borings to determine the grain size of the deposits and verify estimates of deposit bulk density determined by empirical methods. Mathematical models of sedimentation processes are considered in Chapters 14 and 15.

Reservoir may be generally performed at intervals of about 5 to 20 years, but this can vary substantially depending on budgetary constraints, rate of storage depletion, the type and importance of the uses threatened by sediment accumulation, and management requirements. In reservoirs with very low rates of sedimentation, the intersurvey period may be several decades. Unscheduled surveys may be called for after a major flood delivers a large volume of sediment to the reservoir, and partial surveys may address specific issues such as shoreline erosion, delta advancement, and flood studies in delta and backwater areas. Periodic cross-section surveys should also be made in areas below the dam where the riverbed is expected to adjust because of the reduced sediment supply and changed stream-flow regime.

If the goal is to identify long-term sediment accumulation trends, more than 20 years of survey record encompassing several surveys may be needed before a reliable trend can be established. During the first years of reservoir operation, the apparent rate of storage loss may be higher than the long-term rate because of incomplete sediment compaction. When the intersurvey sedimentation volume is small compared to the total reservoir volume, estimates of deposition rate can be significantly affected by use of different survey techniques or volume computation algorithms.

Reservoir volume computations are performed by either range-line or contour surveys. The original volume of reservoirs is generally computed using the contour method based on preimpoundment topographic mapping. The range-line method uses a system of ranges (cross sections) selected and surveyed after initial impounding. Each range line is tied to the initial elevation–capacity relationship of the reservoir reach corresponding to that range (as determined by preimpoundment contour survey) and provides the base against which all future surveys will be compared. The range lines are resurveyed at intervals, and the elevation–capacity relationship is recomputed for each reach on the basis of the change in the cross-sectional area of each range line. This method has been widely used, as it allows sediment accumulation to be tracked using minimum field data.

The contour method entails the complete survey of the reservoir and preparation of a bathymetric contour map. This

method is more accurate than the range-line method and gives a more complete picture of the pattern of sediment deposition. Contour surveys are facilitated by modern GPS and bathymetric measurement equipment and are preferred today.

Every survey method incorporates different types of data collection errors and approximations in the algorithms for volume computation. The same types of field data and computational algorithm must be used for each survey if results are to be strictly comparable. Therefore, when updating from the range method to contour surveying, compute the reservoir volume using both methods to determine how much of the apparent intersurvey volume change is attributable to differences in methodology.

Bathymetric surveys are typically performed using GPS positioning system in combination with a depth sounder, both connected to a portable computer that records the resulting  $x$ ,  $y$ ,  $z$  coordinate data into a file that can be processed subsequently to draw a contour map. Survey systems can also incorporate navigational features that allow the planned tracks to be laid out prior to the survey, giving directional instructions and positional plots to the operator during the survey. An example of this method is provided by Odhiambo and Boss (2004).

Accurate contouring requires that the data be checked and contour lines adjusted during postprocessing to eliminate contouring errors introduced by automated mapping. Because error-correction effort declines as the density of data points increases, the distance between survey lines used for automated contouring should be shorter than the reservoir width, and a much higher data densities should be obtained if possible. The data density will ultimately be limited by data-collection budget since a typical surveying speed is about 2 m/second. An example of survey track lines for construction of a contour map is given in Fig. 12-9.

On large reservoirs, if the pool is drawn down or emptied regularly, the lake surface area can be photographed from aircraft or satellite at different reservoir stages to construct a contour map based on the area of the water surface at each stage.

When computing average specific sediment yield ( $\text{tn}/\text{km}^2/\text{year}$ ) based on the sediment volume trapped in a reservoir, it is necessary to compensate for sediment trapping by upstream reservoirs constructed over the period covered by the data. The changing area of the watershed effectively contributing sediment can be expressed as *effective watershed-years* by the following expression:

$$\left( \begin{array}{c} \text{Effective} \\ \text{Watershed} \\ \text{Years} \end{array} \right) = \left[ \left( \begin{array}{c} \text{Unregulated} \\ \text{Area} \end{array} \right) + \left( \begin{array}{c} \text{Regulated} \\ \text{Area} \end{array} \right) * \left( \begin{array}{c} \text{Sediment} \\ \text{Release} \\ \text{Efficiency} \end{array} \right) \right] * \text{Years}$$

where the sediment release efficiency =  $1 - \text{trap efficiency}$  for upstream reservoirs. The time period in years should be

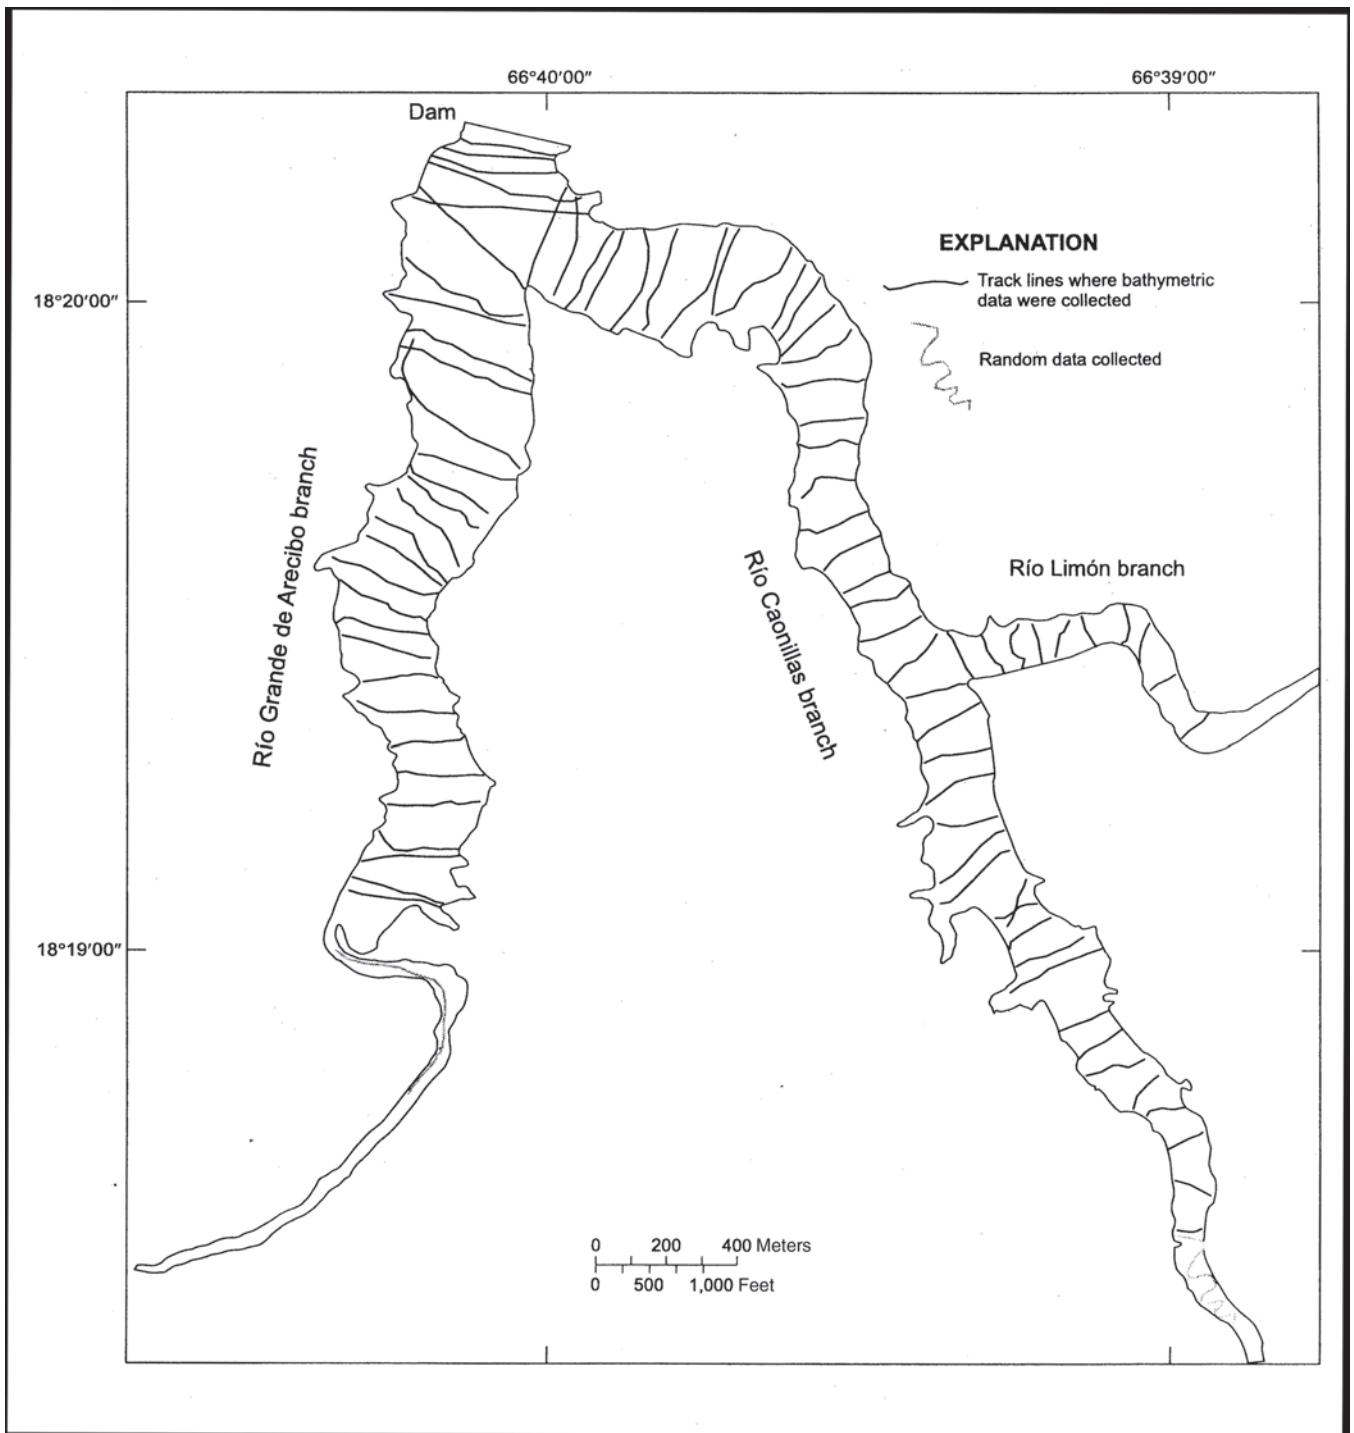

Fig. 12-9. Hydrographic track lines for contour surveying of a reservoir (Soler-López 2001).

computed for each interval of upstream reservoir construction and summed to obtain the effective sediment-contributing area as the basis for computing specific yield.

**12.6.1.2 Deposit Thickness over Event Horizons**  
Lacking reliable original bathymetric data, sediment thickness over a datable horizon can also be used to determine sedimentation rate. Cesium 137 is a man-made isotope produced

only by the atmospheric testing of thermonuclear devices and dispersed globally. It was first produced in measurable amounts in 1954; its concentration peaked in 1964 and declined rapidly thereafter following signature of the international treaty to ban atmospheric testing. Cs<sup>137</sup> is tightly sorbed onto clay particles and penetrates only a short distance into clayey soils. As these soils are washed into lakes and reservoirs, they mark

radioactive horizons corresponding to the initiation of significant nuclear weapons testing and the peak weapons testing activity. This marker can be used to determine sedimentation depths overlying this event horizon both in reservoirs and in natural lakes. Cores are obtained, sectioned, and counted in a gamma-ray spectrometer. With a half-life of 30 years,  $Ce^{137}$  will be useful as a dating tool into the first decades of the twenty-first century (McHenry and Ritchie 1980). If the watershed has been impacted by a large fire, volcanic eruption, Chernobyl radioactivity, and so on, these events may also leave similar datable horizons within the sediments. An extensive bibliography of erosion and sedimentation studies based on  $Ce^{137}$  are located at <http://hydrolab.arsusda.gov/cesium137bib.htm> (accessed March 12, 2006).

Horizon-dating methods have several important limitations. When a reservoir is drawn down, sediments can be mobilized and reworked, making horizon-dating methods useful only in areas of continuous deposition. Also, the depth of sediment deposition in reservoirs is uneven, making it necessary to core and analyze samples from a number of locations to reliably map deposition thickness.

Sediment depth over the density horizon corresponding to the original bottom can also be determined by a sub-bottom profiler, which uses a higher-frequency sonar signal (200 MHz) for bathymetric mapping in combination with a lower-frequency signal (4–28 MHz). The lower-frequency signal penetrates finer sediment and is reflected from underlying denser layers corresponding to the original bottom, allowing the sediment thickness to be mapped. For example, a 28-MHz subbottom signal was used by Odhiambo and Boss (2004) in an Arkansas study that penetrated sediment deposits not more than about 1 m thick. Subbottom profiling is limited by several factors: thick sediments cannot be penetrated, coarse sediments that have prograded over previously deposited fines may register as a false preimpoundment bottom, and sonar signals are also strongly reflected by the gas-liquid interface generated by the anaerobic decomposition of organic sediment, which creates methane bubbles.

## 12.6.2 Sediment Yield Estimation from Fluvial Data

Fluvial sediment data are required to determine variations in sediment yield over time. Techniques and methods for sediment measurements are addressed in Chapter 5. However, the collection of accurate fluvial sediment data has potential sources for error that should be understood by users. For more information on procedures and potential sources of error, consult Guy and Norman (1970), Glysson (1987), Edwards and Glysson (1988), and Walling and Webb (1981, 1988). The USGS suspended sediment database is available at <http://co.water.usgs.gov/sediment/>.

**12.6.2.1 Sediment Rating Curves** Fluvial sediment load is determined by the product of stream-flow and discharge-weighted sediment concentration. See Appendix D on estimation of sediment discharge. Sediment load is

usually computed from a long-term discharge record and a sediment rating curve that relates concentration to stream flow. The rating curve is constructed from instantaneous discharge–concentration data pairs, but the resulting relationship typically exhibits considerable scatter, and sediment concentration may vary over two log scales at a given discharge. Furthermore, the large floods or hurricane events responsible for much sediment transport may be represented by very few data points, if any at all.

Sediment load is the product of concentration and discharge, and when plotted as a function of discharge, it will exhibit less apparent scatter than a concentration–discharge plot using the same data because the discharge term occurs on both the ordinate and the abscissa. Both Ferguson (1986) and Glysson (1987) have cautioned against use of rating curves of load versus discharge because they can incorporate significant spurious correlation.

A sediment rating curve developed from several years of field data and that includes sampling of flood events can be applied to a longer-term discharge data set to estimate long-term sediment yield. In these computations, the time base for the rating curve must be representative of the discharge data set time base. For example, one would not apply a rating curve derived from instantaneous discharge–concentration data pairs to a hydrological record consisting of average daily flows in a flashy mountain stream, yet this same procedure may be acceptable in a river with a slowly rising and falling hydrograph. Published USGS data typically report total daily load versus average daily discharge.

Recommended procedures for the development of accurate rating curves have been summarized by Cohn (1995). Appendix D also provides guidance on methods currently used by the USGS. Regression techniques commonly used to develop rating curves incorporate a significant undercounting bias and will produce sediment loads significantly lower than observed even when applied to the data set from which the regression was derived. In some cases, this error can undercount sediment discharge by 50%. It is important to back test a rating relationship by applying it to the original stream-flow data set to ensure that it accurately computes the total load. Also, a multiple-slope relationship should be used as necessary to restrict maximum sediment concentration to realistic values at high discharges. Without this precaution, the resulting relationship will ascribe an inordinate amount of sediment yield to the highest discharges, thereby skewing the results of sediment management simulations.

The suspended sediment concentration in streams is determined primarily by watershed processes responsible for delivering fine sediment to channels, but bed material transport is controlled primarily by channel hydraulics. Whereas stream discharge is a consequence of rainfall, suspended-sediment concentration is also influenced by many watershed parameters not directly related to discharge, such as seasonal changes in land use and vegetative cover, variation in rainfall intensity and erodibility, exhaustion

of erodible sediment supply by antecedent events, and variable arrival times of runoff from subbasins having large differences in sediment yield (Chapter 17).

If sediment concentration varies directly as a function of discharge, there will be a single-valued relationship between discharge and concentration (or load). However, sediment concentration and discharge often do not peak simultaneously, creating graphs of concentration versus discharge that are looped rather than single-value functions (Williams 1989). Error-free sampling over multiple events of this type will produce a sediment-rating curve of "average" conditions including both rising and falling limbs of the hydrographs. Additional scatter is produced by seasonal variations in rainfall intensity, rain versus snowmelt events, seasonal or long-term changes in vegetative cover, different antecedent conditions, and so on.

Within a highly scattered discharge–concentration data set may reside seasonal or within-event patterns that can be exploited to reduce reservoir sedimentation. A clockwise loop in the concentration versus discharge graph indicates that most sediment is discharged during the rising limb of the hydrograph, and water in the falling limb has a much lower sediment concentration. This may be caused by declining erosion rates in the latter part of the storm as rainfall intensity diminishes and the readily erodible sediment supply is exhausted. To the extent the sediment-laden portion of the hydrograph is made to bypass or pass through the storage pool, sedimentation will be reduced. Similarly, early-season flows may carry more sediment than subsequent flows because of the seasonal increase in vegetative cover and seasonal exhaustion of readily erodible sediment supply. Frequent sediment sampling is required to determine if the scatter typically inherent in sediment data conceal temporal patterns of sediment transport that may be used for sediment management.

**12.6.2.2 Monitoring Sediment Yield by Turbidity Measurements** If frequent sediment concentration data are available, sediment load can be computed directly as the product of discharge and concentration at short intervals (e.g., every 15 minutes) instead of relying on a sediment-rating curve (Chapter 5). With this level of detail, the temporal variation in sediment concentration and load will also be apparent, which can be helpful in detecting looped rating curves and in planning sediment-routing strategies.

In rivers with rapidly rising and falling hydrographs, sampling is required at short sampling intervals to accurately track sediment yield. However, short-interval sampling using an automatic pumping sampler produces many samples with high laboratory costs. Also, the sample bottles in an automatic sampler can be filled prior to the end of a prolonged or multiple-peak event, leaving part of the event unsampled. Resultant undercounting errors as high as 50% by conventional sampling and rating curve techniques are discussed by Walling and Webb (1981, 1988) and Olive and Rieger (1988).

The combination of pumped samplers and turbidity measurement has been shown to represent a viable strategy for improving the quality of sediment discharge data. There

is no direct relationship between turbidity and suspended-sediment concentration, yet the discharge–sediment relationship is also a poor predictor of sediment loads as evidenced by the order-of-magnitude scatter typical of concentration–discharge graphs. However, turbidity can be recorded every few seconds, averaged, and logged to onboard memory, thereby eliminating the error due to the unreported periods that occur with manual and pumped sediment samplers.

*Specific turbidity* is the turbidity measured in formazin units divided by the mass particle concentration in mg/L. Because the optical properties of a suspension vary as a function of grain size and other factors, specific turbidity changes over the duration of an event as the grain size distribution varies. Fines have a much higher specific turbidity than sands. Specific turbidity can vary by an order of magnitude as a function of the suspended-sediment particle sizes (Foster et al. 1992; Gippel 1995).

Time-stratified and flow-stratified turbidity sampling schemes have been compared by Thomas and Lewis (1993). A protocol for suspended-sediment sampling based on turbidity reported by Lewis (1996) uses pumped samples to periodically calibrate the turbidity–concentration relationship to overcome the problem of variations in specific turbidity. This protocol generates more accurate data than a pumped sampler working alone while simultaneously collecting fewer pumped samples for analysis. Because suspended-sediment concentration varies over a cross section, sediment concentration at the fixed sampling point used by automatic samplers or turbidity sensors must be correlated against depth-integrated samples.

### 12.6.3 Neural Network Models for Sediment Yield

Neural network models have been demonstrated useful for better definition of the relationship between hydrologic parameters and sediment concentration. The neural network model is essentially a nonlinear black box that correlates outputs to inputs by training its internal algorithms and their weighting scheme against a calibration data set. Applications of neural networks in hydrology have been reviewed by the ASCE Task Committee (2000a, 2000b). Unlike the single-parameter sediment rating curve, which relates concentration to discharge, a neural network model can incorporate multiple parameters including both current and antecedent values for stream flow, rainfall, temperature, and other parameters from one or more gauging stations in the watershed.

One approach is to use the neural network to develop rating relationships based on channel hydraulic characteristics. Jain (2001) and Sen et al. (2004) have used this approach to develop a model to predict suspended-sediment concentration in the Mississippi River based on time-series data including using both current and lagged values of discharge and suspended-sediment concentration. Nagy et al. (2002) developed a more generalized sediment transport model correlating suspended-sediment concentration to eight unlagged channel hydraulic characteristics.

An alternative approach is to predict suspended-sediment concentration or discharge based on channel plus watershed hydrologic parameters or watershed parameters alone. For example, Cigizoglu and Alp (2003) accurately predicted suspended sediment in the Juniata River, Pennsylvania, on the basis of both current and lagged values of discharge and rainfall but found that Thiessen-averaged rainfall alone was not an adequate predictor in this 8,690-km<sup>2</sup> watershed. In a smaller 92-km<sup>2</sup> watershed in northeastern India, Raghuwanshi et al. (2006) predicted both runoff and sediment yield for both daily and weekly time steps from temperature and rainfall data alone.

#### 12.6.4 Sediment Yield Estimation by Spatial Modeling

Computationally intensive techniques can significantly improve the ability to predict and manage sediment, particularly when baseline data and good calibration data sets are available (Chapter 17). There are many alternative approaches, but no generally accepted methodology has yet emerged. This is due in part to the wide diversity of questions that can be addressed by these models plus regional differences in data availability, engendering problem-specific model formulations.

Spatially distributed data may be analyzed in a GIS-type framework to compute the yield of both water and sediment from the watershed on the basis of soil, land use, and hydrologic input parameters, and the resulting runoff and its sediment load is then routed to the watershed exit. Empirical soil erosion models have been in use for many decades, and parameter values are widely available, but the sediment delivery process must be simulated by other means. An example of the coupling of empirical erosion prediction models with a sediment delivery module to simulate sediment yield is presented by Kothyari et al. (1996).

Alternatively, physically based models that simulate both sediment detachment and transport processes may be coupled with fluvial routing procedures to simulate sediment yield. An example of the latter is the continuous water and sediment modeling approach demonstrated on watershed scales ranging from 17.7 to 9,000 km<sup>2</sup> by Arnold et al. (1995). This model coupled continuous physically based erosion prediction models with a routing scheme based on reasonably available data and was successfully tested against both annual and monthly sediment discharge data at the largest watershed scale. As an advantage, spatial data can be used to simulate the impact of alternative land use scenarios and identify areas where erosion control would provide the highest benefit, taking into account both erosion rate and the sediment delivery process. Neural network models can also be incorporated into a GIS framework (Doris et al. 2004).

The GIS environment can also be used to organize, interpret, and manipulate massive amounts of spatial data. The ongoing development of a GIS-based sediment assessment and management model incorporating 250 sediment gauging stations and spatial sediment yield data across the

1 × 10<sup>6</sup>-km<sup>2</sup> watershed tributary to the Three Gorges Project has been described by Lu et al. (1999).

## 12.7 SEDIMENT DEPOSITION IN RESERVOIRS

The understanding and prediction of deposition patterns is important for a variety of reasons. Delta deposition can cause a stream to aggrade upstream of a reservoir and affect flood levels, groundwater levels, bridge clearance, commercial and recreational navigation, and environmentally sensitive areas. The shape of the stage-storage curve will change because of sedimentation, affecting different beneficial pools within the reservoir. Deposition by turbidity currents can interfere with low-level intake at the dam, even with as little as 1% storage loss in the impoundment (Garcia 1999; De Cesare et al. 2001). Observations of deposition patterns can also be helpful in developing strategies for sediment management. Reservoir surveys are undertaken at intervals can document both the volume and the pattern of sediment deposition.

### 12.7.1 Trapping and Releasing Efficiency

*Trap efficiency* is the percentage of the total inflowing sediment load that is trapped within a reservoir over a stated period of time. *Release efficiency* is the amount of sediment exiting a reservoir, expressed as a percentage of the inflowing load, and is the complement of trap efficiency:

$$\begin{aligned}\text{trap efficiency} &= \text{sediment trapped/inflowing sediment} \\ \text{release efficiency} &= \text{released sediment/inflowing sediment} \\ &= (1 - \text{trap efficiency})\end{aligned}$$

From the standpoint of sediment management, sediment release efficiency is a more useful concept than trap efficiency because it can be used to express events in which sediment discharge exceeds sediment inflow, as occurs during flushing and some sediment-routing events. Sediment trapping or releasing efficiency is not constant but is influenced by factors including detention period, inflowing sediment characteristics, and reservoir operation.

For preliminary screening of sediment trapping or release, two methods have been widely used. Brune (1953) developed an empirical relationship between the *capacity:inflow* (C:I) ratio and long-term trap efficiency (Fig. 12-10). Trap efficiency declines as sedimentation reduces the capacity:inflow ratio. Temporarily lowering the reservoir pool during a flood (pass-through sediment routing) reduces both detention time and sediment trapping. This straightforward method is widely used to make preliminary estimates, as the data required are usually readily available. Another well-known method, that of Churchill (1948), requires information on reservoir capacity, reservoir length, and inflow during the study interval and is better oriented to the analysis of specific events. Strand and Pemberton (1987) recommend use of the Brune curve for large storage

**Fig. 12-10.** Relationship between reservoir hydrologic size (capacity:inflow ratio) and sediment-trapping efficiency by Brune and the sedimentation index approach by Churchill (Strand and Pemberton 1987).

or normally ponded reservoirs and Churchill's method for settling basins, small reservoirs, and flood-retarding structures.

Churchill's (1948) relationship to predict sediment trapping is based on a reservoir sedimentation index, defined as the ratio of retention period to mean flow velocity through the reservoir. The Churchill curve has been converted to dimensionless form in Fig. 12-10 by multiplying the sedimentation index by the gravitational constant,  $g$ . Definitions of the terms required to compute Churchill's sedimentation index are as follows:

*Capacity* is the mean volume of the operating pool during the analysis period ( $m^3$ ).

*Inflow* is the mean daily inflow during the analysis period (m/second).

*Retention period* is the capacity divided by the inflow (seconds).

*Length* is reservoir length (m) at the mean operating pool level during the analysis period.

*Velocity* is the mean velocity (m/second), computed as *inflow* divided by the mean cross-sectional area ( $m^2$ ) of the pool. The cross-sectional area can be computed as *capacity* divided by *length*.

*Sedimentation index* is the retention period divided by the velocity.

For more than a preliminary analysis, mathematical modeling is required. Models of lake and reservoir sedimentation model are presented in Chapter 2.

### 12.7.2 Depositional Geometry

A highly generalized depiction of sedimentation processes was presented in Fig. 12-4. The coarse fraction of the inflowing load creates a delta deposit where the main river or side tributaries enter the reservoir. Depending on the inflowing load, delta deposits can range from silt to cobbles. The delta may be divided into the topslope and foreslope deposits, and the downstream limit of the delta is characterized by a rather abrupt reduction in grain size (Chapter 2). This change in grain size may occur even in reservoirs lacking an obvious delta (Fan and Morris 1992a). Although the delta can often have a slope about one-half of the original river streambed, there can be wide variations in delta topslope. Deltaic deposits not only extend into the reservoir, but they also extend upstream because of backwater effects (Chapter 2). This can be exacerbated by ice jams in reservoir headwater areas that retard flow and produce sedimentation further upstream than might otherwise be predicted. Mathematical modeling is the recommended method for predicting deltaic deposition patterns (U.S. Army Corps of Engineers 1989). The mechanics of deltaic sediment deposition is addressed in Chapter 2.

The depositional sequence within a single cross section illustrated in Fig. 12-2 shows that sediments first fill the deepest part of each cross section and subsequently spread out across the submerged floodplain to create broad flat sediment deposits. However, depositional patterns can also be more complex. Previously deposited sediments can be reworked and moved further downstream during drawdown, and large floods can transport coarse sediment deeper into the pool, prograding over finer sediment and producing layered deposits. Multiple deltas can be formed, each corresponding to a different pool elevation, and side tributaries can discharge coarser materials into an area where only fine sediment would otherwise be encountered. During periods lacking significant flood events, sediment deposits may consist only of fines and organic material, and shallow sediment samples collected during that period may not reveal coarser materials transported and deposited during flood events. The cores presented by Evans et al. (2002) provide a good example of depositional horizons of coarse sediment corresponding to floods in a hydrologically small reservoir.

### 12.7.3 Turbid Density Currents

*Turbid density currents or turbidity currents* are sediment-laden density-driven currents that flow along the bottom of the reservoir (Garcia 1993, 1994). These currents are caused primarily by density differences between clear and sediment-laden water, but cold water flowing into a warmer pool can also form temperature-driven density currents carrying suspended solids along the bottom of the reservoir. When significant amounts of suspended solids are present, the density differences imparted by the solids are much more important than temperature-induced density differences.

Turbid density currents occur frequently and are important in explaining sediment deposition patterns. The mechanics of sediment transport and deposition by turbidity currents in lakes and reservoirs is considered in Chapter 2. These currents focus fine sediment transport along the deepest part of the cross section instead of mixing sediments uniformly across the cross section. These currents are the primary reason that sediments in reservoirs fill from the bottom up within each cross section (as in Fig. 12-2) instead of having a more uniform depth of sediment deposits across the cross section.

Under favorable conditions, the turbulence generated by turbidity current motion will maintain a significant amount of sediment in suspension, thereby maintaining the driving force that sustains the motion of the current until it reaches the dam. Prior to the construction of Glen Canyon Dam further upstream, turbid density currents were documented to travel 129 km along Lake Mead to Hoover Dam (Grover and Howard 1938), the longest documented travel distance of turbidity currents in any reservoir. Although turbid density currents commonly occur in reservoirs, they often fail

to reach the dam because the suspended sediment settles out of the current. Sediment loss diminishes the gravitational density difference driving the current, causing it to slow down, which in turn allows it to drop more of its sediment load. This cycle continues until the current dissipates. Turbidity currents will also dissipate if the inflow of turbid water at the upstream end of the reservoir stops before the current reaches the dam (Fan and Morris 1992a; DeCesare et al. 2001).

Turbidity currents reaching a dam or other submerged obstruction will create a submerged lake of muddy water, and sedimentation from this muddy lake will leave horizontal deposits of fine sediment extending upstream from the dam, as illustrated in Fig. 12-4. Deposits of this nature indicate that turbidity currents are transporting a significant amount of sediment to the dam. The release of turbid water from low-level outlets while the reservoir surface water is clear also indicates a turbidity current that reaches the dam. Indicators of turbid density currents may also be observed where the turbid water enters the reservoir and plunges beneath the surface. The *plunge point* or *plunge line* is marked by a dramatic change in water color. The conditions for plunging of a muddy turbidity current are discussed in Chapter 2. The plunging flow tends to create a surface countercurrent that flows upstream, and floating debris becomes trapped near the plunge line by the two opposing currents.

Turbidity current movement may be best ascertained by monitoring, from which data required for numerical modeling may be obtained (De Cesare et al. 2001). Modeling of turbidity currents is also addressed in Chapter 2.

### 12.7.4 Bulk Density of Sediment Deposits

Typical values of bulk density for reservoir sediments are given in Table 12-5. A more accurate empirical method for estimating initial bulk density was developed by Lara and Pemberton (1963). To estimate initial specific weight, reservoir operation should be classified into one of the following categories: (1) sediment always submerged or nearly

**Table 12-5 Typical Specific Weights for Reservoir Deposits, t/m<sup>3</sup> or g/cm<sup>3</sup> (Geiger 1963)**

Dominant grain size	Always	
	Submerged	Aerated
Clay	0.64–0.96	0.96–1.28
Silt	0.88–1.20	1.20–1.36
Clay-silt mixture	0.64–1.04	1.04–1.36
Sand-silt mixture	1.20–1.52	1.52–1.76
Sand	1.36–1.60	1.36–1.60
Gravel	1.36–2.00	1.36–2.00
Poorly sorted sand and gravel	1.52–2.08	1.52–2.08

**Table 12-6 Coefficient Values for Specific Weight Computation by Lara-Pemberton Method**

Operational Condition	Initial Weight (kg/m <sup>3</sup> [lb/ft <sup>3</sup> ])		
	$W_c$	$W_m$	$W_s$
Continuously submerged	416 (26)	1,120 (70)	1,554 (97)
Periodic drawdown	561 (35)	1,140 (71)	1,554 (97)
Normally empty pool	641 (40)	1,150 (72)	1,554 (97)
Riverbed sediment	961 (60)	1,170 (73)	1,554 (97)

submerged, (2) normally moderate to considerable drawdown, (3) normally empty reservoir, and (4) riverbed sediments. The grain size of the deposit must also be apportioned into sand, silt, and clay fractions by weight percent. Specific weight may be computed from the values in Table 12-6 and the equation

$$W = W_c P_c + W_m P_m + W_s P_s$$

where

$W$  = specific weight of the deposit (kg/m<sup>3</sup>, lb/ft<sup>3</sup>);  
 $P_c$ ,  $P_m$ , and  $P_s$  = weight percentages of clay, silt, and sand, respectively, for deposited sediment; and  
 $W_c$ ,  $W_m$ , and  $W_s$  = initial weights for deposits of clay, silt, and sand, respectively.

### 12.7.5 Sediment Consolidation over Time

Sandy sediments attain their ultimate bulk density virtually as soon as they are deposited, but fine sediments may compact and consolidate for decades. If a constant mass of fine sediment accumulates in a reservoir each year, the volumetric rate of sedimentation will be highest in the first year and will appear to decline in subsequent years because the volume occupied by the second year's sediment deposition is decreased by compaction of the first year's deposit. To compensate, all sediment volumes can be adjusted to account for 50 years of compaction, by which time sediments have typically approached their ultimate density.

Sediment compaction over time is described in the equation by Lane and Koelzer (1943):

$$W_t = W_1 + B \log t$$

where

$W_t$  = specific weight of deposit at an age of  $t$  initial years,  
 $W_1$  = initial weight at the end of the first year of consolidation, and  
 $B$  = parameter value given in Table 12-7.

**Table 12-7 Coefficient Values for Computing Sediment Consolidation**

Operational Condition	Value of Coefficient $B$ (kg/m <sup>3</sup> [lb/ft <sup>3</sup> ])		
	Sand	Silt	Clay
Continuously submerged	0	91 (5.7)	256 (16)
Periodic drawdown	0	29 (1.8)	135 (8.4)
Normally empty reservoir	0	0	0

For sediment deposits containing mixed grain sizes, determine the value of  $B$  as the weighted average of the tabulated values, based on the weight percent of each grain size in the deposit.

### 12.7.6 Prediction of Sedimentation Patterns

The Bureau of Reclamation developed the empirical area reduction method for predicting the change in the stage-storage relationship due to sedimentation, based on observations at reservoirs in the United States. This method is described by Strand and Pemberton (1987) and by Morris and Fan (1998). In this method, the user determines the reservoir trap efficiency, places the reservoir into one of four geometric classes, and then follows a procedure to apportion the sediment deposition into different depth ranges on the basis of empirical relationships. This is the accepted method for predicting adjustments to the stage-storage curve in the absence of computer modeling. However, it is not suited for use in reservoirs where operating rules are modified to reduce sedimentation. More detailed information on depositional patterns requires computer modeling as described in Chapters 14 and 15.

## 12.8 SEDIMENT MANAGEMENT IN RESERVOIRS

### 12.8.1 Sediment Control Strategies

Sediment management strategies in reservoirs may be divided among five basic strategies:

1. *Sediment yield reduction.* Apply erosion-control techniques to reduce sediment yield from tributary watersheds. These techniques will typically focus primarily on soil stabilization and revegetation.
2. *Sediment storage.* Provide sediment storage volume adequate for the anticipated sediment yield over a "long" period of time either in the reservoir itself or in upstream impoundments or debris basins.

3. *Sediment routing*. Pass sediments around or through the storage pool to minimize sediment trapping by employing techniques such as offstream storage, temporary reservoir drawdown for sediment pass-through, and release of turbid density currents.
4. *Sediment removal*. Remove deposited sediment by dredging or hydraulic flushing.
5. *Sediment focusing*. These techniques are designed to tactically rearrange sediments within the impoundment to solve localized problems such as impacts from delta deposition. Any washout of sediment from the reservoir that may occur is incidental to the primary objective.

In reviewing options, a full range of management alternatives should be analyzed. An example of this approach is described by Harrison et al. (2000) for Solano Lake, California. Optimal management may include two or more strategies applied simultaneously or at different points in the reservoir life. The applicability of different strategies varies at different stages of reservoir life, being a function of the reservoir's hydrologic size (capacity:inflow ratio), beneficial uses, and other factors, such as environmental regulations.

Techniques such as sediment routing require significant pool drawdown and use part of the natural inflow to transport sediment beyond the storage pool, making it impossible to capture and regulate 100% of the flow. Consequently, some types of routing techniques will not be feasible at hydrologically large reservoirs. However, sedimentation will eventually convert large reservoirs into small ones, and sediment-routing techniques may become feasible at a future date.

### 12.8.2 Sediment Yield Reduction

Erosion control to reduce sediment yield is widely recommended to prolong reservoir function but is most difficult to implement successfully. Many reservoirs, particularly in developing areas, have experienced accelerated erosion from intensified land use and deforestation, despite recommendations for erosion control. Even when land use changes to less erosive patterns, many years may be required before significant reduction in sediment yield occurs. For example, 20 years after transition to less erosive land use within the 1,150-km<sup>2</sup> Buffalo River basin in Wisconsin, Faulkner and McIntyre (1996) could not detect any reduction in sediment yield.

Accelerated soil erosion has many negative impacts in addition to reservoir sedimentation. Clark (1985) estimated that storage loss in reservoirs accounted for only 11% of total annual erosion costs of \$6.1 billion (1980 dollars) in the United States, where the largest single cost was impairment of water quality for recreational use. Biological impacts were not estimated in that study. In less developed countries, the largest impacts of soil erosion may be borne by small

hillside farmers who experience loss of soil fertility and reduced soil moisture—holding capacity and declining yields as topsoil is washed away.

Appropriate land use practices are well known and readily demonstrable on model farms or experimental watersheds. However, implementing and sustaining good land use practices by many thousands of land users across a watershed is highly problematic. A good overview of the socioeconomic barriers to the adoption of soil conservation measures by farmers of all income levels and on every continent is provided by Napier et al. (1994). Land users will not altruistically change their practices to reduce sedimentation of a downstream reservoir, especially if the reservoir benefits accrue to another community. Sustained improvements will not be achieved unless land users understand how they will directly benefit from these practices. For this reason, successful watershed management programs must be developed as a community-level effort with readily identifiable benefits to land users.

Because measures to reduce erosion typically benefit many parties in addition to dam owners, any dam owner attempting to reduce sediment yield from a watershed may have many potentially helpful alliances. For example, in the North Fork Feather River watershed in California, where the Rock Creek and Cresta hydropower dams were experiencing sedimentation problems, the dam owner, PG&E, catalyzed the implementation of a community-based coordinated resource management group to implement watershed management activities. The group eventually expanded to involve 17 different institutions and community groups, all having a vested interest in erosion control and sediment management. Participants included landowners desiring to control streambank erosion; state and federal forestry agencies desiring to stabilize eroding logging roads; federal, state, and local environmental resource agencies; fishermen and other recreational users; environmentalists; and tourist interests (Harrison and Lindquist 1995; Morris and Fan 1998).

The literature on watershed management is extensive; the reader is referred to the following sources for publications and contacts:

- Natural Resources Conservation Service ([www.nrcs.usda.gov](http://www.nrcs.usda.gov)). This is the lead national agency for erosion control in rural areas, with local offices in communities throughout the nation.
- Environmental Protection Agency ([www.epa.gov](http://www.epa.gov)). Regulates water quality and sediment discharge from construction sites through the NPDES program and has numerous publications.
- Soil and Water Conservation Society ([www.swcs.org](http://www.swcs.org)). Focus on agricultural soil conservation in the United States and worldwide.
- Conservation Technology Information Center ([www.ctic.purdue.edu](http://www.ctic.purdue.edu)). Focus on mechanized agriculture in the United States. Also contains electronic listing of

watershed management programs and contacts throughout the United States.

- International Erosion Control Association ([www.ieca.org](http://www.ieca.org)). Trade publication focusing on manufacturers of erosion-control equipment and materials with a focus on urban areas.

### 12.8.3 Provision of Large Storage Volume

Sedimentation has traditionally been “controlled” by providing a storage volume large enough to postpone anticipated sedimentation problems for 50 to 100 years. The “sediment pool” assigned to reservoirs has typically consisted of the dead storage space below the lowest outlet, but sediment deposits are frequently not focused in that zone, and sedimentation problems may be caused by deposits in the delta or other areas prior to filling of the provided sediment storage pool.

An often-used strategy for increasing the storage volume in the face of sedimentation issues is to raise the dam. Garbrecht and Garbrecht (2004) offer an interesting historical example of successive raising of the Marib diversion dam in Yemen between 940 B.C. and its final destruction around A.D. 570 to accommodate both increased sediment upstream of the dam and an increase in land level as much as 15 m in the downstream irrigation area due to silt loads in the diverted irrigation water. Loehlein (1999) described the raising of pool elevations in a flood-control reservoir due to sediment accumulation.

A 500-year horizon should be considered for analysis of the geomorphic evolution of the impounded river reach and its sediment management alternatives. Against the argument that this is an unreasonably long time frame, consider that Schnitter (1994) has documented dams with operational lives exceeding 1,000 years. Among all types of engineered infrastructure, dams are unique in terms of their longevity and their interrelationship to the geomorphic processes along rivers. The time frame for their analysis should consider their potential operational life (including prolongation by sediment management) and the structure’s long-term impact on the fluvial sediment balance.

The objective of long-term analysis is to define, on a preliminary basis, the probable time frames and types of sedimentation problems to be anticipated, the potential sediment management strategies potentially feasible as a function of reservoir age, and any long-term sediment management elements that can be incorporated into current design or operational practices. Sedimentation problems are both difficult and costly to cure, and the consideration of long-term consequences can help both the design and regulatory communities to identify effective long-term solutions. For example, it is often assumed that reservoirs will be dredged or alternative reservoir sites developed in the future. However, if the land area required for either of these two options is not acquired

or otherwise protected by zoning restrictions, the planned-for alternative may no longer be feasible when it is needed. Similarly, if bank instability due to long-term channel incision below a dam is anticipated, it would be prudent to create no-development buffer zones along the riparian corridor where bank erosion is anticipated.

This long-term analysis is limited to geomorphic and sedimentation issues within and below the impounded reach and does not necessarily imply 500-year computer simulations, and it would not impact the time frame normally used for socioeconomic or similar evaluations. It seeks to extrapolate geomorphic processes along the impounded river reach to their logical conclusion and to identify any feasible present-day actions or design strategies that will help ameliorate long-term negative consequences.

### 12.8.4 Sediment-Routing Strategies

#### 12.8.4.1 Offstream Reservoir for Sediment Bypass

The ideal way to manage sediment is to prevent it from entering the reservoir. High volumes of sediment-laden floodwaters can be bypassed around a storage pool by placing the pool offstream and diverting only relatively clear water from moderate flows into storage (Fig. 12-11). The key feature of the offstream reservoir is an intake system that has a limited inflow capacity and will therefore exclude most flood flow and its associated sediment because the flood discharge will be much greater than the intake capacity. Additional sediment exclusion can be achieved by closing the intake during floods with high sediment concentration or in anticipation of hurricanes.

As compared to a conventional onstream reservoir, an offstream reservoir can generate many benefits in addition to a reduced rate of storage depletion:

- The dam does not pose a barrier to migratory aquatic species or to navigation.
- Instream water quality (e.g., temperature, dissolved oxygen) is not altered by the reservoir.
- Riparian wetlands and river corridor habitats are not submerged.

**Fig. 12-11.** Conceptual representation of sediment exclusion by an offstream reservoir.

- The dam does not impact bed-load transport processes essential to maintain instream sediment transport, river morphology, and the ecological integrity of instream ecosystems.
- The large-capacity onstream spillway is eliminated.
- Low sediment loading and turbidity levels in the reservoir benefit users, such as water filtration plants, by reducing coagulant and sludge handling costs.
- The intake can be closed to exclude contaminants from hazardous waste spills, treatment plant malfunctions, or periodic water quality degradation by fertilizers or other nonpoint runoff.

These environmental advantages can favor offstream reservoirs over conventional structures, independent of sediment-loading considerations. However, offstream reservoirs may not develop the full yield potential of the stream because sediment-laden flood flow is not diverted to storage, especially in hydrologic environments with annual runoff concentrated in a short time period.

An example of this strategy is the offstream reservoir supplied from Río Fajardo, Puerto Rico, which began filling in 2006. Suspended sediment loads in Puerto Rico are high. To achieve a multicentury reservoir life, the impoundment volume for an onstream reservoir becomes controlled by the size of the sediment storage pool rather than the water conservation pool.

Río Fajardo is a flashy mountain stream in a moist tropical environment with a 38-km<sup>2</sup> watershed area. Behavior simulations using 33 years of daily data and a continuously open intake were used to develop the relationship between storage, yield, and sediment loading. At the selected design point, 37% of the long-term stream flow is diverted into the reservoir and thence to municipal use, but less than 10% of the suspended sediment load enters the reservoir and none of the bed load material. Firm yield for the offstream design is only 5% less than for a conventional onstream reservoir having the same conservation pool volume, but with the

low sedimentation rate, there is no need to oversize the reservoir to provide a large sediment storage pool.

The half-life of Fajardo offstream reservoir is estimated to exceed 1,000 years, as compared to only 180 years for a larger-volume instream reservoir originally proposed on this same river. To sustain reservoir capacity indefinitely, dredging of volumes less than 0.5 Mm<sup>3</sup> per event are planned at intervals of about 200 years in this 4.5 Mm<sup>3</sup> reservoir. A spoil disposal site adjacent to the reservoir has been reserved for this purpose. Offstream reservoirs have also been used for sediment control at nine sites in Taiwan, two of which are described by Wu (1991).

**12.8.4.2 Sediment Bypass of Onstream Reservoirs** In some cases, it may be possible to construct a reservoir onstream yet bypass sediment. For the passage of large sediment-discharging events, this would be most readily accomplished by locating the reservoir at the terminus of a meander and diverting flood flows across the meander floodplain (Annandale 1987).

The trapping of bed material by dams is an important environmental issue, and at several sites, processes have been used to move gravels from the delta upstream of the reservoir and deposit it below the dam. Procedures may involve trucking or pipeline, or on a steep channel even a tunnel may be used. The Asahi hydropower dam in Japan is constructed in a narrow gorge on a steep gravel-bed river. A low-head concrete diversion dam constructed immediately upstream of the reservoir intermittently diverts flushing flows and entrained gravels into a tunnel that runs parallel to the reservoir and then discharges below the powerhouse. This costly alternative was implemented to help preserve a popular recreational fishery below the dam.

**12.8.4.3 General Characteristics of Pass-Through by Drawdown** Sediments are maintained in suspension by high-velocity flows; they become trapped in reservoirs as flow velocity diminishes and hydraulic retention time increases. By opening high-capacity gates to minimize reservoir level, drawing down the pool as much as possible to

**Fig. 12-12.** Longitudinal profile of Three Gorges Reservoir, Yangtze River, China (modified from Lin et al. 1993).

pass sediment-laden floods at the highest possible velocity, the opportunity for deposition is minimized. The reservoir pool is refilled at the end of the drawdown period.

Pass-through techniques are based on translating the inflowing flood hydrograph and accompanying sediment through the pool with the least possible attenuation. Although the high flow velocities generated by drawdown may scour some of the previously deposited sediment, the outflowing concentration will be similar to the inflowing concentration. Discharging sediment with a high flow eliminates excessive sediment concentrations and sediment redeposition in the channel below the dam, two serious problems that normally accompany sediment flushing.

Drawdown duration and operating rules will vary depending on hydrologic characteristics and reservoir size. Three distinct procedures are described. First, in large reservoirs such as the Three Gorges Project in China, drawdown is performed on a seasonal basis. Second, in smaller reservoirs, drawdown may be accomplished by the prediction of hydrographs for specific runoff events. Third, in very small reservoirs or diversions with limited storage, gate operation may be performed on the basis of a rule curve that does not require hydrograph prediction.

Techniques to optimize operating rules in multiple reservoirs to achieve specific sediment management objectives in river channels and pool areas has been demonstrated by Nicklow and Mays (2000) and Nicklow and Bringer (2001). These studies used data from the literature to formulate a three-reservoir network to demonstrate the interfacing of the HEC-6 sediment transport model with an optimization scheme. The HEC-6 model solves the hydraulic and sediment transport equations that govern the physical parameters of the system under the overall control of the optimization algorithm (Chapter 14). The control scheme operates within the systemwide constraints imposed by established operating parameters such as storage levels and release rates to optimize the specific sediment-management objectives.

Pass-through will tend to establish and maintain the river channel, but in wide reservoirs the off-channel areas will continue to be depositional during impounding periods, and a channel-floodplain configuration can develop over a number of years, similar to the geometry associated with flushing as discussed in Section 12.8.6. Although routing can substantially reduce the rate of sediment accumulation, the ultimate reservoir volume that can be sustained by this method is limited by the channel dimension.

#### **12.8.4.4 Pass-Through by Seasonal Drawdown**

Under seasonal drawdown, the pool is seasonally lowered or emptied to pass sediment-laden flows through the reservoir, which is refilled during the late part of the wet season. In areas with strong rainfall seasonality, runoff from initial wet-season rains may transport considerably more sediment than late-season runoff, when vegetation has regrown to protect the soil. Sediment pass-through techniques incorporated into

the Three Gorges reservoir in China have been described by Lin et al. (1989, 1993), Chen (1994), and Morris and Fan (1998).

The 39-km<sup>3</sup> Three Gorges reservoir on the Yangtze River has been designed to achieve sediment balance across the impounded reach after approximately 100 years, allowing the project to operate indefinitely while passing  $530 \times 10^6$  tn/year of sediment and 451 km<sup>3</sup> of water. This is achieved by designing a hydrologically small reservoir (C:I ratio 0.087) with adequate low-level outlet capacity to operate in seasonal drawdown mode. A conventional impounding reservoir of this same capacity on the Yangtze River would have a half-life of less than 100 years.

A conceptual profile of the Three Gorges reservoir is shown in Fig. 12-12. The reservoir is gradually drawn down during the dry season by making releases for hydro-power and downstream navigation. Outlets and turbines will be operated during the initial part of the flood season to maintain the reservoir pool at a low level. This empties the flood storage pool and also generates high flow velocities along the reservoir, which is generally not more than 1 km wide along its 600-km length. These high velocities will transport most suspended sediment and sandy bed material through the reservoir and beyond the dam. Once equilibrium conditions have been reached, gravels will continue to be trapped and must be removed by dredging. About  $2 \times 10^6$  m<sup>3</sup> of sand and silt is also expected to be dredged annually in the vicinity of the navigational locks at the dam.

#### **12.8.4.5 Pass-Through by Hydrograph Prediction**

At hydrologically small reservoirs on rivers lacking prolonged and predictable periods of high flow, it may be possible to draw down the pool in anticipation of floods, pass the sediment-laden water through the reservoir with the shortest possible detention time, and refill the reservoir with the recession limb of the storm hydrograph. This strategy was analyzed at Puerto Rico's Loíza (Carraízo) reservoir ( $26.8 \times 10^6$  m<sup>3</sup> original volume, 538-km<sup>2</sup> tributary watershed), the primary water supply for San Juan (Morris and Hu 1992; Morris et al. 1992; Morris and Fan 1998).

The spillway crest equipped with high-capacity Tainter gates that control most of the usable storage pool. The reservoir has a capacity:inflow ratio of only about 0.06, and stream-gauge records show that over half of the inflowing sediment is delivered to the reservoir by large storms occurring on the average of only two days per year. This points to significant sediment reduction by passing large flows and their associated sediment through the reservoir.

The total volume of water upstream of the dam can be continuously computed during tropical depressions as the sum of two components: the water already in the reservoir and the water predicted to arrive on the basis of rainfall already received. Reporting rain gauges within the watershed, coupled with hydrologic software, can predict the volume of the recession hydrograph from received rainfall, and a

**Fig. 12-13.** Proposed operational sequence for sediment pass-through at Loíza reservoir, Puerto Rico. See text for description.

combination of stage gauges and hydraulic modeling can compute within-reservoir volume.

The proposed operational sequence is illustrated in Fig. 12-13. (A) When a storm begins, the reservoir's gates are opened to release a volume of water equal to the volume of runoff water accumulating in the watershed as predicted from the recession hydrograph computations but not yet delivered to the reservoir. (B) As the storm continues and more water accumulates in the watershed, gate openings are increased, and the reservoir is progressively lowered until all gates are fully open. (C) The gates remain fully open as long as the total water volume tributary to the dam exceeds the total volumetric capacity of the dam. (D) During the storm recession, the gates are closed as soon as the total tributary water volume drops to the full reservoir volume. Gate closure at this point allows the reservoir to refill completely with water during the next 24 hours (Morris and Hu 1992; Morris et al. 1992).

**12.8.4.6 Drawdown by Rule Curve** At very small reservoirs, pool drawdown for sediment pass-through during floods may be regulated by a rule curve based only on the rate of inflow. A rule curve of this type was implemented at the Cowlitz Falls dam in Washington State, which impounds a hydrologically small reservoir having a capacity:inflow ratio of

only 0.3% (Locher and Wang 1995). This rule curve is shown in Fig. 12-14. A similar rule-curve operation has been studied at the Rock Creek and Cresta hydropower reservoirs on the North Fork Feather River, California (Chang 1996).

**12.8.4.7 Routing of Turbid Density Currents** Turbid water entering a reservoir typically plunges to the bottom and will flow along the original (but now submerged) riverbed. Under favorable conditions, the turbidity current will be transported to the dam where it can be released through a low-level outlet. Turbidity currents can carry fine sediment into the vicinity of the dam and obstruct low-level outlets even though there is little sediment accumulation elsewhere within the reservoir. When the reservoir profile is viewed longitudinally, the accumulation of a flat bed of sediment deposits extending upstream from the dam is an indication that turbid density currents reach the dam (Fig. 12-4).

Turbid density currents are inherently unsteady and are influenced by the variable discharge of the inflowing hydrograph, varying suspended sediment concentration, and variation in reservoir level over the duration of the event. The forward velocity of the density current is maintained by the continued inflow of turbid water, and when inflow ceases, the turbidity current will stall. In highly favorable situations

Fig. 12-14. Rule curve for sediment pass-through at Cowlitz Falls Dam, Washington (Locher and Wang 1995).

in China, it has been possible to release as much as 50% of the inflowing sediment as a turbid density current.

Gravity-driven density currents will run along the bottom of the reservoir seeking the lowest part of the cross section. In newly impounded reservoirs, this corresponds to the original river channel. In reservoirs where a channel is maintained by sediment routing or flushing, the turbidity current and its deposits will be focused along this channel, thereby facilitating the removal of turbidity current deposits during subsequent free-flow events. At the Cachí hydropower reservoir in Costa Rica, it was found that 18% of the total inflowing sediment load was accounted for by turbidity currents that ran along the flushing channel and passed through the turbines, and an additional 54% of the total inflowing load was deposited along the length of this channel prior to reaching the hydropower inlet and was removed by subsequent flushing events (Sundborg and Jansson 1992). However, if the submerged channel fills with sediments, the turbidity current will tend to spread across the flat bottom of the reservoir, reducing its velocity and sediment transport capacity, dropping its sediment load, and causing it to stall and dissipate.

De Cesare et al. (2001) undertook monitoring and numerical modeling of turbidity current processes at the Luzzone alpine hydropower reservoir in Switzerland with an average bed slope of about 4%. Turbidity current velocities up to about 0.4 m/second were observed for smaller inflow events. Turbidity currents caused sediment accumulation in front of the dam that required reconstruction of the intakes even though the reservoir had lost only 1% of its capacity to sedimentation. Turbidity currents had focused sediment accumulation beneath only 8% of the reservoir surface area.

Equations needed for the analysis of turbidity current phenomena in lakes and reservoirs are presented in Chapter 2.

### 12.8.5 Sediment Removal by Hydraulic Dredging

Dredging is any activity involving removal of sediment from underwater. Dredging in reservoirs is generally understood to have the objective of removing sediment to sustain or recover volumetric capacity. However, *tactical dredging* may be focused in a limited area to remove sediments from the vicinity of an intake or a navigation channel, and the dredged sediments are

not necessarily removed from the pool. Information on dredging is presented by the U.S. Army Corps of Engineers (1987), Turner (1996), Herbich (1992), and Morris and Fan (1998).

Dredging is being used increasingly for the removal of sediment deposits from reservoirs. However, dredging can be considered a sustainable method for controlling sedimentation only if it can be repeated indefinitely. If a reservoir is to be dredged once, it will need to be dredged again. Assuming that the first dredging consumes the best available disposal site, sediment disposal for each subsequent dredging will become increasingly problematic and costly.

The two major impediments to large-scale dredging in reservoirs are high cost and limited availability of sediment disposal sites, and the cost of slurry transportation to distant disposal sites can dominate the cost of a dredging project. An example of a large reservoir-dredging job undertaken in the United States is the removal of  $6 \times 10^6 \text{ m}^3$  of sediment from the Loíza reservoir in Puerto Rico during 1997 at a cost of about \$10/m<sup>3</sup> including dredging cost, land acquisition and construction of three sediment-disposal sites, engineering, permitting, and environmental protection (Morris and Fan 1998).

Most reservoir dredging employs conventional hydraulic dredges having a cutter head, a submerged "ladder" pump near the cutter head to lift the slurry (if dredging to depths greater than about 10 m), a main pump on the dredge, and a pipeline to convey the slurry to the point of discharge. Booster pumps may also be required along the discharge pipeline. Because of the requirement for portability, dredges in reservoirs typically have discharge lines not larger than about 400 mm (16 in.) in diameter, although transportable dredging equipment up to 760 mm (30 in.) in diameter can be manufactured.

Dredged material is discharged to a diked containment area where it is allowed to settle, with supernatant return to the reservoir or other water body. Because of bulking of fine sediment, the containment area volume must be larger than the volume of sediment removed. The *bulking factor*, the ratio of sediment volume deposited in the containment area to the in situ sediment volume, may range from 1.0 for sands to about 1.5 for clays. The suspended sediment concentration in the supernatant will depend on the hydraulic loading rate in the spoil area plus the layout to prevent short-circuiting.

When dredging is completed and the disposal area dewatered, dredged sediments may be used beneficially. Sediments dredged from Lake Springfield, Illinois, were converted to agricultural use after 3 years. When dredging involves sands and gravels, the coarse material may be separated from the fines and used as construction aggregate.

Siphon dredges eliminate the dredge pump by discharging through the base of the dam and into the downstream channel, using the static head in the reservoir to discharge the dredged slurry. The typical arrangement involves a floating dredge, a submerged suction pipe that may be fitted with a mechanical cutter head, and a submerged line that discharges to the riverbed through the base of the dam. Intermittent reservoir spills scour and carry away the deposited sediment.

This system has been used most notably in Algeria and China but has not been applied in the United States because of environmental regulations. The largest system to date is the 700-mm siphon dredge at the Valdesia hydropower dam in the Dominican Republic, no longer operational. Small-scale U.S. experiments with this type of system have been performed by Hotchkiss and Xi (1995). Because the maximum hydraulic head is limited by the available static head, siphon dredge systems typically do not extend more than about 2 km upstream of the dam.

In considering the feasibility of tactical dredging, it is important to consider that it may be simply creating a hole into which sediment inflows will be focused and quickly refill, and as such it may represent a costly and futile effort. For example, Loehlein (1999) noted that 66,000 m<sup>3</sup> of sediment were dredged from the Conemaugh River reservoir in Pennsylvania within 120 m of the dam, yet over a single winter, 38,000 m<sup>3</sup> of sediment had refilled into the dredged area. Plans for additional dredging were abandoned.

#### 12.8.6 Sediment Removal by Hydraulic Flushing

Hydraulic flushing involves the opening of bottom outlets to completely empty the reservoir and allow stream flow to scour sediment deposits. Sediment flushing may be distinguished from pass-through because its principal objective is to scour and remove previously deposited sediment. The flushing flow will erode a "main channel" through the sediments, typically following the original river thalweg, but deposits on the normally submerged "floodplain" will be unaffected by scour (Fig. 12-15). Subsequent flushing events may deepen or widen the main channel to approximately the width of the preimpoundment stream channel, but sediments on the floodplain area will not be removed. The outflowing sediment concentration is typically one or two orders of magnitude higher than the inflowing concentration. Case studies on flushing are reported by Morris and Fan (1998) and White (2001). An overview of the method and empirical methods to evaluate flushing parameters are presented by Atkinson (1996) and White (2001).

For flushing to be effective, the reservoir must be emptied with free flow along its length and through the outlet. In contrast, operation of bottom outlets under partial drawdown, referred to as *pressure flushing*, will redistribute sediment primarily within the reservoir, eroding upstream deposits and redepositing this material closer to the dam where water remains impounded. Similar processes occur as a result of normal changes in the reservoir's operational level. Pressure flushing will develop and maintain a scour cone in sediment deposits upstream of the bottom outlet, but the scour effect does not extend a significant distance either upstream or laterally.

The reservoir volume at each cross section that can be sustained free of sediment by free-flow flushing is determined by the combination of channel width and angle of repose of

**Fig. 12-15.** Configuration of deposits in a reservoir subject to drawdown for sediment routing or flushing showing main channel with a stable thalweg profile along which turbidity currents will be focused. The floodplain submerged during normal impounding will continue to accumulate sediment, but the annual deposit thickness on the floodplain during each period will decline as the floodplain level rises. In narrow reaches, the main channel may extend across the entire width of the impoundment, and floodplains may be absent.

the sediment deposits (Fan and Morris, 1992b). On the basis of information reported in the literature, Atkinson (1996) presented an empirical equation to predict the self-formed flushing channel width:

$$W_f = 12.8 Q_f^{0.5}$$

where  $Q_f$  = flushing flow ( $\text{m}^3/\text{second}$ ) and  $W_f$  = flushing channel width (m). This equation provides a good fit with the available data sets and has the same form as the Lacey regime relation for irrigation canals, but Lacey's multiplier of 4.8 (in SI units) is lower. However, no reasonably reliable general purpose relationship could be found for predicting flushing channel side slopes.

Flushing removes previously deposited sediment using a small percent of the annual discharge water at flow rates low enough to pass through bottom outlets with minimal backwater upstream of the dam. However, the volume of water released by emptying the reservoir will typically exceed the flushing volume itself. This impact is lessened when the released water is used for hydropower production or the reservoir is normally drawn down by annual irrigation deliveries. Flushing durations of several days

are typical at hydropower sites, whereas flushing periods of weeks to months durations have been used at larger reservoirs. There is little experience with hydraulic flushing in the United States due to downstream environmental impacts.

The transport of coarse material through a reservoir is the key to achieving long-term equilibrium by flushing. Low discharge rates through low-level outlets may not be adequate to mobilize and transport a significant fraction of the coarse material delivered to the reservoir by floods.

When a main channel is maintained by flushing, density currents during impounding periods will focus fine sediment deposition along the submerged channel to be removed during the next flushing event. Without flushing these sediments would first infill the channel and then spread across and deposit on the submerged floodplain. Well-documented annual flushing at the Cachí hydropower reservoir on Río Reventezón in Costa Rica (Jansson and Rodríguez 1992; Morris and Fan 1998) is illustrative of the procedure. At Cachí, the pool is drawn down at 1 m per day over a 30-day period by turbine operation, followed by a three-day period during which the bottom gate is opened and the river flows freely along the bottom of the reservoir. At the end of the flushing period, the bottom gate is closed, allowing the

reservoir to refill and resume normal operation. Flushing is conducted during the wet season to provide a high flushing flow and allow rapid refilling of the pool.

At the Cachí reservoir, this flushing procedure releases 73% of the inflowing load, as compared to only 18% of the inflowing load when the reservoir was operated at a continuously high water level. Because of the presence of turbid density currents that flow along the flushing channel, most fine sediments are deposited in the main channel and can be flushed out every year. The principal material that continues to be trapped at Cachí is the coarse bed-material load, which is advancing into the reservoir as a delta and is not effectively mobilized by hydraulic flushing.

The generalized sequence of sediment release during flushing events is shown in Fig. 12-16. The release of the greater part of the annual sediment inflow over a period of only a few days and at flow rates limited by bottom outlet capacity produces extremely high peak sediment concentrations. Experience at sites in Costa Rica, Iran, Switzerland, France, and China indicates that peak suspended sediment concentrations exceeding 200,000 mg/L should be expected during flushing. These concentrations will smother or suffocate aquatic organisms in addition to impacts by the release of potentially anoxic bottom water from the reservoir, the oxygen demand exerted by organic sediment, and elevated ammonia concentrations (toxic to fish). Fine sediment released by flushing can also clog coarse-bed river channels, infill natural pools and navigation channels, affect aquifer recharge from stream flow, clog spawning gravels, obstruct intakes and irrigation channels, make the water unfit for

municipal or industrial use, and so forth. The releases needed to move flushed sediment through the downstream system will typically exceed the volume required to remove the material from the reservoir. To date there has been little systematic investigation of means of modifying flushing schemes to reduce environmental impacts to more acceptable levels.

Liu and Tominaga (2003) have reported on an “environmentally friendly” flushing scheme involving the simultaneous flushing of two reservoirs sequentially located along the Kurobe River in Japan, using high flows to minimize suspended sediment concentration. Environmental impacts were further mitigated by the construction of fish refuges along the downstream channel. However, this site has limited fines and oxygen-depleting organics, and during 10 flushing events over a 9-year period, minimum dissolved oxygen levels never fell below 5.8 mg/L (59% saturation) despite suspended sediment concentrations as high as 161,000 mg/L.

### 12.8.7 Sediment Focusing

Sediment focusing encompasses hydraulic techniques designed to redistribute sediment within the reservoir. Sediment deposition is naturally focused in deeper parts of the reservoir by turbidity currents, as described in previous sections, and the construction and maintenance of channels or other in-reservoir features can in some cases be used to hydraulically focus sediment deposition in areas where they lessen adverse impacts. Dredging may be used as part of this strategy, principally as a means to alter flow patterns and thereby influence sediment transport and deposition processes. An example is the study of delta deposition processes in Lake Sharpe on the Missouri River (Teal and Remus 2001). Options evaluated were a reduced pool level to move sediment deposits into deeper portions of the reservoir and the construction of dikes.

## 12.9 DAM REMOVAL

There is an increasing focus on the decommissioning and removal of older dams made obsolete by sedimentation or safety considerations or in the interest of environmental enhancement. To date, most dam removal projects have been limited to smaller structures with limited amounts of sediment accumulation. An ASCE (1997) guideline on the retirement of dams is available. Chapter 23 deals specifically with the numerical modeling of sediment transport following the removal of a dam.

Dam removal is in many ways similar to flushing; riverine flow is re-established along the length of the reservoir, and sediments are released, but following dam removal sediment deposits will continue to be scoured until a new stable geometry has been reached along the formerly impounded

**Fig. 12-16.** Variation in sediment concentration and other parameters immediately downstream of a dam during reservoir flushing (Morris and Fan 1998).

reach. Depending on the volume of sediments and stream flow, this process may occur in a period of weeks to decades. Similar to flushing, the highest concentration of sediment release can be anticipated immediately after free-flowing river conditions are established across the deposits. In the case of staged removal, a new peak in sediment concentration may be anticipated as each successive removal stage exposes a new layer of sediments to scour (Chapter 23).

The release of high sediment concentrations and loads can produce a wide range of environmental and socioeconomic impacts: closure of intakes and requirement to provide alternative water supplies; bed aggradation, which increases flood hazard and groundwater levels; navigation impairment; and conflict with recreation, sport fisheries, and tourism. Environmental impacts can potentially include massive mortality through the entire aquatic food chain. As a mitigating circumstance, these impacts will gradually lessen as the sediment is washed downstream and out of the system.

MacBroom (2005) has characterized the geomorphic process of channel evolution associated with dam removal and noted that sediment release will not necessarily create adverse impacts in the removal of small dams. Several points are important in planning for dam removal. (1) All potentially involved parties should be represented in project planning. (2) It is essential to have a complete inventory of potential impacts, and, to the extent possible, these impacts should be quantified. (3) The goals of impact mitigation should be clearly defined and prioritized, identifying critical species or economic activities for mitigation. (4) Alternatives should be understood, as should the inevitable trade-offs. For example, partial dam removal may reduce downstream sediment loading and environmental impact, but it will not restore the aquatic migration corridor. (5) The planning process should lead to a clear understanding and consensus of the river management approach and procedures to be used during the removal process.

Several strategies may be employed reduce the impact of sediment releases. Dam removal can be performed by lowering the crest in stages to release sediments at a lower and more controlled rate. Alternatively, it may be determined more feasible to simply remove (or notch) the entire structure at once, pushing the sediments through the downstream system as rapidly as possible and then allowing the stream and riparian ecosystems to recover. Dam removal and sediment release may be timed on a seasonal basis to minimize impacts to downstream species of critical concern.

Sediments may be partially or completely removed prior to dam removal. In this case it is important to define the stable geometry of the postdam deposits and focus removal on those areas where the sediments could be expected to be removed by fluvial action as opposed to areas that will remain as terraces following dam removal. In reservoirs where submerged sediment deposits will remain as terrace deposits after dam removal, dredging of the postdam channel and deposition on these terrace areas may be an option for minimizing sediment release to the downstream channel.

If the regime of stream flow and sediment load entering the impounded reach is similar to preimpoundment conditions, the channel scoured through the deposits can be anticipated to resemble the geometry of the original preimpoundment channel. Quantification of this channel width and its progression over time is necessary to compute sediment loads below the dam. A dam removal express assessment model (DREAM) for estimating sediment release has been advanced by Cui et al. (2006a, 2006b). More information about the components of this model can also be found in Chapter 23.

Chang (2005) used the FLUVIAL-12 sediment transport model to analyze the proposed removal of Matilija dam in California on the Ventura River, illustrating the application of an erodible boundary model that adjusts channel dimensions throughout the simulation, as opposed to an erodible bed model in which the bed width must be input as a parameter value. The simulated enlargement of a cross section in the delta portion of the reservoir over a period of years as simulated by modeling is presented as Fig. 12-17.

Definition of channel side slopes is a critical element in determining the amount of sediment that will be released. Rather than to allow channel slopes to naturally come to their stable angle of repose, it may be desirable to cut them back to create a more natural channel and floodplain configuration and a more stable channel reach. This would also eliminate the potential for future slope failures that could deliver large new sediment volumes to the river after it had experienced recovery from the initial perturbation.

Sediment deposits may contain contaminants that constrain removal options. Rathbun et al. (2005) described a general screening framework for possible contaminants, and Bennett et al. (2002) described a detailed sediment assessment program at two reservoirs in Oklahoma. Chapters 21 and 22 address contaminant processes in sediments as well as sediment oxygen demand in lakes and reservoirs, respectively.

## 12.10 CONCLUDING REMARKS

Sustainable sediment management represents a relatively new area of focus within the engineering community, and attainment of this goal is not impossible. However, it must be recognized that the "sedimentation problem" is ultimately neither about sediment nor about water itself but about the services provided by water. At most sites it will not be economically feasible to indefinitely maintain levels of water utilization corresponding to the original sediment-free reservoir, and work beyond sedimentation engineering will be required. Themes such as water conservation, more efficient irrigation, and alternative energy sources will all eventually come into play to address sedimentation impacts. Legal sedimentation aspects, addressed in Chapter 20, might also play an important role. These broader themes should also be considered as essential components of the sustainability equation.

**Fig. 12-17.** Anticipated morphological changes in the channel as it incises through delta deposits of Matilija dam, California, following proposed dam removal (Chang 2005).

## CHAPTER 13

### *Ice Effects on Sediment Transport in Rivers*

*Robert Ettema*

#### 13.1 INTRODUCTION

The winter cycle of river-ice formation seasonally grips many rivers in large areas of the Northern hemisphere. The cycle affects river-channel capacity to convey water and sediment, it may aggravate riverbank erosion, and it may perturb the stability of alluvial channels. The severity with which the cycle of river-ice formation affects sediment-transport dynamics for rivers depends on a combination of factors related to the cycle's duration and coldness (usually expressed as accumulated degree-days of freezing). Figure 13-1 indicates the extent of the Northern hemisphere that annually experiences at least 1 month of average air temperature below 0 C.

Of major importance is the seasonal availability of water flow. Under natural conditions in many rivers, the winter cycle of ice is accompanied by a decline in water runoff and channel flow. Rates of sediment supply and channel transport diminish commensurately. Runoff and channel flow subsequently increase during spring thaws, and it is then that ice-cover effects on sediment transport become significant. For many flow-regulated rivers subject to the ice cycle, though, ice effects on sediment transport and alluvial-channel behavior are of special interest. Substantial flows may occur while such rivers are ice-covered in winter.

Also important are the materials composing the bed and bank of a river. Diverse other factors, such as north-south river flow orientation and snowfall, also can exert significant influences. The overall impacts of all these factors on sediment transport and channel morphology vary widely from one river to the next and differ from reach to reach along a river. The impacts may be distinct and clearly observable, for rivers in permafrost or annually subjected to severe ice runs following ice-cover breakup in spring. They may be obvious from stunted riparian vegetation, scarred trees, or gouged channel features. They may be subtle and blurred by the inherent complexities and apparent irregularities of

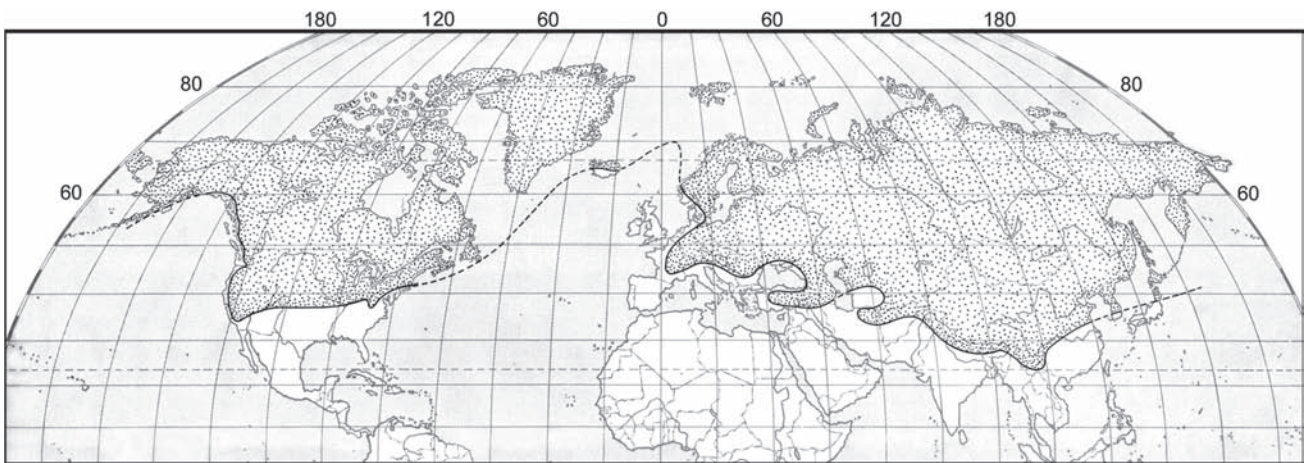

alluvial-channel flow. They also may be intermittent, being significant at one site on one occasion, but not the next. A good deal of the variability in ice impacts is attributable directly to variability in flow conditions.

Ice effects on sediment transport may be noticeable over varying scales of time and channel length. On the scales of months and of miles of channel, for instance, ice alters the relationship between flow rate, flow depth, and sediment transport rates. As it forms, an ice cover usually increases and redistributes a channel's resistance to flow and reduces its overall capacity to move water and sediment. In a sense, because the channel's bed roughness does not actually increase (in fact it may decrease; Smith and Ettema 1997), the effect of ice-cover presence on channel morphology may be likened to the effect produced by a reduction in energy gradient associated with flow along the channel. More precisely, it may be likened to a change in thalweg geometry; the additional flow energy consumed in overcoming the resistance created by the cover offsets a portion of the flow's energy that the channel dissipates by thalweg lengthening or bifurcation. This sort of postulation, though fun and possibly sound theoretically, may be difficult to verify practically, because ice covers vary in length, thickness, and roughness along most rivers. The fact remains that, at present, scant data exist for rivers.

On the local scale, an ice cover over a short reach may redistribute flow laterally across the reach, accentuating erosion in one place and deposition in another place. Such local changes of the bed may develop during the entire cycle of ice formation, presence, and release. They may develop briefly, lasting slightly longer than the ice cover, and disappear shortly after the cover breaks up. Or they may trigger a change that persists for some time. In any event, they should be verifiable from a site investigation.

Ice may dampen or amplify erosion processes locally. Obvious damping effects of ice are reduced water runoff from a watershed, cementing of bank material by frozen

**Fig. 13-1.** Area of Northern Hemisphere that experiences at least one month per year with average air temperatures less than 0°C.

water, and ice armoring of bars and shorelines by ice-cover setdown with reduction in flow rates. Yet ice may amplify erosion and sediment-transport rates, notably during the surge of water and ice consequent to the collapse of a large ice jam.

In recent years, growing interest in the wintertime management of reservoir-regulated rivers that become ice-covered, especially the winter environments of such rivers, has made it necessary to better understand and model flow and transport processes in ice-covered alluvial channels. The need has become especially acute for river reaches in which flow regulation results in significantly larger wintertime flows than occurred during preregulation conditions. For such situations it is necessary to develop more accurate estimates of flow stage, quantity of sediment conveyed, and possible changes in channel morphology. Even for essentially unregulated or wild rivers, such as the Yellowstone River shown in Fig. 13-2, it has become important to understand channel response to the winter cycle of ice.

The present chapter describes how the ice cycle may affect sediment transport, locally as well as over long reaches. It is necessary to point out that the literature dealing with ice effects on sediment transport and channel morphology is not extensive. Moreover, what exists contains a fair amount of hypothesis and conjecture. Inevitably, therefore, this chapter also contains its share of hypothesis and conjecture. An unavoidable difficulty is that ice can have various and, at times, apparently contradictory effects. General conclusions about the net effects of ice are not at all straightforward to state, except to say that ice effects are closely related to velocity and elevation of flow; i.e., higher flows incur higher impacts under ice-covered conditions than under open-water conditions.

This chapter does not address the influence of permafrost on sediment transport. Permafrost is an important factor

affecting riverbank and channel stability of high-latitude rivers. Scott (1978) and Lawson (1983), for example, provide some insights into channel behavior in permafrost. Johnston (1981) and Andersland and Anderson (1990) usefully describe the geotechnical properties of permafrost.

This chapter begins with an introductory description of the typical cycle of ice formation, ice effects on flow distribution, and ice-cover breakup in rivers (names commonly used for the various ice formations are introduced in *italics*). It then briefly describes how ice can directly entrain and transport sediment from the beds of certain rivers. Subsequently, it goes on to discuss the typical mechanisms whereby ice and cold water influence sediment transport by flow in rivers. The latter portion of the chapter addresses river-ice influences on

**Fig. 13-2.** The Yellowstone River, Montana, under an ice cover, whose formation, presence, and eventual breakup significantly influences sediment-transport dynamics, channel-thalweg location, and riverbank erosion.

channel stability. Of particular interest, in this regard, are rivers whose inflow is regulated by upstream dams.

### 13.2 ICE FORMATION

During autumn and into winter, river water cools. In cold regions, such as indicated in Fig. 13-1, it usually cools to the water-freezing temperature, or momentarily to a fraction of a degree below it (supercooling is needed to nucleate or initiate ice growth), whereupon ice rapidly forms. For a river whose inflow is regulated by a large reservoir, water temperature decreases with downstream distance of flow, and initial ice-cover formation develops commensurably at some distance downstream of the reservoir.

Ice-cover formation over a river comprises several main processes, which Fig. 13-3 (from Matousek 1984) usefully summarizes in terms of bulk velocity of flow,  $U$ , and heat flux to air,  $\phi$ . The ice terminology in Fig. 13-3 is explained further in the ensuing sections of this chapter. Implied in this figure are the influences of vertical and lateral mixing within the flow, as well as the strength of thin newly formed ice. As water cools below 4°C, it becomes lighter, and thereby more difficult to mix within the body of flow.

One formation process is static or thermal, and could be called the *bankfast-ice* process. It occurs for flows of negligibly small surface velocity and is evident as ice growth outward from riverbanks. *Frazil-ice* formation starts with the supercooling of water over some portion of flow depth. *Skim ice* may form on flows whose surface velocity and turbulence levels are sufficiently low so that only a surface

layer of water supercools, resulting in thin sheets of ice. As flow velocity and turbulence levels increase, the initial formation of ice becomes more dynamic. The full depth of water at some reach may supercool, so that frazil-ice crystals form throughout the flow. Frazil-ice formation usually dominates ice formation on alluvial rivers whose flow has sufficient velocity to move bed sediment. A given reach of river may undergo all three forms of ice growth, depending on the distribution of flow velocity upstream of and through the reach.

For river flow in a watershed unregulated by dams, factors related to channel size and air-temperature variation with altitude and latitude determine rate of water cooling and where ice first appears and gradually envelops a channel. Though exceptions exist, ice first forms in the upper reaches of a watershed for most rivers that drain toward the south (e.g., the Mississippi River). For northward draining rivers (e.g., the Red River of the North, the Mackenzie River), or rivers with more or less east-west orientations (e.g., the Yellowstone River, the Yukon River), the sequence of ice formation occurs in a more complicated manner along the length of the river.

An important factor influencing first ice formation in a channel whose flow is regulated by an upstream reservoir is the temperature of the water released into the channel. In most situations, the reservoir changes the temperature of the flow entering the channel; besides storing water volume, a reservoir stores heat. During freeze-up conditions in late fall and winter, the flow entering the channel is warmer than the flow in the channel prior to construction of the reservoir. Consequently, the reservoir likely will cause ice formation to

**Fig. 13-3.** Types of initial river-ice formation as a function of flow velocity and surface heat-loss rate;  $C$  is Chezy coefficient, and  $\phi$  is rate of heat loss per unit area of river water surface (Matousek 1984). Larger flow velocity,  $U$ , results in greater mixing and cooling of flow over its full depth.

begin further downstream along the channel than it did prior to construction of the reservoir. The thermal influence of a reservoir on ice-cover formation can be demonstrated quite readily. If, prior to construction of the reservoir, the flow entering the channel reach was at the freezing temperature of water (0 C), ice potentially could begin forming throughout the full length of the channel. For example, if a 3-m-deep flow of 4 C water were released with an average velocity of 1 m/s and exposed to -20 C air under representative conditions of heat loss (say, 20 W/m<sup>2</sup> / C), the flow would travel almost 117 km downstream from the reservoir before cooling to 0 C. If the initial temperature of the water leaving the reservoir were 1 C, the distance would be reduced to about 30 km. Therefore, as the water in the reservoir's water cools during winter, the ice cover on the river may progress further upstream. Water density is greatest at 4 C, and therefore water at the elevation of a reservoir's outflow conduit, usually placed low through the dam, is likely to be at this temperature.

Cold, clear, windy nights are especially conducive to ice formation. During such nights, rivers lose heat at maximum rates to the atmosphere by means of long-wave radiation, convection, and evaporation. Consequently, it is common for ice to form, or at least to form at its greatest rate, during the night.

### 13.2.1 Bankfast Ice

As can be seen from the river view shown in Fig. 13-4, bankfast ice (also called border ice) usually is the first type of ice to appear along a river. It forms in low-velocity zones along banks. The top layer of the water adjacent to the bank mixes minimally with lower layers and soon becomes supercooled in frigid air, while water elsewhere is still above the freezing temperature. Ice fragments in the air and at the riverbank nucleate the supercooled water at the surface. The nucleated

water propagates an ice sheet on the water surface outward from the bank. The edge of the ice sheet eventually extends to a zone of turbulent water, whereupon its further progress depends on thermal atmospheric exchange. The growth does not stop just because the water is above the freezing temperature, though it slows. It continues growing by virtue of net heat loss of water fringing the bankfast-ice edge. Bankfast-ice extension accelerates when drifting frazil slush and small pans lodge against it. The slush and pans fuse in rows to the dendrite crystals extending from the bankfast-ice edge, and they may form successive layers in the outward progressing border ice.

Bankfast-ice growth is a prominent ice-formation process in small rivers and streams with mild slopes. Together with skim ice, it is the static type of ice growth that occurs in lakes during calm but frigid weather. In the context of bank-erosion concerns, the effects of border ice on bank-material strength and loading are not well understood. For instance, not much is known about how bankfast-ice growth affects freezing of groundwater within a riverbank.

### 13.2.2 Skim Ice

When surface velocities are low, the surface layer of flow may become supercooled and spawn frazil ice, which rises and forms fragile, thin sheets of skim ice (e.g., Matousek 1984; Ashton 1986). Marcotte (1984) reports large sheets of skim ice forming when surface velocities of flow along the St Lawrence River were about 0.3 m/s; he reports that, in very cold weather, skim ice may form at surface flows with velocities of about 1.0 m/s. Sheets of skim ice drift until they gently lodge against each other along a river. The river then quickly freezes over completely. Skim ice and bankfast ice are common ice forms on rivers and streams whose slopes are sufficiently mild so that flow velocities are of the magnitude ranges tentatively indicated above.

### 13.2.3 Frazil Ice

For fully turbulent flow, frazil-ice formation begins with the formation of frazil-ice crystals throughout the depth of flow in an ice-generation zone. It is an especially striking and dominant feature of river behavior in cold regions.

Frazil ice appears quickly in a flow that supercools to a fraction of a degree below the freezing temperature of water, i.e., nominally about -0.01 to -0.1 C. As frazil crystals form, the latent heat of fusion they release gradually raises the water temperature to 0 C. During this period, the frazil is in what is termed the "active" state, in which it fuses readily with solid objects that it contacts (e.g., other frazil ice crystals, sediment on the riverbed, boulders, and some aquatic plants). For a flow-regulated river, the zone of active frazil formation may be fixed and extend only a few hundred feet, producing frazil conveyed downstream by the flow. The continuous variation in weather conditions in nature (notably,

**Fig. 13-4.** Bankfast ice formed along a bank of the Missouri River. Frazil-ice slush and pans drift in center channel.

fluctuations in air temperature, wind speed, and net heat loss by means of radiation) causes the zone to shift. Lowering air temperature or water flow rate, for example, causes the zone to move upstream. Supercooling could occur at the same river site for several days, depending on daily fluctuations in weather and flow. As an ice cover forms and progresses downstream along an unregulated river, the zone of frazil-ice production may also move downstream.

Frazil crystals grow rapidly in size, fuse to each other, agglomerate, and (owing to ice buoyancy) rise to the water surface if able to drift for a sufficient distance of flow. When initially in supercooled water, frazil crystals fuse to almost any solid boundary in the flow. For instance, they may fuse to the river bottom, forming an accumulation termed *anchor ice*. As frazil drifts, it rises to the water surface, agglomerates, crusts over, and forms ice pans, which have a hard, flat circular top and an approximately hemispherical accumulation of slush below. At this stage, the water no longer is supercooled and the frazil is termed inactive frazil; it has lost its propensity to fuse readily.

Long reaches of rivers may become covered with drifting *slush*, *pans*, and *floes* formed of fused pans. Figure 13-5 (adapted from Michel 1971) illustrates the genesis of an ice cover formed primarily from frazil ice. In deep sections with relatively low surface velocity, or in other locations with low surface velocities, the ice coverage concentrates. The pans and floes drift with the flow until they become congested (such as in a traffic jam) or lodge against some constriction. Once cover has started, it progresses upstream rapidly as a juxtaposed layer of pans and floes cemented with frazil slush. It is typical for ice covers on large rivers to progress upstream at a rate of about 40 km per day in this manner (e.g., Michel

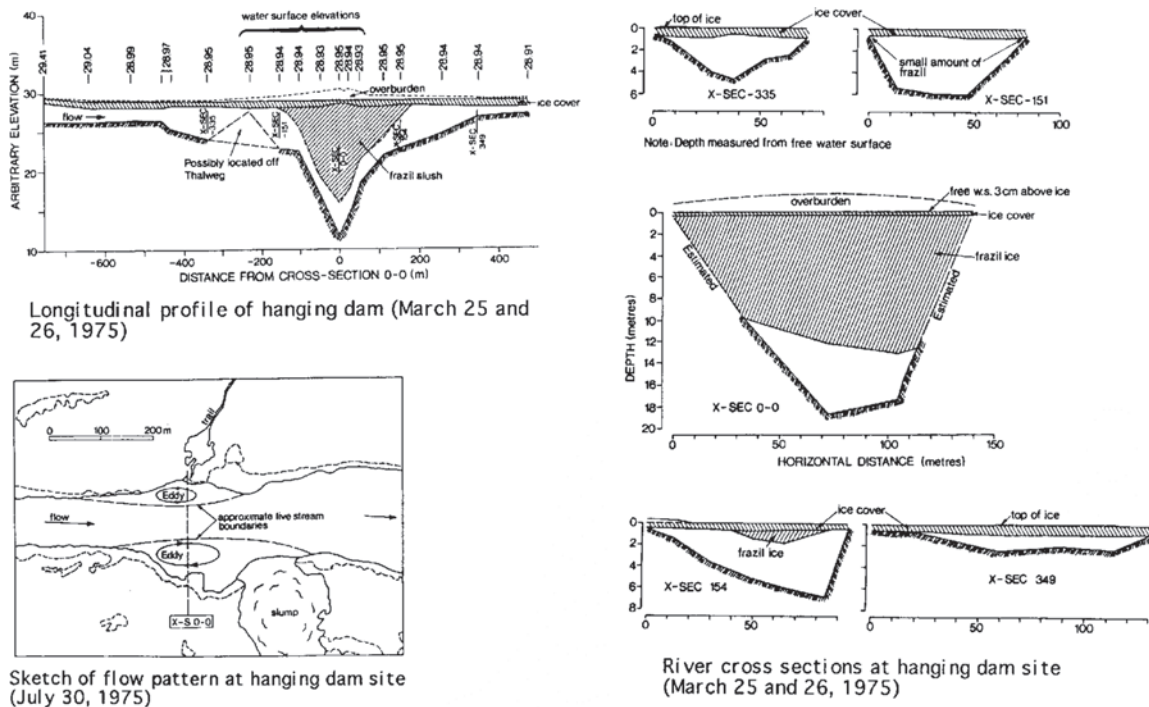

1971). Alternately, a pile-up of ice may occur and form what is termed a freeze-up jam. *Freeze-up jams* retard flow and raise water levels, possibly causing flooding upstream of the jam toe. Several flow-related variables influence the upstream progression of a level cover comprising juxtaposed pans and floes. However, an approximate rule of thumb (e.g., Michel 1971; 1978; Ashton 1986) is that a level cover may develop when the Froude number for flow at the site is about 0.1 or less; i.e., the Froude number  $= U/(gY)^{0.5} < 0.1$ , in which  $U$  = bulk flow velocity,  $Y$  = flow depth, and  $g$  = gravitational acceleration. For typical rivers, it is easier to use simple velocity criteria; e.g., frazil slush passes under the front of an ice cover when flow velocity exceeds about 0.6 m/s, and frazil pans will go under when velocity exceed about 2 m/s. The cover still may progress upstream when ice passes under its front if the rate of ice arrival at the cover front exceeds the rate at which ice is subducted beneath the front.

When the upstream front of the cover reaches a high-velocity section of a river, large amounts of slush and pans are forced under the front and conveyed beneath the cover. The slush sometimes forms clusters and *granules* or *pebbles* conveyed long distances under ice covers, being transported as a form of “bed load” of frazil that rumbles along the cover underside (Shen and Wang 1995). The granules, as well as slush and small pans, may come to rest and accumulate in zones of lower velocity beneath the cover. Chacho et al. (1986) describe similar transport of frazil along the underside of the ice cover of the Tanana River, Alaska.

Large accumulations of ice may develop under the cover and be resistant to shoving. In some situations, they may form a feature known as a *hanging dam*. Ice moving under

**Fig. 13-5.** The genesis of frazil ice in a river or stream. The water cools until slightly supercooled, whereupon frazil ice crystals rapidly appear, agglomerate as slush, develop as ice pans, which then may align juxtaposed as an ice cover.  $t_w$  = temperature of water.

**Fig. 13-6.** A hanging jam of frazil ice may develop under an ice cover when flow velocities exceed those needed to form an ice cover of juxtaposed pans of ice. This example, taken from Beltaos and Dean (1981), shows a hanging dam in the Smoky River, Alberta.

the cover progressively accumulates in locations of reduced flow velocity, concentrating the flow velocity so that it locally scours the river's bed (a later section of the chapter further discusses this concern) and increases flow area. The hummocking of an ice cover can be a clue to the presence of a hanging dam. As hanging dams and similar accumulations increase in size, they increase flow resistance, raise water level, reduce and possibly redistribute flow velocity, and enable the cover to continue progressing upstream. Figure 13-6, taken from Beltaos and Dean (1981), depicts typical aspects of a hanging dam in the Smoky River, Alberta.

For steep, highly turbulent streams, another form of dam building occurs. Weirs of anchor ice (frazil ice bonded to the bed, not the ice cover) may extend up from the streambed, reducing flow velocity and enabling the cover to progress upstream. The anchor-ice weirs retard the flow and eventually help a cover form over the flow.

In relatively steep, swift-flowing channels, frazil ice may not develop to the level cover of juxtaposed pans or covers with hanging dams. Instead, the higher flow velocities associated with steeper channels, pans, and slush, sometimes mixed with snow, form a jumbled accumulation known as a freeze-up jam. Such jams may be free-floating or partially grounded on the bed. The remnant of such a jam in a gravel-bed reach of the Yellowstone River, Montana, is depicted in Fig. 13-7. The jam clogged much of the reach, especially in shallower, slower current portions to the side of the river's thalweg.

A cover of pans and slush solidifies contiguously between the ice pieces and may thicken thermally. The contiguous solidified cover resists the hydrodynamic drag exerted by the water and the streamwise component of the cover's weight. The cover may locally buckle, shove, hummock, and bummock at weak spots as the cover progresses upstream, the flow rate fluctuates, and/or air temperature changes.

**Fig. 13-7.** The remnants of a freeze-up jam in the Yellowstone River, Montana. The jam comprised frazil slush and pans mixed with snow and is partially grounded.

### 13.3 ICE-COVER EFFECTS ON FLOW DISTRIBUTION

An ice cover imposes an additional resistant boundary that decreases a channel's flow capacity and vertically redistributes streamwise velocity of flow in a channel. If the cover is free-floating, it may reduce the erosive force of flow in the channel and thereby reduce rates of sediment transport. However, cover presence also may laterally redistribute flow, usually concentrating it along a thalweg. If the thalweg lies close to one side of a channel, flow concentration may locally increase bank erosion and channel shifting. On the other hand, if the thalweg is more or less centrally located in a channel, the cover may reduce bank erosion and channel shifting. Additionally, if the full cover is fixed to the riverbank, it may increase locally flow velocities and rates of sediment transport.

The variability of flow response to ice cover makes it difficult to draw simple overall conclusions about ice-cover effects on a river's bed and banks. The net effects will vary from site to site.

If the flow rate and channel slope are assumed constant, the main individual effects of a uniformly thick ice cover on a straight uniformly deep alluvial channel are as follows:

1. Raised water level (ice-covered depth exceeds open-water depth for the same flow rate);
2. Reduced bulk velocity of flow (discharge/flow area);
3. Reduced drag on the channel bed;

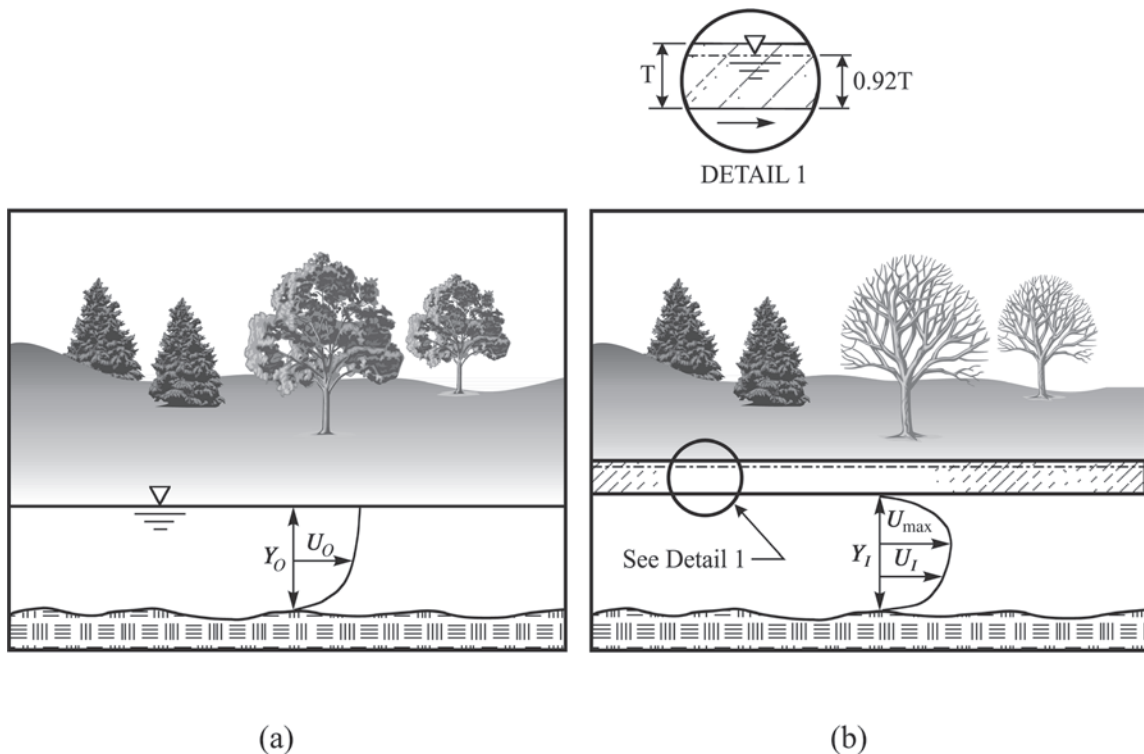

4. Reduced velocity of secondary currents (i.e., currents associated with transverse circulation of flow in the channel);
5. Reduced rates of bed-sediment transport; and
6. Altered size and shape of bed forms (notably dunes).

The effects are evident in the comparison of Figs. 13-8(a and b) and the ensuing explanation, which considers cover effects on flow distribution in fixed-bed channels. Section 13.6 discusses flow and sediment transport in ice-covered alluvial channels.

#### 13.3.1 Ice-Cover Influence on Vertical Distribution of Flow (Fixed Bed)

The direct effect of imposing a level ice cover on a two-dimensional open-water flow is to increase the wetted perimeter of the flow substantially. For a wide channel, the wetted perimeter is almost twice that for the open channel flow. The usual consequence is increased water depth for constant discharge and bed slope, as indicated in Figs. 13-8(a and b). Because roughness characteristics of the ice-cover and the bed likely differ, the influence of the roughness of the bed and the ice-cover underside on velocity distribution and flow resistance must be taken into account. However, doing so accurately is not straightforward.

For the same uniform two-dimensional flows (one open-water, the other covered, as in Figs. 13-8(a and b)) having

**Fig. 13-8.** Presence of a free-floating ice cover usually increases flow depth and redistributes flow.

the same unit discharge and energy slope, the ratio of flow depths is

$$\frac{Y_I}{Y_O} = \frac{U_O}{U_I} = \left(2 \frac{f_I}{f_O}\right)^{1/3} \quad (13-1)$$

in which  $Y$  and  $U$  define the flow depth and the bulk velocity, respectively;  $f$  is the Darcy-Weisbach resistance factor; and subscripts  $O$  and  $I$  refer to open-water and ice-covered flows, respectively. Because the overall resistance coefficient for the ice-covered flow,  $f_p$ , exceeds  $0.5f_O$  (where  $f_O$  is the resistance coefficient for the same discharge during open-water flow),  $Y_I > Y_O$ . Typically, flow depth increases by about 10 to 30%; i.e., the covered flow is about 10 to 30% deeper than the open-water flow for the same discharge. Bulk velocity of flow decreases by the same amount. The actual piezometric water level in the channel would be about 0.92 times the ice-cover thickness,  $T$ , above the cover underside; the density ratio of solid ice and water is 0.92. The cover floats with a freeboard of about  $0.08T$  above the water level. The freeboard can be suppressed or even slightly negative if there is a thick snow layer on top of the ice cover.

The resistance factor for covered flow,  $f_p$ , is a composite value expressing the total resistance exerted by the bed and the cover; i.e., for two-dimensional flow,

$$f_I = \frac{4\tau_{\text{tot}}}{\rho U_I^2} = \frac{4(\tau_b + \tau_i)}{\rho U_I^2} \quad (13-2)$$

in which

$\tau_{\text{tot}}$  = combined flow resistance exerted by the bed and the ice cover;

$\rho$  = water density;

and subscripts  $b$  and  $i$  refer to the channel bed and ice-cover underside, respectively. Equation (13-2) implies that a change in resistance at one surface will alter  $U_I$  and thereby alter the flow resistance exerted by the opposite surface.

The customary practice (e.g., Michel 1978; Ashton 1986; Beltaos 1995) is to calculate flow resistance in ice-covered channels using what is termed the two-layer hypothesis, whereby flow resistance is taken to be a linear composite of flow resistance attributed to flow drag along the bed and ice-cover underside. In accordance with this hypothesis, each resistance coefficient or drag contribution is assessed independent of the other. The resistance coefficients are related to boundary roughness (bed or ice underside) normalized with the part of the total flow depth extending from the pertinent boundary to the elevation of the velocity maximum. This approach entails use of the Sabaneev equation, a semiempirical approximation proposed by A. A. Sabaneev (Nezhikovskiy 1964),

$$n_I = n_b \left[ \frac{1 + (n_i/n_b)^{3/2}}{2} \right]^{2/3} \quad (13-3)$$

in which

$n_b$  and  $n_i$  = values of Manning's resistance coefficient associated with the bed and the ice cover, respectively; and

$n = R^{1/6} f^{0.5} / (8g)^{0.5}$ , with

$R$  = hydraulic radius.

The two-layer hypothesis is inadequate for estimating bed-form geometry, flow resistance, rates of sediment transport, and dispersion processes. Significant physical inaccuracies arise in partitioning covered flow in accordance with the two-layer hypothesis and applying Manning's equation to estimate flow resistance for each part. Flow resistances, both at the bed and at the ice cover, directly alter distribution of flow velocity. They affect the length scales and intensities of turbulence across the full depth of flow. Flow resistance is not simply the sum of flow drag determined from linear variation for each boundary, independent of the other boundary. In effect, there occurs an interactive "cross-torque" between the ice cover and the bed.

Even when the two roughnesses are identical, strictly speaking it is not physically meaningful to partition the flow at the plane of maximum velocity. Though, in this case, the plane may coincide with the plane of zero shear stress and mid-depth, the upper limit of the turbulence structures in the flow scales with the full flow depth, and turbulence diffuses and interacts across the flow. Differences in ice-cover and bed roughnesses offset the elevations of maximum velocity and zero shear stress. The offset increases when the roughness of one boundary is markedly greater than that of the other boundary.

The wind tunnel experiments carried out by Hanjalic and Launder (1971) and Reynolds (1974), for flow through a duct with top and bottom boundaries of differing roughness, and the flume experiments conducted by Gogus and Tatinclaux (1981) and Muste et al. (2000) are worth mentioning. These studies found, as expected, that the difference in top and bottom roughness shifted the position of the maximum streamwise velocity toward the roughest surface. In addition, the central region of the flow is characterized by strong diffusion of turbulent shear stress and kinetic energy from the rougher wall to the smoother one. The result is an appreciable offset of the plane of maximum velocity and zero-shear-stress plane. For a fully developed asymmetric flow, the noncoincidence of the surfaces of zero shear stress and mean velocity caused the production of turbulent kinetic energy to be negative over the central portion of the flow. In other words, a loss of turbulence energy occurs locally that affects velocity distribution over this portion. This loss of turbulence energy in the region where the smoother- and rougher-wall turbulence structures mix is attributable to the net interaction of Reynolds stresses of opposing sign.

Several recent studies report data on turbulence quantities for flow in ice-covered channels. One study (Muste et al. 2000), conducted with simulated free-floating ice cover

and constant discharge in a laboratory flume, shows that cover presence decreases Reynolds stresses in the near-bed region and that rougher covers further decrease Reynolds stresses in the near-bed region. Turbulence was measured using laser-Doppler velocimetry. For a free-floating cover, such reductions in Reynolds stresses follow from overall reductions in bulk velocity of flow. Cover presence, however, did increase Reynolds stresses near the top of the flow. Martin and Roy (1999) report field measurements of turbulence for the Sainte-Anne River, Quebec. Their measurements, taken using an electromagnetic velocity meter, indicate that a damping of larger-scale turbulence structures occurs. Sukhodolov et al. (1999) used an acoustic-Doppler velocimeter to investigate turbulence structures in an ice-covered sand-bed reach of the River Spree, Germany. They found that the spatial scale of turbulence ejections emanating from bed forms was as large as flow depth, whereas sweeps scaled at about 0.7–0.8 flow depth.

### 13.3.2 Ice-Cover Influence on Lateral Distribution of Flow (Fixed Bed)

An ice cover imposes an additional flow-retarding boundary that decreases the flow-conveyance capacity of a channel and redistributes flow vertically and laterally. Vertical redistribution of flow is marked by flow depth increase (usually) and by null flow velocity at the cover underside. Lateral

redistribution of flow, though, depends on how the ice cover forms, is attached to the channel banks, and thickens. It can be explained using the Darcy-Weisbach flow-resistance equation, written here for open-water flow in a channel of uniform depth,

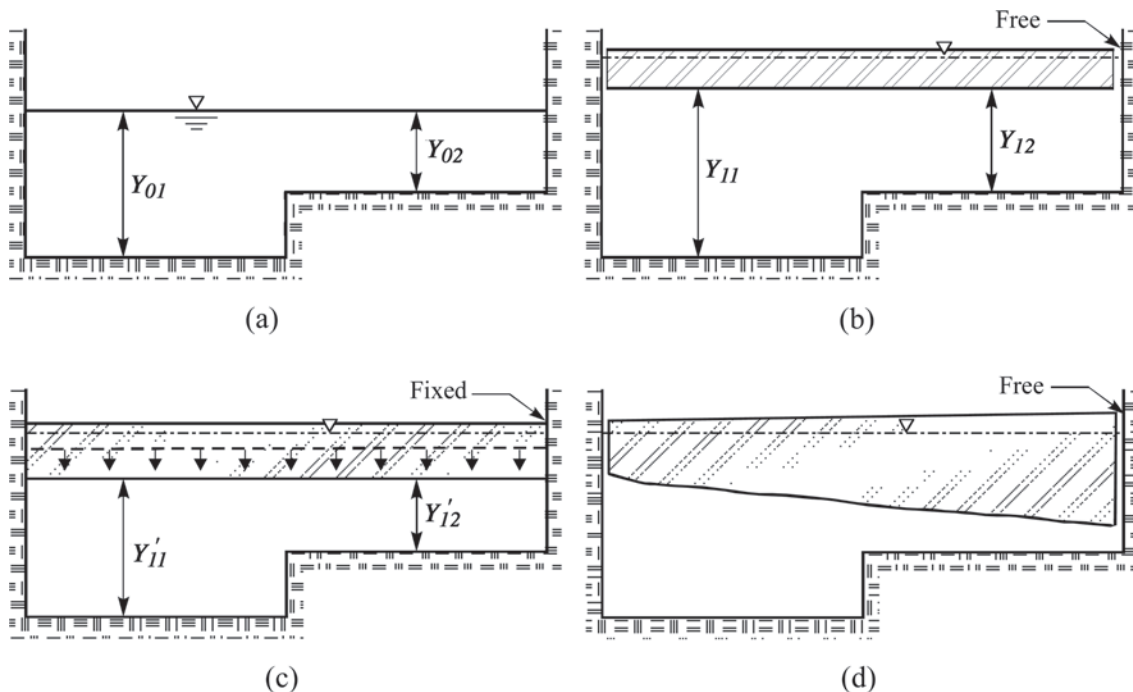

$$Q_o = Y_o B (8gR_o S_o / f_o)^{1/2} = K_o S_o^{1/2} \quad (13-4)$$

in which

$Q_o$  = flow rate;  
 $B$  = flow width; and  
 $K_o$  = unit conveyance.

Cover presence may laterally redistribute or concentrate flow in accordance with lateral variations in flow depth and/or ice-cover thickness. This impact can be illustrated in simple terms using an idealized channel comprising two bottom elevations of equal width, as in Figs. 13-9(a–d). Flow in such a channel may be described approximately in terms of two conveyance components,  $K_{o1}$  and  $K_{o2}$ , one component (1, 2) associated with each bottom elevation.

For constant flow, a free-floating, uniformly thick ice cover reduces the relative magnitudes of the two conveyance components. It smears flow over the full channel width, as  $K_{i1}/K_{i2} < K_{o1}/K_{o2}$  (Fig. 13-9(b)). However, if the ice cover were fixed to the channel banks and thickened, the reverse

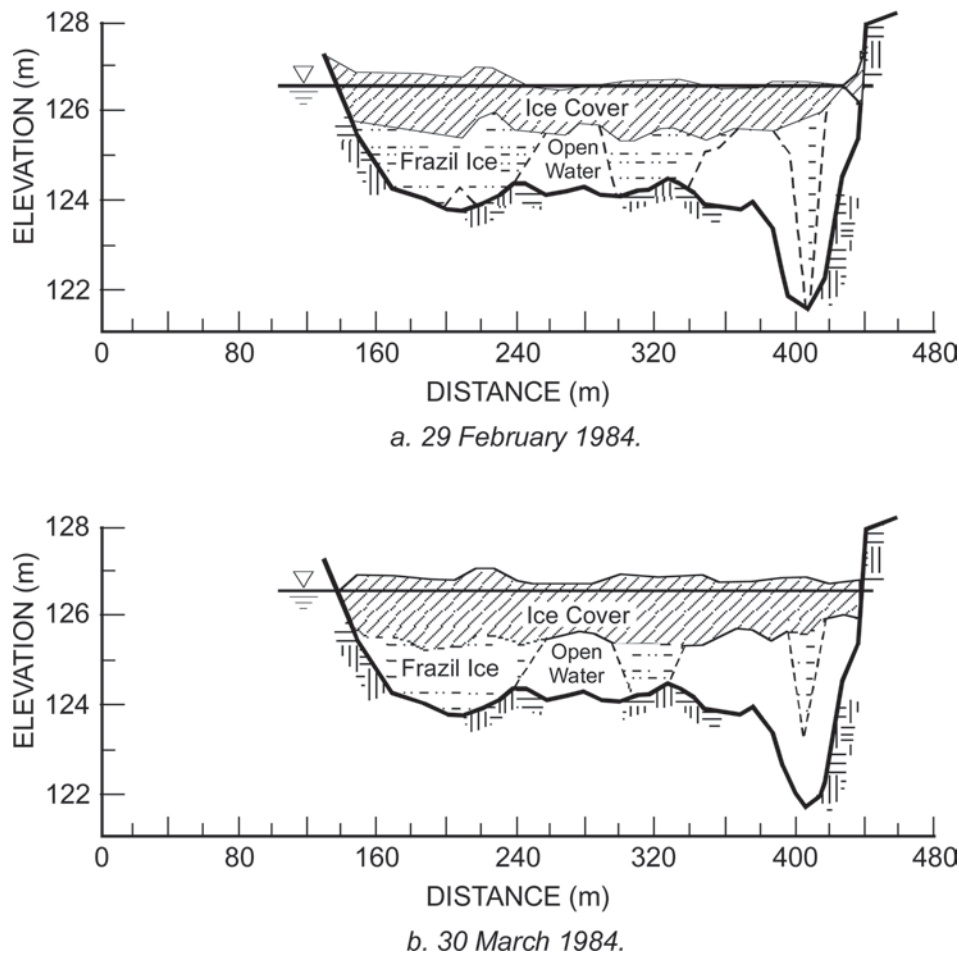

**Fig. 13-9.** An ice cover may reduce open-water proportions (a) of flow conveyance in lateral segments of a two-part compound channel if the cover is level and free floating (b); increase them if the cover is fixed and thickens (c); or, increase them if the cover is not uniformly thick (d).

would occur:  $K_{I1}/K_{I2} > K_{O1}/K_{O2}$  (Fig. 13-9(c)), because flow depth decreases more in the shallower portion. Under this condition, cover squeezes or concentrates flow along a thalweg, where flow is deeper. If the thalweg lies close to one side of a channel (e.g., near the outer bank of a bend), such a concentration of flow may promote thalweg shifting and deepening. On the other hand, if the thalweg is located more or less centrally in a channel, a fixed cover may deepen or entrench the thalweg. An important further point is that the cover, by reducing flow through the shallower portion, may trigger further reductions in conveyance through the shallower portion by promoting ice accumulation (frazil slush or pans) and/or bed-sediment deposition there. Additional flow concentration is possible if the cover is not uniformly thick (Fig. 13-9(d)), if ice is grounded on the channel bed, or if shorefast/accumulated ice develops from one or both banks.

Lateral variations in cover thickness, however, may further concentrate flow in a channel of nonuniform depth and may override the more subtle effects described for a level ice cover. Significant lateral and streamwise variations in

cover thickness may occur in channels with significant variations in flow depth and velocity. Because flow velocities decrease with decreasing flow depth, velocities usually are lower in regions of shallower flows and often in the wake of flow obstructions, such as bars. Ice covers whose formation involved substantial amounts of frazil-ice slush may become thicker in regions of shallower flow. Lower values of flow conveyance in those regions also result in relatively faster bankfast-ice formation. Also, because flow velocities are lower, ice (frazil slush and ice pieces) is less readily conveyed through those regions and is prone to accumulate. Figure 13-10 illustrates the accumulation of ice at a cross-section of the Tanana River, Alaska, at two times during winter (Lawson et al. 1986). That river is comparable to the lower Missouri River in flow rates, but is of steeper slope and more braided in channel morphology, and its flow is not regulated.

Further concentration of flow is possible if an ice cover is not free to float upward with increasing flow rate. Hydraulic analyses usually assume (e.g., Michel 1978; Ashton 1986;

**Fig. 13-10.** Nonuniform ice accumulation across a section of the Tanana River, Alaska (Lawson et al. 1986).

Beltaos 1995) that ice covers are free-floating; i.e., streamwise cracks separate the floating ice cover from adjoining bank-fast ice. Actually, a cover may not always be free-floating. A stationary cover exposed to very frigid air may fuse to the channel banks. The cover then becomes constrained from freely floating up or down with changes in the flow, at least initially. Therefore, increasing flow discharge is forced partially beneath the ice cover, initially increasing flow velocities before flow erodes the bed beneath the cover. The extent to which a flow may be pressurized beneath a cover apparently has not yet been measured (the usual assumption is that covers are free-floating). An estimate would suggest that the pressure-head increase above the hydrostatic would be approximately equal to the ice thickness, the increment in water depth retained by the upstream end of the cover. Therefore, the thicker the cover the greater the pressurization possible. Eventually, the pressure would force the cover to bow upward. Also, as flow rises at the upstream end of the cover, some of it will pass over the cover. As the flow increases further, the upward pressure causes the cover to develop longitudinal cracks parallel to the banks and to float freely on the water surface. It is conjectured (e.g., Beltaos 1990) that pressure-flow conditions can only exist for a brief time, because small increases in flow suffice to cause longitudinal cracking of ice covers of thickness about 0.3 m or less; pressure flows may be more common under very thick covers. Some evidence (Zabilansky et al. 2000) suggests that scour of the channel bed may relieve the pressurized flow in alluvial channels. Very little information exists on this flow condition, especially with regard to how it may locally affect the channel bed and banks.

### 13.3.3 Ice-Cover Influence on Secondary Currents

For constant discharge, a free-floating level ice cover reduces bulk flow velocity and alters the vertical distribution

of streamwise flow. In doing so, it usually dampens secondary currents.

For instance, it reduces the centrifugal acceleration exerted on flow around a river bend; though only one study has investigated this effect (Tsai and Ettema 1994). That study found that cover presence alters patterns of lateral flow distribution in a channel bend. The two sketches in Figs. 13-11 (a and b) show the main alteration, which is a splitting of the large secondary-flow spiral into two weaker spirals; owing to centrifugal acceleration acting on moving water, a large secondary-flow spiral is typical of many curved channels. The presence of a level ice cover reduces radial components of velocity and lateral bed slope in channel bends, causing the bed level to rise near the outer bank. Tsai and Ettema found a reduction in lateral bed slope of about 10%. This ice-cover effect would tend to retard bank erosion in channel bends, because it may result in reduced flow velocities near the outer bank of a bend. In other words, this effect of cover presence may dampen streamwise oscillations in bed elevation and oscillations in channel position. The dampening effect that an ice cover is calculated to have on the angle of transverse slope of the bed around a 180° bend is evident in Fig. 13-12, taken from Tsai and Ettema (1994).

## 13.4 ICE-COVER BREAKUP

Ice-cover breakup and clearance from a river typically coincide with substantial increases in water-flow rates in the river. Not coincidentally, these events also are periods of substantial sediment movement in alluvial rivers. For many rivers in cold regions (notably those in permafrost), breakup flows are considered to be the dominant channel-forming flows. The processes attendant to breakup and jamming are reasonably well understood; not so the impacts of breakup and jamming on channel erosion and sediment transport.

**Fig. 13-11.** Ice-cover effects on secondary currents in a channel bend (a) open-water flow; (b) ice-covered flow.

**Fig. 13-12.** Ice-cover effects on transverse bed slope around an alluvial-channel bend (Tsai and Ettema 1994). The effects, determined from a flume experiment and a numerical simulation, show that cover presence reduces transverse slope.

With the onset of warmer weather, ice-cover strength and thickness decrease. Ice strength usually decreases more significantly than ice thickness (Ashton 1986). In most situations, an ice cover may “rot” or “candle,” becoming porous and greatly weakened before thinning. Also, with the onset of warmer weather, flow increases as snow melts, possibly accompanied by rain. Increased flow rate and depth increase the hydraulic load exerted against an ice cover, raising uplift pressure and drag, which results in hinge cracks and transverse cracks, respectively. Additionally, increased water elevation creates more surface area for ice to move.

The breakup of a river ice cover may be considered as occurring in three phases. Not all of them may occur. The phases are the prebreakup weakening of the cover, the breakup and ice run, and the breakup jam. For most river reaches, an ice cover weakens, disintegrates or breaks up,

and then its fragments drift downstream. In some rivers, ice-cover breakup is followed by the development of *breakup ice jams*. For one of several reasons, certain reaches in those rivers have insufficient capacity to convey the broken ice.

The prebreakup begins with the start of runoff from the watershed when solar radiation begins to melt the snow cover, even before the average daily air temperature exceeds 0°C. The discharge in the river begins to increase, exerting an uplift pressure on the ice cover, possibly with water flowing over the cover as well as under it. With increasing discharge, the ice cover fractures in several places. For a long reach with low velocities, the break usually occurs first along the banks. The central part of the cover floats freely, but the border ice may be flooded. In areas of high flow velocity, water may rise and flow over the cover through numerous uplift fractures. Several pieces of ice may detach and begin to move downstream on the ice cover. As the discharge increases and

is accompanied by daily fluctuations (responding to daytime variations in air temperature and solar radiation), ice pieces detach themselves at regions of highest flow velocity and accumulate at the front of regions of the stronger ice cover over the low-velocity reaches.

The occurrence of an *ice run* depends on a combination of flow conditions and ice-cover strength. In this regard, the direction of flow can be important. Rivers flowing into warmer regions usually begin cover breakup at the downstream end of the ice cover. The cover then progressively breaks up in an upstream direction, with the ice moving downstream in an orderly manner, provided it does not develop a jam at some congestion location. Rivers flowing into colder regions (e.g., rivers flowing north, in the Northern hemisphere) usually begin breakup near the upstream end. Breakup may also begin for river reaches for which the inflow hydrograph includes a higher peak flow rate than the outflow hydrograph, owing to flow-resistance attenuation of the hydrograph.

#### 13.4.1 Breakup Ice Jams

It is not uncommon for ice to clear a river by means of a series of breakup jams. An initial jam forms from ice first broken over a reach upstream. Increased flow and warming cause the jam to be released, and then to be dislodged and break more ice, forming new jams downstream. Eventually, by means of this stop-go process, the flow shunts ice from the river. In the continental United States, breakup jams may occur at any time once an ice cover has formed on a river. Though spring is the usual time for breakup to occur, mid-winter thaws may cause a river to experience a series of freeze-up and break-up events. At latitudes higher than those of the continental United States, breakup jams usually occur with the onset of spring.

Many aspects of breakup-jam formation and release remain inadequately understood. An inherent difficulty with ice jams is that they radically alter the stage-discharge relationship for a river reach; a moderate flow rate in a jam-covered channel usually produces a flow stage much higher than that produced by the same flow under open-water conditions. Jam formation and release may occur in fairly gentle or gradual manners. They also may occur rapidly, especially if they involve a steep hydrograph of flow or a surge. Abrupt jam release creates a surge similar to that obtained with dam-break flow; surges and ice runs have been clocked at speeds in excess of 5 m/s (Beltaos 1995).

The net effects (detrimental and beneficial) of ice-jams on channel morphology and river ecosystems have not been extensively investigated and therefore are not well understood. Of particular and common concern is the formation of ice jams at bridges, such as that shown in Fig. 13-13. Ice jams lodged against bridges not only impose substantial lateral and uplift forces on bridges, but also may aggravate constriction scour of the channel bed at the bridge site.

Fig. 13-13. Ice jam at a bridge across the Iowa River, Iowa.

### 13.5 SEDIMENT TRANSPORT BY ICE

Sediment-laden ice slush and clumps of ice-bonded sediment may appear during the early stages of ice formation in certain rivers and or streams subject to the winter cycle of ice formation. The ice slush and clumps comprise a mix of frazil ice and anchor ice that once was briefly bonded to the beds of such rivers and streams. The amounts of sediment entrained or rafted with the ice slush and clumps can produce a substantial momentary surge in the overall quantity of sediment moved by some rivers and streams, though at present there are no reliable measurements or estimates of ice-rafted sediment-transport rates. Much of the entrained sediment becomes included in an ice cover, where it remains stored until the cover breaks up. Though ice-rafting of sediment is known to occur (observations are reported by, for example, Barnes 1928; Wigle 1970; Michel 1972; Benson and Osterkamp 1974; Kempema et al. 1993), the implications of its occurrence largely remain unknown.

The short treatment given in this section limits itself to ice transport of sediment in rivers and streams. Shallow coastal (marine and lacustrine) waters in cold regions also are prone to bed-sediment entrainment and ice-rafting by frazil and anchor ice. Barnes et al. (1982), Osterkamp and Gosink (1983), Reimnitz and Kempema (1987), Kempema et al. (1993), Barnes et al. (1994), and Kempema (1993) describe coastal locations where ice entrains significant quantities of sediment. Storms in frigid weather conditions agitate coastal waters and can produce large quantities of frazil ice. The mechanisms whereby anchor ice forms in coastal waters include the same elements that cause anchor ice to form in rivers and streams. The formation mechanisms for coastal anchor ice are complicated, however, by the more complex flow conditions of coastal waters and by salinity considerations in marine systems. Ice can significantly affect sediment erosion and deposition in estuaries and tidal reaches of rivers. Desplanques and Bray (1986)

and Morse et al. (1999) describe the influence of ice accumulation in estuaries of the northeast portion of the Bay of Fundy. The accumulations form as ice walls from stranded ice and included sediment. The ice walls confine flow and can accentuate localized channel scour. Of particular concern in this regard is scour near hydraulic structures such as bridge piers and abutments.

The mechanisms whereby ice entrains and transports sediment are not well understood. Also, the distances over which ice-rafted sediment typically may be transported are not really known. To date the only detailed laboratory investigations of the entrainment mechanisms are the studies reported by Kempema et al. (1986; 1993). A handful of experiments on anchor ice formation have been conducted, though (e.g., Tsang 1982; Kerr et al. 1998). The experiments and field observations indicate that the following two mechanisms contribute to anchor ice formation:

1. The prime mechanism is frazil ice adhesion to bed sediment. Large-scale turbulence in comparatively shallow, swift-flowing rivers and streams can mix suspended ice crystals and flocs of active frazil ice across the full depth of flow, as sketched in Fig. 13-14. When the flow is supercooled, the frazil ice may adhere to bed sediment or individual boulders and accumulate as a porous and spongy mass (Wigle 1970; Arden and Wigle 1972; Tsang 1982; Beltaos 1995). Rapids and riffles are common locations for anchor ice formation (Marcotte 1984; Terada et al. 1997). Altberg (1936) reports the occurrence of anchor ice in river flows as deep as 20 m. The foregoing references report rapid rates of anchor ice growth, such that large volumes of anchor ice form in a short period.

2. A much less significant mechanism for sediment transport is direct ice growth on the bed or on objects protruding from the bed. Together with frazil ice, supercooled water can be mixed across the flow depth. The downdraft of supercooled water chills objects in the flow (e.g., boulders and debris of various types) and enables ice to nucleate and form directly on those objects. The resultant ice crystals are relatively small and develop a fairly smooth and dense ice mass (e.g., Ashton 1986; Kerr et al. 1998).

The diurnal formation of frazil and anchor ice (as mentioned in Section 13.2) may result in repeated ice-rafting events along a river reach, each event potentially entraining substantial quantities of bed sediment. Under conditions of sufficiently frigid weather and substantial flow turbulence, extensive areas of a river's bed can become blanketed by anchor ice. Arden and Wigle (1972), for instance, describe anchor-ice formation along a several-mile reach of the Upper Niagara River, New York; the anchor ice attains sufficient bulk during a single night so that it reduces inflow into the river from Lake Erie by 20 to 30%. Usually, once the surface of a river reach is ice-covered and its water prevented from supercooling, anchor-ice formation and consequent ice rafting cease.

Because the larger sizes of sediment on a river bed protrude more into the flow, they usually are more affected by the thermal condition of the flow than by that of the bed on which they rest. Significant heat flux can occur from a sub-bed zone that is at 1 to 2°C and supercooled flow (typical supercooling is about  $-0.01$  to  $-0.1$  C) essentially over the full flow depth of a river or stream. Consequently, larger amounts of anchor ice typically form on coarser bed sediment. Several factors militate against extensive anchor ice formation on

**Fig. 13-14.** Frazil ice accumulated in the lee of a dune, which migrates and envelops the frazil ice, eventually forming an ice-bonded clump of sand. This photo was taken from a flume experiment described by Kempema et al. (1993). (Photo taken by Ed Kempema, University of Wyoming.)

river beds of fine noncohesive sediment. In particular, such sediments are readily lifted and therefore cannot hold a significant anchor ice accumulation (Arden and Wigle 1972; Marcotte 1984).

The laboratory studies conducted by Kempema and his coworkers provide interesting insights into aspects of anchor-ice formation in the presence of bed forms. Their experiments, which were conducted with a racetrack-shaped flume fitted with sand beds in a ripple regime, show how frazil flocs become sediment-laden and lose their buoyancy as they tumble along the flume's sand bed and eventually become included within an ice-sand clump of anchor ice. As the negatively buoyant flocs of frazil and sediment accumulate in the trough of ripples (as illustrated in Fig. 13-15), they become infiltrated by sand, buried, and compressed. The resulting clumps of bonded ice and sediment may then enlarge as additional frazil flocs fuse to them, or as the clumps grow further amid supercooled water.

Eventually, a clump of anchor ice accumulation may attain sufficient buoyancy to lift sediment from the bed. The resulting concentrations of suspended sediment that the ice conveys can get quite high. Kempema et al. (1986) calculate that a neutrally buoyant clump of ice-bonded sediment may contain up to 122 grams of sediment per liter of ice and sediment. Kempema (1998) measured sediment concentrations in released anchor ice masses in southern Lake Michigan of 1.2 to 102 g/L, with an average concentration of about 26 g/L.

Accumulations of anchor ice also move gravel and cobbles. Martin (1981) mentions an instance where anchor ice

entrained and moved boulders up to 30 kg in weight. Such ice rafting can move cobbles and boulders through long reaches of relatively sluggish flow deep pools in rivers.

Kempema et al. (1993) report that interactions of suspended sediment and frazil ice in the water column may directly result in the inclusion of suspended sediment in ice slush. The exact nature of the interactions and the likelihood of their occurrence, require further examination. Nonetheless, Barnes (1928) and Altberg (1936) mention an intriguing observation that frazil-ice formation appears to remove suspended sediment from a flow; after a frazil-ice event, water seems clearer. When frazil and anchor ice form, it is possible that they may diminish bed-sediment entrainment and transport. Initially, accumulating frazil and anchor ice would bind bed sediment, thereby retarding entrainment. Also, by virtue of the ice concentrations involved, frazil ice may dampen flow turbulence, a key factor in suspended-sediment transport. Once anchor ice lifts from a bed, however, it would entrain and convey sediment, although that sediment may become frozen and temporarily stored in a floating ice cover.

### 13.6 ICE-COVER EFFECTS ON SEDIMENT TRANSPORT BY FLOW

The extent to which sediment transport by flow responds to ice-cover formation and presence has yet to be fully determined. Some responses are reasonably well understood, some barely recognized; few have been investigated

**Fig. 13-15.** Independent variables usually associated with flow in a loose-bed channel indicated here for an ice-covered reach.

rigorously. The interactions affect the full gamut of relationships between flow discharge and stage, macroturbulence structures, sediment-transport and mixing processes, and channel stability. This section discusses the interactions and raises practical issues stemming from them.

An essential feature of alluvial channels is that their morphology and flow-resistance characteristics alter in response to changing flow and sediment conditions. Simply put, flow and bed interact. During frigid winters, river ice modifies the interaction, over a range of scales in space and time.

The literature on river-ice hydraulics currently contains little information about ice effects on loose-bed hydraulics. Virtually all analyses of ice-covered flows (whether the ice cover is sheet ice or jammed ice) treat the bed as being fixed and thereby of constant hydraulic roughness. By the same token, the extensive literature on loose-bed hydraulics says little about flow resistance and sediment transport in alluvial channels when they are ice-covered.

### 13.6.1 Parameters

Dimensional analysis of variables associated with flow in a loose-bed channel (Fig. 13-15) provides a useful framework for discussing loose-bed issues in river-ice hydraulics. It quickly and formally identifies most of the interactions between cover, flow, and bed. Typically, a dependent quantity  $A$  of a channel may have the following functional dependence for flow in a reach that has a comparatively wide channel comprising a bed of uniform-diameter sediment under a uniformly thick ice cover:

$$A = f_A(Q, Q_s, \nu, \rho, \rho_s, d, g, S_0, B, T, k_i) \quad (13-5)$$

In Eq. (13.5),

$Q_s$  = sediment discharge into reach;

$\nu$  = kinematic viscosity of water;

$\rho$  = water density;

$\rho_s$  = sediment density;

$d$  = median size of bed particles;

$g$  = gravity acceleration;

$S_0$  = channel slope;

$B$  = reach width;

$T$  = ice-cover thickness; and

$k_i$  = hydraulic roughness of ice-cover underside.>

The dependent quantities of practical concern for the reach are flow depth, hydraulic radius, bulk velocity of flow, flow-energy gradient, sediment-transport capacity of the flow in the reach, and possibly thalweg alignment through the reach.

Though ice-cover properties  $T$  and  $k_i$  actually may also be dependent variables, especially for ice covers formed from accumulated drifting ice, here they are treated as independent variables. The variable  $k_i$  directly affects flow

resistance, whereas cover thickness,  $T$ , affects flow insofar as it is of use in characterizing cover rigidity and elevation of hydraulic grade line. The present focus is on the ways in which existing ice cover modifies interactions between flow and bed. An interesting broader discussion would consider how flow and bed interaction influence cover formation. That discussion might include thermal variables, such as water temperature.

In terms of nondimensional parameters and, for convenience, considering unit discharges of water,  $q (= Q/B)$  and sediment  $q_s (= Q_s/B)$ , Eq. (13-5) may be restated as

$$\Pi_A = \varphi_A \left( \frac{q}{\nu}, \frac{q_s}{\nu}, d \left( \frac{g \Delta \rho}{\rho \nu^2} \right)^{1/3}, \frac{\rho_s}{\rho}, S_0, \frac{d}{k_i}, \frac{T}{d} \right) \quad (13-6)$$

in which sediment diameter,  $d$ , is used as the scaling or normalizing length. Here, sediment discharge is total sediment discharge. Also,  $\Delta \rho = \rho_s - \rho$ .

The second and third parameters can be combined to express sediment transport more usefully nondimensionally as

$$\frac{q_s}{\nu} \left[ d \left( \frac{g \Delta \rho}{\rho \nu^2} \right)^{1/3} \right]^{-3/2} = \frac{q_s}{\sqrt{g(\Delta \rho / \rho) d^3}} \quad (13-7)$$

For most situations,  $\rho_s / \rho$  is more or less constant (about 2.65). Thus Eq. (13-6) reduces to

$$\Pi_A = \varphi_A \left( \frac{q}{\nu}, \frac{q_s}{\sqrt{g(\Delta \rho / \rho) d^3}}, d \left( \frac{g \Delta \rho}{\rho \nu^2} \right)^{1/3}, S_0, \frac{d}{k_i}, \frac{T}{d} \right) \quad (13-8)$$

In Eqs. (13-6) and (13-8), for example, Froude number,  $F = (q/Y)/(gY)^{0.5}$  is a dependent parameter, because flow depth,  $Y$ , is a dependent variable.

For the case of a long, rigid, and uniformly thick, free-floating ice cover, the significance of  $T/d$  diminishes, and Eq. (13-8) simplifies to

$$\begin{aligned} \Pi_A &= \varphi_A \left( \frac{q}{\nu}, \frac{q_s}{\sqrt{g(\Delta \rho / \rho) d^3}}, d \left( \frac{g \Delta \rho}{\rho \nu^2} \right)^{1/3}, S_0, \frac{d}{k_i} \right) \\ &= \varphi_A \left( R, \frac{q_s}{\sqrt{g(\Delta \rho / \rho) d^3}}, D_*, S_0, \frac{d}{k_i} \right) \end{aligned} \quad (13-9)$$

in which  $D_* = d(g \Delta \rho / [\rho \nu^2])^{1/3}$ , and  $R = q/\nu$ .

Many relationships in alluvial-channel hydraulics are expressed in terms of particle Reynolds number,  $R_* = u_* d / \nu$ ,

and Shields parameter,  $\theta = \rho u_{*b}^2 / (g \Delta \rho d)$ ; here,  $u_{*b}$  = shear velocity associated with bed component of velocity distribution. In this regard, using  $D_* = (R_*)^2 / \theta$ , Eq. (13-9) can be recast more usefully as

$$\begin{aligned} \Pi_A &= \varphi_A \left( R, \frac{q_s}{\sqrt{g(\Delta \rho / \rho) d^3}}, D_*, S_0, \frac{d}{k_i} \right) \\ &= \varphi'_A \left( R, \frac{(R_*)^2}{\theta}, \frac{d}{k_i}, \frac{q_s}{\sqrt{g(\Delta \rho / \rho) d^3}}, S_0 \right) \end{aligned} \quad (13-10)$$

Most equations for bed load transport relate transport rate empirically to flow intensity,  $\theta$ , (e.g., ASCE 1975; Raudkivi 1998). As shown subsequently in this chapter, the combined parameter  $\theta d / k_i$  is convenient for indicating how cover roughness moderates  $\theta$ . To simplify the discussion, the inflow and outflow rates of sediment,  $q_s$ , are taken to be equal, thereby relaxing Eq. (13-10) to

$$\Pi_A = \varphi''_A \left( R, R_*, \eta \frac{d}{k_i}, S_0 \right) \quad (13-11)$$

which also recasts  $\theta$  as  $\eta = \theta / \theta_c$ , thereby expressing  $\theta$  relative to a critical value,  $\theta_c$ , for incipient sediment movement. Many relationships for  $\Pi_A$  are expressed in terms of  $\eta$  or excess flow intensity,  $\eta - 1$  (ASCE 1975).

The ensuing discussion considers how the parameters in Eq. (13-11) influence flow and sediment movement. It begins with a brief review of the pertinent cold-water properties.

### 13.6.2 Water-Temperature Effects

Ice is attended by cold water, usually at or slightly above 0 C. Most empirical relationships for alluvial-channel hydraulics are based on data obtained with water in the range from 10 to 20 C. All but one of the independent parameters in Eq. (13-10) directly involve water properties:  $\nu$ ,  $\rho$ , and  $\Delta \rho$ . Reduced water temperature increases kinematic viscosity,  $\nu$  (it increases 100%, when water cools from 25 to 0 C), and slightly changes  $\rho$  (it increases about 0.3%, when water cools from 25 to 0 C, but attains a maximum at 4 C). An increase in  $\nu$  directly reduces  $R$  and  $R_*$  values, at constant  $q$ . In so doing, it increases flow drag on the bed, decreases particle fall velocity, and thereby increases flow capacity to convey suspended sediment overall. By and large, the effect of low water temperature can be taken into account using  $R$ ,  $R_*$ , and  $\theta$  (insofar as it scales particle size and fall velocity relative to bed shear velocity,  $u_{*b}$ ). The quantitative impacts of increased fluid viscosity on macroturbulence are unclear as yet.

A fair number of studies have investigated water-temperature effects on sediment transport or sediment fall velocity. The studies confirm that sediment-transport rate increases with decreasing water temperature. Lane et al. (1949)

and Colby and Scott (1965) show such a trend in field data taken from the Missouri, Colorado, and Middle Loup Rivers. Extensive flume experiments are reported by Ho (1939), Straub (1955), Colby and Scott (1965), Taylor and Vanoni (1972), and Hong et al. (1984). Taken together, the flume data confirm that sediment transport rates increase as water temperature decreases, the increases becoming substantial when water temperature drops below about 15 C. The flume data reported by Hong et al. (1984), for instance, show that the mean concentration of bed-sediment transport increased by factors of up to 7 and 10 for a water temperature drop from 30 to 0 C. The increase, obtained with  $d = 0.11$  mm, is attributable to increased concentration of sediment transport in a bed layer (layer thickness taken as  $d\eta^{0.5}$ ) and increased uniformity of concentration distribution over the flow depth. The latter effect is largely owing to the reduced fall velocity of suspended particles. Hong et al. (1984) concluded that temperature reduction significantly increases bed-level concentration of sediment movement only if bed-layer Reynolds number,  $R_B$  (defined by Hong et al. as  $\{u_* d\eta^{0.5}\} / \nu$ ) exceeds about 20;  $R_B = R(\eta)^{0.5}$ .

Several studies have looked at water-temperature affects on particle fall velocity (e.g., Interagency Committee 1957). No study seems yet to have looked at the settling velocity of cohesive sediments, or cohesive-sediment behavior overall, at water temperatures close to 0 C. For example, Huang (1981) examined water-temperature effects on cohesive-sediment fall velocities for the range from 32 C down only to 6.1 C.

### 13.6.3 Sediment Movement and Bed Forms

The overall magnitude of the tractive force (drag and lift components) that flow exerts on bed particles, together with the impacts of flow turbulence on all its scales, prescribes bed sediment motion. Ice-cover presence influences water drag on the bed and turbulence generation by redistributing flow and reducing the rate of flow energy expenditure along the bed. In so doing, cover poses three practical issues in using Eq. (13-10).

The first issue concerns estimation of  $\tau_b$  or  $u_{*b}$ , shear stress or velocity associated with the channel bed. These variables are considerably more difficult to estimate than for open-water loose-bed hydraulics. A second issue is that the dependent loose-bed parameters ( $\Pi_A$ ) of practical importance for alluvial-bed flows typically are estimated using semiempirical relationships developed for open-water conditions. Simply stated, at issue is the applicability of open-water empirical relationships to ice-covered flow.

A third issue concerns the streamwise variation of the flow and sediment-transport capacity of an ice-covered channel. If the sediment-transport capacity of an ice-covered channel is less than the rate at which sediment load is supplied to the channel, the bed must locally aggrade. If the converse holds, the bed must degrade locally. The former condition usually prevails for free-floating cover, because bulk velocity of flow

decreases. The latter condition may occur when the cover is fixed and/or thick (large  $T/d$ ), because the bulk velocity of flow under the cover increases. The various states of ice-cover condition complicate prediction of flow resistance and sediment transport in ice-covered alluvial channels.

The intrinsically complicated aspect of estimating flow resistance and sediment transport is that the single relevant length scale for ice-covered flow is the total flow depth,  $Y$ , which itself usually is a dependent variable. For open-water flow, flow drag on the bed can be characterized using  $R$  and  $D_*$ , because they are not explicitly dependent on flow depth and flow velocity, depending instead on  $q$  as well as water and particle properties.

Two practical concerns are whether river ice influences bed form geometry and, if so, whether its influence is describable using relationships developed for open-water flow. These issues have implications for estimation of flow resistance and mixing processes. Following from Eq. (13-10), bed form length,  $L$ , and steepness,  $\delta$ , can be expressed functionally as

$$L_* = L/d = \varphi_{L_*} \left( R, R_*, \eta \frac{d}{k_i}, S_0 \right) \quad (13-12)$$

and

$$\delta = H/L = \varphi_{\delta} \left( R, R_*, \eta \frac{d}{k_i}, S_0 \right) \quad (13-13)$$

in which  $H$  = bed form height. Equations (13-12) and (13-13) indicate that ice-cover presence should influence bed form geometry. The practical concern is accurate estimation of  $\eta$  or  $u_{*b}$ . Figures 13-16 and 13-17 show that bed form geometry in ice-covered flow essentially conforms to the same relationships as prevail for open-water flow. Figure 13-17 shows additionally that an ice cover, by reducing excess flow intensity at the bed,  $\eta - I$ , reduces bed form steepness for the range of values indicated.

However, there is an important cover influence not immediately evident from Eqs. (13-12) and (13-13) and Figs. 13-16 and 13-17. The influence is not adequately described in terms of cover influence on  $\eta$  or  $u_{*b}$ . Bed forms generate macroscale turbulence, or coherent turbulence structures. Cover presence, by redistributing flow, influences the development of macro-turbulence and its consequences for bed sediment suspension as well as other dispersive processes. Recent experiments by Ettema et al. (2000) suggest that smooth level cover may invigorate macroturbulence generation, mildly increasing the frequency of structures generated from bed forms and enabling them to penetrate the full depth of flow.

### 13.6.4 Flow Resistance

The issues concerning flow resistance hinge on the issues mentioned above for sediment entrainment, bed forms,

**Fig. 13-16.** Flume data on bedform length in ice-covered flow conform to empirical open-water curves developed by Yalin (1992).

and macroturbulence. They entail estimation of resistance coefficients,  $f_b$ , associated with the bed and the ice cover, and then estimation of flow depth,  $Y$ , given  $q$ . From Eq. (13-11),

$$Y/d = Y_* = \varphi_{Y_*} \left( R, R_*, \eta \frac{d}{k_i}, S_0 \right) \quad (13-14)$$

Eq. (13-14), however, is not immediately useful for predictive purposes, because open-water methods estimate  $Y$  as a composite of form-drag and skin-friction resistance components. It is more useful to use the Darcy-Weisbach relationship for flow in a wide channel with a free-floating ice cover written in terms of unit discharge,  $q$ ,

$$Y_I = \left( \frac{f_I q^2}{4gS} \right)^{1/3} \quad (13-15)$$

with flow hydraulic radius  $R_I = Y/2$ ,  $f_I = 0.5f_b \left( 1 + \frac{f_I}{f_b} \right)$ ,

and  $f_b = f'_b + f''_b$ . The functional relationship for each of these component resistance coefficients can be adjusted in terms of parameters used by existing empirical, estimation relationships; e.g.,

1. for bed-surface resistance

$$f'_b = \varphi_{f'_b} \left( R, D_*, S_0, \frac{d}{k_i} \right) \quad (13-16a)$$

**Fig. 13-17.** Flume data on bedform heights in ice-covered flow conform to empirical open-water curves developed by Yalin (1992).

2. for form-drag resistance attributable to bed forms, such as dunes,

$$f_b'' = \varphi_{f_b''} \left( R, D_*, S_0, \frac{d}{k_i} \right) = \varphi_{f_b''} \left( R, D_*, f_b', \frac{d}{k_i} \right) \quad (13-16b)$$

3. and for the ratio

$$\begin{aligned} f_i/f_b &= \alpha = \varphi_\alpha \left( R, D_*, S_0, \frac{d}{k_i} \right) \\ &= \varphi'_\alpha \left( R, R_{*b}, S_0, \eta \frac{d}{k_i} \right) \end{aligned} \quad (13-16c)$$

Again, an immediate practical issue implicit in Eqs. (13-16a–c) is that flow resistance in ice-covered alluvial channels can be estimated using open-water relationships, provided the influence of  $\eta d/k_i$  in conjunction with the other parameters can be determined. If its influence can be determined, open-water relationships, such as those given by Einstein and Barbarossa (1952) and Engelund and Hansen (1967), can be used to predict bed resistance in ice-covered loose-bed flow. A semiempirical expression for Eq. (13-16c) is given in Fig. 13-18, which contains data from several flume studies.

Smith and Ettema (1997) developed a method, based on laboratory flume data, for estimating flow resistance in

ice-covered alluvial channels. Their method is iterative and uses the following assumptions:

1. The mechanics of bed-form formation essentially is the same for open-water and ice-covered channels.
2. Methods for predicting bed-form drag in open-water flow (e.g., the Einstein-Barbarossa method or the Engelund method) can be used to predict bed form drag in ice-covered flow. This can be done by replacing the bulk drag term,  $\rho g Y_l S$ , with an estimate of the actual bed shear stress in an ice-covered flow.
3. The ratio of boundary shear stresses along the bed to those along the cover underside is estimated as

$$\alpha = \tau_i/\tau_b = 0.84(\eta d/k_i)^{-0.20} \quad (13-17)$$

Equation (13-17) is an equation fitted to the flume data shown in Fig. 13-18. The limits of the equation have yet to be determined for values of  $\eta$  beyond those indicated in Fig. 13-18.

The proposed method requires the following input variables: cover roughness,  $k_i$ ; median bed-sediment diameter,  $d$ ; submerged specific gravity of bed sediment,  $\Delta\rho/\rho$ ; unit discharge of water,  $q$ ; channel slope,  $S_0$ ; and, an initial guess at flow depth,  $Y_l$  (say,  $Y_l \approx 1.2Y_0$ ). The procedure uses the Einstein-Barbarossa method for predicting bed form resistance and predicts values of flow depth,  $Y_f$ .

Fig. 13-18. Resistance ratio,  $\alpha$ , for an ice-covered flow in an alluvial channel.

### 13.6.5 Bed-Sediment Transport

A basic issue concerns an imbalance between rate of bed-sediment supply to an ice-covered reach,  $q_s$ , and the sediment-transport capacity of that reach,  $q_{st}$ . This issue involves the complex problem of spatially varied flow and sediment transport, with all its repercussions for local channel slope and morphology. The sediment-transport capacity of an ice-covered channel can be expressed functionally as

$$\frac{q_{st}}{\sqrt{g(\Delta\rho/\rho)d^3}} = \varphi_{q_{st}} \left( R, R_{*b}, S_0, \eta \frac{d}{k_i} \right) \quad (13-18)$$

This equation functionally characterizes bed-load and suspended-load portions of bed-sediment transport. A fundamental issue relates directly to estimation of  $\eta$  or  $R_{*b}$ . However, cover influence on macroturbulence now becomes especially significant, because macroturbulence affects sediment entrainment and suspension.

**13.6.5.1 Laboratory Data** When examined in terms of  $\eta$ , or  $u_{*b}$ , data on bed load capacity of ice-covered flow experiments concur well with the open-water trend shown in Fig. 13-19 for Meyer-Peter and Mueller's formulation (1948) and Einstein's method (1950). Essentially, if  $\eta$  can be

estimated, bed-load transport in an ice-covered channel can be estimated using an open-water method, such as the two used in Fig. 13-19. The data in Fig. 13-19 encompass the dune-bed and ripple-dune regimes.

Estimation of suspended load in an ice-covered channel is not as straightforward as bed-load estimation. Suspended load depends not only on the bed shear stress, or  $u_{*b}$ , but also on macroturbulence and flow distribution. As mentioned previously, cover presence likely significantly alters these. So far, there is no direct way to account for macroturbulence effects on suspended load.

By virtue of its reduction of bulk velocity of flow,  $U$ , and thereby  $\tau_b$  and  $\eta$ , a free-floating ice cover typically reduces a channel's capacity to transport bed sediment. At certain zones within a channel, where the cover concentrates flow, sediment-transport rates may increase locally, however. Several laboratory studies have investigated cover-presence effects on sediment transport rate (Sayre and Song 1979; Wuebben 1986; Wuebben 1988b; Smith and Ettema 1995; Ettema et al. 2000). They all involved a free-floating cover that rises and subsides with changing flow rates. Their findings confirm that cover presence reduces rates of sediment transport. The rates decline rapidly with cover presence. Bed-load transport rate, for instance, can be almost halved

**Fig. 13-19.** Bedload data compared with curves generated using Einstein's procedure and the Meyer-Peter and Muller formula developed from open-water data. Covered-flow data conform to the same curves developed using open-water data.

by an ice cover that raises flow depth 15%, for a constant flow rate; this estimate assumes, reasonably, that bed-load transport rate  $\propto \tau_b^2 \propto U^4$ , with  $U$  decreasing by 15%;  $\tau_b$  is shear stress acting on the bed and  $U$  is bulk velocity of flow (ice-covered or open water). An important point here is that sediment eroded under an ice cover may not be transported far from the erosion location.

**13.6.5.2 Field Data on Bed-Sediment Load** Few field studies have been conducted in which rates of sediment transport were measured for ice-covered channels. The studies indicate the inherent difficulty of obtaining such measurements and of interpreting them. Lawson et al. (1986) conducted an extensive study of flow and sediment movement at a reach of the Tanana River, Alaska. They obtained measurements of bed-load and suspended-load rates at one cross section. The rates were comparable in magnitude to rates measured during a survey conducted about a year earlier at two cross sections in close proximity to that used by Lawson et al. Burrows and Harrold (1983) describe the earlier survey. Together, these data sets indicate a great reduction in the ratio suspended load relative to the bed-load from summer to winter. The reduction is attributed tentatively to reduced flow of melt water from glaciers drained by the Tanana River. Laboratory data obtained by Lau and Krishnappan (1985) and Ettema et al. (2000) show the opposite result, which both studies attribute to

cover underdamping of turbulence generated by flow over bed forms.

Alterations in flow distribution often complicate evaluation of ice-cover effects on transport rates for. This difficulty is evident in Fig. 13-2, which shows an ice cover over the Yellowstone River, near Fallon, Montana, and from figures such as Fig. 13-10, which shows nonuniform ice accumulation across the Tanana River. The series of shear lines evident in the ice cover on the Yellowstone River (Fig. 13-2) indicate that the flow area has successively narrowed. Flow-width alteration is more difficult to predict than flow depth change due to ice. The formation of subchannels within an ice-covered channel may accentuate narrowing of the flow area, especially if the channel is not prismatic. The subchannels form when accumulations of frazil slush or other ice pieces develop under the ice cover. In effect, they duct the flow in a manner that significantly alters the flow distribution from that attributable to the imposition of a level ice cover.

**13.6.5.3 Field Data on Suspended Load** The few field studies on sediment transport during ice-covered flow focus on suspended load and do distinguish between bed sediment and washload sediment.

The study carried out by Tywonik and Fowler (1973) focused on the measurement of suspended-sediment load in several rivers in the Canadian prairie (e.g., Assiniboine River and Red River). They report that periods of ice cover

on these rivers coincide with periods of low discharge and, therefore, low rates of suspended-sediment transport. In addition, they experienced considerable difficulty in making the suspended-load measurements, owing to frigid weather conditions and the presence of slush ice.

For most cold-region rivers, the major sediment-transport event each year occurs during the large flows associated with ice runs resulting from the dynamic breakup of an ice-cover or the release of a breakup ice jam, if a jam develops. In addition to the large flow rates usually involved, these events may produce severe gouging and abrasion of banks by moving ice. The resultant sediment transport comprises a mix of bed sediment and fine sediment washed into the river during snowmelt. Bed-load measurements are very difficult to obtain under ice-run conditions.

Two studies, though, have provided some suspended-load data from individual breakup events. Prowse (1993) measured suspended-load concentrations during ice breakup of the Liard River, Northwest Territories. His data show a gradual increase in concentration with increasing water discharge immediately prior to breakup. When breakup occurred, suspended-load concentration increased by an order of magnitude, being comparable to concentrations associated with peak open-water flows of about two to five times the peak flow at breakup. Data obtained by Beltaos and Burrell (2000) during ice breakup on the St John River, N.B., show a similar trend.

### 13.6.6 Local Scour beneath Ice Jams

The erosive behavior of a flow may increase locally beneath an ice jam if the jam concentrates flow, increasing the magnitude of its velocity and turbulence. Also, an ice jam may deflect flow, altering its direction in a manner that aggravates bank erosion or channel shifting. This mechanism locally increases flow velocity, and it may occur when flow and ice pieces are forced beneath an ice accumulation, such as an ice jam or an ice cover. Localized scour of an alluvial

bed or bank of a channel may occur in the vicinity of an ice cover when the flow field at the cover locally increases flow velocities and thereby increases flow capacity to erode bed or bank sediment. There are several conditions under which this mechanism may occur.

The most severe condition typically occurs near the toe of an ice jam (freeze-up or breakup), as illustrated in Fig. 13-20. There, where jam thickness is greatest and flow most constricted, increased flow velocities may locally scour the bed (Neill 1976, Mercer and Cooper 1977, Wuebben 1988a). Channel locations recurrently (nominally every year) subject to ice jams may develop substantial scour holes. Tietze (1961) and Newbury (1982), for example, suggest instances of such scour holes at sites of recurrent freeze-up jams. In most circumstances, the scour hole would have no lasting or adverse effect on channel morphology, because it would gradually fill once the jam was released. It is conceivable that in certain circumstances, nonetheless, the localized scour could have a longer-term effect on channel morphology—e.g., if it promoted bank erosion at the jam site, or led to the wash-out of the channel feature triggering the jam, such as an island or bar.

To a lesser extent, local scour of bed and bank may also occur when ice pieces collect at the leading edge of an ice cover or at some channel feature (e.g., a set of channel bars) that impedes their drift. These situations are quite marginal in extent, likely occurring more or less randomly along a channel, and are short-lived. However, they potentially may trigger more severe erosion in some situations.

### 13.6.7 Constriction Scour and Local Scour at Bridge Piers

The consequences of ice-cover presence for constriction scour and local scour depth at bridge piers have yet to be examined. The prime ice-related concern is that a bridge crossing may congest ice passage in a river and, thereby,

Fig. 13-20. Flow acceleration and local scour beneath an ice jam.

trigger an ice jam, such as illustrated in Fig. 13-13. Should the toe (thickest part, as sketched in Fig. 13-20) of the jam coincide with the bridge site, the jam would constrict flow through the bridge site and consequently aggravate constriction scour, as well as local scour caused by pier or abutment presence. Wuebben (1988a) describes this situation. Some work has gone in to developing instrumentation for monitoring scour depths near bridge piers in ice-covered flow (Zabilansky 1998). In summary, though, ice effects on scour likely are essentially the same as those caused by debris accumulation at bridges.

As mentioned in Section 13.5, the formation of ice walls in tidal channels can constrict flow through bridge openings in such channels (Desplanques and Bray 1986).

### 13.7 RIVER-ICE EFFECTS ON ALLUVIAL-CHANNEL MORPHOLOGY

An open question is the extent to which the seasonal appearance and disappearance of river ice perturbs the stability of alluvial channels in cold regions. It seems from limited field observations (e.g., Mackay et al. 1974; Zabilansky et al. 2002) that river ice may exert a compound impact of hydraulic and geomechanical impacts that continually destabilize certain planform geometries of channel subject to substantial, reservoir-regulated flow during frigid winters.

The volume of literature dealing with river-ice influences on channel morphology and bank erosion is not large. Moreover, what exists contains a fair amount of hypothesis and conjecture; there is a lack of rigorous investigation into most ice effects. Indeed, the issues of whether ice modifies channel morphology and reduces or amplifies bank erosion are still matters of considerable debate. On one hand, some articles (e.g., Neill 1982; Blench 1986) largely seem to dismiss the influences. On the other hand, there are fairly numerous anecdotal articles (e.g., Marusenko 1956, Lane 1957, Collinson 1971, MacKay et al. 1974, Hamelin 1979, USACE 1983, Doyle 1988, Uunila 1997, Milburn and Prowse 1998) and the odd review article (Ettema 1999) suggesting ways in which river ice perceptibly affects channel morphology. The dismissive articles would seem to draw their conclusions overhastily, basing them on cursory observations of overall planforms of a few rivers. They do not consider the impacts of reservoir regulation of flow during winter, take into account the diversity of channel morphologies, nor consider the important ephemeral impacts of ice that trigger local changes in thalweg, without appearing to alter channel planform appreciably. There is a need for quantitative information documenting and ranking the importance of ice impacts.

Several factors influence alluvial channel stability. Most of them are explainable in terms of the equation

$$\Pi_A = \varphi_A'' \left( R, R_*, \eta \frac{d}{k_i}, S_0 \right) \quad (13-11)$$

Dependent variables of practical interest are average depth of flow,  $Y$ , and hydraulic radius,  $R$ , as well as channel width,  $B$ ; sinuosity,  $\zeta$ , and shape; flow-energy gradient,  $S$ ; and sediment-transport capacity,  $q_{st}$ . Significant changes in any of the independent variables in Eq. (13-11) may alter  $R$ ,  $\zeta$ , or  $q_{st}$  and may destabilize the alluvial reach. The greatest natural disturbances typically result from changes in water and sediment inflow rates  $q$ , or  $q_s$ . (In some respects, ice influences on channel morphology are discussed more conveniently in terms of total discharge rates  $Q$  and  $Q_s$ , because of the three-dimensional nature of channel morphology. The present discussion, however, continues in terms of unit discharges.)

A relatively long, level ice cover, for instance, practically doubles the wetted perimeter of flow in a channel, and it thereby significantly increases the boundary resistance exerted on the flow. Ice accumulated as an ice jam increases flow resistance by locally constricting flow. Increased flow resistance typically results in increased flow depth, altered flow distribution, and reduced flow drag on the bed—at least for fixed-bed channels. For a given channel, ice impacts on channel bed and banks increase in significance as unit water discharge,  $q$ , increases. Sediment entrainment and transport increase with increased flow in a channel when ice-covered channel as with open-water flow. Increased flow also increases the velocity of moving ice and increases the possibility of over-bank flow. River-ice impacts likely become more significant when water discharge fluctuates appreciably; then the prospects for other adverse ice influences increase, such as ice-cover breakup followed by ice jamming.

#### 13.7.1 Hydraulic Impacts

River ice may exert the following hydraulic impacts on a channel reach:

1. By reducing the sediment-transport capacity of a river reach, ice redistributes bed sediment along the channel. Whatever local effects river ice may exert, overall river ice usually reduces the channel's overall capacity to convey the eroded sediment a significant distance from the erosion location. Consequently, bars may develop in response to flow conditions under river ice and be washed out shortly after the cover breaks up. In situations where a significant load of bed sediment enters a long reach that has a free-floating ice cover, river ice may tend to cause mild aggradation of the channel it covers. In situations where the reach is under a fixed ice cover, local degradation may occur.
2. Through its effects on lateral distribution of flow resistance and, thereby, flow and boundary drag, river ice may modify channel cross-sectional shape developed under open-water flow conditions.

3. Congestion or jamming of river ice at one channel location may divert flow into an adjoining channel, which then enlarges (anabranching/thalweg avulsion), or over a bank, which may result in a channel cutoff (avulsion).
4. Difficulties in ice passage through channel confluences may initiate ice jamming at confluences (Ettema et al. 2000; Ettema and Muste 2001). In turn, an ice jam may modify confluence bathymetry.
5. By imposing additional flow resistance, a free-floating ice cover diminishes the effective gradient of flow energy available for sediment transport and alluvial-channel shaping. It consequently alters channel-thalweg alignment.

Ice jams, especially breakup ice jams, likely exert the greatest ice-hydraulic impact on unregulated alluvial channels. Mackay et al. (1974), for instance, describe the significant impacts that breakup ice jams exert on the Mackenzie River. For channels regulated by reservoirs used for hydropower generation during winter, ice-cover formation and presence can exert significant effects (e.g., Zabilansky et al. 2002). In overall terms, ice impacts have yet to be rigorously investigated or even to be assessed quantitatively. Brief discussions of the impacts ensue.

**13.7.1.1 Ice-Cover Influence on Local Elevation of Channel Bed** A basic issue concerns an imbalance between unit rate of sediment supply to an ice-covered reach,  $q_s$ , and the sediment-transport capacity of that reach,  $q_{st}$ . This issue involves the complex problem of spatially varied flow and sediment transport, with all its repercussions on local channel slope and morphology. If the sediment-transport capacity of an ice-covered channel,  $q_{st}$ , were less than the rate at which sediment load was supplied to the channel,  $q_s$ , the bed elevation must rise locally. Conversely, if  $q_{st} > q_s$ , the bed elevation must drop locally. The former condition usually would prevail for a floating cover, because bulk velocity of flow decreases.

The latter condition may occur when the cover is fixed and/or thick, because the bulk velocity of flow is forced to increase substantially under the ice cover, with some flow spilling over the cover, as indicated in Fig. 13-21. An ice jam, by constricting flow, may scour a riverbed locally, especially at the jam's toe (Neill 1976; Wuebben 1988a), as shown in Figure 13-20.

**13.7.1.2 Channel Anabranching, Avulsions, and Cutoffs** Channels with tight meander loops or with subchannels around numerous bars or islands are prone to ice-jam formation. Such channels typically have insufficient capacity to convey the incoming amount of ice. Their morphology may be too narrow, shallow, curved, or irregular to enable drifting ice pieces to pass. Jam formation may greatly constrict flow, causing it to discharge along an alternate, less resistant course. Prowse (2001), King and Martini (1984), and Dupre and Thompson (1979) suggest that ice-jam induced avulsion plays a major role in shifting the distributary channels of river deltas. Zabilansky et al. (2002) indicate that ice-induced avulsions of subchannels may occur in sinuous-braided reaches of the Missouri River.

At sites where a river flows in two or more subchannels, ice-cover formation can trigger a switch of the principal thalweg from one subchannel to the other. Figure 13-22 illustrates the processes involved. When a rougher ice cover forms in one subchannel, the cover partially diverts flow from that subchannel to the subchannel with the smoother ice cover. The subchannel with the smoother ice cover then enlarges while the rougher-covered subchannel shrinks. Survey observations from the Fort Peck reach of the Missouri River (Zabilansky et al. 2001) suggest that thalweg switching is a recurrent process and that switches may take several winters to fully occur. Strictly speaking, such switching is a stochastic dynamic process that may be narrow-banded about a dominant period (e.g., a certain number of winters). It also may be broad-banded due to several factors (e.g., variability of flow conditions during a year or during ice-cover formation).

Fig. 13-21. Flow in a channel reach constricted by a fixed ice cover.

When an ice jam forms in a meander loop, upstream water levels may rise to the extent that flow proceeds overbank and across the neck of a meander loop. If the meander neck comprises readily erodible sediment and the flow is of sufficient scouring magnitude, flow diverted by the jam may result in a meander-loop neck cut, whereby a new channel forms through the neck, and the former channel is left largely cut off. A meander cutoff shortens and steepens a channel reach, the consequences of which are felt upstream and downstream of the cutoff reach. The net effect of ice jams, in this regard, is to reduce channel sinuosity. Mackay et al. (1974), for instance, cite examples of such events.

If, on the other hand, the meander loop is wide and not easily eroded, overbank flow resulting from an ice jam may have the reverse effect. Rather than the net consequence being the erosion of channel through the meander loop, overbank flow may deposit sediment, thus raising bank height and reinforcing the meander loop. Eardly (1938) reports that ice jams cause substantial sediment deposition on the flood plain of the Yukon River. A similar event is reported in Simon et al. (1999) for the Fort Peck reach of the Missouri River. Overbank deposition of sediment, together with ice-run gouging and abrasion of sediment erosion from the lower portion of a bank, may oversteepen riverbanks.

**Fig. 13-22.** Ice-cover formation in a sinuous-braided channel may alternate the location of the major subchannel. Two scenarios for alternation of major subchannel were identified: (a) A relatively short initial accumulation of drifting ice in subchannel 1 may divert ice into subchannel 2, which then becomes extensively enveloped by a rough ice cover. Meanwhile, subchannel 1 freezes over with a smooth ice cover, or may remain partially open. The greater flow resistance in subchannel 2 causes flow to favor subchannel 1, which then enlarges. (b) A relatively long initial accumulation of drifting ice in subchannel 1 may divert ice and flow into subchannel 2, which then becomes extensively enveloped by a less-rough ice cover. The greater flow resistance in subchannel 1 causes flow to favor subchannel 2, which then enlarges.

**13.7.1.3 Channel Confluences** By virtue of their role in connecting channels and thereby concentrating ice within a watershed, confluences are perceived as locations especially prone to the occurrence of ice jams. Fairly numerous accounts exist of jams in the vicinity of a confluence (Tuthill and Mamone 1997). Flow and ice concentration in a confluence may cause ice to jam within a confluent channel, within the confluence itself, or at some distance downstream from the confluence. Various mechanisms may trigger jams in the vicinity of confluences. Confluence bathymetry plays a significant role in jam initiation, and in turn jamming can modify confluence bathymetry; see Ettema and Muste (2001).

**13.7.1.4 Cover Influence on Thalweg Alignment** Ice cover reduces the effective energy gradient of flow (and thereby the stream power) available for sediment transport and channel shaping. Therefore, cover formation may trigger a change in thalweg alignment.

Figures 13-23(a to c) suggest that, in terms of flow drag on the channel bed, a covered flow is effectively equivalent to a deepened and slowed open-water flow. For a constant flow rate, this influence is equivalent to a reduction in channel slope (or reduced stream power). Figure 13-24 tentatively relates thalweg and channel sinuosity to channel slope (in effect, to energy gradient and stream power). It suggests that thalweg sinuosity is relatively sensitive to change in energy gradient, much more sensitive than is overall channel sinuosity. For a given flow rate, sediment provenance, and bed-sediment composition, thalweg sinuosity and channel planform change as channel slope

changes. Fig. 13-24 indicates that, for a given flow rate and bed sediment size, channels lengthen or branch into sub-channels as channel slope increases. Channel lengthening and branching are mechanisms whereby an alluvial-channel flow increases flow resistance (and thereby rate of energy use) to offset increased flow energy associated with a larger channel slope.

When the channel is ice-covered (Fig. 13-23b) and  $q$  is constant, flow resistance imparted by the cover deepens the flow to  $Y_i$ . The unit discharge may be written as

$$q_l = q_o = Y_l (8gR_l S / f_l)^{1/2} \quad (13-19)$$

It is assumed here that the overall reach slope,  $S_o$ , and channel width do not change significantly. Cover presence, by reducing flow velocity, reduces the portion of flow energy gradient (or stream power) expended as flow drag along the channel's bed.

For an alluvial channel, a reduction in energy gradient usually implies an adjustment in planform geometry. Because an ice cover deepens and slows flow in a channel, the channel responds as if it were at a flatter slope. In effect, the channel responds as if it were conveying an equivalent open-water flow whose cross-sectional area was as shown in Fig. 13-23(c), but whose energy gradient was reduced. The effective hydraulic radius, resistance coefficient, and energy gradient of the equivalent flow are  $R_e$ ,  $f_e$ , and  $S_e$ , respectively; with  $R_e \approx 2R_l$  and  $S_e < S_o$ . For this equivalent open-water flow,

**Fig. 13-23.** A simplified sketch illustrating flow in an initial open-water flow (a) deepened by an ice cover (b) for the same flow rate. The ice-covered channel essentially experiences flow at a raised depth and reduced average velocity (c) (i.e., at a reduced slope, or energy gradient,  $S_e$ ).

$$q_l = q_o = Y_e (8gR_e S_e / f_e)^{1/2} \quad (13-20)$$

Equations (13-19) and (13-20) give

$$\frac{S_e}{S_o} = \left( \frac{f_e}{f_o} \right) \left( \frac{Y_o}{Y_e} \right)^2 \left( \frac{R_o}{R_e} \right) \approx \left( \frac{f_e}{f_o} \right) \left( \frac{Y_o}{Y_e} \right)^3 \approx \left( \frac{Y_o}{Y_e} \right)^3 \quad (13-21)$$

Equation (13-21) assumes the wide-channel approximation  $R_o \approx Y_o$  and  $R_e \approx Y_e$  and, because the bed sediment does not change and if the ice cover is fairly level, the ratio  $f_e/f_o \approx 1$ .

Equations (13-19) through (13-21), though entailing simplifying assumptions, lead to a clear result. Because covered flow depth,  $Y_e$ , usually exceeds open-water depth,  $Y_o$ , the ratio  $S_e/S_o$  is less than 1. Therefore, the energy gradient (and stream power) available for sediment transport and channel formation decreases when a channel becomes ice-covered. For a typical situation, say,  $Y_o/Y_e \approx 0.8$ ,  $S_e/S_o \approx 0.5$ ; in other words, for a given flow rate in a channel of given length, approximately half the rate of energy expenditure is available for sediment transport and channel forming. The effect of an ice cover, therefore, is to trigger a shift in thalweg sinuosity and alignment so as to balance flow-energy availability and use. However, given the magnitude

and duration of flow likely needed to shift the thalweg of a channel, this ice-cover effect likely is significant only for alluvial channels whose flow is regulated by an upstream dam (notably a hydropower dam) that releases substantial flows during winter.

Figure 13-24 suggests, for instance, that halving the slope of a meandering channel (say, from 0.008% to 0.004%) will reduce thalweg sinuosity; i.e., the thalweg attempts to straighten and the meander wavelengths shorten, as sketched in Fig. 13-25.

For sinuous braided channels, as in Fig. 13-26, ice-cover formation and associated decrease in energy gradient may cause flow to concentrate in a single thalweg of greater sinuosity than the open-water thalweg. For braided channels, ice-cover presence may concentrate flow into the larger subchannels.

**13.7.1.5 Jam-Collapse Surges** The surge created by the collapse of an ice jam usually generates high velocities of flow that entrain considerable amounts of sediment from the channel bed as well as channel banks and possibly flood plains. As noted in Section 13.4, surge speeds up to about 5 m/s have been recorded for break-up ice jams (Beltaos 1995). Such surges can be very erosive. Anecdotal evidence exists of a case where a surge resulted in the complete removal of a small island in a river. Not unexpectedly, concentrations of suspended sediment greatly increase during the passage of a surge, as mentioned in Section 13.6.5.

**Fig. 13-24.** Variation of channel and thalweg sinuosity,  $\zeta$ , with channel slope,  $S_o$ . Figure adapted from Schumm and Khan (1972).

**Fig. 13-25.** Conceptual influence of an ice cover on a meandering channel of more-or-less uniform flow depth. The cover may cause the thalweg to straighten and meander loops to shorten.

**Fig. 13-26.** River-ice impact on the thalweg of a sinuous-braided channel. An ice cover causes the main thalweg to become more sinuous.

### 13.7.2 Impacts on Riverbanks

River ice may influence channel cross-section shape, alignment, and bed elevation through several geomechanical impacts on riverbanks:

1. Reducing riverbank strength by increasing pore-water pressure or by producing rapid drawdown of

the bank water table during dynamic ice-cover or ice-jam breakup. This impact is part of the overall consequences of freeze-thaw behavior for riverbanks under frigid conditions.

2. Tearing, battering, and dislodging riverbank material and vegetation during collapse of bankfast ice.
3. Gouging and abrading riverbank material and vegetation during an ice run.

The three impacts reduce riverbank resistance to scour and increase the local supply of sediment to the channel. The first two impacts are not well studied. The third has received some attention, but the extent to which it affects channel shape is unclear. It is normal for river channels and floodplains subject to ice to be denuded of larger vegetation, as is sketched in Fig. 13-27.

Engelhardt and Warren (1991), for instance, briefly describe the consequences of such combined processes for the Missouri River downstream of dams in Montana and North Dakota. Increased rates of ice-covered flow, increased movement up and down riverbanks, bank freezing at higher elevation, and more frequent freeze-thaw cycles exacerbate bank erosion. The consequences become noticeable in early spring, when large portions of riverbanks fail. Similar observations are reported by Zabilansky et al. (2001).

The ensuing subsections briefly discuss these impacts, beginning with a short review of riverbank-strength response to freezing and thawing.

**13.7.2.1 Freeze-Thaw Influences on Riverbank Strength** It is well known that the freezing and thawing of soil affect the erosion of riverbanks adjoining rivers and lakes. Lawson (1983; 1985) and Gatto (1988; 1995), among others, provide extensive reviews of the subject. In short, because frozen soil is more resistant to erosion

Fig. 13-27. Severe ice runs may inhibit riparian vegetation growth along riverbanks and floodplains.

than is unfrozen soil, riverbanks are less erodible while frozen. Freezing and thawing, however, usually weakens soils, making thawed (or thawing) riverbanks more susceptible to erosion. The net consequences for the overall rate of riverbank erosion, therefore, remain a matter of debate. Most likely, the net consequences vary regionally and from site to site.

Freeze-thaw cycles affect soil structure, porosity, permeability, and density. These changes in soil properties can substantially reduce soil shear strength and bearing capacity; strength reductions of as much as 95% are reported (Andersland and Anderson 1990). Such adverse effects on soil strength depend on soil-particle size and gradation, moisture content, the number and duration of freeze-thaw cycles, and several other factors. Though there is no single, standard test to determine whether a soil is prone to significant weakening due to freeze-thaw (Chamberlain 1981), particle size is commonly used as an approximate indicator of soil sensitivity to freeze-thaw weakening. Soils containing fine sands and silts are especially sensitive, because they are permeable and susceptible to change in soil structure. By virtue of their particle size (about 0.1 to 0.06 mm) and the surface-tension properties of water, fine sandy and silty soils absorb moisture more readily

than do coarser or fine sediment. Clayey soils are less sensitive, because of their low permeability. The variability of soil properties along a riverbank and within a specific riverbank location causes the effects of riverbank freezing to differ along a reach.

Gatto (1995) suggests that an eroding riverbank is especially subject to deep penetration of freezing, thereby making more of the riverbank prone to freeze-thaw weakening and erosion. The absence or stunted extent of vegetation that characterizes many eroding riverbanks results in diminished insulation of the riverbank and increased heat loss to air. In addition, the crest region of a riverbank experiences greatest heat loss, owing to the crest's exposure to air on at least two sides. Because of its exposure to wind, the crest may also accumulate less snow. Less snow, in turn, means deeper frost penetration during winter and faster thaw in spring. However, less snowmelt is available to percolate into the riverbank. Questions exist about the exact manner in which border ice is anchored to the riverbank, and other factors (notably, variations in water-table (or piezometric) surface and moisture content of the top zone of the riverbank) would modify the extent of the frozen zone and its connection with river ice. Presumably, if the top portion of the riverbank and upland were dry, the riverbank crest might be the zone of

least heat loss, because the distance between air and water table is greatest there.

As the upper zone of frozen ground thaws, melt water likely drains down, over the surface of the still frozen ground. The riverbank, weakened by thaw expansion of ground and subject to the seepage pressures, is in its least stable, annual condition.

Several studies (e.g., Harlan and Nixon 1978; Reid 1985) have found that south-facing riverbanks (in the northern hemisphere) experience lesser thickness of freezing, all else being equal, than north-facing riverbanks. The explanation for this is that south-facing riverbanks receive more insolation (energy in the form of short-wave radiation from the sun). South-facing riverbanks also may undergo more diurnal frequent freeze-thaw cycles (Gatto 1995). The net effect of riverbank alignment on weakening of riverbank material has yet to be determined.

**13.7.2.2 Reduction of Riverbank Strength** Flow stage and stage fluctuations influence seepage pressures and the freeze-thaw behavior of riverbanks. Higher flow stage raises water table in a riverbank, and a rapid drop in flow stage may momentarily reduce riverbank stability by increasing seepage pressures and thereby reducing the shearing resistance of the material comprising the riverbank. Ice-cover formation raises flow stage, whereas cover breakup may abruptly lower it. River-ice formation, thereby, may weaken riverbanks.

Riverbank freezing is closely linked to bankfast-ice formation along a channel, though the details of relationship between them are unclear. They depend on riverbank condition (material, vegetation, snow, etc.), the relative elevations of water table and flow stage, and temperatures of groundwater and river water. The strength of bankfast-ice attachment

to a bank depends on the relative elevations of the water table and flow stage and on the relative water temperatures. A relatively warm (i.e., several degrees above freezing) flow of groundwater into a river will retard bankfast-ice growth and weaken its hold on the bank. The growth of a thick fringe of bankfast ice, on the other hand, may affect seepage flow through the bank, possibly constricting it and slightly raising the water table. This is especially significant for regulated rivers, for which flows do not diminish during winter.

**13.7.2.3 Bankfast-Ice Loading of Bank** Bankfast-ice weakening of banks likely is significant for steep banks, typically those banks containing sufficient clay to be termed cohesive. It also likely is significant for banks whose water table declines in elevation away from flow elevation in a channel, because the bankfast ice is less securely anchored into the bank. This erosion mechanism seems not to have been investigated heretofore but was observed, e.g., along the Fort Peck reach of the Missouri River (Zabilansky et al. 2001). When the flow stage in a channel drops, portions of an ice cover attached to a bank during the higher flow stage may be left momentarily cantilevered from the bank. The cantilevered ice soon collapses, weakening and wrenching bank material as it does so.

Figure 13-28 illustrates how bankfast ice might weaken a bank. The ice cover freezes into the bank. The extent of the root is limited by groundwater elevation and temperature and by the nature of the bank material. When the water level in the channel drops and the ice cover breaks up, ice attached to the bank is cantilevered out from the bank, rotates, and tears a portion of the bank as it drops. It is difficult to get direct field observations of this mechanism for bankfast ice attached to vertical banks. For the moment, evidence for

Fig. 13-28. Collapse of shorefast ice may erode banks when flow stage is lowered.

it is circumstantial. There is evidence for a related mechanism commonly termed plucking, which is the loss of riprap stones frozen to an ice sheet. Wuebben (1995), for instance, discusses plucking concerns extensively in the design of riprap for bank protection.

**13.7.2.4 Gouging and Abrasion of Banks** During heavy ice runs resulting from ice-cover break-up or ice-jam release, large pieces of ice potentially may gouge and abrade channel banks. There exists significant evidence showing that it substantially affects channel-bank morphology subject to dynamic ice runs (Marusenko 1956; Hamelin 1979; Smith 1979; Martinson 1980; Uunila 1997; USACE 1983; Doyle 1988; Brooks 1993; Wuebben 1995; Wuebben and Gagnon 1995). Such channels usually are relatively steep and convey high-velocity flows. Moreover, their ice covers typically break up fairly dramatically in concert with a sudden rise in flow, due, for example, to rapid snowmelt and/or rain. The resultant ice rubble comprises hard, angular blocks of ice.

One study of 24 rivers in Alberta (Smith 1979) led to the intriguing hypothesis that ice runs enlarge channel cross sections at bank-full stage by as much as 2.6 to 3 times those of comparable-flow rivers not subject to ice runs. The hypothesis is based on a comparison of the recurrence interval of bank-full flows in the 24 rivers and an empirical relationship between the cross-section area and flow rate for bank-full flow. The channel-widening effect of ice runs is plausible. However, the extent of widening indicated seems overlarge and requires further confirmation. Kellerhals and Church (1980), in a discussion of Smith (1979), argue against Smith's hypothesis. They suggest that other factors have led to an apparent widening of the channels analyzed by Smith; e.g., recent entrenchment of major rivers in Alberta and ice-jam effects of flow levels. Moreover, it is possible that the banks are somewhat protected by a band of ice forming a shear wall flanking the riverbanks. It is interesting to contrast Smith's hypothesis with a further hypothesis mentioned previously that ice jams may promote channel narrowing by causing overbank flow (e.g., Uunila 1997). For channels whose dominant channel-forming flow coincides with ice-cover breakup, overbank loss of flow reduces the flow rate to one that can be accommodated by the channel.

In many situations, notably those in which an ice run is sluggish, a shear wall of broken ice may fend moving ice from contacting the bank. The shear wall usually becomes smooth-faced, and protects riverbanks from direct ice impact or gouging. Running ice, if sufficiently thick, may still gouge the lower portion of a bank. Significant gouging may occur downstream of the toe of a jam, before the arrival of sufficient ice rubble to form shear walls. A surge front released from the jam may fracture an ice cover into large slabs, which then are set in motion. The surge front typically moves faster than the ice rubble comprising the jam, but gradually attenuates. Typically, ice gouging occurs within a relatively short reach of a river.

Ice gouging and abrasion, though, can be severe for channel features protruding into the flow. In addition, channel locations with a substantial change in channel alignment are especially prone to ice-run gouging and abrasion; e.g., a sharp bend, point bar, and portions of a channel confluence. There is a little information on how ice runs affect the local morphology of these sites. Two features have been observed in gravelly rivers: ice-push ridges and cobble pavements. Ice-push ridges form when a heavy ice run gouges and shoves sediment along the base of banks (e.g., Bird 1974). The gouged sediment piles up as ridges beneath the ice run as it comes to rest as a jam. The finer sediments eventually get washed out, leaving the more resistant gravel and boulders in ridges. The ridges usually develop in the vicinity of locations subject to recurrent ice jams.

Cobble pavements may cover bars and the lower portions of banks subject to ice gouging and abrasion. Essentially, an overriding mix of ice and cobbles removes the finer material from the surface of the bars or banks. The resultant cobble surface comprises cobbles whose major axis is aligned parallel to the channel and whose size gradually decreases downstream (Mackay and Mackay 1977). The resultant cobble pavement may extend for many miles along the banks of large northern rivers, such as the Mackenzie and Yukon Rivers (Kindle 1918; Wentworth 1932).

The gouging and abrasion of the lower portion of banks, in conjunction with overbank sediment deposition during ice-jam flooding, may produce an elevated ridge or bench feature along some northern rivers. These features have been dubbed *bechevniks* for Siberian rivers (Hamelin 1979). A *bechevnik* is the marginal strip comprising the lower portion of a riverbank and the exposed portion of the adjoining river bed that, in days gone by, formed a convenient path for towing boats upstream manually or by horse; *becheva* apparently is Russian for towrope. Figure 13-29 illustrates the main features of a *bechevnik*, which may form partly from ice abrasion and partly from the deposition of sediment and debris left by the melting of ice rubble stranded after ice runs.

Moving ice also may grind banks formed of soft rock (e.g., sandstones and mudstones) or stiff clay. Danilov (1972) and Dionne (1974), for instance, describe how moving ice has affected rock banks of rivers such as the St Lawrence River. The extent of erosion, though, is less than for banks formed of alluvial sediment.

Ice-run gouging and abrasion have an important, though as yet not quantified, effect on riparian vegetation that, in turn, may affect bank erosion and channel shifting. Where ice runs occur with about annual frequency, riparian vegetation communities have difficulty getting established. Ice abrasion and ice-jam flooding may suppress certain vegetation types along banks, as illustrated in Figs. 13-27 and 13-28 for a *bechevnik*, possibly exacerbating bank susceptibility to erosion. This aspect of river ice has yet to be further investigated.

**Fig. 13-29.** Sketch of a bechevnik. Figure adapted from Hamelin (1979).

**Fig. 13-30.** Hydraulic impacts (e.g., thalweg shift and bank-toe erosion), together with geomechanic impacts (e.g., freeze-thaw weakening of bank material, elevated seepage pressures, bankfast-ice loading) may weaken and erode channel banks, especially along channel bends, and results in continual overall channel destabilization.

Scrimgeour et al. (1994) and Prowse (2001) provide useful early reviews.

### 13.7.3 Combined Hydraulic and Geomechanical Impacts on Channels

A single hydraulic or geomechanical impact of river ice may disturb a channel, but not necessarily destabilize it. A combination of hydraulic and geomechanical impacts, though, may destabilize a channel. A shift in thalweg alignment or a bank failure alone may not destabilize a channel. The channel may adjust back more or less to its stable open-water condition once open-water conditions resume. Besides, a single ice impact may be damped or possibly constrained. For instance, flow concentration along a thalweg may be damped by an increase in bed resistance resulting from an increase in bed-form size, and bank erosion may be damped as bank slope consequently flattens. High banks, which deposit a large mass of sediment into the channel, or scour-resistant strata (e.g., a clay layer or rock outcrop) may constrain thalweg shifting or entrenchment.

It probably is not surprising that channels usually considered less stable under open-water conditions are more likely to be adversely impacted by river ice. Sinuous point-bar, sinuous braided, and braided alluvial channels are especially prone to river ice impact, especially if they have steep banks formed of fine and partially cohesive sediments. The thalwegs of such channels usually lie close to the outer banks of bends, and the banks themselves are prone to bank-fast-ice loading, lack of vegetation cover (typical of eroding banks), and freeze-thaw weakening. Figure 13-30 illustrates this susceptibility. The thalweg lies close to the bank, so that the flow continually erodes the bank-toe, thereby keeping the bank steep and possibly undercutting it. Snow cannot protectively blanket the bank face. Frost penetration potentially is deep, the water table is held relatively high, and the channel shifts, destabilized.

An intriguing question is whether the destabilizing impacts of river ice uniquely modify alluvial-channel morphology. Only a tentative answer can be suggested at this moment. It is likely that the major geometric parameters do not change appreciably (e.g., channel thalweg sinuosity, width, hydraulic radius, meander radius). However, river ice likely increases irregularities in channel planform and the frequencies with which channel cross section and thalweg alignment shift. In a sense, it adds noise to the signal form of an alluvial-channel in dynamic equilibrium.

## CHAPTER 14

# *Computational Modeling of Sedimentation Processes*

*William A. Thomas and Howard Chang*

### 14.1 INTRODUCTION

The notion that a river channel is stable is often accompanied by the mental image of a river channel whose bed profile, cross sections, and channel pattern do not change over time. However, dynamic equilibrium is a more appropriate concept for describing a stable alluvial channel. Dynamic equilibrium is the process by which an alluvial river transports its water-sediment mixture. Typical responses of a channel that is in dynamic equilibrium are deposition of sediment on the bed and erosion from it, channel widening and channel narrowing, bank failure and bank migration, smoother banks and rougher banks, the growth and removal of bank vegetation, and changes in the channel planform. Seldom do these processes occur singly. They are closely interrelated, and they seem to be delicately balanced to maintain a dynamic state of equilibrium. Experience has shown that changing or limiting one of these responses can impact the others (see Chapter 18).

The study of how a river develops is called river morphology by Leopold (1994) and Rosgen (1996) and fluvial geomorphology by Schumm (1971). River morphology studies correlate the dimensions, planform, and movement of a river channel with the historical loads imposed on it (see Chapter 6). The river can be described in terms of six variables:

- channel width;
- channel depth;
- channel slope;
- hydraulic roughness;
- bank line migration;
- channel pattern.

For example, the historical channel width is correlated with the historical water discharges and the type of materials that formed the banks of the channel. The channel depth and longitudinal slope are correlated with water discharge and the size of sediment particles. The meander pattern and changes in channel planform are correlated with channel width, slope,

and water discharge. In each case these variables are correlated with the load imposed on the river. That load is composed of the water-sediment mixture conveyed by the river and the base-level energy control.

However, the correlations are empirical and do not describe the physics of the processes. Without physical theories one is not able to calculate the reaction of a channel to changes in the loads imposed upon it. Therefore, river morphology studies alone are not adequate for project design, but they do make valuable contributions to river engineering. First, they identify the variables that river engineers must analyze and change in the design of a new project or in the restoration of an existing river to a historical condition. Second, river morphology studies recognize that those variables are interrelated. Third, the variables are identified as the dependent variables in a river system and not the independent variables. Fourth, the river morphology approach recognizes that the materials through which a natural river flows are extremely diverse, and it allows nature to aggregate the microdistributions of force and resistance into average values for the six variables listed above. Finally, river morphology studies provide a framework for identifying and organizing the data that are essential for the computational modeling of river systems.

This chapter presents a systematic procedure for applying one-dimensional computational sedimentation models to the study of alluvial rivers. A computational sedimentation model includes the five basic processes of sedimentation: erosion, entrainment, transportation, and deposition of mixtures of sediment particles, and compaction of sediment deposits. Of paramount importance is the fact that computational sedimentation models may include only some of the equations that are needed to predict the morphology of a river channel. Therefore, the river morphology equations that are included in one-dimensional computational sedimentation models need to be identified, and the model should then be used in combination with river morphology principles to perform the desired sediment study.

The water-sediment mixture conveyed by a channel and the base-level control go together to determine the load on the river system. The load is the independent variable in the correlations discussed above. The six variables that are listed are the dependent variables. The significance of classifying these variables as either dependent or independent has to do with project stability. A design can change the value of an independent variable, but if a dependent variable is changed it will not remain changed. For example, a project in which the channel width is increased will not function as designed without continual maintenance because channel width is a dependent variable. Two- and three-dimensional models are discussed in Chapter 15.

## 14.2 LOCAL SCOUR AND DEPOSITION

This chapter does not address local scour or deposition. Local scour, as compared to channel degradation, refers to the scour hole that forms around a bridge pier, downstream from a hydraulic structure, along the outside of a bend, etc. The process involves fluid forces beyond local boundary shear. Such forces come from three-dimensional flow accelerations, pressure fluctuations, and gravity forces on the sediment particles. Three-dimensional computational models that make such calculations are in various stages of development, but at present the complexity of local scour processes relegates analysis to empirical equations or physical model studies.

Local deposition refers to deposits over a relatively small space, as opposed to channel aggradation, which raises the bed profile of the river over a substantial distance. Local deposition can be predicted with one-dimensional equations provided that adequate attention is given to the rate of expansion of the flow, both horizontally and vertically.

## 14.3 GENERAL EQUATIONS FOR FLOW IN MOBILE BOUNDARY CHANNELS

### 14.3.1 Energy and Continuity Equations

The one-dimensional differential equations of gradually varied unsteady flow in movable bed channels are extensions of the Saint-Venant equations for rigid boundary channels. They are the equation of continuity for sediment, the equation of continuity for water, and the equation of motion for the water-sediment mixture. The forms developed by Chen (1973) are as follows:

$$\frac{\partial(\rho Q)}{\partial t} + \frac{\partial(\rho Q U)}{\partial x} + gA \frac{\partial(\rho y)}{\partial x} = \rho gA (S_o - S_f + D_l) \quad (14-1)$$

$$\frac{\partial Q}{\partial x} + \frac{\partial A}{\partial t} + \frac{\partial A_d}{\partial t} q_w = 0 \quad (14-2)$$

$$\frac{\partial G_s}{\partial x} + (1 - P) \frac{\partial A_d}{\partial t} + \frac{\partial A_s}{\partial t} - g_s = 0 \quad (14-3)$$

where

- $A$  = end area of channel cross section;
- $A_d$  = volume of sediment deposited on the bed per unit length of channel;
- $A_s$  = volume of sediment suspended in the water column per unit length of channel;
- $D_l$  = momentum loss due to lateral inflow;
- $g$  = acceleration of gravity;
- $G_s$  = sediment discharge;
- $g_s$  = lateral sediment inflow per unit length of channel, outflow (-), inflow (+);
- $P$  = porosity of the bed deposit (volume of voids divided by the total volume of sample);
- $Q$  = water discharge;
- $q_w$  = lateral water inflow per unit length of channel, outflow (-), inflow (+);
- $S_f$  = friction slope;
- $S_o$  = slope of channel bottom;
- $t$  = time;
- $U$  = flow velocity;
- $x$  = horizontal distance along the channel;
- $y$  = depth of flow;
- $\rho$  = density of the water.

The following assumptions were cited in deriving these equations:

1. The channel is sufficiently straight and uniform in the reach so that the flow characteristics may be physically represented by a one-dimensional mode.
2. The velocity is uniformly distributed over the cross section.
3. Hydrostatic pressure prevails at every point in the channel.
4. The water surface slope is small.
5. The density of the sediment-laden water is constant over the cross section.
6. The unsteady-flow resistance coefficient is assumed to be the same as for steady flow in alluvial channels and is approximated from resistance equations applicable to alluvial channels or from field survey.

### 14.3.2 Sediment Transport Equations

Sediment transport equations are so numerous and varied that only the most general functional form is selected to demonstrate the significant parameters,

$$G_s = f(\bar{U}, r, S_f, b, d_e, s, SF, d_{si}, P_i, s_l, T, C_{fm}) \quad (14-4)$$

where

- $\bar{U}$  = mean velocity at vertical;
- $r$  = hydraulic radius;

$S_f$  = slope of energy gradient;  
 $b$  = width;  
 $d_e$  = effective grain size of the bed material mixture;  
 $s_s$  = specific gravity of the particles;  
 $SF$  = shape factor of the particles,  $i$  in the bed mixture;  
 $D_{si}$  = diameter of each size class,  $i$  in the bed mixture;  
 $P_i$  = fraction of each size class,  $i$  in the bed mixture;  
 $s_f$  = specific gravity of the fluid;  
 $T$  = water temperature;  
 $C_{fm}$  = concentration of fine sediment in the water column.

The variables  $U$ ,  $r$ ,  $S_f$ , and  $b$  are the hydraulic parameters. Sediment grain parameters are  $d_e$ ,  $s_s$ ,  $SF$ ,  $D_{si}$ , and  $P_i$ . Fluid parameters are  $S_p G_f$ ,  $T$ , and  $C_{fm}$ .

Computational modeling requires that sediment transport be calculated by size class. Therefore, if the transport function is a single-grain-size representation, the computational model must provide a separate bed-sorting algorithm to account for hiding and armoring processes. Even the multiple-grain-size functions require additional, sophisticated bed-sorting algorithms to accommodate the nonequilibrium conditions in the entrainment, transportation, and deposition processes being modeled (Copeland 1993).

To date most researchers in sedimentation have dealt with sand-bed streams (see Chapter 2). Less is known about gravel transport (see Chapter 3). Even less research has been conducted on cobble/boulder transport than has been conducted for gravels. Cohesive sediment transport is not understood as well as noncohesive sedimentation (see Chapter 4). The processes include electrochemical forces, and the presence of the sediment particles can change the properties of the water-sediment mixture. Transport capacity does not obey the equilibrium principle, which states that the number of particles being deposited must equal the number being eroded.

### 14.3.3 Diffusion and the Diffusion Equation

In mathematical modeling of sediment processes, the sediment discharge potential is computed at each discrete cross section. These potentials reflect the current hydrodynamic forces in the flow field. However, the actual suspended sediment concentration profiles do not adjust immediately to changes in hydrodynamic forces. Both advection and diffusion are significant processes in the physics of adjustment.

The concepts of diffusion in turbulent flow are presented in Chapter 2 of this volume. For nonequilibrium sediment transport, the transport potential must be corrected for the advection-diffusion processes to account for conditions where the development length for equilibrium sediment transport is longer than the grid size  $\delta x$ . The correction for deposition is different from the correction for entrainment.

One approach to accommodating the diffusion process is to include the advection-diffusion equation in the entrainment and deposition calculations for material moving between the bed and the water column. Another approach is to approximate the diffusion process with entrainment and deposition coefficients. In either case the objective is to distinguish between the actual transport rate  $C'_s$  and the transport capacity  $C_s$  for the equilibrium condition.

Generally,

$$C'_s < C_s \quad \text{for} \quad U/x > 0 \quad (14-5)$$

and

$$C'_s > C_s \quad \text{for} \quad U/x < 0 \quad (14-6)$$

In the diffusion theory of sediment transport, the concentration of suspended load  $C$  is described by the convection-diffusion equation,

$$\frac{\partial C}{\partial t} + u \frac{\partial C}{\partial x} + \frac{\partial}{\partial x} \epsilon_x \frac{\partial C}{\partial x} = -\alpha w_s (C - C_*) \quad (14-7)$$

The first term in Eq. (14-7) accounts for a nonsteady concentration of sediment with respect to time. The second term accounts for the nonuniform distribution of concentration in the direction of flow. Each of those two terms is zero for equilibrium sediment transport with no local inflows. The third term accounts for the diffusion process.

The right-hand side of the equation accounts for the mass transfer between the bed and the water column. Mass transfer is based on the sediment deposition and the entrainment rates, where  $C_*$  is the equilibrium concentration of sediment or the potential carrying capacity of a specific flow, and  $\alpha$  is a dimensionless coefficient that characterizes the rate at which the new carrying capacity is attained. The term  $-w_s C$  represents the actual flux; the second term,  $w_s C_*$ , is the transport capacity flux. In other words, the rate of deposition (or entrainment) by the flow is proportional to the difference between the actual suspended load and the sediment transport capacity of the flow.

The value of  $\alpha$  must be determined separately for the cases of deposition and entrainment because of the different physical forces that dominate. The deposition case is the simpler of the two because it depends on the settling velocity of the sediment particles. Zhang et al. (1983) propose the expression

$$\alpha = 1 + \frac{P}{2} \quad (14-8)$$

where  $P$  is the Peclet number, defined as  $6w_s/\tau U_*$ .

In the case of entrainment, they propose the following relationship for  $\alpha'$ :

$$\alpha' = \frac{2}{P} + \frac{P}{4} \quad (14-9)$$

In solving Eq. (14-7) appropriate boundary conditions and initial conditions are required. The upstream boundary condition is given by

$$C = C_o \text{ at } x = x_o \quad (14-10)$$

where the subscript o designates values at the upstream boundary.

Another approach to accommodating the diffusion process in sedimentation modeling is using entrainment and deposition coefficients. In the case of deposition the settling velocities of the individual sediment grain sizes can be used to calculate the deposition coefficients. However, the entrainment process is not associated as strongly with the settling velocity of the sediment particles as it is with the hydrodynamic forces in the flow field. A surrogate parameter for estimating the entrainment coefficient is flow distance. Flow distance refers to the distance that the water-sediment mixture has to travel before the velocity and sediment concentration profiles reach equilibrium. The concept comes from physical modeling in a flume. Some claim that, in a flume, the distance from the headgate that is required for the flow to attain the theoretical vertical velocity-distribution profile predicted by the log-velocity distribution law is 100 times the flow depth. By similitude, the travel distance in the flume can be used to approximate requirements in the river. For example, use flow depth as the scaling parameter. Therefore, the distance in the river that is needed for the sediment concentration to increase from a lower to a higher equilibrium value could be approximated as a coefficient times the flow depth.

#### 14.3.4 Allocation of Scour and Fill

In one-dimensional modeling the solution of the sediment continuity equation provides a change in the cross-sectional area. That end area change must then be allocated to each coordinate point across the cross section. Different computational models approach the allocation calculation differently. In any case the computation of sedimentation processes is one-dimensional, which, at best, relegates the allocation calculation to an approximation. Consequently, the shape of the cross section is not a question to address with a one-dimensional sediment model. Perhaps some observations of different conditions will aid in understanding the different modeling approaches to this issue.

Emmett and Leopold (1963) investigated scour and fill of the bed profile and of the channel cross section in both ephemeral and perennial streams. They used scour chains,

so conditions during the passage of the hydrograph were not measured. However, in a stable river channel on a perennial stream, sediment tends to deposit in the crossings and to erode from the bends during a flood event. After the flood passes, the deposition/erosion sequence will switch, so the crossings will tend to erode and sediment will deposit in the bends. The distribution of erosion and deposition across a cross section will be shaped by the same hydraulic forces that shaped the initial cross sections. Therefore, deposition will not be horizontal nor will it fill the deepest portion of the cross section first. The allocation can be made as a veneer over the surface of the original cross section. Similitude suggests that both deposition and erosion can be applied to the cross section using the veneer concept. Thomas utilized this concept in developing HEC-6 (HEC-6 1977; 1993; Thomas 2002).

In the ephemeral channels of the arid southwest, visual observation suggests that the surface of the channel cross section is usually horizontal at the beginning and at the end of a runoff event. However, during the flood runoff it is reasonable to suspect that the cross section will be reshaped by hydrodynamic forces and sedimentation processes appropriate for flow through a river bend. That is, the secondary flow cells will move the thalweg toward the outside of the bend and will form the classical point bar pattern on the inside of the bend. In ephemeral streams the veneer concept is probably a poor approximation to actual sedimentation processes in the cross section during the passage of an flood event. Chang utilized that observation in developing FLUVIAL12 (1985).

A horizontal deposit is more likely in reservoir deposition than it is in a river channel. In a reservoir the bed material load seems to deposit in the original channel section first. It fills the channel feature, and the water-sediment mixture spills out laterally. When the reservoir level falls the channel will cut through the delta deposit in, perhaps, some new location. However, unless there is a change in the runoff discharges, the width and depth of the new channel will be very similar to those of the original channel. Consequently, a one-dimensional model is able to predict the rate of delta growth and the resulting water surface elevations even though it does not mimic the channel avulsion process.

The physics of sedimentation processes are such that a natural levee tends to build along the top bank of the channel (James 1985). Those forces are also active in reservoir deposition. Sediment size and water velocity are the significant parameters in determining how far sediment particles move away from the channel. This is not a one-dimensional process, and one-dimensional models approximate the process differently.

Some sedimentation models are built around the concept that the width and depth of a river channel will be adjusted to effectively reduce the streamwise variation in stream power as the river seeks to establish a new equilibrium. In such models, the allocation of scour and fill across a section for a time step is assumed to be a power function of the effective tractive force  $\tau_o - \tau_c$ . Chang proposes the equations for allocating scour and fill

$$\Delta z = \frac{(\tau_o - \tau_c)^m}{\sum_B (\tau_o - \tau_c)^m} \frac{\Delta A_b}{\Delta Y} \quad (14-11)$$

where

$\Delta z$  = the local correction in channel-bed elevation;

$\tau_o = \gamma DS$  = local tractive force;

$\tau_c$  = critical tractive force;

$m$  = exponent;

$y$  = horizontal coordinate; and

$B$  = channel width.

The value of  $\tau_c$  is zero in the case of fill.

The  $m$  value in Eq. (14-11) is generally between 0 and 1; it affects the pattern of scour-fill allocation. For the schematic cross section shown in Fig. 14-1, a small value of  $m$ , say 0.1, would mean a fairly uniform distribution of  $\Delta z$  across the section; a larger value, say 1, would give a less uniform distribution of  $\Delta z$ , and the local change will vary with the local tractive force or will vary roughly with the depth. The value of  $m$  is determined at each time step so the correction in channel bed profile will result in the most rapid movement toward uniformity in power expenditure, or linear water surface profile, along the channel.

Equation (14-11) can only be used in the absence of channel curvature. The change in bed area at a cross section in a curved reach is

$$\Delta A_b = \frac{1}{r_f} \int r dz dr \quad (14-12)$$

where  $r_f$  is the radius of curvature at the discharge centerline or thalweg. Because of the curvature, adjacent cross sections are not parallel and the spacing  $\Delta s$  between them varies across the width. Therefore, the distribution of  $\Delta z$  given in Eq. (14-11) needs to be weighted according to the  $r$ -coordinate

Fig. 14-1. Schematic cross-sectional change.

with respect to the thalweg radius  $r_f/r$  (Chang, 1985). The equation is

$$\Delta z = \frac{(\tau_o - \tau_c)^{m/r}}{\sum_B (\tau_o - \tau_c)^{m/r}} \cdot \frac{\Delta A_b}{\Delta r} \quad (14-13)$$

### 14.3.5 Channel Width

Channel width is one of the morphological variables listed previously. If the channel is too narrow for the runoff hydrology, the banks will erode, causing the channel width to increase. Likewise, in a channel experiencing bed erosion, banks will fail, resulting in channel widening. Modelers must accommodate changes to channel width, and the approach depends on the requirements of the model.

### 14.3.6 Planform and Bankline Migration

The natural alignment of an alluvial river channel is the result of hydrodynamic forces, sedimentation processes, and soil mechanics principles (see Chapter 8). The hydrodynamic forces are calculated from the conservation of energy, conservation of mass, and flow resistance. Sedimentation processes, as defined above, are the erosion, entrainment, transportation, and deposition of mixtures of sediment particles and the compaction of sediment deposits. Soil mechanics principles describe bank stability. However, channel-bed and bank materials are not homogeneous. The native materials range from inorganic and organic sediment particles to vegetation. The inorganic sediments range from cohesive clays to noncohesive boulders, and the organic sediments range from leaves to large woody debris. These different materials exhibit different strengths and weaknesses. They resist hydrodynamic forces via complex interactions that vary in time and space. For example, bank failure will remove trees and vegetation from the banks, resulting in a change of bank roughness. The effect of such a change in boundary roughness on energy dissipation is especially significant when the width/depth ratio is small.

For example, during the decade of the 1950s, creeks in northern Mississippi were converted into straight canals to improve drainage. The conversion changed the channel width and the slope. The first reaction of the creeks was erosion of the bed. Soon the bed had eroded so deeply that the banks became too high to remain stable, and bank failures occurred on a grand scale. As the channel became deeper, the bank-full water discharge increased, and that increased the amount of the total runoff energy that had to be dissipated on the channel bed and banks. The eroded banks not only were exposed to larger stresses from the larger channel discharges but also were exposed to erosive forces from raindrop impact.

At the same time that bank failure was increasing the channel capacity, it was reducing the hydraulic roughness. Two processes were involved. First, as the width/depth ratio increased, the effect of bank roughness on the composite hydraulic roughness of the channel cross section increased.

Second, the eroding banks removed the prevailing vegetation and prevented new growth. Consequently, the benefit of vegetation roughness on the banks was eliminated.

As the water and sediment mixture left the channelized reach at the downstream end, it entered the natural creek. However, the concentration of bed material load in the flow from the channelized reach was higher than could be transported in the natural creek. Transport capacity had returned to prechannelized conditions and was considerably less than in the channelized portion of the creek. Consequently, a deposition zone developed. The new deposits changed the current pattern, which initiated a new meander pattern. It is significant that where the channels were straightened during construction, they remained straight during the eroding phase of the channel evolution. However, when flow reached the deposition zone, channel meander intensified.

As time passed, all six channel parameters changed in the creeks of northern Mississippi. The amount of change showed significant variation from place to place. It is common to apply computational models to such problems and to use river morphology principles in developing the one-dimensional model. The channel evolution model proposed by Schumm et al. (1984) describes these processes.

The development of a river channel is often controlled by the microdistribution of its boundary materials along the stream corridor and not by the average of these distributions. Moreover, a single downed tree can realign an entire channel, change the channel pattern, and not change the channel width.

#### 14.4 SIMILARITY BETWEEN COMPUTATIONAL MODEL STUDIES AND PHYSICAL MODEL STUDIES

A computational model study can be organized into ten tasks as follows:

1. Assemble available data from office files: maps, cross sections, suspended sediment measurements, bed load data, bed material measurements, soil types/sediment yield, hydrographs, water temperature, observed water surface profiles, reservoirs in the basin, construction activities.
2. Develop geometric data set and run a steady-state water discharge: run a 2-year peak discharge to identify trouble spots and data gaps.
3. Make a reconnaissance trip through the study area: identify locations of bank and bed instability; observe features that will aid in establishing  $n$ -values of the bed, banks, and overbanks; give particular attention to locations appearing to be trouble spots; prepare requests for additional/missing data.
4. Calibrate  $n$ -values: run the model in fixed-bed mode to compare calculated water surface elevations to observed values; add sediment and run the model in

movable-bed mode; confirm that the calculated water surface approximates the observed value.

5. Develop the sedimentary data set: develop the bed gradation; develop the inflowing sediment concentration; select the transport function; develop the gradation of the inflowing sediment concentration.
6. Calibrate the model: estimate the channel-forming discharge in each segment; run a series of steady flows and confirm sediment delivery; run historical hydrographs and sediment concentrations and demonstrate that the model results will match specific gauge plots if data are available; confirm that model results match annual sediment yields.
7. Run base test: run the no-action condition using future conditions hydrology and sediment concentration.
8. Run plan test: define the conditions to be tested and organize into a series of model tests; install the conditions into the base test model, one at a time, and run.
9. Analyze results: compare the results of the plan test with those from the base test to evaluate how much impact sedimentation will have on the plan and how much impact the plan will have on stream system morphology.
10. Perform a sensitivity analysis: change the boundary condition values or the initial condition values by 25% and rerun; express model results as a comparison with those for the base test and the plans tested.

This list of tasks is not a recipe. It is suggested as tasks one can use to organize a model study. Exceptions to this organization are acceptable. However, it is desirable to document the reasons for exceptions.

The rationale for these ten tasks comes from the similarity between computational model studies and physical model studies. That rationale is presented in more detail in the subsections that follow.

##### 14.4.1 Model Limits

In physical model studies, the expression "model limits" refers to the limits of the prototype area that will be constructed in the model. The prototype refers to the actual project being studied. The space inside the model limits is the area that will be included in the model. Model construction is the process of molding the  $(x,y,z)$  dimensions of the prototype into the dimensions required for the scale model. Measurements of hydraulic parameters and the resulting sedimentation processes are made in the model area. The same concepts are followed in computational modeling. The process of converting the area of the prototype that is within the limits of the computational model into a digital representation of the prototype is called model development.

The location of model limits is not arbitrary. The inflow end of the model must be in a location where the inflowing water discharge and sediment concentration by particle size are known. The tailwater elevations at the outflow end

must be known. Moreover, these known values must not be changed by any changes that happen within the model area during the simulation period. The data assembled in Task 1 will be valuable in establishing model limits.

#### 14.4.2 Headgate and Tailgate

In physical model studies the main water supply at the upstream end enters the model area through a headgate that regulates the inflowing water discharge rate and the flow pattern. Flow leaves the model area at a tailgate that regulates the tailwater elevation. These facilities provide the necessary boundary conditions for the model study. In this case, boundary conditions do not refer to the geometry or surface conditions within the model area.

#### 14.4.3 Boundary Conditions for the Computational Model

Mathematically, computational sedimentation modeling is an initial-boundary value problem. That is, there are more unknowns to be solved than there are equations. Therefore, the problem is conditioned by prescribing the missing unknowns at the inflow and outflow boundaries of the model. There are four boundary conditions: the inflowing water discharge, the inflowing sediment concentration by particle size, the tailwater elevation, and the water temperature.

The need for inflowing water and sediment loads form a requirement in the computational model that is analogous to the headgate of a physical model. The need for a tailwater elevation (i.e., base-level control) in the computational model is analogous to the requirement for a tailgate in a physical model study.

#### 14.4.4 Survey Data for Initial Conditions

The initial geometry of the prototype in the model area is needed to establish the starting conditions for the model study. Surveyed data must have sufficient resolution to establish hydraulic and sediment controls throughout the model area. These data are used for model design and construction. Tasks 2 and 3, cited above, pertain to model design and construction.

#### 14.4.5 Survey Data for Final Conditions

A final geometry of the prototype in the model area is needed at the end of a sufficiently long period of time to verify the computational model.

#### 14.4.6 Model Calibration

Model calibration is a process used in both physical and computational modeling. It is the process of demonstrating that the model is behaving like the prototype. Although the

parameters being observed in a physical model are often more detailed than those in the computational model, the concept of demonstrating agreement with the prototype is the same in both. Tasks 4, 5, and 6 pertain to calibration of the computational model.

#### 14.4.7 Base Test and Plan Tests

To minimize model biases, the usual procedure in physical model studies is to run a base test in which existing conditions are extended into the future. The project being studied is then inserted into the model and the test is rerun. The impact of the plan is measured by comparing the model results of the plan test with those from the base test. This same procedure is suggested for computational modeling. Tasks 7 through 10 pertain to running the model tests and analyzing the results.

#### 14.4.8 Selection of Physical Model versus Computational Model

One of the most difficult tasks is deciding whether to use physical modeling or computational modeling in a sedimentation study. Dimensionality and scale are important technical parameters in the decision. Time and cost are important economic parameters. Each project has specific needs that must be factored into decisions as that project is moved through the formulation process. In the early planning phase, preliminary estimates of sedimentation are adequate most of the time. A key consideration is whether the impact of sediment on the project, or the impact of the project on the stream system morphology, could reverse decisions about project feasibility. In the engineering and design phase, sedimentation questions must be resolved in detail. It may be necessary to switch from computational models to physical models to achieve the necessary detail. These general concepts are discussed more specifically in the following examples.

For example, if the decision involves how to align and position a navigation channel within the river cross section, the problem needs a physical model. This is a three-dimensional hydrodynamic problem having a movable boundary. Computational modeling of such processes is evolving, but it is still largely experimental. Physical modeling is appropriate for such studies, provided the modeling approach recognizes what the significant sedimentation processes are and includes those processes in model calibration. The accuracy of physical modeling is affected by the scale distortion. In rigid-boundary hydraulics, the scale distortion may not be a serious problem, but in the case of erodible-boundary hydraulics, the scale distortion may not be totally overcome. Consequently, the selection of the modeling materials is very important.

On the other hand, if the decision requires prediction of maintenance dredging for a navigational channel located in the deepest part of the cross section, a one- or two-dimensional

model is adequate. The one-dimensional model will not predict where the deepest part of the cross section will be, but it will predict the size of cross section that is required to transport the inflowing sediment load.

Decisions involving flow in bends are three-dimensional. Also, when the decision requires predicting the concentration of sediment that would be diverted through an outflow structure, either a physical model or a three-dimensional computational model is required. Neither one- nor two-dimensional computational models account for the secondary flows that control the distribution of the bed material load.

Flow through an expansion or contraction can usually be treated as a two-dimensional process. Sedimentation processes can be analyzed with a two-dimensional model or, if conveyance limits that approximate the rate of expansion can be established, the calculation can be made with a one-dimensional model. Examples are a dike field or a sediment trap.

If the decision involves flood elevations, either in a reservoir or in an open river site, reliable predictions can be made without knowing exactly where the deepest part of the channel will form in the cross section. Such a problem can be evaluated using a one-dimensional computational model.

The performance of hydraulic structures is a three-dimensional problem. Decisions involving sedimentation processes should probably be analyzed with a physical model at this point in time. However, the utility of three-dimensional computational models is advancing at such a rate that one should consider that approach in the model selection phase of a study.

## 14.5 DATA TYPES AND RESOLUTION

### 14.5.1 Introduction

Generally, data requirements are grouped into two types. One type helps the engineer to understand the historical behavior of the prototype. The other data group is the data that are needed to develop and operate the computational model. The data used to understand the behavior of the prototype are summarized in the next paragraph.

**14.5.1.1 History of Prototype** The *project area and study area boundaries* should be marked on a project map to delineate the area needing data. Add the lateral limits of the study area and the tributaries to this study area map. *Bed profiles* from historical surveys in the project area are extremely valuable for determining the historical trends that which the model must reconstitute. Use *aerial photographs* and aerial mosaics of the project area to identify historical trends in channel width, meander wavelength, rate of bank line movement, and land use in the basin. Analyze *stream gauge records* to determine the annual water yield to the project area and the water yield from it. Obtain annual peak discharge frequency curves for the project. These are useful for assessing the historical stability of hydraulic parameters

such as width, depth, velocity, slope, and channel pattern. Analyze the stage-discharge curves in and around the project reach for trends. It is important to work with measured data. Do not regard the extrapolated portion of a rating curve as measured data. An example of this is shown in Fig. 14-2 where the measured flows are less than 52.39 m<sup>3</sup>/s (1,850 cfs) and the project formulation flows range up to 453.07 m<sup>3</sup>/s (16,000 cfs). Hydraulic data such as measured water surface profiles, velocities, and flood limits in the project reach are extremely valuable. Local action agencies, newspapers, and residents along the stream are sources of information when field measurements are not available.

**14.5.1.2 Model Development** Developing the one-dimensional representation of a three-dimensional open channel flow problem is an art. It requires one to visualize the three-dimensional flow lines in the actual problem and translate that image into a one-dimensional model. This step will often require several iterations to arrive at an acceptable model. The concept is one of developing representative data. A successful approach is to creep up on a solution by first running an approximation of the problem using simplified geometry and hydrology and the best sediment data available. Next, a fixed bed model of the actual geometry should be developed and run using three steady-state water discharges: low-flow, median-flow, and high-flow. Sediment should be added to this model and run with the same three discharges. Finally, the actual hydrology should be run to verify model calculations, to run the base test, and to run the plan tests.

### 14.5.2 Geometric Data

Mobile-bed water surface profile models calculate the water surface elevation and the bed surface elevation as they change over time. It is necessary to prescribe the starting geometry. This is done using cross sections for one-dimensional models. After that, computations will either aggrade or degrade the cross sections in response to mobile-bed theory. The cross sections never change locations.

**14.5.2.1 Cross-Sectional Layout and Spacing** It is customary to view and lay out cross sections from left to right, facing downstream. As in fixed-bed calculations, it is important to locate the cross sections so that they model the channel contractions and expansions.

It is particularly important in mobile boundary modeling to recognize where conveyance limits are needed. That is, if it is not physically possible for flow to expand laterally to the full width of the prototype, then determine how much of the cross section will convey flow and set conveyance limits in the model. Conveyance limits can result from internal embankments or from the lateral rate of expansion of a flow jet.

There is no theory for spacing cross sections. Some studies have required distances as short as a fraction of the river width. Other studies have allowed cross sections to be

Fig. 14-2. Extrapolated discharge rating curve.

spaced from 16 to 32 km (10 to 20 mi) apart. The objective is to develop a model that will reconstitute the historical response of the streambed profile. The usual approach is to start with geometry that has already been developed for water surface profile calculations and transform it into geometry needed for sedimentation calculations.

There may be cases where cross sections must be eliminated from the data set to preserve model behavior. An example is a cross section in a bend or at a junction where the shape of the section is molded by three-dimensional hydraulic forces. It is not possible to reconstitute the shape of such sections with a one-dimensional hydraulic-sediment transport calculation. Those cases are the exception.

Document cross section locations for future reference using a layout map such as Fig. 14-3. River mile (or channel station) is suggested for the cross section identification number. It makes it much easier to use or modify an old data file if the cross sections are referenced by their position along the river rather than an arbitrary cross section number.

**14.5.2.2 Hydraulic Roughness** In a fixed-bed hydraulics study a range of  $n$ -values is typically chosen. The low end of that range provides velocities for riprap design, and the high end of the range provides the water-surface elevations for flood protection. In movable-bed studies such an approach is not satisfactory. The relationship between

sediment transport and hydraulic roughness is too significant. Manning's  $n$ -values, which do not agree with that relationship, will either predict too much sand yield, too little sand yield, too much bed degradation, or too much bed aggradation. Analytical procedures that link  $n$ -values with hydraulic and sediment parameters are called bed roughness predictors. Models often provide bed roughness predictors. If so, modelers are encouraged to use these procedures in computational sedimentation. Brownlie (1983) developed a procedure for calculating the  $n$ -value in sand-bed streams. The procedure predicts the bed regime as well as the transition between upper and lower regimes.

Limerinos (1970) correlated field measurements to provide an equation for channel roughness in gravel-bed streams. Although not strictly a bed roughness equation, it was developed from data in which the channels were wide relative to their depth. Consequently, it can be used as a bed roughness predictor. The procedure does not predict bed regime.

Jarrett (1985) published a regression equation for composite channel roughness in Colorado streams. Although it may provide dependable results, it should be used as a composite channel roughness equation and not as a bed roughness equation.

Other methods for calculating  $n$ -values will surely become available as time passes, but the present bed roughness predictors are not substitutes for field measurements.

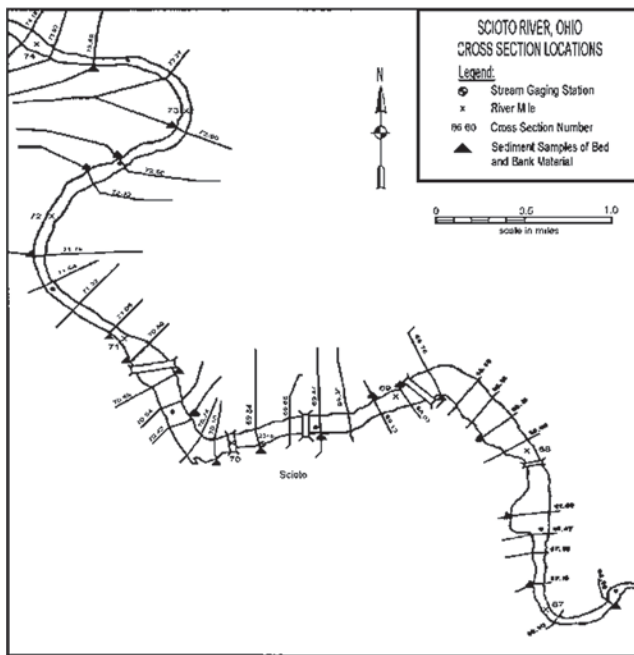

Fig. 14-3. Cross-sectional locations.

Measurements of water surface profiles and water discharges provide data that can be compared to model calculations. That is the most dependable technique for demonstrating hydraulic calibration. The second most dependable method is to reconstitute measured gage records.

Regard data sets collected from a flood event as snapshots in time. When several of those snapshots are used along with the bed roughness predictors, the resulting calculation will account for variations in the hydraulic/sediment parameters during the entire runoff hydrograph. As a result, model performance will improve significantly.

In using bed roughness predictor equations, it is important to separate bed roughness from bank roughness. The equations do not include banks in the data set. Because bed roughness is completely tied to analytical equations, it cannot be used as the calibration parameter to match the calculated water surface elevation to historical flood profiles. That leaves bank roughness as the calibration parameter. There are no bank roughness equations, but the selection of  $n$ -values is not arbitrary. A systematic procedure for the selection of overbank  $n$ -values was developed by Arcement and Schneider (1989). They used Cowan's approach to associate  $n$ -value with surface grain, surface regularity, and surface vegetation materials. Their approach provides a systematic procedure for the selection of bank  $n$ -values, also. To apply this approach, document prototype conditions with photographs during the field reconnaissance.

The separation of bed from bank  $n$ -values requires that a composite channel  $n$ -value be calculated before the calculation of hydraulic parameters for the channel subsection. Compositing methods are described in Chow (1959).

Contraction and expansion losses, sometimes referred to as minor losses, are often included in sedimentation models. The information on contraction and expansion losses is more sparse than that for  $n$ -values. King and Brater (1963) give values of 0.5 and 1.0 for a sudden change in area accompanied by sharp corners and values of 0.05 and 0.10 for the best case. Design values of 0.10 and 0.20 are suggested. They cite Hinds (1928) as their reference. Values often cited by the U.S. Army Corps of Engineers are 0.1 and 0.3, contraction and expansion respectively, for gradual transitions. An acceptable alternative is to increase  $n$ -values to account for the effect of an irregular bank alignment.

### 14.5.3 Sediment Data

#### 14.5.3.1 Size and Properties of Bed Sediment Reservoir

The bed sediment reservoir is the space in the bed of the stream from which sediment can be eroded or onto which it can be deposited. This reservoir occupies the entire width of the channel, and in some cases the width of the overbank also. However, it might have zero depth, as in a concrete channel, at a rock outcrop, or over an erosion-resistant clay layer.

##### 14.5.3.1.1 Gradation of the Bed Sediment Reservoir

It is necessary to prescribe the gradation of sediment in the bed sediment reservoir. Section 14.5.3.1.2 gives insight into selecting sample locations for use in calculating an inflowing sand and gravel discharge rate. This section gives information to consider in selecting locations for sampling the bed. Studies need representative gradations for calculating sediment-transport capacity plus representative gradations for calculating stream-bed stability.

It is important to group bed samples according to geomorphological features and to select from the groups depending upon the purpose of the computation. For example, two samples were taken in the dry at 27 cross sections spaced over a 32 km (20-mi) reach of the creek in one study. One set of samples was near the water's edge and the other was from the point bar deposits about half the distance from the water's edge to the vegetated bank. These samples were considered as two populations, statistically, and sieved separately. The resulting gradations were plotted as bed gradation profiles, Fig. 14-4. The midbar samples were used to develop sediment transport rates for model calibration because they were taken from material deposited during high water. However, the results from the water-edge samples were used in the long-term simulations because the primary purpose of the study was to test for stream-bed erosion and these samples were coarser than the midbar population.

It is important to recognize that sampling the bed for a sedimentation study is an art. It is one of those activities that must result in providing representative data for a one-dimensional model. That means representative in the  $(x, y, z, t)$  coordinate system. It is common for one-dimensional models to develop a representative gradation for the bed surface at a cross section and to treat that bed as a homogeneous mixture

Fig. 14-4. Bed sediment profiles.

in the vertical. That is not adequate in cases where distinct layering is present in the bed-sediment reservoir. Bed layering is likely to be more of a problem on a coarse-bed stream than on a sand-bed stream. For example, bed layering is common at bridges because they are usually located at contractions. Pronounced bed layering can be created by a major flood runoff. In cases when layering is a problem, the model must be run in such a way as to approximate the effect of the change in bed gradation with respect to depth.

**14.5.3.1.2 Sampling Concepts** Sampling is largely a matter of experience. Sampling equipment and its operation have been standardized, but there are no standards for identifying the locations for collecting samples. The objective is to produce representative data. In this case “representative data” means a bed gradation curve that will produce the measured sediment concentrations in the flow field when used in concert with the representative channel hydraulics data.

In the absence of standards, the following general concepts are offered.

- The first choice of sample location is to sample in the dry. This allows the engineer to see the variability of the bed surface material and to collect samples that are representative of the active bed surface area.
- Use standard, calibrated sampling equipment and procedures. The Federal Interagency Sedimentation

Project, located at the U.S. Army Engineer Waterways Experiment Station in Vicksburg, Miss., is responsible for standardizing sampling equipment.

- Organize sample sites into groups according to similar morphological features. Point or alternate bar samples probably provide the most representative gradations to use in calculating equilibrium sediment transport.
- In sand-bed streams, sample the depth of the active layer. If that is difficult to ascertain, favor about a 50 mm (2-in) depth, because that is the zone covered by the BM54 sampler.
- In gravel-bed streams, sample the surface layer and about 1 ft beneath the surface. Analyze the samples separately and composite the resulting gradations. Note the maximum size present on the bed surface, and include the larger sizes in bed gradation curves, because they will be necessary for bed stability calculations. Large sample volumes are recommended to avoid bias.
- Collect a sufficient number of bed and bank samples to provide a representative bed gradation for equilibrium sediment transport theory. The samples can be spatially weighted provided the distribution of sediment in the flow field is uniform over that same space. Otherwise, sample weighting should be adjusted in favor of the most active portion of the cross section for transporting bed material.

The sample locations cited for sediment transport calculations often miss the coarsest sizes in the stream bed. Therefore, also sample the stream bed in the geomorphological locations where coarser sediments are known to collect, such as deeper parts of the cross sections and the crossings. These samples will be important in bed profile stability calculations.

**14.5.3.1.3 Variability of Samples** There is often more variability from one side of the channel, or the point bar, to the other side than there is along the length of the sampled reach. Take a sufficient number of samples to be sure that this variability has been represented. A test of sufficiency is when the addition of one more sample does not change the composite bed gradation curve for the reach by a significant amount.

**14.5.3.1.4 Test for Sufficiency** The final test for sufficiency is to run the sampled gradations in the computational model using water discharges from the hydrograph prior to the time when samples were collected. The first event will entrain a high concentration from the new disturbed bed; subsequent iterations with that same water discharge should produce bed material load concentrations that match prototype measurements.

### 14.5.3.2 Size and Concentration of Inflowing Sediment Load

**14.5.3.2.1 Inflowing Sediment Concentrations** Occasionally suspended sediment concentration measurements, expressed as milligrams per liter, are available. These are usually plotted versus water discharge, Fig. 14-5. As in most cases, the concentrations in Fig. 14-5 show a great deal of scatter; however, such graphs are useful in developing or extrapolating the inflowing sediment data. It is desirable in most cases to develop the best estimate of the inflowing sediment concentration curve using the concentration graphs and then convert those values into sediment discharges in tons/day. That result is a sediment discharge rating curve, Fig. 14-6. The scatter is reduced from Fig. 14-5 but that is not because the correlation is better. It is because water discharge is being plotted on both axes. A scatter of about 1 log cycle is common in such graphs.

**14.5.3.2.2 Grain Size Classes** The total sediment discharge should then be partitioned into grain size classes. Table 14-1 shows the procedure that was developed for the Clearwater River at Lewiston, Id. Figure 14-7 is a graph of the sediment discharge by grain size class.

Fig. 14-5. Sediment concentration measurements.

Fig. 14-6. Sediment discharge rating curve.

**14.5.3.2.3 Calculating Sediment Inflow with Transport Theory** When no suspended sediment measurements are available, the inflowing sediment boundary condition must be calculated with sediment transport theory. There is no theory for calculating the wash load concentration from sediment samples of the stream bed. This calculation can be made only for sand- and gravel-bed sediment using equilibrium sediment transport functions. The calculation should be made by particle size for the full range of water discharges in the study hydrograph.

Select the reach of channel very carefully for this calculation. The first choice is a reach approaching the project where the slope, velocity, width, and depth at one representative of the historical hydraulics. This reach should have a history of conveying the inflowing sediment load without aggradation or degradation. The selected reach should also have a bed surface that is in equilibrium with the sand and gravel discharge being transported by the flow. Finally, the selected reach should have locations where the bed gradation can be measured using standard procedures.

The second choice for calculating the inflowing sediment concentration is a reach within the project area. A location near the upstream end of the project is desirable. It is important that the selected location be a stable reach and have a history of conveying the inflowing sediment discharge without appreciable aggradation or degradation.

An example of an inappropriate location for calculating the inflowing sediment load is a reach within the project where dredging is performed.

Einstein made the following suggestions for choosing a river reach to apply his bed-load function. His suggestions are also appropriate for other equilibrium sediment-transport functions.

In practical calculations of the bed-load function for a particular river reach, the length of the reach must be sufficient to permit adequate definition of the over-all slope of the channel. The channel itself should be sufficiently uniform in shape, sediment composition, slope and outside effects such as vegetation on the banks and

**Table 14-1 Distribution of Sediment Load by Grain Size Class (Clearwater River at Lewiston, Idaho)**

Grain size <sup>a</sup> diameter mm (1)	Classification (2)	Percent of total bed load <sup>b</sup> (3)	Bed load ton/day (4)	Percent of total suspended load <sup>c</sup> (5)	Suspended-load ton/day (6)	Total load Cols. (4) + (6) ton/day (7)

Total		100.00	1,900	100.00	400,000	401,900

<sup>a</sup>Values were read from the sediment load curve, 1972.74 measurements. (Total bed load, tons/day 1900.)

<sup>b</sup>These values were calculated by analyzing measured hydraulic parameters and measured bed loads using the computer program "Total River Sand Discharge and Detailed Distribution" by F. B. Toffaleti. (Total suspended load, tons/day 400,000.)

<sup>c</sup>These are representative values determined graphically by plotting the results of sieve analyses and developing a single percentage finer curve from all samples analyzed. (Total sediment load 401,900.)

Water discharge, cfs 200,000.

overbanks, that it can be treated as a uniform channel characterized by an over-all slope and by an average representative cross section. (Einstein 1950, p. 45)

Having located a suitable reach, measure a sufficient number of cross sections to establish the width, depth, and slope of the channel in that reach. Composite the measured cross sections into a single cross section that is representative of the river just upstream from the project. Again, quoting from Einstein on the description of a river reach:

One problem is that of determining how a number of cross sections can best be averaged. As the river reach is to be treated as a uniform channel with constant cross section and slope, in which only uniform flows are studied, a representative or average slope must be found, together with the average section. If a sufficiently long and regular profile exists for the river under consideration, the general slope of the reach should be taken from it. In the absence of such a profile, the slope must be derived from the cross sections themselves. Under all conditions, the cross sections must be tied together

by a traverse which gives their relative elevations and the distance between them along the stream axis. Then the wetted perimeter and the wetted area are calculated for various water surface elevations. These are plotted in terms of the water surface elevation for each cross section.

It is fairly common usage to construct the stream profile from the lowest points of the sections. This procedure is satisfactory for a long profile. If the reach is short, however, the use of a low-water surface is more satisfactory as the influence of insignificant local scour-holes is excluded. If such a low-water profile is not recorded when the sections are surveyed, a profile found from the area-curves may be substituted. A characteristic low-water discharge may be selected for the streams. The average velocity for such a flow can be estimated roughly. By division of the two one may find the corresponding low-water area of the cross sections. If the water-surface points which give this area at the different sections are connected, an approximate low-water surface is defined which represents a profile that is more regular and more representative than the profile of the low points of the bed.

Fig. 14-7. Sediment discharge rating curve by particle size class.

After the representative slope is selected, by fitting a straight line through the profile points, this slope may be used in averaging the cross sections. This can be done by sliding all the sections along this average slope line together into, for instance, the lowest section. (Einstein 1950, pp. 45–46)

Einstein applied this procedure to Big Sandy Creek near Greenwood, Miss. Eleven cross sections were selected. They were spaced roughly at three times the channel width for a total distance of 5181.6 m (17,000 ft) along the channel. Both bend and crossing sections were included. Using a low-flow water discharge and low-flow water velocity, the low-flow wetted area was calculated to be 4.65 m<sup>2</sup> (50 sq ft). When the elevation for 4.65m<sup>2</sup> (50 sq ft) was read from the individual cross section area-elevation curves and plotted versus channel station, the least-squares regression line through the points provided the channel slope. The slope was 0.00105 ft/ft in this example.

It is also important to develop a representative sample of the bed gradation for the equilibrium sediment transport

analysis. In the example application of his bed load function to Big Sandy Creek Einstein wrote:

The grain-size composition of the bed is determined by sampling. A bed which appears to be very uniform, such as that of Big Sand Creek, may be described by three to five samples. Each of the four samples listed . . . was a composite of three or four cores, taken in the same cross section at evenly spaced points over the total width of the channel. The individual samples were obtained by means of an auger or a pipe-sampler and were taken down to a depth of about 2 feet, the estimated depth of scour or active bed movement (Einstein 1950, pp. 45–46).

Treat the calculation of the inflowing sediment load as if it were a calculation to verify a sediment transport function. That is, locate the sample reach so that the point where the concentration is needed is at the downstream end. To the maximum extent possible, collect samples of the bed sediment over the same reach covered by the cross sections.

However, avoid using average geometry and bed gradation over extended lengths of a river when calculating the equilibrium sediment transport entering a study area. Instead, focus attention on the river channel approaching the point of interest. Use the following rules of thumb:

- Sample the bed surface gradation at and upstream from the gauge.
- Sample for a distance of 50 to 100 times the depth of flow. The idea is to provide a sufficient distance to allow the vertical distribution of velocity and sediment concentration in the water column to approach equilibrium conditions as depicted by hydraulic forces that are reasonably close the average over the reach.

#### 14.5.3.2.4 Typical Bed Gradation on a Point Bar

Figure 14-8 illustrates a typical bed surface gradation pattern on a point bar. Use such information to determine where to sample for a sediment transport calculation. Note that the typical grain sizes found on the bar surface form a pattern from coarse to fine, but there is no one location that always captures the precise distribution that will represent the entire range of processes in the prototype. The bed gradation controls the sediment discharge calculation. For example, true, multiple grain size transport functions like Laursen and Toffaleti show that the rate of transport increases exponentially as the grain size decreases, Fig. 14-9. There is no simple rule for locating samples. The general rule is “always seek representative samples.” That is, select sampling locations very carefully and avoid anomalies that would bias

Fig. 14-8. Gradation pattern on a bar.

either the calculated sediment discharge or the calculated bed stability against erosion.

**14.5.3.2.5 Sediment Inflow from Tributaries** The sediment inflow from tributaries is usually more difficult to establish than it is for the main stem because there are usually fewer data on the tributary. The recourse is to use the site reconnaissance to assess each tributary. For example, look for a delta at the mouths of the tributaries. Look for channel bed scour or deposition along the lower end of the tributary. Look for drop structures or other controls that would aid in stabilizing a tributary. Look for significant deposits if the tributaries have concrete linings. These observations guide the investigation of tributary sediment discharges.

### 14.5.4 Hydrologic Data

**14.5.4.1 Main Stem Water Inflows** Although a design water discharge is of interest, a single value is not adequate for a movable-bed computational model study. Simulating the change in channel behavior as the result of a flood requires the analysis of complete hydrographs. Consequently, the water discharge hydrograph must be developed. This step can involve manipulations of measured flows, or it can require a calculation of the runoff hydrograph.

Historical flows are needed for model calibration/verification because the model must reconstitute the historical behavior of the river, but future flows are needed to forecast the future stream-bed profile.

The length of the hydrograph period is important. Trends of a tenth of a foot per year becomes significant during a 50- or 100-year project life. On the other hand, a long-period hydrograph becomes a computation burden. Usually the bed profile changes are sufficiently slow to allow some aggregation of the forces involved. Therefore, aggregating the energy of a varying hydrograph into extended numbers of days is acceptable in most cases. For example, Fig. 14-10 shows the histogram for a year of mean daily flows.

In cases where measured flows are not available, the computational model still provides the framework for analyzing sedimentation in the project. Calculate hypothetical runoff hydrographs.

**14.5.4.2 Tributaries** Tributaries are a lateral boundary condition. They should be located, identified, and grouped as required to define the increase in water discharge as the drainage area increases along the project reach. The tributaries should be shown on the cross section location figure. Keep in mind that a 10% increase in water discharge will normally produce more than a 10% increase in bed material transport capacity. The transport relationship is nonlinear.

Often the tributaries are not gauged, and it is necessary to develop tributary inflows by analytical means. Table 14-2 illustrates such an approach in which six tributaries were grouped into three inflow points and their water discharges were calculated from the main stem discharge gage record.

Table 14-2 shows the 2-year flood peak at four locations along the project channel. These flood peaks were calculated

by a rainfall-runoff-routing program from subbasins. The peaks were then subtracted to determine the three lumped tributary inflow values, column 3. The ratio of  $Q$ -main at River Mile 7.903, 13,648/17,692, was calculated to determine  $f$ -main, column 4. The tributary discharge, 4,044, was divided by  $Q$ -main, 17,692, to determine the  $f$ -trib coefficient, 0.2296, in column 5. These tributary discharge coefficients were then applied to all flows in the long-term hydrograph of the study to calculate tributary inflows.

**14.5.4.3 Tailwater Elevation** The tailwater elevation specifies the water surface elevation at the downstream end of the project. It is referred to as a tailwater elevation (or base level) because it establishes the energy gradeline at the downstream end of the model. It can be a stage-discharge rating curve, such as Fig. 14-2, or it can be a stage hydrograph.

When a backwater condition exists, such as at the mouth of a tributary or in a reservoir, use a stage hydrograph as the boundary condition. Be sure it covers the same period of time as the inflow hydrographs.

**14.5.4.4 Water Temperature** The final boundary condition is the temperature of the inflowing water sediment mixture. Develop representative values by month or season if measurements are lacking.

**14.5.4.5 Boundary Condition Changes over Time** The historical water inflows, sediment concentrations, particle sizes, tailwater elevations, and water temperatures may change

in the future. That possibility should be evaluated for each project and the appropriate modifications made to the water sediment boundary condition values.

### 14.5.5 Operating Rules

The usual procedure for controlling the water surface elevation in a large reservoir is to follow a prescribed rule curve. Similarly, low-head dams may be operated to control the water surface at a gauge several miles upstream from the dam. Diversion structures are designed to pass a prescribed water discharge. In these cases the depth of flow is being controlled by manipulation of hydraulic structures and not by friction losses. This creates a modeling requirement called "operating rules." An operating rule is an internal boundary condition that will control the model.

### 14.5.6 Data Sources

**14.5.6.1 General** The data that will be needed to develop the model may come from office files, from other federal agencies, from state or local agencies, and from the team making the field reconnaissance of the project site.

**14.5.6.2 U.S. Geological Survey (USGS)** USGS topographic maps and mean daily discharges are used routinely in hydraulics and hydrology studies and are common

Fig. 14-9. Sensitivity of sediment transport potential to grain size.

Fig. 14-10. Histogram for a year of mean daily

Table 14-2 Distribution of Runoff by Tributary, 2-Year Flood Peak

River mile	<i>Q</i> -main cfs	<i>Q</i> -trib cfs	Discharge coefficients	
			<i>f</i> -main	<i>f</i> -trib
0-7.903	17,692			
		4,044	0.7714	0.2286
7.903-11.942	13,648			
		4,777	0.6500	0.2699
11.942-17.346	8,871			
		1,696	0.8088	0.0959
17.346-21.005	7,175			

data sources for sediment studies, also. However, mean daily flows are often not adequate for sediment studies, and data for intervals less than 1 day or stage-hydrographs for specific events can be obtained, through strip-chart stage recordings, by special request. It may be preferable to use USGS discharge-duration tables rather developing such in house, and these are available from the state office of the USGS. Water quality data include suspended sediment concentrations and grain size distributions. Published daily maximum and minimum sediment discharges for the year and for the period of record are available, as are periodic measurements of particle size gradations for bed sediments.

**14.5.6.3 National Weather Service (NWS)** There are cases where mean daily runoff can be calculated directly from rainfall records and expressed as a flow-duration curve without detailed hydrologic routing. In those cases use the rainfall data published monthly by the National Weather Service for each state. Hourly and 1-day interval rainfall data, depending on the station, are readily accessible. Shorter interval or period-of-record rainfall data would require contact with the NWS National Climatic Center at Asheville, N.C.

**14.5.6.4 Soil Conservation Service (SCS)** The local SCS office is a good point of contact for historic and future estimates of land use, land surface erosion, and sediment yield. They have soil maps, ground cover maps, and aerial photos that can be used as an aid in estimating sediment yield. Input data for the universal soil loss equation one available for much of the United States. The SCS also updates reservoir sedimentation reports for hundreds of reservoirs throughout the country every 5 years, providing a valuable source of measured sediment data.

**14.5.6.5 Agricultural Stabilization and Conservation Service (ASCS)** This agency of the Department of Agriculture accumulates aerial photographs of crop lands for allotment purposes. However, those photographs will include the streams crossing those lands and are extremely valuable for establishing historical channel behavior, because overflights are made periodically.

**14.5.6.6 U.S. Army Corps of Engineers** Because the Corps gathers discharge data for operating projects and for those being studied for possible construction, considerable data from the study area may already exist. The Corps has acquired considerable survey data, aerial and ground photography, and channel cross sections in connection with flood plain information studies. Corps laboratories have expertise and methods to assist in development of digital models.

**14.5.6.7 State Agencies** A number of states have climatologic, hydrologic, and sediment data collection programs. Topographic data, drainage areas, stream lengths, slopes, ground covers, travel times, etc. are often available.

**14.5.6.8 Local Agencies, Businesses and Residents** Land use planning data are normally obtained through local planning agencies. Cross section and topographic mapping data are often available. Local agencies and local residents have some

of the most valuable information to the engineer in their verbal and photographic descriptions of changes in the area over time, of channel changes from large flood events, of caving banks, of significant land use changes and when these changes occurred, of channel clearing/dredging operations, and other information. Newspapers and those who use the rivers and streams for their livelihood are valuable sources of data.

## 14.6 MODEL CALIBRATION

Computational studies fall into two general categories: (1) computational model studies and (2) computational analysis studies. Computational model studies are applications for which the model has been calibrated according to the formal procedures described in this chapter. Often the available field data are not sufficient to permit a formal calibration, but computational modeling is still the best method for analyzing the problem. In these cases model tests are devised so that engineering judgement can be used to assess the credibility of the calculated results. The resulting studies are called computational analysis studies.

Historically, there has not been a formal procedure for the calibration of computational models. Consequently, there has not been a formal definition of the word "calibration". It has been used to describe the initial work of adjusting a computational model until the calculated results matched whatever field data were available in the project area. This chapter proposes a formal calibration procedure. The word "calibration" will be reserved for those computational studies that have adequate field data to permit the implementation of the calibration procedure. Many studies will not have sufficient field data to calibrate models under this definition. Such studies will be beneficial because they will include the full computational capability of the model. Consequently, they will be called computational analysis studies rather than computational model studies.

Some believe that the word calibration should be reserved for instrumentation and have introduced the term "circumstantiation" to describe the process of demonstrating agreement between model and prototype. Their argument is based on the fact that model parameters are often adjusted using circumstantial evidence, whereas calibration is the result of scientific measurements. This chapter will continue the use of the term calibration.

### 14.6.1 Definitions

**14.6.1.1 Calibration** Calibration is the process of arriving at roughness coefficients, a sediment transport function, model parameters, and representative data on the study area that will allow the model to calculate values that agree with values measured in the prototype. For a one-dimensional model, the representative data are developed by transforming the three-dimensional ( $x, y, z$ ) space of the

prototype into a one-dimensional digital representation. Variables of interest are water surface elevations, velocities, depths, widths, hydraulic roughness values, the concentrations of sediment in the water column, the gradation of the sediment in the water column, the gradation of sediment in the bed, the delivery of sediment along the study area, and aggradation/degradation of the channel.

A model cannot be calibrated using a data set that was also used by that model to calculate some of its boundary conditions.

The field data used for model calibration should contain measured values of parameters similar to those for which the model is being calibrated. For example, if the purpose of the model study is to calculate aggradation or degradation of the channel profile, the calibration data should contain field data that include some historical information on the channel profile. The model is expected to reconstitute those measurements when it is provided with the boundary conditions that existed when the measurements were made. On the other hand, if the purpose of the model study is to evaluate the change in a water surface elevation as sedimentation processes change the channel over time, the calibration criteria should contain some field measurements of historical water surface elevations in the study area.

The examples in this section are given to illustrate the concept of model calibration. They are only a starting point for deciding what is required for a model to be calibrated. They are necessary, but they may not be sufficient to provide complete calibration for the general case. In principle, the requirements for calibration are based on the questions to be answered by the model results, and it is the responsibility of the engineer to develop and justify the steps that are required.

**14.6.1.2 Verification** A calibrated model is not necessarily a verified model. Verification is sometimes called a split record test. It demonstrates that the calibrated model will match the prototype during a period of time that is not used in calibration. The calibration parameters cannot be adjusted during model verification. Only the boundary conditions can be changed to those for the verification period.

**14.6.1.3 Computational Modeling** Computational modeling is the formal process of assembling data that provide the geometry of a study reach at two points in time and that provide a continuous record of the inflowing water discharge, the inflowing sediment load, and the downstream stages between those two points in time. Geometric data are provided by hydrographic/topographic surveys. The initial model geometry is developed from the first survey. The model is then run using the recorded hydrological and sedimentary boundary conditions, and the calculated results at the end of the simulation are compared with prototype values in the second survey.

**14.6.1.4 Computational Analysis** An alternative to computational modeling is computational analysis. Computational analysis is the application of a computational model

to a problem in which model calibration is not possible. Many sedimentation studies are made where there are not adequate prototype data to calibrate the model. Perhaps there is only one survey of the prototype. Perhaps there are two surveys, but boundary condition data are not available during the time period between the two. Perhaps the river is so highly disturbed that computational modeling is not possible. Whatever the case, computational analysis allows the engineer to use the latest technology in mobile boundary computations in decision making. Such studies are very useful because they recognize that we live in a movable-boundary world. How the study area responds to the systematic application of hydrodynamic and sedimentation theories illustrates how sensitive the area is to sedimentation processes. Often one can gain sufficient understanding to predict how reliable a plan will be by comparing the calculated results from the plan test with those from the base test.

In some cases, a computational analysis will demonstrate that the questions being asked are sufficiently sensitive to sedimentation processes so that prototype data must be collected before proceeding with a design.

#### 14.6.2 Fixed-Bed, Steady-State Hydraulic Calibration

Model calibration is approached in phases. The first phase is to reconstitute the water surface profile that was measured at the time the hydrographic survey was made. When the channel was dry during that survey, choose a low flow from the testing hydrograph. The purpose is to check the model geometry for consistency in width, depth, and slope and to check  $n$ -values. The mean error between calculated and measured water surface elevations should normally be within  $\pm 153$  mm (0.5 ft), or 10% of the flow depth, whichever is smaller. Because most surveys are made during low-flow-periods, this first test will be the low-flow test.

The next fixed-bed test should use a water discharge that is approximately the channel-forming discharge. In any case, the flow should not be out of banks for this test. The purpose is to check the geometry for consistency with regime concepts in channel widths and depths and to confirm channel  $n$ -values while all flow is still confined to the channel cross section. This  $n$ -value may be different from that developed for the low-flow condition. If so, the  $n$ -value should vary in the vertical later when hydrographs are included in the calibration process.

The final fixed-bed test should use the maximum water discharge in the testing hydrographs. At this point the calibration of the movable-bed model becomes more exacting than is usually performed for a fixed-bed calculation. That is, not only must the water surface elevation match known elevations but also the flow distribution between the channel and the overbanks must match the true prototype values. The only parameters available to achieve such a match are geometry and  $n$ -values. Geometry is usually more reliable than  $n$ -values, but it has been reduced to a one-dimensional

approximation of the prototype. Therefore, ascertain that the cross sections and reach lengths are the best representation of the flow conditions in the prototype. Additional adjustments in both water surface elevation and the percentage of flow that is conveyed in the channel are made with the  $n$ -values. The process is neither random nor arbitrary. The resulting values must pass the test of "reasonableness." Keep the process of selecting  $n$ -values systematic. Base the estimates on physical conditions by using a procedure such as that of Arcement and Schneider (1989).

### 14.6.3 Fixed-Bed, Unsteady-State Hydraulic Calibration

When the hydraulic calculations include the unsteady-flow terms, as in the Saint-Venant equations, the calibration of the routing model involves storage in the geometric model. This is an important adjustment because the hydraulic results drive the sedimentation calculations. Calibration of an unsteady-flow model is such a formidable process that the reader is referred to unsteady-flow modeling procedures. The process will not be presented here. The same cautions apply as presented earlier for steady-state, fixed-bed calibration.

### 14.6.4 Movable-Bed, Steady-State Hydraulic/Sediment Calibration

Start with a steady-state discharge that approximates the channel-forming discharge. In the more arid regions where streams are ephemeral the 10-year flood peak is usually a reasonable value for these calculations. Elsewhere, a discharge about equal to the 2-year flood peak is usually a reasonable value. In a regime channel this calculation can be made with the channel full discharge. Ascertain that the model is producing acceptable hydraulic results by not only reconstituting the water surface profile but also plotting the water velocity, depth, width, and slope profiles. This test will often reveal width increases between cross sections that are greater than the expansion rate of the fluid and therefore require conveyance limits. Extremely deep bend sections will occasionally indicate velocities that are not representative of sediment transport around the bend, and the recourse is to eliminate them from the model. The results from running this discharge will also give some insight into how close the existing channel is to a regime condition. That is, if there is overbank flow, justify that it also occurs in the prototype and is not just a numerical condition.

It is useful to determine the model performance for the channel-forming discharge because, if the channel is near regime, this should cause very little aggradation or degradation. Before focusing on sediment transport, however, demonstrate that the Manning  $n$ -value for the channel is appropriate for the movable boundary. Make whatever adjustments are necessary to ensure that the  $n$ -value for the stream-bed portion of the cross section is in reasonable

agreement with that from bed roughness predictors. Also, the sediment transport rate will usually be higher on the first computation event than it is on subsequent events because there is usually an abundance of fines in the bed samples that will be flushed out of the system as the bed layers are formed. The physical analogy is starting water flow down a newly constructed ditch. It is important to balance the sizes in the inflowing bed-material sediment load with transport potential and bed gradation. The scatter in measured data is usually sufficiently great to require smoothing, but the adopted curves should remain within that scatter.

It is useful to repeat this steady-state test for the maximum water discharge in the testing hydrograph. The key parameters to observe are water surface elevations, flow distribution between channel and overbanks, and velocities. However, each study is unique, and one should regard this paragraph as suggestions to illustrate thinking and not a list that is both necessary and sufficient.

**14.6.4.1  $n$ -Values** The first approximation of  $n$ -values was coded into the original model. At this point refine those values using field observations of stage or velocity.

**14.6.4.2 Water-Surface Profiles** With movable-bed calculations active, it is important to recheck the model-to-prototype comparison for water surface elevations. Because prototype measurements are like snapshots in time, it is important to run prototype boundary conditions for a sufficiently long period for the bed surface profile to resemble that in the prototype when the data were surveyed.

**14.6.4.3 Flow Distribution** Reevaluate the calculated flow distribution, similar to that in the fixed-bed test, and adjust  $n$ -values or geometry if needed.

**14.6.4.4 Coordination of Inflowing Gradation with Bed Sediment Gradation** The bed gradation is prescribed as an initial condition for the bed sediment reservoir. The inflowing sediment discharge is prescribed as a boundary condition. These data sets are related. That is, if the prototype is in equilibrium, the inflowing sediment load will be transported by grain size class without excessive deposition or erosion. That requires confirmation because the calculation is sensitive to the transport function selected for the study. Observe model transport by grain size and adjust either the inflow or the bed gradations, depending on which is regarded as the weaker data set.

**14.6.4.5 Sediment Yield** One should confirm that the calculation sediment yields in the computational model match the annual yields for the watershed. Figure 14-11 is an example of such a comparison. It is important to develop consistent units before making such a comparison. That is, if the published sediment yields were calculated from suspended sediment measurements, then either convert the computational model results into the suspended sediment component of the total sediment load or add the load moving in the unmeasured zone in the prototype to the suspended measurements. The Toffaleti transport function will facilitate such an estimate by displaying the vertical distribution of sediment in the water column. Most other transport functions do not offer that feature.

Fig. 14-11. Measured and calculated annual sediment yield.

**14.6.4.6 Sediment Transport Profiles** Another useful graphic is a plot of calculated sediment discharge versus river mile. It will show sources and sinks, which can then be one compared to the geometry data and to visual observations to test for reality. This will aid in improving the one-dimensional representation of the prototype to eliminate “numerical shadows” from the scour and deposition calculations.

**14.6.4.7 Selection of Calibration Parameters** Correlate model to prototype conditions in broad terms recognizing one dimensional approximations. For example, profiles of the bed elevation may exhibit little or no correlation with the prototype, but cross-sectional area changes should correlate with prototype behavior. Reconcile zones and amounts of aggradation and degradation by expressing accumulated volumes rather than depths. Reconcile accumulated weights passing each cross section.

#### 14.6.5 Movable-Boundary, Unsteady-State Calibration

The final phase in model calibration is the movable-bed unsteady-state test. This is required for both unsteady-state and steady-state hydraulic calculations because the sedimentation equation is an unsteady-state equation. This phase utilizes both single-event and period-of-record

hydrology. Of particular interest are the zones of deposition and erosion depicted during the passing of a hydrograph. When the stream is in a relatively equilibrium condition, these zones should cycle. When the graph of bed change versus time shows a trend to continue either deposition or erosion, investigate the cause. Resolve these issues starting with the most upstream location and continuing toward the downstream end of the model. Begin with the cross section showing the greatest change in bed elevation. Even if only one cross section is not responding properly, the model results downstream and sometimes upstream from it are not reliable.

### 14.7 BASE TEST

The most appropriate use of a movable-bed simulation is to compare an alternative plan of action with a base condition. In most cases the base condition is the predicted future behavior of the river in a “no-action future.” In a reservoir study, for example, the base test would calculate the behavior of the reservoir reach of the river without the dam in place. In many cases, the base test simulation will show little or no net scour or deposition. These are the river reaches that

are near equilibrium (i.e., where scour approximately equals deposition) under existing conditions.

Two sets of boundary conditions are needed: one set is for model calibration and the other set is for analyzing the plan test. That is, model calibration is a task designed to demonstrate that the model calculations match historical prototype behavior. The calibration task begins with a survey of the model area, called initial conditions, and runs to a second survey of the model area. It is necessary to know the boundary conditions that existed between those two surveys. That requirement dictates the selection of boundary conditions for model calibration.

However, boundary conditions for the base test must represent the future conditions in the project. They will be the same as those for the plan tests unless the plan tests are designed to investigate a change in the boundary conditions. For example, if the purpose of the model study is to investigate a channel modification, the base test would be conducted with the same boundary conditions as the plan test. The length of the simulation hydrograph for the base test is usually selected by considering the economic life of the project.

It is likely that the hydrology and sediment boundary condition values for the calibration period will not be representative of the long-term future hydrology and sediment boundary condition values. However, if the purpose of the model study is to investigate what will happen in a river as the result of a change in the boundary conditions, the base test values will be different from the plan test values, but they should contain the same period of time.

## 14.8 PLAN TEST

The project alternatives can be simulated by modifying the base data set appropriately. In case of a reservoir, a dam can be simulated by inserting operating rule data into the base test model. For a channel improvement project, cross-sectional geometry and roughness can be changed. If a major change is required, make the evaluation in steps. That is, change one parameter at a time so that the model results will be easier to interpret.

For example, it is best to analyze a channel modification project in three steps. First, change the hydraulic roughness values and run future flows in the existing geometry. Second, insert the modified cross sections and complete the analysis by running the alternative to be tested. Finally, add the contraction and expansion coefficients for the modified channel design and run the plan test.

Use model results from each of the above steps as an aid in predicting future conditions. Rely heavily on engineering judgment when analyzing model results. Look for surprises in the calculated results. These surprises can be used by the experienced river engineer to locate data inadequacies and to better understand the behavior of the

prototype system. Any unexpected response of the model should be analyzed and should be justified before the results are accepted.

## 14.9 INTERPRETATION OF RESULTS

### 14.9.1 Form of Study Results

Results from the plan tests should be expressed in terms of change from the base case. This will provide an assessment of the impacts of proposed projects on the stream behavior. The impact of sedimentation on the performance of the project should be presented in units appropriate to the decisions which need to be made. For example, a flood channel will require maintenance to remove sediment deposits. These units are usually cubic yards. However, the parameter to measure in arriving at a maintenance schedule will most likely be the water surface. The results of the sedimentation study should include the locations of deposits and their resulting impact on the water surface profile.

### 14.9.2 Sensitivity Tests

It is desirable during the course of a study to perform sensitivity tests. Quite often part of the input data (such as inflowing sediment load) will be missing or will contain measurement error. The impact of these uncertainties on model results can be studied by modifying the suspected input data by  $\pm x\%$  and rerunning the simulation. If little change in the simulation results, the uncertainty in the data is of no consequence. If large changes occur, the input data need to be refined. Refinement should then proceed by using good judgment and by modifying only one parameter at a time. Sensitivity studies performed in this manner will increase the modeler's understanding of model behavior and that understanding will aid in predicting the behavior of the prototype.

## 14.10 EXAMPLES TO ILLUSTRATE MODEL APPLICABILITY

One-dimensional computational models of sedimentation have been used in a variety of studies over the past three decades. Examples are

- to confirm land acquisition for a run-of-river reservoir that required simulating sedimentation processes in that reservoir for a 50-year life;
- to calculate the stability of a hydraulic fill prior to placing it across the Mississippi River to arrest the upstream movement of salt water from the Gulf of Mexico during low water;
- to predict the water surface profile in setting a levee grade in a backwater area of a reservoir;

- to reconstitute the degradation trend downstream from dams;
- to design erodible bed channels with bank protection and grade control structures;
- to predict general scour at a bridge crossing for bridge design or evaluation;
- to evaluate the impacts of instream sand and gravel mining;
- to predict maintenance dredging for existing and proposed navigation projects;
- to study degradation and aggradation in the development of the Atchafalaya Basin and Delta;
- to predict the stream-bed response of a river if water and sediment are diverted out;
- to predict stream stability and maintenance dredging for a flood protection project;
- to predict sedimentation processes following the removal of dams;
- to predict aggradation and degradation in channel modification projects;
- to design sediment traps; and
- to predict the bed roughness and resulting water surface profile due to the transport of sand and gravel through concrete channels.

## 14.11 AN EXAMPLE APPLICATION

An example was provided by Chang (1984) to illustrate the general points in this chapter. The actual study encompassed the lower 3 miles of the San Dieguito River in California, Fig. 14-12. Because this is only an illustration, the entire study area is not reproduced in Fig. 14-12.

### 14.11.1 Model Data

Data for the fluvial processes during the January to March 1993 flood were used for calibration. Channel geometry is defined by 43 cross sections selected along the reach. A total of 17 cross sections were surveyed before the flood and resurveyed soon after the flood. Cross sections not included in the survey were developed from the 1992 topographic map of the river channel. The map has a contour interval of 304.8 mm (1 ft).

Sediment particle-size distributions for the stream bed material are based on samples taken along the study reach. The stream-bed sediment is sand.

The runoff hydrograph for the January to March 1993 flood is shown in Fig. 14-13. This runoff was measured by the county of San Diego at the Hodges Dam. The flood that occurred on January 14, January 16, and January 18, 1993

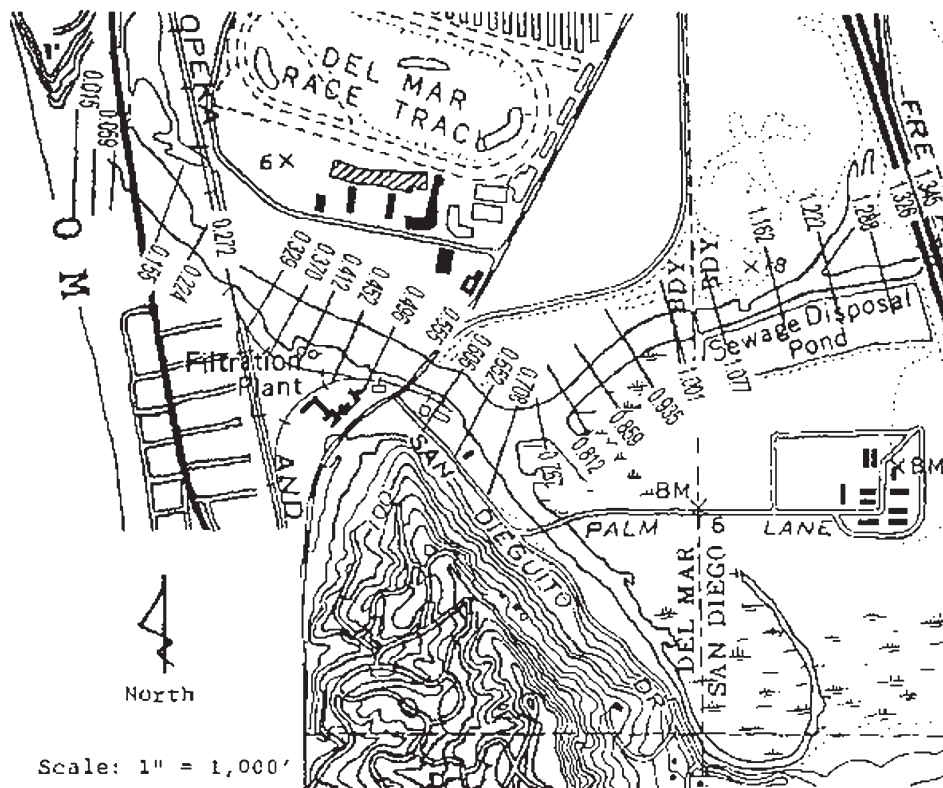

Fig. 14-12. Location of surveyed cross sections (multiply ft by 0.3048 to get m).

had three peaks. The discharges were  $120.43 \text{ m}^3/\text{s}$  (4,253 cfs),  $188.39 \text{ m}^3/\text{s}$  (6,653 cfs), and  $120.43 \text{ m}^3/\text{s}$  (4,253 cfs), respectively. The peak discharge of  $188.39 \text{ m}^3/\text{s}$  (6,653 cfs) has a return period of 14.7 years.

#### 14.11.2 Selection of the Sediment Transport Formula

Numerous formulae have been developed for calculating sediment movement in sand-bed channels. Each one will predict a different sediment transport rate. The selection of the formula to use is best confirmed by comparing calculated results to measurements at the site. However, in an ephemeral stream such as the San Dieguito River, sediment discharge measurements can be made only during floods.

Consequently, data are scarce. Even when suspended sediment measurements are made, there is always the presence of the unmeasured zone near the bed. The substantial movement of the bed material in the unmeasured zone adds uncertainty to the measured data set.

Therefore, the approach to selecting the sediment transport function includes more than just a search for measured sediment concentrations. It also includes consideration of the physical conditions of the fluid, the hydraulic parameters of the flow, and the sediment characteristics of the stream bed.

The engineer can start by comparing the hydraulic and sediment properties at the study site with those used in development of the transport function. The functions passing this test are then submitted to additional testing using measurements other than sediment concentrations.

Measured data include measured changes in channel dimensions. That is, the calculated rate and amount of erosion or deposition in a channel depend on the sediment transport formula used. If a formula overpredicts the sediment transport rate, it will calculate more deposition than the measured values. On the other hand, a formula that underpredicts the transport rate will show less deposition than the measured amount. At a cross section undergoing scour, the amount of scour is overpredicted by a sediment transport formula giving transport rates that are too high and vice versa. The use of calculated changes in bed elevation provides valuable information when the sediment transport function is being selected for a study. Stream channel changes in the lower San Dieguito River during the 1993 flood are characterized by channel-bed scour. The changes were significant.

In this study, the Ackers-White formula, the Engelund-Hanson formula, and the Yang formula (Vanoni 2006), were identified as possible choices. These functions were selected based on the extensive evaluation made by Brownlie (1983).

Fig. 14-13. Hydrograph for January to March 1993 floods (multiply cfs by 0.0283 to get  $\text{m}^3/\text{s}$ ).

Each formula was tested to determine whether or not the computational model would simulate measured channel changes as described in the previous paragraph.

**14.11.2.1 Calculated Sediment Delivery** Sediment delivery is defined as the accumulated sediment load that passes a specified channel cross section. The equation is

$$Y_s = \int_T Q_s dt \quad (14-14)$$

where

- $Y_s$  = sediment delivery;
- $Q_s$  = sediment discharge;
- $t$  = time; and
- $T$  = the specified period of time.

Sediment delivery is widely employed by hydrologists working in watershed management. The quantity commonly used in their work is annual sediment yield. In computational modeling the accumulated sediment load is available, by particle size, at every cross section and for every computational time step. However, when the specified period of time for the sediment delivery calculation is a year, the sediment delivery becomes the annual sediment yield. Referring to the output

from a computational model as sediment delivery preserves the historic definition of sediment yield.

The calculated sediment deliveries of bed material load based on the Ackers-White, Engelund-Hanson, and Yang formulas are shown in Fig. 14-14. These results were compared with the measured data in the final selection of the transport formula for this study.

In the general case the sediment discharge  $Q_s$  can be any part of the sediment load or it can be the total sediment load. In this case it pertains only to bed-material load. It was not necessary to include fine sediment, i.e., silt and clay, in this model because those particle sizes were not present in the samples of bed material. As a result, the conversion factor between volume and dry weight of sediment is  $1633.9 \text{ kg/m}^3$  ( $102 \text{ lb/cu}$ ).

The shape of the sediment delivery graph identifies zones of erosion and deposition along a channel. The plot should be read in the direction of the water flow. A decreasing delivery in the downstream direction, i.e., a negative gradient for the delivery-distance curve, signifies that sediment is depositing into the channel bed and banks. On the other hand, an increase in the sediment delivery in the downstream direction indicates that sediment is being removed from the channel bed and banks. A horizontal sediment delivery plot indicates

Fig. 14-14. Sediment delivery through the study reach (multiply cy by 0.7646 to get  $\text{m}^3$ ).

zero deposition or erosion. Of course, the assumption in this illustration is that local sediment inflow or outflow is zero.

As depicted in Fig. 14-14, sediment delivery through the lower San Dieguito River during the 1993 flood was characterized by general erosion along most of the river reach. Although all three figures show the general trend of erosion, their quantities are nevertheless different. The total calculated erosion for the inlet channel and the west channel is shown in Table 14-3. The inlet channel is from the river mouth to river mile 0.713 and the west channel is from river mile 0.713 to Interstate 5 at river mile 1.345.

The delivery curves shown in Fig. 14-14 have different slopes for the inlet channel and the west channel, and the steeper slopes are in the inlet channel. The average slope for the delivery curve of a channel is the difference in delivery from one end of the reach to the other divided by the reach length. The average change in end area can also be calculated from measured cross sections and compared to the slope of the delivery curve as shown in Table 14-4. The row identified as "Measured" shows volumes calculated from measured cross-sectional changes integrated over the channel length.

Table 14-4 provides a direct comparison of the calculated channel changes with measurement. The amount of erosion is considerably overpredicted by the Ackers-White formula. It is slightly overpredicted by the Engelund-Hanson formula. The calculated results based on the Yang formula are similar to the measured values. For this reason, the Yang formula was selected for application on the lower San Dieguito River.

Both simulation and measurement show that the inlet channel underwent greater erosion than did the west channel. The modeler can use such information to understand the prototype. For example, a possible cause for this difference is that the inlet channel is replenished by beach sand after each episode of storm flow.

**14.11.2.2 Reconstitution of the Measured Bed Profile** Profiles of the calculated bed surface and water surface are shown in Fig. 14-15. The results based on the Yang formula are closer to prototype measurements than the results using the Ackers-White or the Engelund-Hanson

formula. The differences are within 5%. For this reason, the Yang formula is selected for application on the lower San Dieguito River.

It should be noted that the version of Ackers-White formula used in this study is the earlier version. It was included in the Brownlie evaluation. Ackers and White have since modified this formula.

### 14.11.3 Calculated Changes in Channel Geometry

Calculated changes in river channel geometry are presented as changes in longitudinal channel-bed profiles and in channel cross sections. These changes reflect the spatial variations in sediment delivery described above.

**14.11.3.1 Longitudinal Profiles** Channel-bed profiles computed with the Engelund-Hanson and Yang formulae are generally similar (Fig. 14-15). The bed profiles at the peak flow are highly uneven, with the low points at channel bends and channel contractions. The channel-bed profiles become quite smooth toward the end of the flood. These results indicate that contraction scour is more pronounced during high flow and it becomes much less during low flow. The low point in bed profiles at a channel bend is related to deeper scour near the concave bank. This phenomenon will also be demonstrated by cross-sectional changes described in a later section. It can be seen from the relatively smooth channel-bed profiles at the end of the flood that channel-bed scour is at a maximum near the river mouth and it decreases gradually in the upstream direction.

For the simulated changes based on the Ackers-White formula, the extent of degradation is considerably greater than that based on the other two formulae. The deeper scour depths are related to the greater sediment delivery predicted by the Ackers-White formula.

**14.11.3.2 Channel Cross Sections** Calculated cross-sectional changes along the river reach are exemplified by those presented in Figs. 14-16 and 14-17. Each figure

**Table 14-3 Simulated Sediment Deliveries (multiply cuyd by 0.7646 to get m<sup>3</sup>)**

Formula used	Simulated sediment delivery, cuyd		
	River mouth	Entrance of inlet channel	West channel
Ackers-White	520,000	309,000	184,000
Engelund-Hanson	205,000	107,000	83,100
Yang	151,000	65,800	48,800

**Table 14-4 Calculated and Measured River Channel Erosion**

Formula used or measured	Total erosion, cuyd		Average change in cross section, sq ft	
	Inlet channel	West channel	Inlet channel	West channel
Ackers-White	211,000	125,000	1,513	1,010
Engelund-Hanson	98,000	23,900	703	193
Yang	85,200	17,000	611	137
Measured	87,500	17,770	628	144

(multiply cuyd by 0.7646 to get m<sup>3</sup>; multiply sq ft by 0.09290 to get m<sup>2</sup>)

Fig. 14-15. Calculated bed and water surface profiles (multiply ft by 0.3048 to get m).

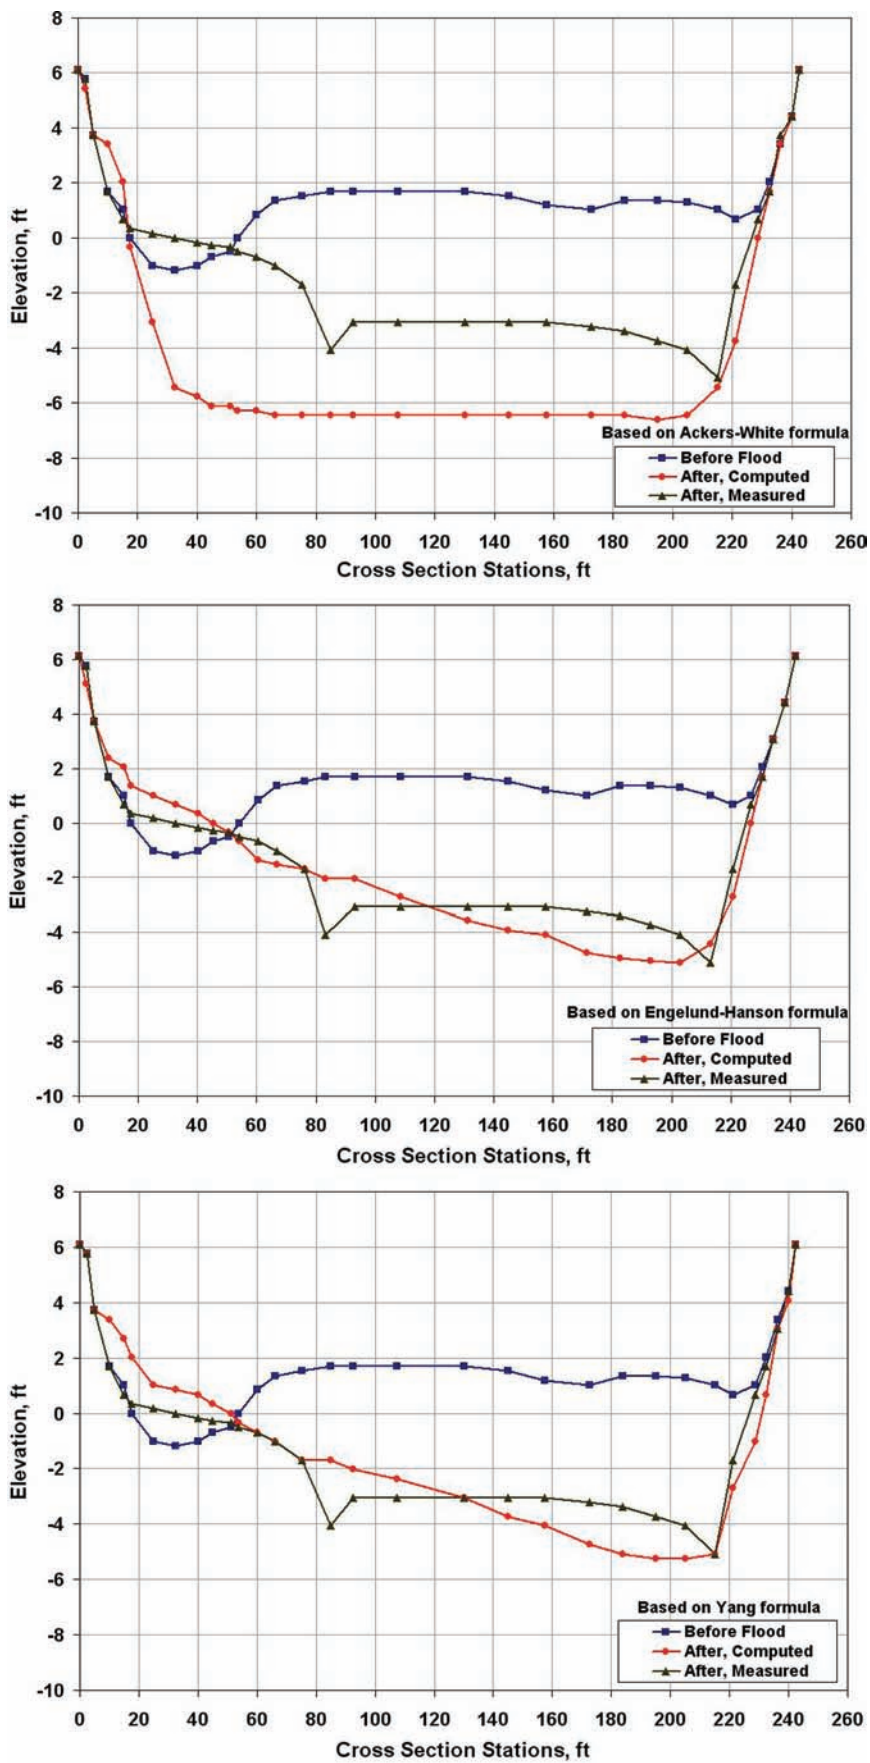

Fig. 14-16. Calculated and measured cross-sectional changes at Sect. 0.412 (multiply ft by 0.3048 to get m).

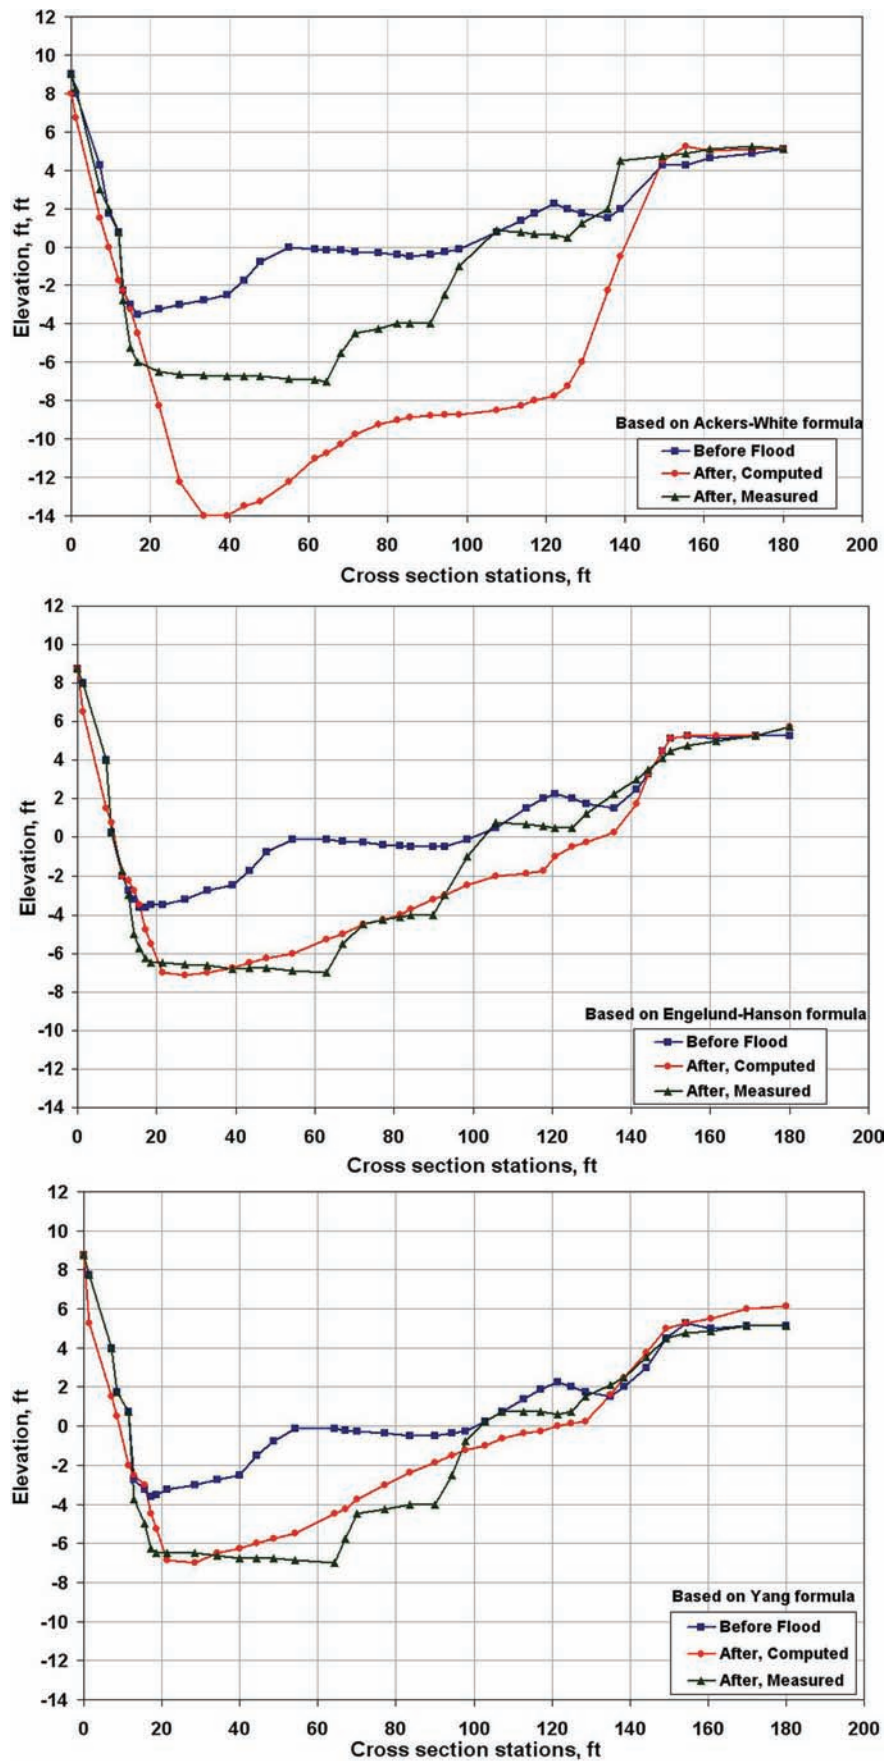

Fig. 14-17. Calculated and measured cross-sectional changes at Sect. 0.652 (multiply ft by 0.3048 to get m).

includes the following three channel-bed profiles: (1) The initial bed profile based on the preflood survey; (2) the calculated cross-sectional profile on the date of the postflood survey; and (3) the surveyed postflood cross-sectional geometry.

These figures provide comparisons of simulated and measured cross-sectional geometries. Cross-sectional changes simulated based on the Ackers-White formula far exceed the measured changes. It is therefore concluded that the results are unacceptable and that the Ackers-White formula cannot be used for this study.

Simulated cross-sectional changes based on the Engelund-Hanson formula are generally supported by the measurement. It can be seen that the net change in cross-sectional area as simulated tends to exceed the measured change. In other words, the scour is slightly overpredicted by the Engelund-Hanson formula. For the inlet channel, the overprediction is 12% averaged over the channel reach; the overprediction is 30% for the west channel, as summarized in Table 14-5.

Calculated cross-sectional changes based on the Yang formula are generally supported by the measurement. For the inlet channel, the scour is underpredicted by 2.7% averaged over the channel reach. For the west channel, the scour is overpredicted by 5%. It may therefore be concluded that the Yang formula is the most applicable to the lower San Dieguito River.

The simulated patterns of scour and fill are also used to demonstrate the complex channel geometry adjustments during floods. For the erosional changes, the scour pattern at a cross section is affected by the geometries of adjacent cross sections and channel curvature. Section 0.652 is located in a channel bend, and the shape of the cross section is influenced by the channel curvature. To approximate such morphological adjustments, the mathematical model must be able to calculate nonuniform patterns of deposition and erosion.

A general comparison of the calculated and surveyed cross-sectional profiles may be assessed as follows. The erosional changes as simulated by the Yang formula are clearly consistent with the survey. Any discrepancy between simulated and measured results may be attributed to the following factors.

1. A nonhomogenous horizontal distribution of the bed sediment (i.e., sediment particle sizes on and in the

stream bed are not uniformly distributed at a cross section). The presence of coarse materials usually affects the pattern of channel changes, and a one-dimensional mathematical model does not account for such sediment distributions.

2. A horizontal distribution of the suspended sediment concentration in the inflowing water that is not in equilibrium with hydraulic forces at the current cross section. A one-dimensional mathematical model does not account for such sediment distributions.
3. Imprecision in measurements such as the size of the flood discharge, the river cross section, and the bed material composition.
4. Imprecision in computations related to the roughness coefficient, the sediment transport formula, etc.

Despite the differences between the calculated and measured cross-sectional changes, the calculated change in cross-sectional area and the pattern of erosion and deposition along the longitudinal profile are consistent with the survey. This validates the model for predicting longitudinal profiles and general cross-sectional end area changes along the lower San Dieguito River.

## 14.12 AVAILABLE COMPUTATIONAL MODELS

The Subcommittee on Sedimentation, Interagency Advisory Committee on Water Data investigated available computational sedimentation models (Fan 1988). In 1986 they initiated a project on the "selection and proper use of computer models to estimate sediment transport." At the end of phase two of that three-phase effort they had selected 12 models for comparison and evaluation. These are presented in Table 14-6.

The field of computational modeling is continually changing. New models are being released and old ones are being improved. Even when originally printed, Table 14-6 was not an exhaustive list of sediment models. Fan writes,

Beginning in the summer of 1987, the Work Group made a survey of the computer sedimentation models developed and implemented in the United States. Public responses to the survey were prompt and overwhelming. Within 2 months, the Work Group received approximately 48 sedimentation models which are available both in federal agencies and in the private sector in the United States. (Fan 1988, p. 3)

It was from this submission of models that the Work Group selected those listed in Table 14-6 for further investigation.

The purpose of this section is to illustrate what is meant by "computational model." It makes no endorsement of a specific model nor does it imply that all are equal in their performance and reliability. The list of available computational models will very likely be obsolete even before it is

**Table 14-5 Comparison of Calculated and Measured Scour**

Formula used	Simulated scour/measured scour	
	Inlet channel	West channel
Ackers-White	241%	678%
Engelund-Hanson	112%	130%
Yang	97.3%	105%

**Table 14-6** Currently Available Computer Models<sup>a</sup>

Model name	Background	Comments
HEC-6	Developed by William A. Thomas during the period 1968 through 1974 and released by the U.S. Army Corps of Engineers, Hydrologic Engineer Center, Davis, Calif. in 1976.	The model is designed to simulate one-dimensional, steady, gradually varied water and sediment flow problems.
TABS2	Developed by a team of researchers at the U.S. Army Waterways Experiment Station, Vicksburg, Miss. during the period 1977 through 1984 and released in 1984.	This is a fully two-dimensional, finite-element solution of the flow and sediment equations.
IALLUVIAL	Developed by F. W. Karim at the University of Iowa under contract with the U.S. Army Corps of Engineers, Omaha, Neb.	It is a one-dimensional, quasi-steady routing model.
STARS	This model is an outgrowth of a model originally developed by Albert Molinas at Colorado State University and was submitted under contract to the Bureau of Reclamation in 1983.	STARS has a unique feature of using a stream-tube concept to vary the hydraulic and sediment transport characteristics across a stream cross section.
GSTARS	Developed by Albert Molinas and Chih Ted Yang for the Bureau of Reclamation and released in 1986.	This is a generalized stream-tube model for alluvial river simulation.
ONED3X	Developed in 1987 by Vincent Lai, U.S. Geological Survey.	This is a coupled multimode method of characteristics.
CHARIMA and SEDICOU	Developed from 1985 through 1987 by Forrest Holly, Jr., University of Iowa. Between 1986 and 1988, Dr. Holly developed SEDICOU, a totally coupled program.	This represents the latest generation in a series of codes whose progenitor was IALLUVIAL. The model is a partially coupled program for mobile bed simulation and can duplicate an IALLUVIAL computation. It is still under active development and modification.
FLUVIAL12	Developed in 1976 by Howard Chang of San Diego State University, Calif.	The model is intended for water and sediment routing in natural and man-made channels. The combined effects of flow hydraulics, sediment transport, and river channel changes are simulated for a given flow period.
HEC2SR	Developed in 1980 by Ruh-Ming Li of Simons, Li and Associates, Inc. (SLA).	This model is designed to simulate watershed sediment yield, aggradation, and degradation in a river basin. It incorporates a sediment-routine program into the HEC2 program developed by Bill S. Eichert, Hydrologic Engineering Center, U.S. Army Corps of Engineers.
TWODSR	Developed in 1988 by Yung-Hai Chen.	This is a two-dimensional model based on an uncoupled, unsteady approach.
RESSED	Developed by Yung-Hai Chen for the Canadian International Project Management (CIPM)-Yangtze Joint Venture.	Developed to study the Three Gorges Project on the Yangtze River in China. This is a simplified quasi-nonequilibrium model for reservoir and river erosion sedimentation related problems.

<sup>a</sup>The first six models are federally owned. The last five are privately owned (1986).

printed. However, the principles presented in this chapter will continue to be useful in evaluating and selecting a computational model.

## CHAPTER 15

# *Two- and Three-Dimensional Numerical Simulation of Mobile-Bed Hydrodynamics and Sedimentation*

*Miodrag Spasojevic and Forrest M. Holly, Jr.*

### 15.1 INTRODUCTION

#### 15.1.1 When Is Multidimensional Mobile-Bed Modeling Necessary?

Although present understanding and conceptualization of mobile-bed processes are still far from complete, one-dimensional mobile-bed numerical models have been used with some success in engineering practice since the early 1980s. As described in Chapter 14 of this manual, such models are most often applied to situations involving extended river reaches and extended time periods, typically to determine the long-term response of a river to natural or man-made changes imposed upon its hydrologic and sediment regime. The mobile-bed and hydrodynamic processes in one-dimensional models must necessarily be expressed in terms of cross-sectional properties such as average velocity, average depth, hydraulic radius, and overall shear stress. Quantities such as bed scour and fill, bed-load transport, sediment-load concentration, and bed-material composition must also be expressed as total cross-sectional values. Although some modelers have developed means of extracting limited two-dimensional information from one-dimensional models, for example, through assumed transverse distributions of shear stress and depth-averaged velocity, the fundamental computation is one-dimensional. Demands on computational resources are generally not a significant factor or expense, and traditional field-data collection efforts are similar to those needed for steady- or unsteady-flow flood modeling.

Whatever their utility for studies of extended time periods and river reaches, one-dimensional models cannot resolve local details of flow and mobile-bed dynamics. Such local details might involve the plan-view distribution of deposition patterns in a reservoir; the scour and deposition patterns associated with flow around the ends of spur dikes or other

river training works; or the scour and deposition provoked by bridge piers. For such problems, two- or three-dimensional models provide the possibility of resolving these kinds of local details, albeit at the cost of significantly increased program complexity and computational resources. In time, if computing power continues to increase at its current breathtaking pace, one may envisage use of two- or three-dimensional models even for large-scale problems such as those amenable only to one-dimensional models at the present time. At present, two- and three-dimensional use is limited to problems requiring resolution of local details over relatively short time periods, often as a complement to one-dimensional models of larger spatial and temporal scope.

#### 15.1.2 Is the Additional Complexity of Multidimensional Mobile-Bed Modeling Justified?

It is often argued, and indeed has been argued since the advent of industrialized computational hydraulics in the 1970s, that the increased complexity and data needs of “the next level of modeling complexity” are not justified given our imperfect understanding of certain physical processes, the inadequacy of field data, and the uncertainty inherent in model results. The authors believe that this is a spurious argument. First, experience has shown that input data needs that may not seem justified at today’s level of modeling capability will soon be justified by tomorrow’s capabilities. Second, why should one compound the uncertainty in model results by adding inadequate field data to a simplified version of complex natural processes? Third, and perhaps most important, more complex models (in this case, two- and three-dimensional ones) obviate the need to describe all the complex and nonhomogeneous processes in a river cross section in terms of global cross-sectional average properties such as mean velocity, discharge, hydraulic radius, and average bed shear. In a two-dimensional

depth-averaged model, one still must relate near-bed processes to the depth-averaged properties in the water column, such as depth-averaged velocity and bed shear stress, but at least the heterogeneity of processes across the channel can be represented. In a three-dimensional model, near-bed processes can be related to the hydrodynamic properties at a computational grid point immediately adjacent to the bed and localized in a plan-view sense.

Therefore the authors believe that whether or not the particular features and requirements of a study mandate the use of multidimensional modeling, the model representation of physical processes can only be improved—or at least made more rational—by adopting a two- or three-dimensional approach. This may not be feasible for all studies because of computer-resource constraints, as described in the following section. But the authors believe it is time to begin planning for a study by asking, in the interest of better representation of physical processes, “Can this be done with a two- or three-dimensional model, or do we have to resort to a one-dimensional approach?” rather than “Can this be done with a one-dimensional model, or do we have to resort to a two- or three-dimensional approach?”

### 15.1.3 Limitations of Computer Resources

One obvious reason to answer the above question “we’ll have to go one-dimensional” is the limitations of computer resources. Memory and disk space are not generally limiting, even for three-dimensional modeling. But the sheer central processing unit (CPU) time requirements of three-dimensional models, even in a parallel-processing environment, obviate any possibility of using them for extended spatial extents and simulation durations within the time frame of a study, at least as of this writing. For example, depending on the computing hardware in use, one-dimensional mobile-bed models covering the order of hundreds of kilometers can be used to perform simulations of the order of decades with a turnaround time on the order of several hours. By contrast, a fully three-dimensional mobile-bed model might require days of CPU time just to obtain a single steady-state solution over a river reach on the order of 20 kilometers. This three-dimensional demand is considerably less if the hydrostatic pressure assumption replaces the vertical momentum equation; and the CPU time per time step in a true unsteady calculation is generally less than that required to obtain a single accurate steady-state solution. Such CPU time requirements depend directly on the number of sediment size classes being transported, the number of subsurface bed strata considered, the type of computational grid (structured or unstructured), and other factors. Nonetheless, computer CPU time requirements can be a significant factor militating against the use of three-dimensional modeling given the calendar time constraints of a typical engineering study.

The CPU time demands of two-dimensional modeling fall somewhere in between those of one-dimensional and three-dimensional, but turnaround time can still be a decisive issue depending on the temporal and spatial extent of the modeling effort.

### 15.1.4 Structure of This Chapter

The remainder of this chapter is structured to provide not only the model user and developer, but also the model “consumer” (i.e., the one paying the bill), with a framework for understanding the conceptual bases of multidimensional models, alternatives for mathematical representation of relevant physical processes, alternative computational grid representations and their associated approximate numerical solution methods, and a sense of what can go wrong. Within this chapter, the authors use the terms “mobile-bed modeling,” “sediment modeling,” and “sediment-process modeling” interchangeably.

Section 15.2 provides a brief overview of typical problem types and available techniques and modeling systems for each. Section 15.3 summarizes the mathematical and numerical bases of the two- and three-dimensional hydrodynamic models that underpin any mobile-bed modeling. Section 15.4 provides an overall conceptual framework for modeling sediment transport and bed evolution. The next three sections, 15.5, 15.6, and 15.7, go into detail in the treatment of sediment processes on or near the bed, those in suspension, and the exchange between the two domains. Section 15.8 deals with the need for empirical closure relations and their role in modeling systems, whereas Section 15.9 focuses on numerical-solution issues related to sediment processes. Section 15.10 provides some background on field data needs and the role of such data in model construction, calibration, and verification. Section 15.11 provides limited examples of two- and three-dimensional mobile-bed model studies. Finally, Section 15.12 provides the authors’ view of the state of the art and future perspectives in multidimensional mobile-bed modeling.

The authors assume that the reader has a general familiarity with the vocabulary of numerical hydraulics, and also with some of its general techniques and support tools. Some of the relevant sections refer to the reader to background texts on computational hydraulics, computational fluid dynamics, and grid generation.

The authors do not pretend to have prepared this chapter from a purely objective framework. Most of the developments and examples build on the authors’ own experiences with their particular conceptualization of the mobile-bed problem and simulation systems they have developed and used. It is hoped that this enables the reader to acquire solid depth and detail on at least one approach to the problem. The authors have tried to use their own frame of reference as a basis for less detailed description of conceptual, mathematical, and numerical approaches used by others.

## 15.2 PROBLEM TYPES AND AVAILABLE TECHNIQUES AND MODELING SYSTEMS—A SURVEY

### 15.2.1 Introduction

In preparation for the more detailed developments in subsequent sections, the authors present here a survey of typical

problems for which two- or three-dimensional mobile-bed modeling may be required. The purpose is to draw attention to the features of each type of problem that may require corresponding features and techniques in a modeling system and to give an admittedly incomplete set of references to two- and three-dimensional modeling systems and applications currently available for each problem type. Table 15-1

**Table 15-1 Summary of Model Capability Requirements**

Section	Type of problem	Two-dimensional (depth-averaged)	Three-dimensional required?	Hydrostatic assumption in three dimensions?	Unsteady flow capability required?	Sediment mixture capability required?	Distinct treatment of bed-load/suspended-load processes?
15.2.2	Reservoir sedimentation	Often sufficient	If reentrainment into outlet structures is studied	OK if entrainment into outlet structures not studied	Sequence of steady flows usually OK	Required	Required unless inflow is fully bed load
15.2.3	Settling basins/tanks/clarifiers	Generally not relevant	Necessary for representation of interaction between geometry and sedimentation patterns	OK if flow is quiescent	Generally not necessary	Required unless sediment load is homogeneous	Not generally required
15.2.4	Riverbend dynamics and training works	Not applicable without special incorporation of secondary flow effects	Needed to capture secondary-flow effects	OK if detailed flow around structures is not an issue	Desirable for study of effects of hydrograph	Required unless sediments are entirely uniform	Required in most alluvial rivers
15.2.5	Mobile-bed dynamics around structures	Not applicable	Required	Generally not acceptable, because vertical accelerations are important	Generally not necessary	Required unless sediments are entirely uniform	Required in most alluvial rivers
15.2.6	Long-term bed evolution in response to imposed changes	Generally irrelevant	For focused local study within larger one-dimensional model	May be necessary for long-term simulation	Must accommodate series of annual hydrographs	If required for the overall one-dimensional model	If required for the overall one-dimensional model
15.2.7	Sorbed contaminant fate and transport	May be appropriate	May be required	OK if flow-structure-sediment interaction is not of primary interest	Likely necessary for studies of resuspension during floods	May not be required if focus is entirely on contaminated fine sediments	Suspension advection-diffusion required

summarizes this inventory. The authors limit their attention to subcritical flow, because supercritical flow capability is rarely needed for problems in which mobile-bed activity is of primary interest.

### 15.2.2 Reservoir Sedimentation

Chapter 12 of this manual is devoted to the issue of reservoir sedimentation, for which prediction and management simulation are best accomplished using two-dimensional (plan-view) models. The present chapter also includes an example application of a two-dimensional model to reservoir sedimentation (Section 15.11).

Although one-dimensional models have been, and indeed still are, used for reservoir sedimentation, by definition they can only resolve the longitudinal distribution of sedimentation, from the headwaters to the dam. Many reservoirs flood not only the incised river channel, but also adjacent floodplain areas; in addition, many have significant lateral embayments and islands. One-dimensional models can resolve such features only in terms of equivalent transverse cross sections, at best including distinct one-dimensional flow paths around islands (in models permitting looped channel structures) and one-dimensional segments extending into lateral embayments.

Of course three-dimensional modeling can also be used for reservoir sedimentation, and might be used if computational resources were available and especially if the local entrainment of sediment into outlet works was to be studied. The general absence of significant recirculation in reservoir flow, as well as the generally low velocities and lack of training structures, argues for a depth-averaged approach being sufficient. However, only a three-dimensional model can resolve and simulate the effects of reservoir density currents if these play a significant role in the sedimentation processes of a particular site. Vertically two-dimensional models have been used for the study of reservoir sedimentation in this case, but these are width-averaged and therefore can only approximately resolve the effects of lateral embayments.

Reservoir sedimentation simulation does not generally require full representation of unsteady-flow hydrodynamics. It is usually necessary only to simulate long-term hydrographs, and this can be done using a series of steady-state inflows and water-surface elevations if necessary. Similarly, sedimentation rates (by size fraction) can be determined for such a series of steady-flow situations and used to generate equivalent sedimentation quantities over time.

When three-dimensional models are employed for reservoir sedimentation, it is generally acceptable to use the vertically hydrostatic pressure assumption in lieu of the vertical momentum equation (see Section 15.3.3). Vertical accelerations are generally not strong in a typical reservoir, at least outside the vicinity of structures. The hydrostatic pressure assumption results in significant reduction in computational time compared to fully three-dimensional formulations.

However, if the local entrainment of deposited sediment into outlet works is being studied, a fully three-dimensional treatment (i.e., with the vertical momentum equation included) may be required.

Reservoir sedimentation studies should be based on simulation models that accommodate sediment mixtures, through individual size classes or some other mechanism. The longitudinal (streamwise) differential sorting is intimately related to the differential transport modes of different sediment sizes (e.g., bed load for inflowing gravels or sands and suspended load for inflowing silts and washload) and to the variation of these transport modes from the upstream depositional delta to the downstream deep pool.

It is very important that both bed-load and suspended-load processes be represented in reservoir sedimentation models, unless there is no suspended load or washload in the inflowing streams. It is characteristic of a reservoir that suspended load or washload in the relatively steep, rapid, shallow inflow may transition through a bed-load mode of movement in the middle or downstream portions of the reservoir, where velocities are low, before being ultimately deposited on the bed. Similarly, fine material deposited during a previous event may become reentrained into bed load or suspended load during dynamic reservoir operations and/or extreme hydrologic inflow events, subsequently to be redeposited further downstream. A model must recognize these distinctly different mechanisms of transport and the associated differences in the time scale of sediment movement to capture the longitudinal sorting of deposited sediment.

A nonorthogonal curvilinear structured grid is usually needed for two- or three-dimensional reservoir modeling, especially to represent a sinuous flooded river channel within the overall embayment. Unstructured grid capability is not generally needed unless it is necessary to reproduce the detailed flow around structures as part of the study.

Reservoir sedimentation modeling is not highly demanding of sophisticated turbulence models, because most of the mobile-bed activity is deposition, and strong jet effects do not generally occur in reservoirs. However, if diffusion of a washload plume in the reservoir is an important factor in downstream deposition, or if sedimentation effects around structures within the reservoir (including intakes) are important in a three-dimensional model, then a simple turbulence model may not be adequate.

When deposited-material compaction and consolidation are included in a study, bed-layering capability is required in the two- or three-dimensional mobile-bed model. Consolidation calculations require knowledge of the age of deposits, and this in turn requires distinct accounting of deposited material, for example, in distinct layers.

Examples of two- and three-dimensional models that have been used for the study of reservoir sedimentation include those of Spasojevic and Holly (1990a; 1990b); Savic and Holly (1993); Olsen et al. (1999); and Fang and Rodi (2000).

### 15.2.3 Settling Basins

Simulation of deposition in engineered settling basins (including sedimentation tanks and clarifiers) is similar to that of reservoir sedimentation, but is somewhat less demanding, at least as long as the sediment is noncohesive, as assumed throughout this chapter. For purely volumetric analyses, one-dimensional modeling may be sufficient. It is difficult to imagine situations in which depth-averaged two-dimensional modeling is needed, though width-averaged two-dimensional approaches may be appropriate. These permit examination of the vertical structure of deposition. Generally, though, three-dimensional modeling is most likely needed. Indeed, the main purpose for performing a model study of a sedimentation basin is to analyze the interaction between the confined, engineered geometry of the basin and the deposition patterns, as input to the design process. Boundary effects are ubiquitous, and are naturally accommodated by three-dimensional modeling. Unless there are strong vertical accelerations near the inlet or the outlet, the hydrostatic pressure assumption may be adequate. Unsteady-flow dynamics is generally not relevant to continuous-flow sedimentation basins, so steady-flow models to determine sedimentation rates may be quite appropriate.

Unless the inflowing sediment is truly of uniform size, it is generally necessary that the modeling accommodate differential particle sizes, especially because this can have a direct bearing on the longitudinal deposition patterns in the sedimentation basin.

To the extent that reentrainment of deposited sediments in the basin is not an issue, it may not be necessary for the model to accommodate bed-load processes and their exchanges with the water column. However, if possible reentrainment near the outlet is under study, it may be necessary to include a full representation of bed-load dynamics and exchange with the water column.

Because settling basins tend to have regular geometric shapes, a simple Cartesian structured grid may be sufficient. Because the diffusive transport of suspended sediments entering the basin can be an important factor in its design, it is important for the model to include at least a one-equation model for turbulence in the horizontal plane. Bed layering is of importance only if sediment reentrainment in flushing operations is anticipated, and then only if significant stratification of sediment sizes is expected.

An example of a model study of sedimentation basins is that of Olsen and Skoglund (1994).

### 15.2.4 River-Bend Dynamics and Training Works

Three-dimensional modeling must be used for the study of mobile-bed processes in river bends and around their associated training works (bendway weirs, spur dikes, etc.). One-dimensional models simply cannot resolve the detailed interaction between flow and sediment within the

cross section. Two-dimensional depth-averaged models cannot normally resolve the secondary currents that are an essential part of this process.

However, some investigators have implemented various special techniques that enable depth-averaged models to approximate secondary flow in bends. Flokstra (1977) substituted semi-empirical velocity distributions for helicoidal flow (obtained from a power law) into the dispersion terms of the depth-averaged equations. Jin and Steffler (1993) introduced the depth averaged moment-of-momentum equations to provide a measure of the intensity of the secondary flow. Duan et al. (2001) computed flow and bed-shear stress by using the depth-averaged model CCHE2D. Empirical functions of three-dimensional flow characteristics, formulated using the results of the three-dimensional model CCHE3D, were used to transform the flow and bed-shear stress into approximate three-dimensional distributions.

In three-dimensional bendway modeling, it is possible to adopt the hydrostatic pressure assumption if the details of water and sediment movement around training structures, or water intakes, are not of primary interest. Otherwise a full three-dimensional treatment is required.

Full unsteady-flow capability, as reflected in an unsteady-inflow hydrograph, is not of primary interest for this type of study, although the ability to simulate the effects of an annual hydrograph may be important, if only through a succession of steady flows. If, on the other hand, the dynamic flood effects of a rapidly varying hydrograph are important to mobile-bed response, full unsteady-flow capability is needed. As mentioned earlier, the combination of fully three-dimensional (nonhydrostatic) flow and full unsteadiness may require computational resources that preclude simulations of any meaningful length in prototype time. If the problem under study involves fairly rapid and/or substantial bed changes in response to some intervention, these changes may provoke corresponding changes in the free-surface elevations and slopes. This may then require either a series of steady-flow computations or truly unsteady simulation to capture the feedback from bed changes to the flow field.

In most alluvial rivers, bed topography and geomorphology are intimately related to the nonhomogeneity of transported sediments, whereby coarser material responds to near-bed currents and shear stresses quite differently from suspended material. Therefore bendway modeling invariably requires the capability to accommodate multiple sediment size classes, as well as the distinct differences between bed-load and suspended-load transport mechanisms.

Riverbend modeling requires a curvilinear grid. It may be orthogonal in regular channels such as the Missouri River, but generally must be nonorthogonal to permit correct representation of natural riverbank and island geometries. When local structure details must be represented (spur dikes, etc.), an unstructured-grid approach may be necessary.

A relatively high level of turbulence modeling (e.g.,  $k-\epsilon$ ) is required, because strong jet diffusive effects around structures may be encountered and be decisive in determining the configuration of deposition zones in the wake of such structures.

Bed-layering capability may not be important for these studies, unless erosion into previously deposited layers of varying composition is foreseen. A particular situation might be erosion into strata provoked by river-training works successfully shifting the channel away from one bank.

Examples of river-bend mobile-bed modeling include those of Wang and Adeff (1986); Minh Duc et al. (1998); Gessler et al. (1999); Holly and Spasojevic (1999); Fang (2000); Wu et al. (2000); Spasojevic et al. (2001); and Spasojevic and Muste (2002). Section 15.11 of this chapter includes an example of a three-dimensional application.

### 15.2.5 Mobile-Bed Dynamics around Structures

This area and the previous one have considerable overlap; indeed, the details of mobile-bed response near training structures in river bends may well be of importance to relatively large-scale modeling of geomorphology in river bends. However, there is also a class of problems for which attention is focused on the structure itself, especially in habitat remediation studies. For example, V-notch weirs, wing dikes, and notched spur dikes may be configured to create low-velocity habitat, requiring a rather delicate balance between sediment through-flow and flow obstruction. Other applications of engineering importance are scour around bridge piers and abutments; scour/stability considerations for pipelines on the riverbed; and stability of structures associated with recreational facilities such as casino boat cofferdams, marinas, and beach-protection works.

Two-dimensional models cannot do justice to this problem. It is tempting to think that a depth-averaged approach may enable at least a plan-view analysis of the effect of the structure on currents and recirculation/deposition. But the flow around such structures and their associated scour holes can be strongly three-dimensional. In addition, such flow can be characterized by significant vertical accelerations, which cannot be captured using the hydrostatic pressure assumption in a three-dimensional model. Therefore this class of problems generally requires fully three-dimensional, i.e., nonhydrostatic modeling.

Full unsteady-flow dynamics is not normally required for this class of study. It may be necessary to run a series of studies of flows to study structure response throughout the expected hydrograph range of conditions, but the dynamic effects per se are generally not of great importance. It should be recognized, however, that insofar as the upstream boundary conditions to such a model, including both bed-load and suspended-load inflows, may reflect the hysteresis effects associated for flood dynamics, the true unsteadiness may have to be taken into account in the formulation of boundary conditions for the series of steady-state conditions.

Except in special circumstances of rivers having uniform sediment, it is generally necessary for the modeling system to accommodate multiple sediment sizes and recognition of the distinctly separate modes of sediment movement on the bed and in suspension. There can be considerable local sorting of sediments in the complex flows around structures, for example, when sediments in suspension are deposited in the recirculation zone behind a structure and then may undergo continued slow transport as bed load, perhaps back toward the structure in some cases.

It is very difficult to provide effective representation of near-field flow around structures with a structured grid. At the very least, this must be a nonorthogonal curvilinear grid, and an unstructured grid is highly desirable. Similarly, this modeling situation puts a premium on an effective high-order turbulence model (e.g.,  $k-\epsilon$ ), because the diffusive exchange of momentum and sediment across zones of highly nonuniform velocity is the very essence of the problem.

Bed layering is generally not of great importance for near-field structure modeling, unless scour into antecedent nonuniform strata is an important issue.

Examples of model studies of mobile-bed dynamics around structures include those of Olsen and Melaaen (1993); Brors (1999); and Spasojevic and Muste (2002). Other examples of local-scour model predictions include those of Zaghoul and McCorquodale (1975) and Jia et al. (2001). Section 15.11 of this chapter includes an example of a three-dimensional application to a problem of structure configurations for habitat restoration.

### 15.2.6 Long-Term Bed Evolution in Response to Imposed Changes

One-dimensional models remain the method of choice for the study of long-term changes in river morphology over extended river reaches. Such changes include upstream regulation, changes in upstream sediment supply, water and sediment diversion/extraction, bank stabilization, and channelization. It can be necessary to focus on these long-term changes within a particular bend or short segment of river, often involving the presence of structures, within the larger context of the extended one-dimensional model. This focused interest is very likely to require three-dimensional modeling, especially if flow-structure-sediment interaction is an issue (e.g., sedimentation in water intakes, maintenance of navigation conditions). This triggers requirements for the same kinds of model capabilities as those described above in Sections 15.2.4 and 15.2.5, and in addition may well require the simulation of multiple annual hydrographs, either in a fully unsteady or a quasi-steady mode.

To the extent that this activity implies the embedding of a local three-dimensional model within a one-dimensional or two-dimensional one, the issue of deriving three-dimensional boundary conditions (e.g., upstream velocity and suspended-sediment concentration fields, bed-load distribution across

the section) from the one- or two-dimensional results, possibly within each time step, is a challenging one. It implies at the very least that the local three-dimensional model boundaries be taken at one-dimensional model cross sections that have relatively parallel and transversely uniform flow, if possible. It may also imply that there must be some feedback from the local three-dimensional model to the cross sections of the overall one- or two-dimensional model, though this may not be necessary.

If the local three-dimensional model is to be run in an unsteady mode, the hydrostatic pressure assumption is very likely to be necessary simply to keep computation time within reasonable limits (see Section 15.3.3). The three-dimensional model's need for treatment of nonuniform sediments, separation of bed load and suspended load, and other such factors is slaved to the comparable requirements for the overall one-dimensional model, depending on the sediment regime in the river.

The grid for an embedded three-dimensional model can generally be a structured curvilinear one, orthogonal in a fairly regular channel but nonorthogonal otherwise. Turbulence model demands are modest, because by definition this type of study is focused on identifying long-term changes rather than local and short-term details of flow and sediment movement; generally a one- or two-equation model should be sufficient—see Section 15.3.4. Bed layering may be quite important, if the long-term evolution of the river includes erosion into antecedent nonuniform strata, including strata that are laid down during the long-term simulation itself.

Although the authors are not aware of a specific application involving direct embedding of a two- or three-dimensional mobile-bed model in an overall one-dimensional extended model, there have been applications of two- and three-dimensional models to long-term bed evolution in specialized reservoir sedimentation contexts (Savic and Holly 1993; Fang and Rodi 2000). In addition, several models have been applied to long-term bed evolution in laboratory contexts.

### 15.2.7 Sorbed Contaminant Fate and Transport and Cohesive Sediment Problems

Modeling of sorbed contaminant fate and transport, be it one-, two-, or three-dimensional, is one of the most challenging activities in mobile-bed modeling. It combines the uncertainties of mobile-bed modeling with the uncertain description of sorption-desorption processes in the multiple transport modes of an alluvial system. In addition, these processes are most important for fine sediments, including cohesive sediments, for which the entrainment, transport, and deposition mechanics can be episodic rather than continuous and are poorly understood. Chapters 4 and 20 of this manual deal with the problems of transport of fine sediment and associated contaminants.

The particular problems associated with sorbed contaminant modeling are essentially the same whether the underlying mobile-bed modeling is one-, two-, or three-dimensional. The overall scope and focus of the study determines the level of dimensionality, whether unsteady capability is necessary, whether the hydrostatic pressure assumption is permissible, etc.

In sorbed contaminant modeling, contaminated fine material, once entrained or otherwise introduced into the system, is transported primarily as suspended load, i.e., essentially at the speed of the water velocity. Therefore it is mandatory that the modeling approach explicitly include advection-diffusion of suspension as a transport mechanism.

The source-sink term for advection-diffusion of suspension is particularly problematic when fine, especially cohesive, sediments are involved. Entrainment of cohesive sediments is understood to occur as episodic bursts of "mass entrainment" once a critical shear stress is exceeded, rather than as a progressive and continuous entrainment driven by the notion of an excess of shear stress over critical, as is generally accepted for noncohesive sediment. Cohesive sediment also tends to flocculate, or clump together once in suspension, and this behavior strongly influences its deposition tendencies and rates. Because salinity is an important parameter governing flocculation, a model must be capable of simulating transport (i.e., advection-diffusion) from a tidal boundary condition in parallel with fine-sediment and sorbed-contaminant transport in an estuary in many cases.

Given the episodic nature of cohesive-sediment dynamics, and the fact that studies of sorbed-contaminant fate and transport are likely to be focused on the risk of reentrainment of contaminants during flood events, this kind of modeling is likely to require unsteady-flow capability. But to the extent that flow-structure-sediment interaction is not an important feature of the study, it may be permissible to base modeling on the hydrostatic pressure assumption, thus enabling unsteady computations within reasonably computer time requirements.

Bed-layering capability is an important feature of models used for sorbed contaminant fate and transport, notably when alternate deposition-entrainment cycles are to be studied. During flood events, entrainment of contaminated sediments is generally from material laid down, and perhaps covered, during previous extended depositional periods. It is only through explicit representation of this layering process, with distinct differentiation of sediment and contaminant characteristics within layers, that this resuspension process can be faithfully represented.

Sorbed-contaminant modeling does not, in and of itself, invoke any special grid requirements; these follow from the physical situation as described in earlier sections. Turbulence modeling can be quite important, because diffusive transport of fine material in suspension can be an

important component of the contaminant fate and transport. Similarly, bed layering can be quite important, because contaminated sediments may lie in antecedent deposition strata that are disturbed through erosion during exceptional floods.

There do not appear to be recent examples of multidimensional sorbed-contaminant modeling in the literature. Earlier examples include those of Onishi and Trent (1982); Onishi and Thompson (1984); and Onishi and Trent (1985).

### 15.2.8 Summary

A common thread running through these discussions of typical modeling situations is that in mobile-bed modeling, there is a tradeoff between model complexity and computer (and human) resources. This is particularly true in the fully three-dimensional unsteady-flow domain (without the hydrostatic pressure assumption), in which, as of this writing, model complexity and fidelity are ultimately limited nearly by the calendar time available for the study. At the other extreme of one-dimensional modeling, computer resources are rarely a limiting factor; but the expert interpretation needed to draw meaningful results from a simplified one-dimensional schematization of reality may be as limiting as computer resources in the three-dimensional case. Two-dimensional modeling falls somewhere between these extremes. Ultimately the modeler must weigh the strengths, weaknesses, and costs of alternative modeling approaches against the objectives and resources of the particular study.

## 15.3 MATHEMATICAL BASIS FOR HYDRODYNAMICS IN TWO AND THREE DIMENSIONS

### 15.3.1 Introduction and Scope

Hydrodynamic and mobile-bed process modeling are intimately related. Although this chapter, and indeed this entire manual, are focused on sediment and mobile-bed processes, it is important for the reader to understand how the formulations and numerical solution of the hydrodynamic processes interact with those of the mobile-bed processes.

The purpose of this section is to provide a summary overview of the hydrodynamic-process formulations generally used in mobile-bed models. The general three-dimensional and two-dimensional equations are presented first, and then issues of simplification of the vertical momentum equation (hydrostatic assumption), solution techniques, coordinate transformations, and turbulence closure models are discussed in turn.

### 15.3.2 Summary of Basic Equations

Although the fields of direct Navier-Stokes and large-eddy simulation hydrodynamic modeling are receiving considerable

attention in the field of computational fluid dynamics, the hydrodynamic formulations used in mobile-bed modeling, at least as of this writing, remain based on the Reynolds-averaged Navier-Stokes equations.

**15.3.2.1 The Reynolds-Averaged Navier-Stokes Equations** The Reynolds-averaged Navier-Stokes equations are derived from the incompressible-fluid Navier-Stokes equations through temporal averaging of instantaneous velocities over an appropriate time scale. This operation results in a shift of the stresses associated with the momentum exchange of correlated fluctuating velocities from the momentum-advection terms to Reynolds stress terms. These Reynolds stresses must then be resolved using an appropriate turbulence model, as discussed in detail in Chapter 16 of this manual.

Water mass conservation is expressed through the Reynolds-averaged mass conservation (continuity) equation

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \quad (15-1)$$

in which

$x$ ,  $y$ , and  $z$  = Cartesian coordinate directions and  $u(x, y, z, t)$ , and  $w(x, y, z, t)$  = time-dependent Reynolds-averaged velocities in the  $x$ ,  $y$ , and  $z$  directions respectively,  $t$  being the time.

The Reynolds-averaged  $u$ -,  $v$ -, and  $w$ -momentum conservation equations are written

$$\begin{aligned} \frac{\partial u}{\partial t} + \frac{\partial(uu)}{\partial x} + \frac{\partial(vu)}{\partial y} + \frac{\partial(wu)}{\partial z} \\ = f_v - \frac{1}{\rho_0} \rho g \frac{\partial z'}{\partial x} - \frac{1}{\rho_0} \frac{\partial p}{\partial x} \\ + \frac{1}{\rho_0} \left( \frac{\partial \tau_{xx}}{\partial x} + \frac{\partial \tau_{yx}}{\partial y} + \frac{\partial \tau_{zx}}{\partial z} \right) \end{aligned} \quad (15-2)$$

$$\begin{aligned} \frac{\partial v}{\partial t} + \frac{\partial(uv)}{\partial x} + \frac{\partial(vv)}{\partial y} + \frac{\partial(wv)}{\partial z} \\ = -f_u - \frac{1}{\rho_0} \rho g \frac{\partial z'}{\partial y} - \frac{1}{\rho_0} \frac{\partial p}{\partial y} \\ + \frac{1}{\rho_0} \left( \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \tau_{yy}}{\partial y} + \frac{\partial \tau_{zy}}{\partial z} \right) \end{aligned} \quad (15-3)$$

$$\begin{aligned} \frac{\partial w}{\partial t} + \frac{\partial(uw)}{\partial x} + \frac{\partial(vw)}{\partial y} + \frac{\partial(ww)}{\partial z} \\ = -\frac{1}{\rho_0} \rho g \frac{\partial z'}{\partial z} - \frac{1}{\rho_0} \frac{\partial p}{\partial z} \\ + \frac{1}{\rho_0} \left( \frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} + \frac{\partial \tau_{zz}}{\partial z} \right) \end{aligned} \quad (15-4)$$

in which

$f = 2\Omega \sin\phi$  is the Coriolis parameter, with  $\Omega$  the angular rotational velocity of the earth and  $\phi$  the latitude;

$\rho(x, y, z, t)$  = density of a mixture of water and suspended sediment;

$\rho_0$  = reference density;

$g$  = acceleration due to gravity;

$z'$  = the vertical direction;

$p(x, y, z, t)$  = pressure; and  $\tau$  = fluid shear-stress tensor, here presumed to incorporate both molecular stresses and those resulting from the Reynolds averaging process.

Molecular stresses, being much smaller than Reynolds stresses, are often neglected. The Coriolis term, which describes the effect of the earth's rotation on the motion of fluid on the earth's surface, is important only when fairly large water bodies are modeled.

Equations (15-1) to (15-4) are considered the fully three-dimensional Reynolds-averaged set. They must be complemented with an appropriate turbulence closure model, possibly involving a parallel set of partial differential equations, before they can be used in a mobile-bed model, as is discussed below.

Equations (15-1) to (15-4) already evoke the Boussinesq approximation, which is valid for incompressible flows with variable density (the variation of gravity can be neglected in all flows considered in this chapter). According to this approximation, if the variation in density is relatively small, it may be assumed that the variation in density is negligible in all the terms in the equations except the gravitational term.

**15.3.2.2 The Hydrostatic-Pressure Simplification** In some applications, it is possible to bring considerable simplification to the fully three-dimensional set (Eqs. 15-1 to 15-4) by invoking the hydrostatic pressure assumption. This is tantamount to ignoring any vertical components of fluid acceleration, so that the pressure varies linearly from the surface to any point below it. If the  $z$  coordinate direction is taken as vertical ( $z \equiv z'$ ), the assumption is formalized as

$$\frac{\partial}{\partial z} \left( z + \frac{p}{\rho g} \right) = 0 \quad (15-5)$$

in which

$$z + \frac{p}{\rho g} = \zeta(x, y, t)$$

is the free-surface elevation above datum.

Introduction of Eq. (15-5) into Eqs. (15-2 and 15-3), through a suitable rearrangement of the variable-density

gravity term and the pressure term to include the free-surface elevation, yields

$$\begin{aligned} \frac{\partial u}{\partial t} + \frac{\partial(uu)}{\partial x} + \frac{\partial(uv)}{\partial y} + \frac{\partial(uw)}{\partial z} \\ = f v - g \frac{\partial(z_b + h)}{\partial x} - \frac{g}{\rho_0} (\zeta - z) \frac{\partial \rho}{\partial x} \\ + \frac{1}{\rho_0} \left( \frac{\partial \tau_{xx}}{\partial x} + \frac{\partial \tau_{yx}}{\partial y} + \frac{\partial \tau_{zx}}{\partial z} \right) \end{aligned} \quad (15-6)$$

and

$$\begin{aligned} \frac{\partial v}{\partial t} + \frac{\partial(vu)}{\partial x} + \frac{\partial(vv)}{\partial y} + \frac{\partial(vw)}{\partial z} \\ = -f u - g \frac{\partial(z_b + h)}{\partial y} - \frac{g}{\rho_0} (\zeta - z) \frac{\partial \rho}{\partial y} \\ + \frac{1}{\rho_0} \left( \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \tau_{yy}}{\partial y} + \frac{\partial \tau_{zy}}{\partial z} \right) \end{aligned} \quad (15-7)$$

in which

$z_b(x, y)$  = bed elevation above datum and

$h(x, y, t)$  = flow depth;

i.e., the free-surface elevation is expressed as  $\zeta = z_b + h$ . The free-surface elevation (or the flow depth) thus replaces the pressure as one of the four dependent variables, and this vastly simplifies the numerical solution of the set. In fully three-dimensional nonhydrostatic modeling, the solution for the pressure field is quite difficult and computationally demanding. The hydrostatic pressure assumption makes it possible to first obtain the free-surface elevation  $\zeta$  or the flow depth  $h$ , for example by solving the depth-averaged two-dimensional problem. The free-surface elevation then becomes a known variable in the second-step solution of the remaining three-dimensional equations.

Equations (15-6) and (15-7) retain the density-gradient terms to account for possible density changes due to changes in suspended-sediment concentration. The density-gradient terms, resulting from the rearrangement of gravity and pressure terms in Eqs. (15-2) and (15-3), are simplified by replacing  $\frac{\partial \rho}{\partial z}$  with  $g(\zeta - z)$ , which amounts to combining the hydrostatic-pressure assumption and the Boussinesq approximation. Density, and therefore density-gradient terms, are evaluated from suspended-sediment concentrations through an appropriate empirical relation.

Equations (15-5), (15-6), and (15-7) make up the hydrostatic-pressure simplification of Eqs. (15-2), (15-3), and (15-4). The continuity equation, Eq. (15-1), remains the same in both systems.

**15.3.2.3 The Depth-Averaged Equations** The hydrodynamic equations for two-dimensional (depth-averaged) mobile-bed modeling are obtained through formal depth-averaging of the full three-dimensional set, Eqs. (15-1),

(15-6), and (15-7). Depth-averaged variables are defined as follows:

$$\tilde{f} = \frac{1}{h} \int_h f dz. \quad (15-8)$$

The depth-averaged mass conservation (continuity) equation then becomes

$$\frac{\partial h}{\partial t} + \frac{\partial(h\tilde{u})}{\partial y} + \frac{\partial(h\tilde{v})}{\partial z} = 0. \quad (15-9)$$

The depth-averaged  $\tilde{u}$ -momentum conservation equation is

$$\begin{aligned} & \frac{\partial(\tilde{u}h)}{\partial t} + \frac{\partial(\tilde{u}\tilde{u}h)}{\partial x} + \frac{\partial(\tilde{v}\tilde{u}h)}{\partial y} \\ &= f\tilde{v}h - gh \frac{\partial(z_b + h)}{\partial x} - \frac{g h^2}{2\rho_0} \frac{\partial \rho}{\partial x} \\ &+ \frac{1}{\rho_0} \left[ \frac{\partial}{\partial x} (\tilde{\tau}_{xx} h) + \frac{\partial}{\partial y} (\tilde{\tau}_{yx} h) \right] \\ &+ \frac{\tau_{sx} - \tau_{bx}}{\rho_0} - \frac{1}{\rho_0} \left[ \frac{\partial}{\partial x} \int_h \rho (u - \tilde{u})(u - \tilde{u}) dz \right. \\ &\left. + \frac{\partial}{\partial y} \int_h \rho (u - \tilde{u})(v - \tilde{v}) dz \right] \end{aligned} \quad (15-10)$$

and the depth-averaged  $\tilde{v}$ -momentum conservation equation is

$$\begin{aligned} & \frac{\partial(\tilde{v}h)}{\partial t} + \frac{\partial(\tilde{u}\tilde{v}h)}{\partial x} + \frac{\partial(\tilde{v}\tilde{v}h)}{\partial y} \\ &= -f\tilde{u}h - gh \frac{\partial(z_b + h)}{\partial y} - \frac{g h^2}{2\rho_0} \frac{\partial \rho}{\partial y} \\ &+ \frac{1}{\rho_0} \left[ \frac{\partial}{\partial x} (\tilde{\tau}_{xy} h) + \frac{\partial}{\partial y} (\tilde{\tau}_{yy} h) \right] \\ &+ \frac{\tau_{sy} - \tau_{by}}{\rho_0} - \frac{1}{\rho_0} \left[ \frac{\partial}{\partial x} \int_h \rho (u - \tilde{u})(v - \tilde{v}) \right. \\ &\left. dz + \frac{\partial}{\partial y} \int_h \rho (v - \tilde{v})(v - \tilde{v}) dz \right] \end{aligned} \quad (15-11)$$

In these equations,  $\tau_{sx}$  and  $\tau_{bx}$  are the  $x$ -direction shear stress at the water surface and bed, respectively, and similarly for  $\tau_{sy}$  and  $\tau_{by}$ . The terms containing the products, such as  $(u - \tilde{u})(v - \tilde{v})$ , represent effective stresses associated with the correlation in deviations of local velocities from their depth averages, and are commonly referred to as the dispersion terms.

**15.3.2.4 Turbulence Closure** One commonly used simplified approach to solve the “turbulence closure problem”

is to express the Reynolds stresses through the Boussinesq eddy-viscosity model (for more detail see Chapter 16 of this manual). The Boussinesq eddy-viscosity model assumes that the Reynolds stress is related to the mean rate of strain (through the so-called eddy viscosity), and to the turbulent kinetic energy. The turbulent kinetic-energy term is usually absorbed into the pressure-gradient term, whereas the mean rate of strain is sometimes subject to further simplification. Thus the Reynolds stress  $\tau_{xx}$  in Eq. (15-2), for example, can be replaced by  $\nu_t(\partial u/\partial x)$ , where  $\nu_t$  is the eddy viscosity. This leads to a new set of equations that, when complemented by an appropriate turbulence model to estimate the eddy viscosities, are now ready to be discretized for numerical solution (possibly after additional coordinate transformation; see below), as follows for the hydrostatic case:

The Reynolds-averaged three-dimensional  $u$ -momentum conservation equation is

$$\begin{aligned} \frac{\partial u}{\partial t} = & -\frac{\partial(uu)}{\partial x} - \frac{\partial(uv)}{\partial y} - \frac{\partial(uw)}{\partial z} \\ & + f v - g \frac{\partial(z_b + h)}{\partial x} - \frac{g}{\rho_0} (\zeta - z) \frac{\partial \rho}{\partial x} \\ & + \frac{1}{\rho_0} \left[ \frac{\partial}{\partial x} \left( \nu_t \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial y} \left( \nu_t \frac{\partial u}{\partial y} \right) + \frac{\partial}{\partial z} \left( \nu_t \frac{\partial u}{\partial z} \right) \right] \end{aligned} \quad (15-12)$$

The Reynolds-averaged three-dimensional  $v$ -momentum conservation equation is

$$\begin{aligned} \frac{\partial v}{\partial t} = & -\frac{\partial(vu)}{\partial x} - \frac{\partial(vv)}{\partial y} - \frac{\partial(vw)}{\partial z} \\ & - f u - g \frac{\partial(z_b + h)}{\partial y} - \frac{g}{\rho_0} (\zeta - z) \frac{\partial \rho}{\partial y} \\ & + \frac{1}{\rho_0} \left[ \frac{\partial}{\partial x} \left( \nu_t \frac{\partial v}{\partial x} \right) + \frac{\partial}{\partial y} \left( \nu_t \frac{\partial v}{\partial y} \right) + \frac{\partial}{\partial z} \left( \nu_t \frac{\partial v}{\partial z} \right) \right] \end{aligned} \quad (15-13)$$

The depth-averaged two-dimensional  $\tilde{u}$ -momentum conservation equation is

$$\begin{aligned} \frac{\partial \tilde{u}}{\partial t} = & -\frac{\partial(\tilde{u}\tilde{u})}{\partial x} - \frac{\partial(\tilde{u}\tilde{v})}{\partial y} \\ & - f \tilde{v} - g \frac{\partial(z_b + h)}{\partial x} - \frac{g h}{2\rho_0} \frac{\partial \rho}{\partial x} \\ & + \frac{1}{\rho_0 h} \left[ \frac{\partial}{\partial x} \left( \nu_t \frac{\partial \tilde{u}}{\partial x} h \right) + \frac{\partial}{\partial y} \left( \nu_t \frac{\partial \tilde{u}}{\partial y} h \right) \right] \\ & + \frac{\tau_{sx} - \tau_{bx}}{\rho_0 h} \end{aligned} \quad (15-14)$$

The depth-averaged two-dimensional  $\tilde{v}$ -momentum conservation equation is

$$\begin{aligned} \frac{\partial \tilde{v}}{\partial t} = & -\frac{\partial(\tilde{v}\tilde{u})}{\partial x} - \frac{\partial(\tilde{v}\tilde{v})}{\partial y} - f\tilde{u} \\ & - g\frac{\partial(z_b + h)}{\partial y} - \frac{gh}{2\rho_0}\frac{\partial\rho}{\partial y} \\ & + \frac{1}{\rho_0 h} \left[ \frac{\partial}{\partial x} \left( v_t \frac{\partial \tilde{v}}{\partial x} h \right) + \frac{\partial}{\partial y} \left( v_t \frac{\partial \tilde{v}}{\partial y} h \right) \right] \\ & + \frac{\tau_{sy} - \tau_{by}}{\rho_0 h} \end{aligned} \quad (15-15)$$

As in the case of similar derivations for constituent transport equations, the Boussinesq eddy viscosity coefficient  $v_t$  is an artificial construct intended to capture the residual shear-stress effects of correlations in velocity deviations from temporal and/or depth averages. As such, the values of eddy viscosity appearing in the three-dimensional equations must be obtained from an appropriate three-dimensional eddy-viscosity model. Eddy-viscosity models vary from very simple, such as constant eddy-viscosity or zero-equation models, to more advanced, such as two-equation  $k-\varepsilon$  or  $k-\omega$  models (Chapter 16). The corresponding eddy viscosities appearing in the depth-averaged equations must be obtained from an appropriate depth-averaged eddy-viscosity model. The diffusion terms in depth-averaged hydrodynamic models, i.e., the effective stresses generated by the depth-averaging process, are typically modeled analogously to and combined with corresponding Reynolds stresses. The additional contribution to eddy viscosity arising from the depth averaging can be accounted for indirectly by adjusting one of the constants in the depth-averaged  $k-\varepsilon$  model (see Rodi 1993).

Equations (15-12) and (15-13) and the continuity equation, Eq. (15-1), are the basis for the flow model built into the CH3D-SED code, used in Sections 15.11.2 and 15.11.3 of this chapter. The flow model built into the MOBED2 code, which is used in example 15.11.4 of this chapter, is based on Eqs. (15-14) and (15-15) and the continuity equation, Eq. (15-9).

### 15.3.3 Role of Hydrostatic Pressure Assumption

The previous section presented three-dimensional hydrodynamic equations both without and with the hydrostatic pressure assumption. Hydraulic engineers are quite accustomed to invoking hydrostatic pressure in the solution of most problems, without having to recall that it implicitly assumes that pressure differences associated with vertical fluid accelerations are unimportant for the problem under study.

As discussed in the previous section, invocation of the hydrostatic pressure assumption vastly simplifies the three-dimensional hydrodynamic problem. Indeed, as of this writing

the computational time required to do a multiple-day unsteady simulation with the hydrostatic assumption is of the same order of magnitude as that required to obtain a single steady-state solution with the fully nonhydrostatic equations. Therefore it is important to consider the circumstances under which it is permissible to invoke the hydrostatic pressure assumption in three-dimensional mobile-bed modeling.

As a general rule, it is necessary to use fully three-dimensional, nonhydrostatic modeling whenever local details of mobile-bed dynamics around structures are of interest. Such structures include river training works such as dikes and bendway weirs, as well as habitat-restoration structures such as v-notched dikes, chevron weirs, or notched weirs. Experience has shown that calculated local velocity fields around structures, particularly near the bed, can be quite different for the hydrostatic and nonhydrostatic cases. This is of course due to the effects of vertical acceleration components near the intersection of the structure and the bed. Because the details of local scour and deposition in the immediate vicinity of such structures can depend quite strongly on the local velocity fields, the hydrostatic assumption can have an indirect but very important influence on mobile-bed behavior near the structure.

However, the overall mobile-bed response to using the hydrostatic-pressure assumption in the calculation of secondary currents has seldom been quantified. Therefore, it is difficult to give some general rule as to when the hydrostatic assumption is and is not acceptable. At the extreme limits, it is perhaps obvious that it is acceptable for studies of overall cross section response to changes in hydrologic or sediment regime, where local flow and sedimentation details are not of primary importance. By contrast, it is perhaps obvious that the hydrostatic assumption is not acceptable in studies focused uniquely on local sedimentation details around structures. In between these extremes, the acceptability of the assumption is a matter of judgment. Whenever it is possible to make preliminary comparative model runs with and without the hydrostatic assumption, in order to glean some insight into the apparent importance of vertical accelerations to the overall sedimentation pattern under study, this should by all means be done.

In the end, the ability to use the full nonhydrostatic equations on one hand, and the ability to perform truly unsteady calculations over some extended period of time on the other, appear as of this writing to be mutually exclusive. However, one would expect fully unsteady, nonhydrostatic modeling to become increasingly feasible as the exponential growth in computational power continues.

### 15.3.4 Solution Techniques and Their Applicability

Approximate numerical solution techniques for the two- and three-dimensional hydrodynamic equations generally fall into one of three categories: finite-difference methods (see, e.g., Shimizu et al 1990; Spasojevic and Holly

1990a; 1990b; 1993; and Lin and Falconer 1996); finite-element methods (see, e.g., Thomas and McAnally 1985; Wang and Adeff 1986; Brors 1999; Jia and Wang 1999; and the RMA-10 model at the Coastal and Hydraulics Lab, U.S. Army Corps of Engineers); or finite-volume methods (see, e.g., Olsen and Melaaen 1993; Minh Duc et al. 1998; Olsen et al. 1999; and Wu et al. 2000). Although there are important differences between finite-element and finite-volume approaches, both can be associated with unstructured grids and thus are grouped together here. It should be mentioned that the method of characteristics has been successfully applied to two-dimensional computation of rapidly varied flow, in particular for dam-break computation (see, e.g., Fennema and Chaudhry 1990), but generalization of codes based on this method to mobile-bed capability does not appear to be in the offing.

Finite-difference methods are based on approximation of partial derivatives by divided differences on a space-time grid. Such grids are called "structured," in that they comprise quadrilaterals (possibly curvilinear), all of which are defined by the same set of coordinate contours parallel (in transformed space) to the physical  $x$ ,  $y$ , and  $z$  axes. Considerable computational economy can be achieved by structuring solution algorithms to proceed along single grid lines in each of the three directions, replacing the need to solve three-dimensional or two-dimensional problems with the solution of multiple one-dimensional problems, usually coupled through multiple iterations. However, this computational economy is obtained at the expense of grid inflexibility and/or excessive computer memory requirements. If the computational grid must be refined (i.e., more grid lines introduced) to provide high resolution in the vicinity of a structure or sharp natural feature, this grid refinement must extend throughout the computational domain, even though it may not be necessary far away from the local feature of interest. Nonetheless, the finite-difference method generally offers a simplicity of programming and intuitive conceptualization of the problem that are not so natural with finite-element methods.

Finite-element and finite-volume methods are integral-based approaches in the sense that they are derived not through approximations of partial derivatives, but rather through consideration of conservation laws applied to volumetric elements and careful evaluation of fluxes (mass, momentum) across nonparallel faces of the elements. The finite-element method is based on the notion of minimizing residuals in an average or integral sense over a volumetric (or surficial) element. The finite-volume method is more directly based on primitive conservation laws and can be interpreted as equivalent to a finite-difference method when quadrilateral or elements are selected as a special case (such an interpretation is not possible when tetrahedral, i.e., triangle-based, elements are used).

Application of the integral principles to one volumetric element is dependent only on the fluxes coming from or going to adjacent elements. This leads to the notion of an unstructured grid, where grid refinement around a local feature is

accomplished through packing of small-scale volumetric elements around the feature. This packing or refinement is purely local, in that the local small scale does not propagate through the mesh of the entire solution domain. Thus local grid refinement can be accomplished without triggering the excessive memory requirements of structured grids. In addition, unstructured grids naturally accommodate dynamic (adaptive) grid refinement driven by spatially variable error detection.

The grid-refinement flexibility of finite-element/volume methods is obtained at the price of computational efficiency. Generally the multiple iterative one-dimensional computations that are possible on a structured (finite-difference) grid cannot be implemented on an unstructured one, because the very notion of continuous coordinate contours, along which partial derivatives are approximated, does not exist. Solution algorithms must generally be fully two- or three-dimensional, incurring the large computational time requirements of matrix inversion, often iterative. In practical terms, the flexibility of unstructured grids is obtained at the cost of practical limits to the duration of unsteady-flow simulations. Such practical limits may become less important as parallel processing becomes increasingly available.

The accurate computation of advection (of momentum or mass) is particularly challenging, and some hydrodynamic codes solve for advection in a separate, dedicated step using a numerical method best suited to the hyperbolic nature of the advective terms (examples include the CYTHERE-ES1 code of Benqué et al. 1982 and TELEMAC as reported by Jankowski et al. 1994). A mobile-bed code driven by a hydrodynamics solver having this feature for momentum advection should logically take advantage of it for the advection of sediment particles in suspension.

For detailed information on numerical-solution techniques for fluid flow equations, the reader may refer to numerous books in this area, such as Fletcher (1991); Hirsch (1991); or Ferziger and Peric (2002).

### 15.3.5 Coordinate Transformations for Finite-Difference Methods

The structured grids of finite-difference methods are, in their primitive form, inherently ill-suited to the representation of natural bank lines, submerged bars, etc. Early two-dimensional hydrodynamic models of the 1970s used "stair-stepping" to represent boundaries that were not aligned with one or the other orthogonal axes of a Cartesian grid (Benqué et al. 1982). The need to work with curvilinear grids quickly became apparent. However, orthogonal curvilinear grids (i.e., those for which coordinate lines intersect at right angles) still are quite inflexible for representation of local features. Further flexibility can be introduced by relaxing the orthogonality requirement to obtain a nonorthogonal curvilinear grid, in which computational cells can deform in an arbitrary manner to better fit the contour lines of natural features. Even then, it is important to maintain cell aspect

ratios within acceptable limits. Transformation of the governing partial differential equations into the coordinate system of the nonorthogonal curvilinear grid is quite tedious and generates many additional terms that must be discretized and evaluated, further increasing the complexity of the computational engine and required computational time. Most of the two- and three-dimensional codes referenced in Table 15-2 (Section 15.4.2) are based on some level of coordinate transformation.

In unsteady-flow simulation, various grid-adjustment schemes have been developed to cope with the time-dependent position of the free surface and the bed. Perhaps the most common approach is referred to as “sigma stretching,” by which the vertical grid structure adapts to changes in the free surface (and changes in the mobile bed elevation) through stretching or compression, the number of grid intervals in the vertical remaining constant.

For detailed information on coordinate transformations, the reader may refer to basic tensor analysis books, such as Simmonds (1994).

### 15.3.6 Turbulence Closure Models

As mentioned earlier, the Reynolds averaging of the Navier-Stokes equations generates correlations between the fluctuating components of local velocities; these are the so-called Reynolds stress terms shown as effective shear stresses in Eqs. (15-2), (15-3), and (15-4). Evaluation of these terms requires some sort of empirical turbulence closure model. Chapter 16 provides a comprehensive overview of the turbulence-modeling problem in the context of mobile-bed hydraulics. In the simplest approach, the Boussinesq eddy-viscosity model is supplemented with a constant eddy viscosity, either simply assigned by the user based on macroscopic flow properties or derived from a zero-equation mixing-length model or equivalent.

More advanced approaches include the use of a one-equation eddy-viscosity model, or more commonly a two-equation eddy-viscosity model such as the  $k-\varepsilon$  formulation (see for example Chapter 16 of this manual or Rodi 1993), in which the transport of the turbulence kinetic energy and its dissipation rate are solved in parallel with the flow solution, leading to eddy viscosity coefficients that reflect local shear and bed effects.

More advanced turbulence modeling techniques, such as direct Reynolds stress modeling and large eddy simulation, have been implemented for accurate calculation of internal flows and aerodynamic flows. However, the authors’ arguments in Section 15.1.4 notwithstanding, the inherent uncertainties and imprecision of the mobile-bed problem would seem to obviate the need to require more than  $k-\varepsilon$  turbulence capability in the hydrodynamic computational engine of a mobile-bed model at the current stage of development, unless such advanced techniques

are readily available and implementable in the mobile-bed model.

## 15.4 OVERVIEW OF MODELS OF SEDIMENT TRANSPORT AND BED EVOLUTION

### 15.4.1 Introduction

Although the Navier-Stokes equations, along with the continuity equation (usually Reynolds-averaged), represent a generally accepted mathematical description (model) of fluid flow, there is no comparable mathematical formulation for the complete processes of sediment-flow interaction. The most recent attempts to formulate a general mathematical model of sediment-flow interaction are based on the two-phase flow approach (Villaret and Davies 1995; Cao et al. 1995; Ni et al. 1996; Greimann et al. 1999; Liu et al., 1997). The attempts are inspired by the history of two-phase flow models in other fields (Ishii 1975; Drew 1983; Elghobashi 1994; Crowe et al. 1996). The basic idea behind the two-phase flow approach is to formulate governing conservation equations for both phases, which include terms defining interaction between phases such as the stress tensor due to phase interactions, or the interfacial momentum transfer term.

However, even though the two-phase flow approach seems promising, its use and even the formulation of the governing equations in flow-sediment problems are still in their infancy. Certain terms in the governing equations that are typically neglected in other fields may require quite a different treatment in the flow-sediment field. The stress between fluid and sediment particles is usually neglected under the assumption that it is much smaller than the turbulent stress between fluid particles. The stress coming from interactions among sediment particles is neglected under the assumption that sediment particles do not contact each other. Both of these assumptions are questionable in the case of high sediment concentrations, especially near the bed. This probably explains a lingering doubt about the use of the two-phase flow approach in the near-bed areas. Furthermore, certain terms in the two-phase flow governing equations, such as the interfacial momentum transfer, require additional modeling to achieve system closure. Such modeling has to be based on a detailed knowledge of turbulence and requires currently unavailable experimental data. Finally, the two-phase flow solution of practical sediment problems, which routinely require long-term simulations, is likely to be CPU-time-prohibitive even in the not-so-near future.

Therefore, virtually all two-dimensional and three-dimensional flow and sediment models used for solving practical problems are based on a simplified concept. The basic idea classifies sediment transport as either suspended load or bed load and defines a set of equations describing suspended-sediment transport, bed-load transport, and bed evolution. Thus, the concept requires artificially partitioning the otherwise single

**Table 15-2 Typical Simplifications Used in Flow and Sediment Modeling**

Model and/or references	Flow	Bed-load transport	Bed-elevation changes	Suspended-sediment transport	Sediment-exchange processes	Sediment mixtures	Base numerical method
SUTRENCH-2D, van Rijn (1987)	Quasi unsteady two-dimensional (width-averaged)	Bed-load-layer concept	Total-load concept	Quasi-unsteady two-dimensional (width-averaged)	Entrainment and deposition	No	Finite-volume with structured grid

and continuous domain of sediment processes into a bed and/or near-bed layer on the one hand, and the rest of the domain on the other. Then the governing equations for the bed and near-bed processes are associated with the bed and near-bed layer, whereas the governing equations for the suspended-material processes are associated with the rest of the domain.

#### 15.4.2 Overview of Conceptual Models of Mobile-Bed Processes

There are several conceptualizations of the bed and near-bed layer, such as the mixing layer proposed by Karim and Kennedy (1982), the bed load layer proposed by van Rijn (1987), and the active layer proposed by Spasojevic and Holly (1990b). Similarly, there is no generally accepted set of governing equations for the bed and near-bed processes. The equations' formulations, even though not so different, may still vary depending on the bed and near-bed layer concept, or simply depending on the approach. More details on the governing equations for the bed and near-bed processes are presented in Section 15.5.

In contrast to the bed and near-bed processes, modeling of suspended-material processes is practically always based on the sediment-transport or advection-diffusion equation with an additional fall-velocity advection term. The suspended-sediment advection-diffusion equation can be derived either from the two-phase flow equations (Greimann et al. 1999) or directly, using the continuum approach, and the assumptions are that the sediment particles' horizontal velocity components are the same as the corresponding fluid velocities and that the sediment particles' vertical-velocity components are equal to those of the appropriate fluid velocity adjusted by the fall velocity. In either case, the result is the familiar suspended-sediment advection-diffusion equation with a special model for particle settling, characterized by a settling velocity. Details on suspended-material modeling are presented in Section 15.6.

The simplified model can only account for the sediment-flow interaction in an indirect way. The flow-sediment interaction in such models is achieved through the flow acting as the driving force for sediment processes and the associated sediment-process feedback to the flow. This sediment-process feedback comprises changes in bed elevation, changes in the flow and the suspended-sediment mixture density, and, possibly, changes in the bed friction coefficient.

This concept of sediment-process modeling based on separation of suspended-material and bed and near-bed processes inevitably requires formulation of sediment-exchange mechanisms. Sediment-exchange processes are commonly formulated as bed and near-bed material entrainment into suspension and suspended-material deposition onto the bed. The same exchange terms, with opposite signs, provide the coupling between equations for near-bed and suspended-material processes. Details on

modeling of sediment-exchange processes are presented in Section 15.7.

Even when these simplifications are made, the development of two-dimensional and three-dimensional flow and sediment models is constrained by the available computing resources. Due to the complexity of the problem and the typical need for long-term simulations, flow and sediment modeling can be prohibitive in terms of CPU time. Therefore, many flow and sediment models adopt further simplification. Table 15-2 summarizes typical simplifications used in flow and sediment modeling. Although the list of models in the table is surely incomplete, the authors hope that the listed models reflect the general scope of current developments in two-dimensional and three-dimensional flow and sediment modeling.

#### 15.4.3 Assessment of Conceptual Bases of Mobile-Bed Models

Because the bed-load flux is a vector parallel to the bed surface, the bed-load transport is essentially two-dimensional. But the flow and the suspended-sediment transport are fully three-dimensional processes. Therefore, two-dimensional flow and suspended-sediment transport models may have restricted applicability, as has been described earlier. On the other hand, use of the two-dimensional equations for flow and suspended-sediment transport is far less demanding of CPU time than use of three-dimensional models, as discussed earlier. The two-dimensional simplification was used extensively during the 1980s, when the available computing resources were typically insufficient for any practically meaningful three-dimensional flow and sediment modeling. The two-dimensional depth-averaged approach was used in the Argos Modeling System (as described by Usseglio-Polatera and Cunge 1985), and MOBED2 (Spasojevic and Holly 1990a; 1990b). TABS-2, as described by Thomas and McAnally (1985), is based on the depth-averaged flow equations, with the bed-load and suspended-sediment transport modeling replaced by the total load concept. Van Rijn (1987) developed the SUTRENCH-2D model in which the flow and suspended-sediment transport are modeled using the two-dimensional width-averaged equations. van Rijn (1987) also developed the SUTRENCH-3D model, in which the flow is modeled using the two-dimensional depth-averaged equations in combination with the assumption of a vertical logarithmic velocity profile, whereas the suspended-sediment transport is modeled using the three-dimensional equations. Shimizu et al. (1990) developed a model based on the depth-averaged suspended-sediment transport equations and quasi-three-dimensional flow equations, assuming a hydrostatic-pressure distribution and using an empirical longitudinal velocity component distribution along the depth.

After being neglected for a few years, during which time a number of three-dimensional flow and sediment

models have been developed and successfully applied, the two-dimensional approach seems to be enjoying renewed popularity. It appears that the price for the sophistication and generality of three-dimensional flow and sediment models is still the often-prohibitive CPU time. Thus, a number of two-dimensional models, often including corrections for three-dimensional effects, have recently been developed to be used for specific applications, perhaps even in combination with three-dimensional models. Minh Duc et al. (1998) presented the FAST2D model with sediment processes, based on the depth-averaged equations for the flow and the suspended-sediment transport, which can be used for relatively long simulations. The CCHE2D model (Jia and Wang 1999), including the depth-averaged flow equations, bed-load transport, and bed-elevation changes, has been developed for cost- and time-effective long-term simulations. Nagata et al. (2000) also developed a model based on the depth-averaged flow equations, bed-load transport, and bed-elevation changes, including the rarely modeled bank erosion. All three models include some kind of correction for three-dimensional flow effects. Brors (1999) reported a three-dimensional model of flow and sediment processes around a submerged pipeline, but its application was limited to consideration of conditions in a two-dimensional vertical plane. Olsen (1999) developed a model based on a combination of the depth-averaged flow equations and three-dimensional suspended-sediment transport, using an empirical expression for the vertical profile of eddy viscosity.

The development of three-dimensional flow and sediment models started in the early 1980s. The simplifications used in three-dimensional models involve both flow-modeling simplifications and the level of complexity included in the sediment equations. One of the typical three-dimensional flow modeling simplifications is the use of the steady-state equations for both flow and suspended-sediment transport (Demuren 1991; Olsen and Melaaen 1993; Olsen and Skoglund 1994; Olsen et al. 1999). Use of this simplification restricts the model's range of applicability, because the sediment processes are naturally unsteady and their effects accumulate in time, eventually affecting the flow computations. Another typical three-dimensional flow modeling simplification is the assumption of a hydrostatic-pressure distribution over the depth as described in Section 15.3.3 above (Sheng 1983; FLESCOT as reported by Onishi and Trent 1985; Wang and Adeff 1986; TELEMAC-3D with sediment processes as reported by Jankowski et al. 1994; Lin and Falconer 1996; CH3D-SED as reported by Gessler et al. 1999). The hydrostatic-pressure assumption is easily violated wherever streamline curvature is significant (e.g., in the vicinity of river-training structures, close to rapidly changing bed surface conditions, in river bends). However, this simplification is still commonly used because it provides for significant CPU time-saving and

thus enables simulations over some significant period of prototype time.

In terms of complexity of sediment-processes modeling, both two- and three-dimensional models in use span quite a wide range. Some models concentrate on bed-load transport and associated bed elevation changes (e.g., the CCHE2D of Jia and Wang 1999 and two-dimensional models of Nagata et al. 2000). Others concentrate on suspended-sediment transport, some including the associated bed elevation changes (e.g., the two-dimensional Argos Modeling System as described by Usseglio-Polatera and Cunge 1985; the three-dimensional FLESCOT model of Onishi and Trent 1985), and some not including bed changes (e.g., the three-dimensional models of Sheng, 1983; Olsen et al. 1999; TELEMAC-3D with sediment processes as described by Jankowski et al. 1994). The three-dimensional model of Lin and Falconer (1996) includes both bed-load and suspended-sediment transport, but does not include bed elevation changes. Models concentrating only on certain aspects of sediment processes are obviously applicable to flow and sediment situations where the corresponding aspects dominate. Examples of such specific flow and sediment situations may include settling tanks or reservoir-sedimentation problems, where suspended-sediment transport and deposition are dominant processes.

More general models recognize that the same sediment particle can remain at the bed surface or move either in suspension or as bed load, all depending on local flow conditions, and attempt to include all relevant sediment processes. Examples of the more general approach among two-dimensional models include SUTRENCH-2D, van Rijn (1987); MOBED2 as reported by Spasojevic and Holly (1990a; 1990b); FAST2D with sediment processes, Minh Duc et al. (1998); and models of Shimizu et al. (1990); Brors (1999); Olsen (1999). Examples among three-dimensional models include SUTRENCH-3D, van Rijn (1987); models of Wang and Adeff (1986); Demuren (1991); Olsen and Melaaen (1993); Olsen and Skoglund (1994); Olsen and Kjellesvig (1998); CH3D-SED as reported by Spasojevic and Holly (1993) or Gessler et al. (1999); and FAST3D with sediment processes as reported by Rodi (2000) or Wu et al. (2000).

Finally, only a few models attempt to include the behavior of nonuniform sediment or sediment mixtures. Spasojevic and Holly (1990a; 1990b) introduced a relatively general approach to the treatment of sediment mixtures with an unlimited number of sediment size classes, as initially developed for the two-dimensional model MOBED2. The approach was subsequently generalized and built into the three-dimensional CH3D-SED model (Spasojevic and Holly 1993). The combined two-dimensional depth-averaged flow and three-dimensional suspended-sediment transport model reported by Olsen (1999) uses a budget method for computing the change in bed grain-size

distribution. The three-dimensional FLESCOT model, as reported by Onishi and Trent (1985), treats three distinct sediment components (clay, silt, sand). Modeling the behavior of sediment mixtures allows accounting for natural phenomena such as differential settling, hydraulic sorting, and armoring.

## 15.5 BED AND NEAR-BED PROCESSES

### 15.5.1 Introduction and Overview

One of the major differences among various two-dimensional or three-dimensional flow and sediment models is the treatment of bed and near-bed processes, including bed-load transport, bed elevation changes, and the exchange between the suspended material and the bed and near-bed material.

Demuren (1991) introduced a simplified model for bed-elevation changes in meandering channels using algebraic equations based on perturbations to equilibrium between bed elevations and bedload transport. Olsen and Melaaen (1993), Olsen and Skoglund (1994), Olsen and Kjellesvig (1998), and Olsen (1999) presented models that solve the three-dimensional mass-conservation (advection-diffusion) equation for suspended sediment using an empirical near-bed concentration as a boundary condition. The near-bed concentration is assigned to computational cells next to the bed surface, but the mass-conservation equation for these cells is not solved. In a somewhat arbitrary manner, the discrepancy in the sediment continuity for computational cells next to the bed surface is used to compute bed-surface elevation changes.

Modeling bed-surface elevation changes is often based on an intuitive sediment mass-conservation equation, usually referred to as the Exner equation, written for the sediment resting on the bed or moving as a bed load. The full form of the Exner equation is

$$\rho_s (1 - p_b) \frac{\partial z_b}{\partial t} + \nabla \cdot \vec{q}_b + E - D = 0 \quad (15-16)$$

where

- $\rho_s$  = density of sediment, assumed to be constant;
- $p_b$  = porosity of the bed material, assumed to be constant;
- $z_b$  = bed-surface elevation;
- $\vec{q}_b$  = bed-load flux;
- $E$  = upward bed-sediment entrainment flux, representing the entrainment of sediment particles from the bed into suspension; and
- $D$  = downward suspended-sediment deposition flux, representing gravitational settling of suspended sediment particles onto the bed.

The Exner equation is essentially two-dimensional in the plane parallel to the bed surface.

The models of Shimizu et al. (1990) and Brors (1999) include both bed load and suspended-sediment transport and use a complete form of the Exner equation. The Argos Modeling System, as described by Usseglio-Polatera and Cunge (1985), and the FLESCOT model, as described by Onishi and Trent (1985), both of which include only suspended-sediment transport, use the Exner equation without the bed-load flux-divergence term. The CCHE2D model of Jia and Wang (1999) and the model of Nagata et al. (2000), both of which include only bed-load transport, use the Exner equation without entrainment and deposition sources. Nagata et al. (2000) also use the bed-load deposition and pickup functions instead of the bed-load flux-divergence term. TABS-2, as described by Thomas and McAnally (1985), which does not distinguish between the bed load and the suspended-sediment transport, uses the Exner equation with an empirical total load flux.

Van Rijn (1987) introduced the bed-load-layer concept and proposed two methods for computing the bed-surface elevation changes. One method is based on the sediment mass-conservation equation for the bed-load-layer control volume, and it is called here the bed-load-layer approach. The other is based on the sediment mass-conservation equation for the control volume spanning the entire flow depth and thus comprising the bed-load-layer control volume and the entire water column with suspended sediment above it. This second method requires combining the bed-load flux and the depth-integrated suspended-sediment flux into the total-load flux, so it is called here the total-load approach. The SUTRENCH-2D and SUTRENCH-3D models of van Rijn (1987) have both the bed-load-layer approach and the total-load approach built in as alternatives. The total-load approach was used in the model of Wang and Adeff (1986), in FAST2D with sediment processes (Minh Duc et al. 1998), and in FAST3D with sediment processes (Wu et al. 2000). Both FAST2D and FAST3D with sediment processes also adapted the bed-load-layer approach to compute the nonequilibrium bed-load flux.

Spasojevic and Holly (1990a; 1990b) introduced an active-layer and active-stratum concept and proposed a method to compute the bed-surface elevation and the active-layer size-class distribution changes in the case of nonuniform sediment, i.e., for natural sediment mixtures. The method, initially implemented in the two-dimensional (depth averaged) MOBED2 model (Spasojevic and Holly 1990a; 1990b), and subsequently generalized and built into the three-dimensional CH3D-SED model (Spasojevic and Holly 1993), is called here the active-layer and active-stratum approach.

### 15.5.2 The Bed-Load-Layer and the Total-Load Approach

Figure 15-1 shows a vertical schematization of the sediment-processes domain, as introduced by van Rijn (1987) and applied by Wu et al. (2000).

Fig. 15-1. Vertical schematization of the sediment-processes domain (van Rijn 1987; Wu et al. 2000).

According to van Rijn (1987), the mass-conservation equation for the bed-load-layer control volume reads

$$\frac{\partial}{\partial t}(h_b \tilde{c}_b) + \nabla \cdot \vec{q}_b + E_b - D_b - E_o + D_o = 0 \quad (15-17)$$

where

- $h_b$  = bed-load-layer thickness;
- $\tilde{c}_b$  = bed-load-layer sediment volumetric concentration averaged over the bed-load-layer thickness;
- $\vec{q}_b$  = bed-load flux;
- $E_b$  = upward sediment enainment flux at  $z = z_b + h_b$ ;
- $D_b$  = downward sediment deposition flux at  $z = z_b + h_b$ ;
- $E_o$  = upward sediment enainment flux at  $z = z_b$ ; and
- $D_o$  = a downward sediment deposition flux at  $z = z_b$ .

Entrainment and deposition fluxes  $E_b$  and  $D_b$  represent the exchange between the bed-load-layer sediment and the suspended sediment through the bed-load-layer control volume ceiling. Entrainment and deposition fluxes  $E_o$  and  $D_o$  represent the exchange between the bed-subsurface sediment and the bed-load-layer sediment through the bed-load-layer control volume floor.

Van Rijn also introduced a similar mass-conservation equation for the bed-subsurface sediment control volume,

$$\rho_s (1 - p_b) \frac{\partial z_b}{\partial t} + E_o - D_o = 0 \quad (15-18)$$

where

- $z_b$  = the bed-surface elevation and is the bed-subsurface control volume ceiling.

Because the bed-subsurface control volume floor does not move, its location, i.e., the subsurface control volume thickness, is irrelevant.

Adding Eqs. (15-17) and (15-18) yields the mass-conservation equation for bed-load-layer and bed-subsurface sediment:

$$\rho_s (1 - p_b) \frac{\partial z_b}{\partial t} + \frac{\partial}{\partial t}(h_b \tilde{c}_b) + \nabla \cdot \vec{q}_b + E_b - D_b = 0 \quad (15-19)$$

The mass-conservation equation for the control volume spanning the entire flow depth, including the bed-load layer and the entire water column with suspended sediment above it, reads (van Rijn, 1987)

$$\frac{\partial}{\partial t}(h \tilde{c}) + \nabla \cdot \vec{q}_T - E_o + D_o = 0 \quad (15-20)$$

where

- $h$  = the entire flow depth;
- $\tilde{c}$  = depth-averaged volumetric suspended-sediment concentration ;
- $\vec{q}_T = \vec{q}_b + \vec{q}_s$  = total sediment load flux;
- $\vec{q}_s$  = depth-integrated suspended-load flux (advection and diffusion).

Adding Eqs. (15-18) and (15-20) yields the mass-conservation equation for bed-subsurface sediment, bed-load-layer sediment, and suspended sediment in the entire water column above the bed load layer:

$$\rho_s (1 - p_b) \frac{\partial z_b}{\partial t} + \frac{\partial}{\partial t}(h \tilde{c}) + \nabla \cdot \vec{q}_T = 0 \quad (15-21)$$

Van Rijn (1987) states that for steady-flow conditions the storage terms  $\frac{\partial}{\partial t}(h_b \tilde{c}_b)$  in Eq. (15-19) and  $\frac{\partial}{\partial t}(h \tilde{c})$  in Eq. (15-21)

can be neglected. This assumption may be inappropriate in cases of extensive deposition (such as settling in reservoirs) or extensive entrainment (e.g., erosion behind river-training structures such as chevron dikes). With van Rijn's assumption, Eq. (15-19) reduces to the specific form of the Exner equation (the location of entrainment and deposition fluxes  $E_b$  and  $D_b$  is well defined)

$$\rho_s (1 - p_b) \frac{\partial z_b}{\partial t} + \nabla \cdot \vec{q}_b + E_b - D_b = 0 \quad (15-22)$$

whereas Eq. (15-21) becomes:

$$\rho_s (1 - p_b) \frac{\partial z_b}{\partial t} + \nabla \cdot \vec{q}_T = 0 \quad (15-23)$$

Either Eq. (15-22) or Eq. (15-23) can be used to compute bed-surface elevation changes. Wu et al. (2000) state that Eq. (15-23) ensures better mass conservation in numerical procedures.

Equations (15-22) and (15-23) can be written in Cartesian coordinates as follows:

$$\rho_s (1 - p_b) \frac{\partial z_b}{\partial t} + \frac{\partial q_{bx}}{\partial x} + \frac{\partial q_{by}}{\partial y} + E_b - D_b = 0 \quad (15-24)$$

and

$$\rho_s (1 - p_b) \frac{\partial z_b}{\partial t} + \frac{\partial q_{Tx}}{\partial x} + \frac{\partial q_{Ty}}{\partial y} = 0 \quad (15-25)$$

where

$q_{bx}$  and  $q_{by}$  =  $x$ - and  $y$ -direction components of the bed-load flux and  
 $q_{Tx}$  and  $q_{Ty}$  =  $x$ - and  $y$ -direction components of the total sediment load flux.

Wu et al. (2000) further modified Eq. (15-24) to account for nonequilibrium effects on the bed-load transport by using the assumption

$$(1 - p_b) \frac{\partial z_b}{\partial t} = \frac{1}{L_s} (q_b - q_{be}) \quad (15-26)$$

where  $L_s$  is the nonequilibrium adaptation length for bed-load transport, and  $q_{be}$  is the bed-load flux under equilibrium conditions. The assumption expressed by Eq. (15-26) was introduced by Wellington (1978), Philips and Sutherland (1989), and Thuc (1991) for the case where the suspended load is negligible (i.e.,  $E_b - D_b = 0$ ). With the components of bed-load flux in  $x$ - and  $y$ -directions expressed as

$$q_{bx} = \alpha_{bx} q_b, \quad q_{by} = \alpha_{by} q_b \quad (15-27)$$

where

$\alpha_{bx}$  and  $\alpha_{by}$  = direction cosines,

and with Eqs. (15-26) and (15-27) introduced into Eq. (15-24), one obtains

$$\frac{1}{L_s} (q_b - q_{be}) + \frac{\partial (\alpha_{bx} q_b)}{\partial x} + \frac{\partial (\alpha_{by} q_b)}{\partial y} + E_b - D_b = 0. \quad (15-28)$$

### 15.5.3 The Active-Layer and Active-Stratum Approach—Sediment Mixtures

Inspired by the mixing-layer concept of Karim and Kennedy (1982), Spasojevic and Holly (1990a; 1990b) introduced the active-layer concept. The active layer (Fig. 15-2) is assumed to comprise sediment moving as a bed load, as well as bed-surface and subsurface sediment already agitated and ready to be set into motion. The active-layer concept is used in conjunction with a modeling approach designed for the treatment of sediment mixtures. Thus, the sediment mixture is represented through a suitable number of sediment size classes.

The active layer is assumed to have a uniform size-class distribution over its thickness  $h_a$ . It is assumed that all sediment particles of a given size class inside the active layer are equally exposed to the flow irrespective of their location in the layer. An active-layer control volume  $\Delta V$  (Fig. 15-2) is defined as having dimension  $\Delta l$  not less than the maximum average saltation length, so that the bed-load flux represents bed-load exchange between two neighboring control volumes.

For a fixed active-layer floor elevation, the mass-conservation equation for size class  $ks$  of sediment in the active-layer control volume is written as follows:

$$\rho_s (1 - p_b) \frac{\partial (\beta_{ks} h_a)}{\partial t} + \nabla \cdot \vec{q}_{bks} + E_{ks} - D_{ks} = 0 \quad (15-29)$$

where

$\beta_{ks}$  = active-layer fraction of the size class  $ks$ , defined as a ratio of the mass of particles of the size class  $ks$  inside the active-layer control volume  $\Delta V$  to the mass of all sediment particles contained in  $\Delta V$ ;

$\vec{q}_{bks}$  = bed-load flux for the size class  $ks$ ;

$E_{ks}$  = upward sediment entrainment flux for the size class  $ks$ ;

$D_{ks}$  = downward sediment deposition flux for the size class  $ks$ .

Fig. 15-2. Active-layer definition sketch.

The entrainment and deposition fluxes are evaluated at some distance above the bed surface, and that location is considered to be the near-bed boundary of the suspended material domain.

As Fig. 15-2 indicates, the only bed-load particles changing the mass balance inside the active-layer control volume are the ones entering and leaving the volume. Other bed-load particles start and end their trajectories inside the same active-layer control volume, remaining within the volume and not changing the mass balance within it. To make possible the use of a conventional bed-material porosity  $p_b$ , the active-layer thickness  $h_a$  in Eq. (15-29) is defined assuming that such bed-load particles are positioned at the bed surface.

Subsurface material below the active-layer control volume is discretized into a sequence of control volumes, one below the other, called here stratum control volumes (Fig. 15-3). Each stratum control volume has the same dimension  $\Delta l$  as the active-layer control volume above it. The bed material inside one stratum control volume is assumed to have uniform size distribution.

The stratum control volume immediately below the active-layer control volume is called the active-stratum control volume. It is possible, indeed likely, that the active-layer and active-stratum elemental volumes have different size distributions. The active-layer floor, which is at the same time an active-stratum ceiling, descends or rises whenever the bed elevation changes due to deposition or erosion occurring in the active-layer control volume. If, for example, the active-layer floor descends, some of the material that belonged to the active-stratum control volume

becomes part of the active-layer control volume, whose homogeneous size distribution thus may change.

In order to represent the exchange of sediment particles between the active-layer and the active-stratum control volumes due to active-layer floor movement, another source term is introduced, called here the active-layer floor source  $F_{ks}$ , again specific to the size class  $ks$ . The mass-conservation equation for the size class  $ks$  of sediment particles in the active-layer control volume then reads

$$\rho_s (1 - p_b) \frac{\partial (\beta_{ks} h_a)}{\partial t} + \nabla \cdot \vec{q}_{bks} + E_{ks} - D_{ks} - F_{ks} = 0 \quad (15-30)$$

The mass of a particular size class in the active-stratum control volume may change only due to active-layer floor movement, i.e., due to exchange of material between the active layer and active stratum, whereas the active-stratum floor elevation remains unchanged. This is expressed by a mass-conservation equation written for the size class  $ks$  in the active-stratum control volume,

$$\rho_s (1 - p_b) \frac{\partial [\beta_{sks} (z_b - h_a)]}{\partial t} + F_{ks} = 0 \quad (15-31)$$

where

$\beta_{sks}$  = active-stratum fraction of the size class  $ks$ ;  
and

$(z_b - h_a)$  = active-layer floor elevation, i.e., active-stratum ceiling.

Fig. 15-3. Stratum control volumes below an active-layer control volume.

Summation of the mass-conservation equations for all size classes in the active-layer control volume and use of the basic constraint

$$\sum_{ks=1}^{KS} \beta_{ks} = 1 \quad (15-32)$$

where

$KS$  represents the total number of size classes,

leads to the global mass-conservation equation for the active-layer control volume:

$$\rho_s (1-p_b) \frac{\partial h_a}{\partial t} + \sum_{ks=1}^{KS} (\nabla \cdot \vec{q}_{bks} + E_{ks} - D_{ks} - F_{ks}) = 0. \quad (15-33)$$

A similar equation can be obtained for the active-stratum control volume,

$$\rho_s (1-p_b) \frac{\partial (z_b - h_a)}{\partial t} + \sum_{ks=1}^{KS} F_{ks} = 0 \quad (15-34)$$

where again Eq. (15-32) is invoked. Summation of Eqs. (15-33) and (15-34) gives the global mass-conservation equation for bed sediment,

$$\rho_s (1-p_b) \frac{\partial z_b}{\partial t} + \sum_{ks=1}^{KS} (\nabla \cdot \vec{q}_{bks} + E_{ks} - D_{ks}) = 0 \quad (15-35)$$

which can be recognized as the form of the Exner equation written for the summation over all sediment size classes.

One global mass-conservation equation for bed sediment (Eq. (15-35)) written for the bed control volume (comprising active-layer and active-stratum control volumes), and  $ks$  mass-conservation equations for active-layer sediment (one Eq. (15-30) for each size class) written for the active-stratum control volume, are used to compute the bed-surface elevation and the active-layer size-class distribution changes. To satisfy the basic constraint (Eq. (15-32)), the equations must be solved simultaneously.

When the overall bed slope is small, the mass-conservation equation for the size class  $ks$  of active-layer sediment and the global mass-conservation equation for bed sediment, Eqs. (15-30) and (15-35), can be written in Cartesian coordinates as follows:

$$\rho_s (1-p_b) \frac{\partial (\beta_{ks} h_a)}{\partial t} + \frac{\partial q_{bxks}}{\partial x} + \frac{\partial q_{byks}}{\partial y} + E_{ks} - D_{ks} - F_{ks} = 0 \quad (15-36)$$

and

$$\rho_s (1-p_b) \frac{\partial z_b}{\partial t} + \sum_{ks=1}^{KS} \left( \frac{\partial q_{bxks}}{\partial x} + \frac{\partial q_{byks}}{\partial y} + E_{ks} - D_{ks} \right) = 0 \quad (15-37)$$

where

$q_{bxks}$  and  $q_{byks}$  =  $x$ - and  $y$ -direction components of the bed-load flux for the size class  $ks$  of active-layer sediment.

## 15.6 SUSPENDED-MATERIAL PROCESSES

### 15.6.1 General Three-Dimensional Formulation

The majority of two-dimensional and three-dimensional flow and sediment models use the advection-diffusion equation with an additional fall-velocity term to describe the suspended-sediment transport. The three-dimensional mass conservation equation for suspended sediment reads

$$\begin{aligned} & \frac{\partial(\rho C)}{\partial t} + \frac{\partial}{\partial x}(u\rho C) + \frac{\partial}{\partial y}(v\rho C) \\ & + \frac{\partial}{\partial z}(w\rho C) - \frac{\partial}{\partial z}(w_f \rho C) \\ & = \frac{\partial}{\partial x} \left( \epsilon_s \frac{\partial(\rho C)}{\partial x} \right) + \frac{\partial}{\partial y} \left( \epsilon_s \frac{\partial(\rho C)}{\partial y} \right) \\ & + \frac{\partial}{\partial z} \left( \epsilon_s \frac{\partial(\rho C)}{\partial z} \right) \end{aligned} \quad (15-38)$$

where

$\rho$  = density of a mixture of water and suspended sediment;

$C$  = dimensionless concentration, i.e., ratio of the mass of the suspended-sediment particles contained in an elemental volume to the total mass of the elemental volume;

$w_f$  = suspended-sediment particle fall or settling velocity;

$u, v$ , and  $w$  = water-velocity components;

$\epsilon_s$  = turbulent mass-diffusivity coefficient, i.e., the eddy diffusivity for sediment-particle transport.

When the dimensional or so-called volumetric concentration  $c = \rho C$  is used, Eq. (15-38) becomes

$$\begin{aligned} & \frac{\partial c}{\partial t} + \frac{\partial}{\partial x}(uc) + \frac{\partial}{\partial y}(vc) + \frac{\partial}{\partial z}(wc) - \frac{\partial}{\partial z}(w_f c) \\ & = \frac{\partial}{\partial x} \left( \epsilon_s \frac{\partial c}{\partial x} \right) + \frac{\partial}{\partial y} \left( \epsilon_s \frac{\partial c}{\partial y} \right) + \frac{\partial}{\partial z} \left( \epsilon_s \frac{\partial c}{\partial z} \right) \end{aligned} \quad (15-39)$$

where the volumetric concentration  $c$  = the ratio of the mass of the suspended-sediment particles contained in an elemental volume to the elemental volume.

The formulations of Eqs. (15-39) and (15-40), based on the dimensional and dimensionless concentrations, are fully equivalent. Most (but not all) model formulations are based on the dimensional concentration, and field and laboratory data are reported in both forms. There is no inherent advantage in using or the other of the two forms.

At the free surface, the vertical sediment flux is zero. Thus, the simplest free-surface boundary condition for Eqs. (15-38) or (15-39) is to set the vertical diffusion and the fall-velocity advection fluxes to zero at the free surface. The near-bed boundary condition for Eqs. (15-38) or (15-39) can be either the specified concentration, or the specified exchange between the suspended-sediment and the bed- and near-bed processes. The exchange is defined as the difference between the upward sediment entrainment flux  $E$  and the downward sediment deposition flux  $D$ , having signs opposite to the same terms in the governing equations for the bed- and near-bed processes. The sediment exchange condition is preferred if the model includes both suspended-sediment processes and the bed- and near-bed processes, because it provides the coupling between the two.

### 15.6.2 Two-Dimensional (Depth-Averaged) Formulation

The depth-averaged form of Eq. (15-39) is:

$$\begin{aligned} & \frac{\partial(h\tilde{c})}{\partial t} + \frac{\partial}{\partial x}(\tilde{u}h\tilde{c}) + \frac{\partial}{\partial y}(\tilde{v}h\tilde{c}) \\ &= \frac{\partial}{\partial x}\left(\tilde{\epsilon}_s h \frac{\partial \tilde{c}}{\partial x}\right) + \frac{\partial}{\partial y}\left(\tilde{\epsilon}_s h \frac{\partial \tilde{c}}{\partial y}\right) + E - D \end{aligned} \quad (15-40)$$

where

$h$  = depth;

$\tilde{c}$  = depth-averaged dimensional (volumetric) concentration;

$\tilde{u}$  and  $\tilde{v}$  = depth-averaged water velocity components;

$\tilde{\epsilon}_s$  = horizontal plane mass-diffusivity coefficient, usually only including the eddy diffusivity and neglecting the dispersion due to depth averaging.

As discussed in Section 15.3.2, model developers have tended to include neither this additional dispersion, nor a tensorial representation to account for the differential effective dispersion parallel and perpendicular to the local flow direction, as described by Holly and Usseglio-Polatera (1984).

### 15.6.3 Formulations for Sediment Mixtures

When the sediment mixture is considered, Eqs. (15-38) and (15-39) can be written for a particular size class. Equation (15-38) for the size class  $KS$  reads

$$\begin{aligned} & \frac{\partial(\rho C_{ks})}{\partial t} + \frac{\partial}{\partial x}(u\rho C_{ks}) + \frac{\partial}{\partial y}(v\rho C_{ks}) \\ &+ \frac{\partial}{\partial z}(w\rho C_{ks}) - \frac{\partial}{\partial z}(w_{fks}\rho C_{ks}) \\ &= \frac{\partial}{\partial x}\left(\epsilon_s \frac{\partial(\rho C_{ks})}{\partial x}\right) + \frac{\partial}{\partial y}\left(\epsilon_s \frac{\partial(\rho C_{ks})}{\partial y}\right) \\ &+ \frac{\partial}{\partial z}\left(\epsilon_s \frac{\partial(\rho C_{ks})}{\partial z}\right) \end{aligned} \quad (15-41)$$

where the dimensionless concentration  $C_{ks}$  = the ratio of the mass of the size class  $ks$  suspended-sediment particles contained in an elemental volume to the total mass in the elemental volume; and  $w_{fks}$  = fall or settling velocity of the size class  $ks$  suspended-sediment particles.

Equation (15-39) for the size class reads

$$\begin{aligned} & \frac{\partial c_{ks}}{\partial t} + \frac{\partial}{\partial x}(uc_{ks}) + \frac{\partial}{\partial y}(vc_{ks}) \\ &+ \frac{\partial}{\partial z}(wc_{ks}) - \frac{\partial}{\partial z}(w_{fks}c_{ks}) \\ &= \frac{\partial}{\partial x}\left(\epsilon_s \frac{\partial c_{ks}}{\partial x}\right) + \frac{\partial}{\partial y}\left(\epsilon_s \frac{\partial c_{ks}}{\partial y}\right) + \frac{\partial}{\partial z}\left(\epsilon_s \frac{\partial c_{ks}}{\partial z}\right) \end{aligned} \quad (15-42)$$

where the volumetric concentration  $c_{ks}$  = the ratio of the mass of the size class  $ks$  suspended-sediment particles contained in an elemental volume to the elemental volume.

The depth-averaged Eq. (15-40) for size class  $ks$  reads

$$\begin{aligned} & \frac{\partial(h\tilde{c}_{ks})}{\partial t} + \frac{\partial}{\partial x}(\tilde{u}h\tilde{c}_{ks}) + \frac{\partial}{\partial y}(\tilde{v}h\tilde{c}_{ks}) \\ &= \frac{\partial}{\partial x}\left(\tilde{\epsilon}_s h \frac{\partial \tilde{c}_{ks}}{\partial x}\right) + \frac{\partial}{\partial y}\left(\tilde{\epsilon}_s h \frac{\partial \tilde{c}_{ks}}{\partial y}\right) + E_{ks} - D_{ks} \end{aligned} \quad (15-43)$$

where

$\tilde{c}_{ks}$  = depth-averaged dimensional (volumetric) concentration of the size class  $ks$  particles;

$E_{ks}$  and  $D_{ks}$  = the upward sediment entrainment flux and the downward sediment deposition flux for the size class  $ks$  particles, respectively.

## 15.7 SEDIMENT-EXCHANGE PROCESSES

### 15.7.1 Introduction

As stated in Section 15.6, the near-bed boundary condition for suspended-sediment computations can be either a specified concentration, or a specified exchange between suspended-sediment and bed and near-bed processes. Prescribing the near-bed boundary condition for suspended-sediment computations, i.e., defining the sediment-exchange processes, has proven to be one of the most challenging problems in mobile modeling.

### 15.7.2 Imposition of Near-Bed Concentration

A number of researchers use the near-bed concentration as a boundary condition for suspended-sediment computations. Examples include Wang and Adeff (1986); Olsen and Melaaen (1993); Olsen and Skoglund (1994); Olsen and Kjellesvig (1998); Brors (1999); Olsen (1999); or Olsen et al. (1999). The near-bed concentration is typically defined as an equilibrium concentration and evaluated using one of the available empirical relations (see Chapter 2 of this manual).

Celik and Rodi (1988) offer a comprehensive critique of using the equilibrium near-bed concentration in nonequilibrium situations. The two authors analyzed equilibrium and nonequilibrium situations based on two relatively simple experiments, both using a wide rectangular channel with a steady uniform flow. The Jobson and Sayre (1970) experiment had a suspended-sediment load, larger than the transport capacity, introduced at the upstream end of a flume with an initially sediment-starved bed. As a result, the upstream portion of the flume saw a nonequilibrium situation with net deposition and a gradual decrease of the suspended-sediment load along the flume, until the transport capacity was reached. The Ashida and Okabe (1982) experiment had clear water at the upstream end of the flume with a sand source on the fixed bed. As a result, the upstream portion of the flume reflected a nonequilibrium situation with net entrainment and a gradual increase of the suspended-sediment load along the flume, again until the transport capacity was reached. In both experiments, an equilibrium situation was achieved asymptotically in the downstream portion of the flume, characterized by an entrainment-deposition balance and no change in suspended-sediment load along that portion of the flume. Both experiments clearly show a significant difference between the actual near-bed concentration in nonequilibrium situations and the equilibrium near-bed concentration. Therefore, imposition of the exchange between the suspended-sediment and the bed and near-bed processes is a preferable boundary condition for suspended-sediment computations in nonequilibrium situations.

### 15.7.3 Imposition of Near-Bed Sediment Exchange

Exchange between the suspended-sediment and the bed and near-bed processes is defined as the difference between

the near-bed upward sediment entrainment flux  $E$  and the corresponding downward sediment deposition flux  $D$ . The governing equations for the bed and near-bed processes contain identical exchange terms, but with opposite signs. Therefore, using sediment entrainment and deposition fluxes  $E$  and  $D$  as boundary condition for suspended-sediment computations also provides a proper coupling between suspended-sediment processes and bed and near-bed processes.

For an equilibrium situation in a wide rectangular channel with a steady uniform flow, eventually achieved in both the Jobson and Sayre (1970) and Ashida and Okabe (1982) experiments, the classical suspended-sediment transport Eq. (15-39) yields

$$w_f c_e + \epsilon_s \frac{\partial c_e}{\partial z} = 0 \quad (15-44)$$

where

$c_e$  = equilibrium concentration.

Equation (15-44), valid at any depth, describes an equilibrium between a downward advective flux due to fall velocity (gravity effects) and an upward diffusive flux due to turbulence.

At some near-bed location, Eq. (15-44) can be written as

$$w_f c_{be} + \epsilon_s \left. \frac{\partial c_e}{\partial z} \right|_b = D - E = 0 \quad (15-45)$$

where

$c_{be}$  = near-bed equilibrium concentration and  
 $\left. \frac{\partial c_e}{\partial z} \right|_b$  = near-bed equilibrium concentration gradient.

Equation (15-45) is the usual starting point in defining sediment entrainment and deposition fluxes  $E$  and  $D$ . Assuming that Eq. (15-39) offers an accurate enough description of sediment transport in near-bed regions, the relation can be thought of as representing a zero near-bed net sediment exchange for an equilibrium situation. By analogy, the near-bed net sediment exchange for a nonequilibrium situation is then represented as

$$w_f c_b + \epsilon_s \left. \frac{\partial c}{\partial z} \right|_b = D - E \neq 0 \quad (15-46)$$

where

$c_b$  = near-bed nonequilibrium concentration and  
 $\left. \frac{\partial c}{\partial z} \right|_b$  = near-bed nonequilibrium concentration gradient.

In most models that include sediment exchange processes, the near-bed sediment deposition flux  $D$  for nonequilibrium situations is defined as a downward advective flux due to the fall velocity, evaluated for the actual (nonequilibrium) near-bed concentration:

$$D = w_f c_b \quad (15-47)$$

The actual near-bed concentration  $c_b$  in Eq. (15-47) is derived from the suspended-sediment computations themselves. This approach was used in models described by Shimizu et al (1990); Spasojevic and Holly (1990a; 1990b); Spasojevic and Holly (1993); Jankowski et al. (1994); Minh Duc et al. (1998); Rodi (2000); and Wu et al. (2000). As an extension to this approach, some researchers (e.g., Jankowski et al. 1994) have proposed introduction of a probability factor into the deposition flux in Eq. (15-47) to account for the possibility that some near-bed sediment particles subjected to downward advection due to their fall velocity may be resuspended without reaching the bed.

Defining the near-bed entrainment flux  $E$  for nonequilibrium situations is a far more difficult task. Celik and Rodi (1984) and van Rijn (1986) proposed evaluating the entrainment flux using its equilibrium value. Thus, because the equilibrium entrainment flux is equal to the equilibrium deposition flux (Eq. 15-45), the entrainment flux becomes

$$E = w_f c_{be} \quad (15-48)$$

Equation (15-48) implies that the entrainment always occurs at its maximum rate (Celik and Rodi 1988). This approach was used in models described by Spasojevic and Holly (1990a; 1990b); Lin and Falconer (1996); Minh Duc et al. (1998); Rodi (2000); and Wu et al. (2000).

Brors (1999) specified the entrainment flux, as it appears in the Exner equation, in terms of the near-bed concentration and concentration gradient. Spasojevic and Holly (1993) introduced the entrainment flux evaluated as an upward near-bed mass diffusion flux,

$$E = -\varepsilon_s \left. \frac{\partial c}{\partial z} \right|_a \quad (15-49)$$

where subscript  $a$  denotes that the mass-diffusion flux is evaluated at a near-bed point some distance  $a$  above the bed surface. Following the basic definition of the derivative, the entrainment flux in Eq. (15-49) is further modeled as

$$E = -\varepsilon_s \frac{c_{a+\Delta a} - c_a}{\Delta a} \quad (15-50)$$

where

$c_a$  = near-bed concentration reflecting the action of near-bed flow on the bed and bed-load particles, whereas

$c_{a+\Delta a}$  = near-bed concentration at distance  $a + \Delta a$  above the bed surface, extrapolated from the suspended-sediment computations.

Equation (15-50) implies that the entrainment varies according to both the near-bed concentration of sediment present on the bed and the concentration of suspended sediment possibly carried by the flow from some upstream location. The concentration  $c_a$  is evaluated by using an empirical relation for the near-bed *equilibrium* concentration (see Chapter 2 for different empirical relations).

When applied in the context of sediment mixtures and the active-layer concept (Spasojevic and Holly 1993), the entrainment flux has to be modified by  $\beta_{ks}$  to reflect the availability of the size class  $ks$  in the active-layer control volume. Then Eqs. (15-49) and (15-50) become, respectively,

$$E_{ks} = -\beta_{ks} \varepsilon_s \left. \frac{\partial c_{ks}}{\partial z} \right|_a \quad (15-51)$$

and

$$E_{ks} = -\beta_{ks} \varepsilon_s \frac{(c_{ks})_{a+\Delta a} - (c_{ks})_a}{\Delta a} \quad (15-52)$$

In the same context, the corresponding deposition flux, defined as in Eq. (15-47), becomes

$$D_{ks} = w_{fks} (c_{ks})_{a+\Delta a} \quad (15-53)$$

More information can be found in Chapter 3.

## 15.8 SYSTEM CLOSURE AND AUXILIARY RELATIONS

### 15.8.1 Introduction

The mass-conservation principles on which the various governing equation sets described earlier are based do not, in themselves, compose a complete mathematical system. There is a further need for additional closure, or auxiliary, relations, often empirical. System closure for sediment processes is highly dependent on the adopted conceptual sediment model and number of sediment processes included in the model. Thus, these issues are presented here through several examples. For convenience, the governing sediment equations for each example are summarized again here.

Most three-dimensional models use Eq. (15-39) as the governing equation for suspended-sediment processes:

$$\begin{aligned} \frac{\partial c}{\partial t} + \frac{\partial}{\partial x}(uc) + \frac{\partial}{\partial y}(vc) + \frac{\partial}{\partial z}(wc) - \frac{\partial}{\partial z}(w_f c) \\ = \frac{\partial}{\partial x} \left( \varepsilon_s \frac{\partial c}{\partial x} \right) + \frac{\partial}{\partial y} \left( \varepsilon_s \frac{\partial c}{\partial y} \right) + \frac{\partial}{\partial z} \left( \varepsilon_s \frac{\partial c}{\partial z} \right) \end{aligned} \quad (15-54)$$

The sediment mass-diffusivity coefficient  $\varepsilon_s$  is typically related to the turbulent eddy viscosity  $\nu_t$  (Brors 1999; Wu et al. 2000) through

$$\varepsilon_s = \frac{\nu_t}{\sigma_c} \quad (15-55)$$

where

$\sigma_c$  = turbulent Schmidt number for sediment (often assumed to be unity).

Major differences among models arise from the treatment of bed and near-bed processes. Different approaches to the

treatment of bed and near-bed processes are classified in Section 15.5 into the bed-load-layer approach; the total-load approach; and the active-layer and active-stratum approach (designed for sediment mixtures).

### 15.8.2 The Bed-Load-Layer Approach

When the van Rijn bed-load-layer approach described earlier is used, the governing equation for bed and near-bed processes becomes Eq. (15-24) (models described by van Rijn 1987 and Brors 1999):

$$\rho_s (1-p_b) \frac{\partial z_b}{\partial t} + \frac{\partial q_{bx}}{\partial x} + \frac{\partial q_{by}}{\partial y} + E_b - D_b = 0. \quad (15-56)$$

The deposition flux  $D_b$  is generally formulated through Eq. (15-47) (models described by Spasojevic and Holly 1993; Brors 1999; and Wu et al. 2000):

$$D_b = w_f c_b. \quad (15-57)$$

The entrainment flux  $E_b$  is usually formulated through Eq. (15-48) (models described by Lin and Falconer 1996 and Wu et al. 2000):

$$E_b = w_f c_{be}. \quad (15-58)$$

When the bed-load-layer approach is used, the governing equations for sediment processes are the mass-conservation equation for suspended sediment, Eq. (15-54), and the mass-conservation equation for bed-load-layer and bed-subsurface sediment, Eq. (15-56). Primary sediment unknowns are the volumetric suspended-sediment concentration and the bed-surface elevation  $z_b$ . Flow-velocity components  $u$ ,  $v$ , and  $w$  are the result of flow computations. The actual near-bed nonequilibrium concentration  $c_b$  is the result of suspended-sediment computations. All other sediment-related terms in Eqs. (15-54) and (15-56), such as sediment mass-diffusivity coefficient  $\varepsilon_s$  (i.e., turbulent Schmidt number  $\sigma_c$ ), bed-load flux  $q_b$ , fall velocity  $w_f$ , and the near-bed equilibrium concentration  $c_{be}$ , are in general functions of flow variables and primary sediment unknowns and are treated as auxiliary relations, often empirical. In addition, the near-bed equilibrium concentration  $c_{be}$  is evaluated at the top of the bed-load layer, so the bed-load-layer thickness  $h_b$  must also be specified on the basis of some empirical or other guidance.

### 15.8.3 The Total-Load Approach

When the total-load approach is used, the governing equation for computing bed-surface elevation becomes Eq. (15-25) (models described by Wang and Adeff 1986; van Rijn 1987; and Wu et al. 2000):

$$\rho_s (1-p_b) \frac{\partial z_b}{\partial t} + \frac{\partial q_{Tx}}{\partial x} + \frac{\partial q_{Ty}}{\partial y} = 0 \quad (15-59)$$

where

$$q_{Tx} = q_{bx} + \int_{h_b}^h \left( uc - \varepsilon_s \frac{\partial c}{\partial x} \right) dz$$

and

$$q_{Ty} = q_{by} + \int_{h_b}^h \left( vc - \varepsilon_s \frac{\partial c}{\partial y} \right) dz \quad (15-60)$$

represent the total-load components combining the bed load with the suspended-load flux (advection and diffusion) integrated from the top of the bed-load layer  $h_b$  to the total depth  $h$ .

When the total-load approach is used, the governing equations for sediment processes are the mass-conservation equation for suspended sediment, Eq. (15-54), and the mass-conservation equation for bed-subsurface sediment, bed-load-layer sediment, and suspended sediment in the entire water column above the bed-load layer, Eq. (15-59). The primary sediment unknowns are volumetric suspended-sediment concentration  $c$  and bed-surface elevation  $z_b$ . The sediment mass-diffusivity coefficient  $\varepsilon_s$  (i.e., turbulent Schmidt number  $\sigma_c$ ), bed-load flux  $q_b$ , and fall velocity  $w_f$ , are treated as auxiliary relations and evaluated through appropriate empirical relations; see for example Chapter 2.

Wu et al. (2000) introduced a modification to the total-load approach to account for nonequilibrium effects on the bed-load transport using Eq. (15-28):

$$\frac{1}{L_s} (q_b - q_{be}) + \frac{\partial (\alpha_{bx} q_b)}{\partial x} + \frac{\partial (\alpha_{by} q_b)}{\partial y} + E_b - D_b = 0 \quad (15-61)$$

where deposition and entrainment fluxes  $D_b$  and  $E_b$  are the same as in Eqs. (15-57) and (15-58), respectively. With this modification, nonequilibrium bed-load flux  $q_b$  also becomes the primary sediment unknown, computed from an additional governing sediment equation, Eq. (15-61). Because direction cosines  $\alpha_{bx}$  and  $\alpha_{by}$  are known parameters, additional auxiliary relations include equilibrium bed-load flux  $q_{be}$  and near-bed equilibrium concentration  $c_{be}$ .

### 15.8.4 The Active-Layer and Active-Stratum Approach—Sediment Mixtures

The active-layer and active-stratum approach (Spasojevic and Holly 1993) uses the following set of governing equations for sediment processes:

The mass-conservation equations for size class  $ks$  of suspended sediment (Eq. 15-42):

$$\begin{aligned} \frac{\partial c_{ks}}{\partial t} + \frac{\partial}{\partial x} (uc_{ks}) + \frac{\partial}{\partial y} (vc_{ks}) + \frac{\partial}{\partial z} (wc_{ks}) - \frac{\partial}{\partial z} (w_{fs} c_{ks}) \\ = \frac{\partial}{\partial x} \left( \varepsilon_s \frac{\partial c_{ks}}{\partial x} \right) + \frac{\partial}{\partial y} \left( \varepsilon_s \frac{\partial c_{ks}}{\partial y} \right) + \frac{\partial}{\partial z} \left( \varepsilon_s \frac{\partial c_{ks}}{\partial z} \right) \end{aligned} \quad (15-62)$$

The mass-conservation equation for the size class  $ks$  of active-layer sediment (Eq. 15-36):

$$\rho_s (1 - p_b) \frac{\partial(\beta_{ks} h_a)}{\partial t} + \frac{\partial q_{bxks}}{\partial x} + \frac{\partial q_{byks}}{\partial y} + E_{ks} - D_{ks} - F_{ks} = 0 \quad (15-63)$$

The global mass-conservation equation for bed sediment, comprising active-layer and active-stratum sediment (Eq. 15-37):

$$\rho_s (1 - p_b) \frac{\partial z_b}{\partial t} + \sum_{ks=1}^{KS} \left( \frac{\partial q_{bxks}}{\partial x} + \frac{\partial q_{byks}}{\partial y} + E_{ks} - D_{ks} \right) = 0. \quad (15-64)$$

where

$$E_{ks} = -\beta_{ks} \epsilon_s \frac{(c_{ks})_{a+\Delta a} - (c_{ks})_a}{\Delta a} \quad (15-65)$$

and

$$D_{ks} = w_{fks} (c_{ks})_{a+\Delta a} \quad (15-66)$$

are entrainment and deposition fluxes for size class  $ks$  sediment, respectively.

The active-layer floor source  $F_{ks}$ , again specific to the size class  $ks$ , can be expressed using Eq. (15-31). When the active-layer floor (active-stratum ceiling) descends, then

$$F_{ks} = -\rho_s (1 - p_b) \frac{\partial}{\partial t} [\beta_{ks} (z_b - h_a)] \quad (15-67)$$

gives the mass of the size class  $ks$ , formerly comprising size fraction  $\beta_{ks}$  of the active-stratum control volume, which becomes part of the active-layer elemental volume. When the active-layer floor (active-stratum ceiling) rises, then

$$F_{ks} = -\rho_s (1 - p_b) \frac{\partial}{\partial t} [\beta_{ks} (z_b - h_a)] \quad (15-68)$$

gives the mass of the particular size class, formerly comprising size fraction  $\beta_{ks}$  of the active-layer elemental volume, which becomes part of the active stratum control volume.

If the sediment mixture in a natural watercourse is represented by a total of  $KS$  sediment size classes,  $KS$  mass-conservation equations for suspended sediment (one Eq. (15-62) for each size class) can be written for each

elemental volume in the suspension above the active layer.  $KS$  mass-conservation equations for active-layer sediment (one Eq. (15-63) for each size class) can be written for each active-stratum elemental volume, and one global mass-conservation equation for bed sediment, Eq. (15-64), can be written for each bed elemental volume (comprising the active-layer and active-stratum elemental volumes). The global set of sediment equations for all size classes, taken as a whole, describes the behavior of a nonuniform sediment, including natural phenomena such as differential settling, armoring, and hydraulic sorting. The following sediment variables are considered primary sediment unknowns: (1)  $KS$  suspended-sediment concentrations  $c_{ks}$  for each elemental volume containing a mixture of water and suspended sediment; (2)  $KS$  active-layer size fractions  $\beta_{ks}$  for each active-layer elemental volume; and (3) one bed-surface level  $z_b$  for each bed elemental volume.

The actual near-bed nonequilibrium concentration  $(c_{ks})_{a+\Delta a}$  is extrapolated from the suspended-sediment computations. The equilibrium near-bed concentration  $(c_{ks})_a$ , bed-load flux  $q_b$ , active-layer thickness  $h_a$ , fall velocity  $w_f$ , and sediment mass-diffusivity coefficient  $\epsilon_s$  are in general functions of flow variables and primary sediment unknowns and are treated as auxiliary relations. The location  $a$  may be evaluated on the basis of some empirical guidance. However, because the parameter  $\Delta a$  has no direct physical interpretation (being defined only for the purpose of estimating the concentration gradient near the bed), both  $a$  and  $\Delta a$  are perhaps best considered calibration parameters as discussed in Section 15.11.

The numerical procedure for solution of the sediment equations is formulated without reference to the specific empirical relations that ultimately must be invoked to evaluate the auxiliary relations. This allows use of any suitable empirical relation to evaluate a particular auxiliary relation and renders the formal numerical procedure independent of any specific empirical relation.

The equilibrium near-bed concentration  $(c_{ks})_a$  (for size class  $ks$  sediment) generally depends on the near-bed flow characteristics. It is evaluated using an appropriate empirical relation, for example that of van Rijn (1984a).

The net bed-load flux is represented here as

$$q_{bks} = (1 - \gamma) \zeta_h \beta_{ks} q_b^t \quad (15-69)$$

where

$q_b^t$  = theoretical bed-load capacity for a bed containing only sediment of the size class  $ks$ , evaluated using an appropriate bed-load predictor such as proposed by van Rijn (1984a).

This load is adjusted by  $\zeta_h$ , a so-called hiding factor accounting for the reduction or increase in a particular

size class transport rate when it is part of a mixture. Empirical relations such as those proposed by Karim and Kennedy (1982) or Shen and Lu (1983) can be used to evaluate  $\zeta_h$ . The adjusted load is modified by  $\beta_{ks}$  to reflect the availability of the particular size class in the active-layer elemental volume. Finally, the load is modified by  $(1-\gamma)$  to reflect the fact that some fraction  $\gamma$  of the particular size-class particles is expected to be transported only as suspended load, with  $\gamma$  typically related to quantities such as the ratio of fall velocity to shear velocity (Rouse number).

The active-layer thickness  $h_a$  is evaluated by an appropriate empirical concept of the depth of bed material that supplies material for bed-load transport and suspended-sediment entrainment. Examples are the concepts of Bennett and Nordin (1977); Borah et al. (1982); or Karim and Kennedy (1982).

Depending on the sediment-particle size, different experimental relations can be used to compute particle fall velocity, as described by van Rijn (1984b).

The sediment mass-diffusivity coefficient  $\varepsilon_s$  is obtained by modifying the turbulent eddy viscosity  $\nu_t$  coefficient to reflect the difference in the diffusion of a discrete sediment particle and the diffusion of a fluid “particle” (or small coherent fluid structure), and also to reflect possible damping of the fluid turbulence by sediment particles, as suggested by van Rijn (1984b).

The equations presented in this section are the basis for the sediment model incorporated in the CH3D-SED code, used in the examples of Sections 15.11.2 and 15.11.3.

### 15.8.5 Two-Dimensional Models

Because the governing equations for bed and near-bed processes are two-dimensional in plan parallel to the bed surface, the major difference between two-dimensional and three-dimensional models arises from the governing equation for suspended-sediment processes. For example, depth-averaged models use Eq. (15-40), i.e., the depth-averaged form of the mass-conservation equation for suspended sediment (model described by Minh Duc et al. 1998, etc.),

$$\begin{aligned} & \frac{\partial(h\tilde{c})}{\partial t} + \frac{\partial}{\partial x}(\tilde{u}h\tilde{c}) + \frac{\partial}{\partial y}(\tilde{v}h\tilde{c}) \\ &= \frac{\partial}{\partial x}\left(\tilde{\varepsilon}_s h \frac{\partial \tilde{c}}{\partial x}\right) + \frac{\partial}{\partial y}\left(\tilde{\varepsilon}_s h \frac{\partial \tilde{c}}{\partial y}\right) + E_b - D_b \end{aligned} \quad (15-70)$$

or, in the case of sediment mixtures, Eq. (15-43), i.e., the depth-averaged form of the mass-conservation equation written for size class  $ks$  of suspended sediment (model described by Spasojevic and Holly (1990a; 1990b)),

$$\begin{aligned} & \frac{\partial(h\tilde{c}_{ks})}{\partial t} + \frac{\partial}{\partial x}(\tilde{u}h\tilde{c}_{ks}) + \frac{\partial}{\partial y}(\tilde{v}h\tilde{c}_{ks}) \\ &= \frac{\partial}{\partial x}\left(\tilde{\varepsilon}_s h \frac{\partial \tilde{c}_{ks}}{\partial x}\right) + \frac{\partial}{\partial y}\left(\tilde{\varepsilon}_s h \frac{\partial \tilde{c}_{ks}}{\partial y}\right) + E_{ks} - D_{ks} \end{aligned} \quad (15-71)$$

Thus, instead of computing point concentrations, depth-averaged models compute depth-averaged concentrations. The near-bed concentration in deposition flux is typically evaluated through some kind of theoretical vertical concentration profile, e.g., the Rouse profile. Entrainment flux is usually evaluated as an equilibrium entrainment equal to the equilibrium deposition, which, in case of sediment mixtures, has to be modified by  $\beta_{ks}$  to reflect the availability of the size class in the active-layer control volume (Spasojevic and Holly (1990a; 1990b)):

$$E_{ks} = -\beta_{ks}(c_{ks})_a \quad (15-72)$$

All other system-closure considerations are basically the same as for three-dimensional models, of course depending on the bed and near-bed processes approach. Equations (15-71) and (15-72), together with the governing equations for bed and near-bed sediment processes and other closure auxiliary relations presented in Section 15.8.4, are the basis for the sediment model incorporated into the MOBED2 code, used in the example of Section 15.11.4.

An important issue that has achieved relatively little attention in multidimensional model development as of this writing is the inclusion of flow- and transport-dependent form roughness associated with mobile-bed bed forms such as dunes and ripples. As long as computer time and memory requirements restrict models to plan-view discretizations that are too coarse to resolve individual dune topography and movement, models should incorporate appropriate empirical formulations combining bed-material and bed-form roughness. The authors—always optimistic—expect that as computing resources and turbulence-model development gradually permit plan-view grid refinement that can capture bed-form activity in fully three-dimensional models, it will be necessary only to include bed-material roughness formulations, because the larger-scale bed form “roughness” will be captured within the model’s own solution for momentum exchange in nonparallel flow.

### 15.8.6 Additional Considerations in Auxiliary Relations

Although the auxiliary relations described above are necessary for minimal closure, they do not, in themselves, account for many other possible subtle complexities in the physical processes. Considerable past and present research has been devoted to developing a better understanding, and conceptualizations, of these complex processes.

For example, Nakagawa and Tsujimoto (1980) studied bed instability due to lag system between bed-shear stress and velocity, which is composed of two elements: (1) the phase lag between sediment-transport rate and bed-shear stress; and (2) lag distance between sediment transport and flow field over a wavy bed. They evaluated the lag distance of bed-load transport for bed shear stress based on the model for bed-load transport that is applicable to such nonequilibrium situations as when sand waves are initially formed. In addition, the potential flow model of flow over a wavy bed was modified to take into account the effects of flow convergence and divergence. Using these models for flow and bed-load transport, the lag system in a perturbed sand bed was clarified, and the hydraulic conditions for unstable bed, which may correspond to the regimes for dunes or ripples and antidunes, was predicted. Kovacs and Parker (1994) derived a vectorial bed-load formulation for the transport of coarse sediment for up to the angle of repose both in the streamwise and transverse directions. They developed a mathematical model of the time evolution of straight river channels, focusing on the evolution processes due to the bank erosion in the presence of bed load only. Lau and Engel (1999) studied, using dimensional and theoretical analysis, together with available experimental data, how a combination of flow and stream bed slope affects the beginning of sediment transport. Damgaard et al. (1997) performed experiments on bed-load transport on steep longitudinal slopes and formulated a semiempirical relation that predicts the transport rate on horizontal as well mild and steep slopes. Kitamura et al. (1998) studied the influence of vegetation on sediment transport capability in channels.

These brief examples are intended only to give the reader a sense of the kinds of additional complexities that may need to be included in mobile-bed models.

## 15.9 MOBILE-BED NUMERICAL SOLUTION CONSIDERATIONS

### 15.9.1 Numerical Coupling of Flow and Mobile-Bed Processes

As of this writing, the simultaneous solution of all governing equations in three-dimensional or even two-dimensional flow and sediment models is not feasible, due to the prohibitive CPU time requirements. Thus, one of the important issues in flow and sediment modeling is how to provide adequate numerical coupling between and among water and sediment processes. In nature, this coupling is between flow and sediment processes in general, as well as between suspended-sediment and bed and near-bed processes. Numerical coupling or uncoupling of these different processes should reflect the nature and importance of the real physical coupling.

Although the flow is the driving force for sediment-transport and bed-evolution processes, the most important sediment feedback to the flow includes bathymetry changes,

changes in the density of water and suspended-sediment mixture, possibly changes in the bed-surface roughness when sediment mixtures are considered, and flow-dependent form roughness associated with bed forms (dunes, ripples). The bathymetry and the bed-surface roughness changes during a time step appropriate for flow computations are usually too small to change the flow domain and flow field significantly. Only the suspended-sediment transport has the same time scale as fluid flow. In most cases, suspended-sediment concentrations in natural watercourses are relatively small and do not change abruptly with time, which suggests that changes in the density of the water and sediment mixture during a time step appropriate to flow computations are generally insufficient to influence the flow field significantly. Therefore, practically all existing two-dimensional and three-dimensional flow and sediment models uncouple water and sediment computations within one time step. Indeed, the same is true for most one-dimensional mobile-bed models. A notable exception is the SEDICOU one-dimensional mobile-bed model (Holly and Rahuel 1990), which represented an experiment in complete coupling of all flow and sediment processes in an unsteady, multiple-size-class environment.

On the other hand, the nature of the real physical coupling between different sediment processes may preclude their complete numerical uncoupling, even at a scale of one time step. The entrainment and deposition fluxes (sediment-exchange processes) are the link relating suspended- and bed- and near-bed-sediment processes. It is generally agreed that the deposition flux depends on the actual near-bed concentration evaluated from suspended-sediment computations. The entrainment flux depends on the near-bed equilibrium concentration, associated with the bed surface, bed-load layer, or active layer, depending on the adopted conceptual model. Deposition and entrainment fluxes appearing in the governing equations for bed and near-bed processes are also commonly used as near-bed boundary conditions for suspended-sediment processes.

The active-layer and active-stratum approach associated with sediment mixtures (Spasojevic and Holly (1990a; 1990b; 1993)) emphasizes the need for some level of numerical coupling between suspended-sediment processes and bed and near-bed processes. Whereas the deposition flux in Eq. (15-66) depends on suspended-sediment concentration, the entrainment flux in Eqs. (15-65) and (15-72) depends on the size-class fraction of active-layer sediment. Therefore, models described by Spasojevic and Holly (1990a; 1990b; 1993) are structured to allow for iterative coupling between suspended-sediment and bed and near-bed sediment processes. The mass-conservation equations for bed and near-bed processes are solved by assuming the suspended-sediment concentration, and therefore the deposition flux, to be known from the previous iteration. An improved estimate of active-layer size fractions and the bed-surface elevation is thus obtained. The mass-conservation equations for

suspended-sediment processes are then resolved for the same computational time step, by assuming the active-layer size fractions, i.e., entrainment flux, to be known from the bed and near-bed processes computations. The whole procedure is repeated iteratively until a convergence criterion is satisfied.

Finally, in the case of active-layer and active-stratum concepts associated with sediment mixtures (Spasojevic and Holly 1990a; 1990b; 1993), the governing equations for bed and near-bed sediment processes require simultaneous solution to satisfy the basic requirement that the sum of all size-class fractions is equal to unity. Application of a chosen numerical method to discretize the global mass-conservation equation for bed sediment (Eq. (15-64)) and the mass-conservation equation for active-layer sediment (Eq. (15-63)) yields a system of nonlinear algebraic equations. The discretized (nonlinear algebraic) equations to be solved simultaneously for the same point at the bed are (1) one discretized global mass-conservation equation for bed sediment and (2) *KS* discretized mass-conservation equations for active-layer sediment. Solution using, e.g., a Newton-Raphson iterative procedure yields (1) one bed-surface elevation and (2) *KS* active-layer size fractions.

### 15.9.2 Choice of Numerical Method for Mobile-Bed Processes

Because a mobile-bed model is typically built into an already existing hydrodynamic model, the basic choice of numerical method for solving the sediment equations usually follows the choice of numerical method for solving flow equations. In certain cases, this is the only available possibility. For example, if the hydrodynamic model uses the finite-element method with an unstructured grid, it is impossible to use a finite-difference method to solve the sediment equations on the same grid. However, it would appear theoretically possible to allow the numerical method for solving the sediment equations to be different from the one used for solving the flow equations. For example, hybrid or split-operator approaches, which use different numerical methods to solve different parts of the same equation, have proven to yield satisfactory numerical solutions. To the extent that the numerical method for sediment equations can be independent of the method used for the flow equations, one can consider the possibility of developing an independent mobile-bed module, which could be used with different hydrodynamic modules. The numerical method for such an independent mobile-bed module would have to be able to support both structured and unstructured grids, which limits the basic choice to either the finite-element or the finite-volume method.

Existing two-dimensional and three-dimensional flow and sediment models use a variety of numerical methods. The finite-element method is used in models reported by Thomas and McAnally (1985); Wang and Adeff (1986); Brors (1999); Jia and Wang (1999); and the RMA-10

model at the Coastal and Hydraulics Lab, U.S. Army Corps of Engineers. Models reported by Shimizu et al. (1990), Spasojevic and Holly (1990a; 1990b), Spasojevic and Holly (1993), and Lin and Falconer (1996), use the finite-difference method. The model reported by Jankowski et al. (1994), i.e., that in Hervouet and Bates (2000), uses a split-operator approach with the method of characteristics used for advection processes and the finite-element method used for the remaining processes. Models reported by Olsen and Melaaen (1993), Minh Duc et al. (1998), Olsen et al. (1999), and Wu et al. (2000) use the finite-volume method associated with a structured grid. As of this writing, no flow and sediment model has been known to use the finite-volume method with an unstructured grid. Advantages and disadvantages of methods associated with structured versus methods associated with unstructured grids have already been discussed in Section 15.3.

It should be noted that the finite-difference method is applied to the governing equations in Cartesian coordinates only in special cases with simple geometry. Models that use the finite-difference method typically require that the governing equations be transformed into curvilinear or body-fitted coordinates to accommodate complex geometries, usually associated with natural watercourses. Models that use the finite-volume method on a structured grid, and thus do not exploit the full potential of the method, also require that the governing equations be cast into in curvilinear coordinates.

Most numerical problems (instability, oscillations, etc.) in solving unsteady flow and sediment equations are caused by advection terms, especially in the case of sharp-front waves. Therefore, the advection terms in the governing flow and sediment equations may require special treatment, usually involving a numerical method that takes into account the hyperbolic nature of advection.

Existing two-dimensional and three-dimensional flow and sediment models typically do not anticipate the existence of bores or moving hydraulic jumps and have no special treatment for advection terms in flow equations. Exceptions include the TELEMAC-3D code, as described by Jankowski et al. (1994) or Hervouet and Bates (2000), which uses the method of characteristics for the momentum advection terms in the flow equations. The bed-load term in the governing equations for bed and near-bed processes, if one considers it as an equivalent advection term, is numerically benign due to the slow nature of the bed-load movement. However, suspended-sediment transport is likely to encounter a sharp-front wave situation. Examples include a postdredging resuspension in the form of a point source, extensive sediment entrainment behind a river-training structure such as a chevron dike, or simply extensive sediment entrainment due to incorrect initial and boundary conditions for sediment.

Several existing two-dimensional and three-dimensional flow and sediment models include special treatment of the advection terms in the suspended-sediment transport equation. For example, the TELEMAC-3D code, as described by

Jankowski et al. (1994), and the MOBED2 code (Spasojevic and Holly 1990a; 1990b), use a split-operator approach combined with the method of characteristics for the advection term in the suspended-sediment transport equation. The CH3D-SED code, as described by Spasojevic and Holly (1993), uses the QUICKEST scheme (Leonard 1979), whereas the model described by Lin and Falconer (1996) uses a modification, called ULTIMATE QUICKEST, of the same scheme, to discretize the suspended-sediment transport equation.

### 15.9.3 Grid-Generation and Adaptive-Grid Issues in a Mobile-Bed Environment

Grid generation was an important issue in the 1980s and early 1990s, when most two-dimensional and three-dimensional modelers had to develop their own grid-generation programs. Most two-dimensional and three-dimensional sediment modelers now use commercial grid-generation software. As of this writing, the grid-generation software associated with computational fluid dynamics applications (aerodynamics, auto industry, ship hydrodynamics, etc.) is quite sophisticated, but typically accepts geometry input files in specific formats, usually generated by design-support software. The grid-generation software associated with computational hydraulics applications, even though less sophisticated, is generally designed to accept the random geometry data associated with field-data collection for natural watercourses.

On the other hand, adaptive grid technology is currently quite an important issue in mobile-bed modeling. Because mobile-bed modeling typically assumes unsteadiness, both free-surface water elevation and bed-surface elevation are dynamically moving boundaries to which the three-dimensional grid has to adapt at each computational time step. The moving free-surface water elevation, usually being nearly horizontal, poses less of a problem than the moving bed-surface elevation, which presents a real challenge. To begin with, the bed surface has a naturally irregular shape, occasionally modified by man-made hydraulic structures such as river-training structures (weirs, lateral or L-shaped dikes, chevrons, bridge piers, etc.). Furthermore, bed-surface elevation changes may be quite uneven throughout a model domain. Newly installed hydraulic structures may cause extensive and rapid local bed-surface elevation changes, e.g., erosion behind the chevron dike followed by accompanying deposition further downstream. Long-term bed-surface elevation changes, such as river meandering, are slow but can accumulate significantly in time.

As of this writing, general treatment of the adaptive-grid problem in three-dimensional flow and sediment models is in the early stages of development. The most important adaptive grid issue in mobile-bed models arises from bed-elevation changes that require grid adaptation in the vertical direction. Most of the existing three-dimensional flow and

sediment models keep the third coordinate direction straight and vertical, making it relatively easy to deal with bed-related adaptive-grid issues. For example, the CH3D-SED model, as described by Spasojevic and Holly (1993), uses a simple partial coordinate transformation, called  $\sigma$ -stretching, for the vertical coordinate direction. The vertical  $\sigma$ -stretching allows for simple redistribution of a fixed number of computational points along the depth at each time step. Grid adaptation in fully three-dimensional hydrodynamic models that do not rely on a straight vertical coordinate has not been fully addressed, either for hydrodynamic or for mobile-bed applications.

The roles of grid refinement and grid sensitivity in the quality of mobile-bed modeling have gotten rather short shrift, especially compared to the attention devoted to these considerations in computational fluid dynamics and fixed-bed computational hydraulics. D. A. Lyn (personal communication, 2002) has aptly posed a number of relevant questions, to wit,

- Should the grid simply be as fine as the budget allows?
- To what extent is it reasonable to accept a coarse grid in one direction, and a fine grid in the other directions?
- Is a coarse-grid high-dimensional (three-dimensional) model solution always better than a fine-grid low-dimensional (two-dimensional) model with more schematic empirical input?
- Can a coarse grid yield misleading results?
- Can a coarse (horizontal) grid be used for a nonhydrostatic problem where rapidly varied flow prevails?
- Are grid-independence tests necessary and practical?
- Does one just choose a grid and accept the fact that details finer than the grid simply cannot be resolved?
- Can/should one accept calibration as a means of working around a coarse-grid limitation?

The easy answer to all of these questions is “it depends.” As mobile-bed modeling development and practice mature, these issues will surely attract more careful attention and hopefully lead to a body of literature and acquired wisdom that respond at least partly to the above questions.

## 15.10 FIELD DATA NEEDS FOR MODEL CONSTRUCTION, CALIBRATION, AND VERIFICATION

### 15.10.1 Field Data for Model Construction

Both two- and three-dimensional models require essentially the same type of bathymetric and geometric data to provide a basic description of the physical domain. An initial bed elevation must be assigned at every grid intersection, node, or spatial element of the plan-view computational mesh of a model, two-dimensional or three-dimensional.

It obviously would not be feasible first to lay out the computational mesh, identify the geographical coordinates of

every point requiring an initial bed elevation, and then visit each location in the field to determine the elevation. In reality, one first obtains the best available “mapping” of the bathymetry through spot elevations, generally taken from a moving vessel with GPS positioning technology, and describing the bed-surface bathymetry at a scale appropriate for the anticipated density of the computational mesh. For example, if it is expected that the mesh will resolve plan-view details at a scale on the order of 10 m, then the density of spot elevations taken in the field should be such that significant bed features of a scale of 10 m or larger can be captured.

Once the actual computational mesh is laid out, the measured spot bed elevations are projected onto the required grid or nodal points. This is done through two-dimensional curve-fitting techniques, by which a two-dimensional curvilinear surface is appropriately fit to the data points, and then grid elevations are extracted from the fitted surface.

In a mobile-bed modeling context, these bed elevations so painstakingly and expensively obtained are nothing more than the initial conditions set for further evolution during the model simulation runs. In this sense, the initial bed elevations do not have the sacred, absolute character they are given in a fixed-bed model. Indeed, the initial bed-elevation data may reflect the movement of dunes several meters high, and an individual dune elevation is not necessarily representative of the bed area associated with a given computational mesh point. In some sense, the initial bed elevations can even be thought of as subject to calibration, and thus grid-dependent, if not model-dependent. If the bed elevation (and associated initial bed sediment size distribution; see further on) assigned to a grid point does not represent a quasi-equilibrium with the model’s hydrodynamic and sediment equations, then the model will respond with rapid scouring (or deposition) in the first few time steps of the mobile-bed simulation, and the initial elevation may have to be adjusted accordingly. If it were feasible to obtain long-term time-averaged bed elevations on a network of points, thus averaging out the influence of dune movement, this would likely reduce, but probably not eliminate, the need for adjustment of initial elevations.

This approach to obtaining initial bathymetry is somewhat different from the traditional one used for one-dimensional river modeling. For backwater and flood-propagation river modeling, the general practice was to obtain transects, or cross sections, of the river channel, each associated with a single one-dimensional computational point. This historical practice was driven not only by its logical correspondence with one-dimensional model needs, but also by the practical pre-GPS need to identify position on a river with reference to distance along a well-defined transect anchored at surveyed points on the river banks. Multidimensional modeling, in contrast, makes good use of developments such as multibeam technology and GPS positioning for more general, off-transect bathymetric data acquisition.

Bed bathymetry must be complemented by geometric descriptions of any structures in the domain of interest. Such structures might include river-training works (submerged or emerged dikes, etc.), bridge pier bases, or hydraulic structures such as weirs, dams, or intake works. In two-dimensional modeling, a plan-view description of the boundaries of such structures may be sufficient. But for three-dimensional modeling, the complete three-dimensional description of the structural surfaces in contact with the flow domain must be obtained with precision at least consistent with the spatial scale of the computational mesh, especially in the vertical. For example, if the mesh is expected to have 10 vertical elements in the vicinity of the structure, then the details of the structure’s wetted surfaces must be described geometrically in sufficient detail to be resolved at 10 points in the vertical.

### 15.10.2 Model Initialization

Initial conditions for water and sediment are far more important in mobile-bed modeling than in fixed-bed applications. In a fixed-bed environment, initial discharges and water-surface elevations must be assigned, but they quickly wash out of the model as boundary-condition influence takes over. Fixed-bed initial conditions can be quite arbitrary without affecting the simulations results of interest.

As is illustrated in the examples at the end of this chapter, mobile-bed models are usually started up in a fixed-bed mode. Somewhat arbitrary initial hydrodynamic conditions (water-surface elevations and velocities or unit discharges, often for horizontal, nil flow) are specified. Then the model is run with fixed bed for a sufficiently long period for the arbitrary initial condition to wash out or stabilize under fixed boundary conditions. At the end of this stabilization period the model should have nearly attained a viable steady-state hydrodynamic solution. Sudden imposition of the inflow boundary conditions on a zero-flow situation may cause unacceptable “sloshing,” including bed uncovering, causing the computation to fail. Such a situation may require a more careful initial condition, or perhaps a progressive phasing in of the boundary inflows, as is the case in purely fixed-bed models.

The initial conditions for sediment must be handled with a great deal of care, because the bed elevations themselves are subject to change through interaction with the initial conditions. Initial sediment conditions fall into three categories: suspended-load concentrations, bed-material size distribution, and subsurface-material size distribution. It should be noted that the following guidelines, driven by the authors’ experience with multiple-size-class models, reflect the special challenges of model initialization for nonuniform sediments. Initial-condition specification for a single-size-class model is considerably less challenging.

**15.10.2.1 Suspended-Sediment Initial Conditions** The initial conditions for suspended sediment comprise

concentration of each size class at each computational point of the two- or three-dimensional grid. These obviously are depth-averaged concentrations in a two-dimensional model, and point concentrations in a three-dimensional model. Because the time scale of movement of suspended sediment is relatively short (as is the time scale of movement of water through the model), a model is generally fairly forgiving of initial suspended-sediment conditions that may not be in equilibrium with the flow, bathymetry, bed-material size distribution, and inflow boundary conditions. The initial suspended-sediment mass advects out of the system fairly quickly, as boundary-condition suspended-sediment inflows progressively influence the model from upstream to downstream.

Of course the suspended sediment does interact with the bed during this washout process, so the initial concentrations must be assigned with reasonable care. For example, if the initial condition specified a grossly exaggerated suspended-sediment load for one or more size classes, that load will tend to be deposited quite quickly and influence the bed elevations in an unrealistic way during the sediment startup period. Similarly, an initial condition of clear water may provoke excessive entrainment from the bed in the sediment startup period as the model seeks to establish a local equilibrium between the water column and the bed material. A reasonable starting procedure is to consider inflow boundary and/or interior suspended-sediment size distributions, vertically and horizontally, and assign them to the model's interior vertical grid lines in a logical fashion. This might involve assigning some sort of average concentration values, based on all available measurements throughout the domain, as initial conditions. An alternative could be to assign average concentrations for subdomains, for example, if there are clear differences in concentration between the main channel and lateral channels. If the boundary inflow concentrations by size class are reasonable to begin with, then the initial suspended-sediment startup period should proceed smoothly, with minimal bed-elevation or bed-composition changes provoked by the suspended-sediment initial condition.

#### **15.10.2.2 Bed-Surface Material Initial Conditions**

The initial conditions for bed-material composition comprise the size distribution (fractional representation of each size class in the model) at each computational grid point, or each computational cell, on the bed. It has been the authors' experience that this initial-condition assignment is quite delicate and unforgiving of casual treatment. Indeed, if the assigned initial bed-material size distribution does not reflect an approximate equilibrium condition given the initial hydrodynamics, bathymetry, and initial suspended-sediment concentrations, then the model will tend to adjust toward equilibrium (as defined by its own intrinsic sediment relations) quite rapidly, and this can cause excessive erosion or deposition in the first few time steps. For example, if the initial bed material distribution at a grid point contains a high fraction of fine silt, and yet there is no fine silt in

suspension, but the initial water velocities and shear stresses are relatively large, the model may call for a large entrainment of fine silt into the water column in the first few time steps. Through the bed-sediment conservation laws, this may result in a large, and unrealistic, erosion of the bed at the particular grid point, essentially distorting the user's assigned initial condition for bed elevations and possibly causing subsequent model failure.

Because the initial bed-sediment size distribution is generally based on, if not taken directly from, actual field measurements, one is tempted to expect that as long as the truth as represented by the field data is assigned to the model, the above scenario of excessive bed adjustment should not occur. However, as is brought out in the examples of Section 15.11, field observations of bed-material size distribution are necessarily quite sparse. The bed-material size distribution assigned to a single computational grid point is implicitly assumed to be representative of the bed material on the entire portion of the bed associated with that grid point. On the other hand, an individual field sample may or may not be representative of an equivalent portion of bed surrounding it. The sample may have been taken from the top of a transient dune as it moved through, or from a briefly exposed lens of fine material, or from a local accumulation of gravel exposed only intermittently as dunes move across it. Whereas in nature the water-sediment response to the local bed-material size distribution remains local, in the model "local" is defined by the plan-view of the computational grid around that point, and therein lies the difficulty in assigning sparse field observations to computational grid points.

Field bed-material samples should be used to make an overall assessment of what appears to be the average bed-material composition in the computational domain, or subdomains, if there are clearly distinct geomorphological regions. Initial model response to average bed-material distributions will suggest the possible need to modify the initial bed-material distribution locally to achieve a nearly equilibrium situation in the initial condition. In this sense, one essentially needs to calibrate, or adjust, the initial bed-material distribution to achieve a benign model startup. This approach obviously presumes that the startup situation is not one of major dynamic change; if this were the case, an extremely detailed set of initial bed-material distributions, i.e., at subgrid scale, would be required.

**15.10.2.3 Subsurface Strata Initial Conditions** The initial conditions for subsurface bed material comprise specification of the thickness of each subsurface stratum and its sediment size distribution below each bed computational point or cell. This initial condition specification can obviously be quite onerous, and may or may not be important, depending on the problem under study and the nature of the bed material. For example, if it is anticipated that only persistent deposition will occur in the region under study, then

there is no need to specify the subsurface structure, because it will never be susceptible to entrainment through contact with the water column. Similarly, if the anticipated maximum depth of erosion in the region under study is such that the bed material is known to be essentially homogeneous to that depth, a single, infinitely deep subsurface stratum having the same size distribution as the initial bed-surface material may be sufficient. But in a general case in which there may be successive cycles of erosion and deposition, and/or the erosion is expected to progress through multiple strata of differing composition (e.g., historical lenses of deposition), the subsurface structure under each bed computational point or cell must be specified with care. Indeed, if erosion progresses into a layer having a size distribution that is markedly finer than that of the material initially above it, the model may display rapid erosion of this layer, and it is important that this be physically realistic and not the result of a careless assignment of excessively fine material to a subsurface layer. Similarly, a very coarse subsurface layer, physical or otherwise, will have a tendency to arrest further erosion.

### 15.10.3 Hydrodynamic and Sediment Boundary Conditions

The hydrodynamic boundary conditions for a mobile-bed model are the same as those required for a fixed-bed model, i.e., generally the water-surface elevation at model outflow boundaries, and unit discharges (two-dimensional model) or three velocity components (three-dimensional model) at all model inflow boundaries. Depending on the particular hydrodynamic model framework, additional combinations of levels, local velocities/unit discharges, or relations between them may be impossible.

Suspended-sediment boundary conditions comprise specifications of the suspended-sediment concentrations, by size class, at all model inflow points. For a two-dimensional model, these are depth-averaged concentrations; for a three-dimensional model, these are concentrations at every grid point in the plane of the inflow boundary.

A special consideration here is that in a model having strongly unsteady hydrodynamics, for example, a tidal model with a reversing flow boundary or even a riverine model with possible reversing flow during strong transients, a boundary may be outflow or inflow at different times during the simulation. Whenever inflow occurs at such a boundary, a corresponding suspended-sediment inflow condition must be assigned.

The inflow suspended-sediment concentrations for three-dimensional models, generally simulating a relatively short portion of a hydrograph, are taken from whatever suspended-sediment measurements are available for the discharges under study. For longer-term two-dimensional modeling, the time-varying suspended-sediment inflow concentrations must be generated from presumed suspended-sediment rating curves applied to a time-dependent inflow hydrograph.

As increases in computing speed lead to the opportunity to make truly unsteady three-dimensional simulations (e.g., for one or more hydrographs), it will become important to acquire truly unsteady sediment-inflow boundary conditions.

As of this writing, few attempts have been made to measure the time history of suspended-sediment concentrations during an unsteady-flow event. However, current efforts by the U.S. Agricultural Research Service and others are leading to a better understanding of how suspended-sediment concentrations vary during a flood event, and such improved understanding should play an important role in setting unsteady inflow boundary conditions for suspended sediment.

The nature of bed-sediment boundary conditions depends on the model formulation. For example, in the authors' two- and three-dimensional models, the formulations are such that bed-sediment inflow boundary conditions comprise specification of the bed-material size distribution at each bed computational point or cell at an inflow boundary. In other formulations, the bed-material inflow condition may be bed-load flux by size class or other equivalent quantity. Inflow bed-material size distributions generally can only be deduced from existing field measurements of bed-material size, the same as used for initialization of the bed material as described above. Inflow bed-load fluxes are difficult to measure, and are more likely deduced from one or another empirical bed-load predictor known, or calibrated, to be applicable to the site under study.

Subsurface strata require no boundary conditions per se, because their interactions are limited to exchanges with the strata immediately above and below during deposition and erosion.

### 15.10.4 Hydrodynamic and Mobile-Bed Calibration and Verification

Mobile-bed model calibration and verification are considerably more challenging and elusive than their fixed-bed counterparts. The complex interactions between hydrodynamic and sediment processes, combined with the highly heterogeneous nature of field observations, make it extremely difficult to isolate, or target, the individual processes and associated empirical coefficients subject to adjustment. This is in contrast to fixed-bed modeling, in which the general reliability and accuracy of the Reynolds averaged-flow equations, combined with appropriate turbulence models, leave characterization of the bed roughness as the primary calibration target. Even the bed-roughness target becomes more elusive in a mobile-bed context, because the roughness comprises the bed composition itself, including flow-dependent bed forms, both intimately coupled with the flow hydrodynamics as well as sediment properties.

For sediment processes, three levels of calibration can be identified. One level is the very discretization of sediment into

appropriate size classes, because model response depends on the degree of resolution, i.e., the number of size classes and the representative particle diameter assigned to each. A second level, having no real counterpart in fixed-bed modeling, is the selection of auxiliary empirical relations most suited to the particular area under study. Such relations can include the bed-load predictor, the suspended-sediment entrainment predictor, the fall velocity predictor, and the bed-roughness characterization, as outlined in previous sections. The third level comprises adjustable parameters within the adopted auxiliary relation. For example, one might choose to use the van Rijn formulation for estimation of near-bed equilibrium concentration, and then be faced with the need to choose an appropriate value of the near-bed distance, which is a critical parameter in that formulation. How does one choose discretizations and relations and parameters at these three levels as part of the calibration process, especially in view of the fact that all three levels interact with each other?

There is no universal answer to this question. A particular size-class discretization and set of auxiliary relations and their associated parameters may not be unique; several different sets may produce equally viable mobile-bed response in a given problem. Ultimately one must simply rely on the not-so-tired notion of good engineering judgment.

The discretization of nonuniform sediment into size classes is driven by the need to achieve resolution as high as possible within the constraints of computational time, and judgment as to the role that the finest and coarsest sediment represented in the field may, or may not, play in the problem under study. Collapsing two or more traditional sediment types (e.g., silt and fine silt) into a single size class with a single representative particle diameter may need to be revisited during the calibration process to ensure that the collapsing and choice of representative diameter does not, in itself, influence the overall mobile-bed response being studied—it is in this sense that the size-class discretization is very much a calibration issue, as is the assignment of initial bed-material composition discussed earlier.

The choice of auxiliary relations should be guided first and foremost by an assessment of the likelihood that a given relation is valid for the particular area under study, based on previous studies and/or similarities between the study site and the conditions under which auxiliary relations were developed. For example, the bed-load predictor adopted for a particular model study ought to be one that might be adopted for general use at that site, based on published information and experience at that site and elsewhere. Still, during the calibration process, it may prove necessary to modify standard parameters in that predictor, or indeed adopt an alternative one based on model response in early trial runs.

Even if one accepts that there is no unique, or best, set of auxiliary relations and their parameters for a given discretization, how does one know that a given set is acceptable in the context of calibration? The situation is quite unlike fixed-bed modeling, in which, for example, measured water-surface

slope, local or global, and perhaps measured local two- or three-dimensional velocities can be used as specific targets for adjusting bed roughness. It is far more difficult to identify individual response indicators in mobile-bed modeling. Imagine that a model's prediction of suspended concentration of a certain size class is an order of magnitude different from available field measurements at a particular location. Is this because of uncertainty arising from the chosen empirical auxiliary relations such as the fall-velocity predictor, suspended-load entrainment formulation, and bed-roughness predictor and their parameters? Or is it perhaps because of the sparseness and natural variability of available field data, which makes it difficult to assign an appropriate initial bed-material composition and/or choose a representative sediment size-class discretization?

Similarly, imagine that a model is showing what appears to be excessive scour at a certain location. What are the roles of the initial bed-material composition, the bed-load predictor, and the suspended entrainment function parameters in these predictors and functions, or the sediment discretization in causing this excessive scour?

These questions point to the need for sensitivity/uncertainty analyses to determine the range of influence of empirical relations on simulation results. They also point to the need for careful engineering judgment in dealing with sparse and stochastic field data, and/or the need for more comprehensive and detailed field data collection efforts.

Regarding calibration/verification of empirical auxiliary relations, it is generally impossible to associate a particular model response with a particular formulation or parameters within it. The only alternative appears to be one of seeking a self-consistent set of relations and parameters, guided by good judgment for the site under study, such that the overall model response conforms to reasonable expectations based on past experience. The overall response indicators most easily observed are bed-elevation changes, changes in bed-material composition, total suspended load concentrations, overall water-surface slopes, etc. A self-consistent set of relations and parameters, with the associated sediment and grid discretization and initial and boundary conditions, is one for which the model persists in a known flow-sediment quasi-equilibrium for some time into the future (if only a few days) with no major changes to bed elevation, total concentrations, bed-material composition, etc.

Another way of looking at this is to say that a self-consistent model, when run some time into the future, will continue to display the same range of variability of observable features (e.g., bed-material composition) that are characteristic of the site from previous observations. Then, when the model is used to study, e.g., structural modifications or long-term response to changes in the hydrologic and sediment-inflow imposed on the area under study, one can have some confidence that the model response is a valid one because it is a self-consistent (but perhaps not unique) representation of the physical site.

### 15.10.5 Special Considerations Regarding Acoustic-Doppler Current Profiling Velocity Data

Acoustic-Doppler current profiling (ADCP) techniques have become quite popular. They offer a combination of accuracy, ability to measure local velocities in three coordinate directions, and rapid field deployment and use.

However, the authors and their colleagues have found that use of ADCP measurements to provide boundary-condition and calibration/verification velocity fields for three-dimensional mobile-bed models must be cautious and mindful of the error that can be induced when the measurements are taken from a moving boat. The need for this caution is based on the experience and analyses reported by Morlock et al. (2002) and Muste et al. (2004a; 2004b).

### 15.10.6 Field Data—What Is the Truth?

In the field of computational hydraulics, both developers and users tacitly accept the notion that measured field data represent some sort of “truth” to which model results should aspire. As legitimate as this viewpoint may be in the abstract, in practice it has to be tempered by careful consideration of the temporal and spatial scales that a model is capable of resolving.

A numerical model cannot resolve hydrodynamic or mobile-bed processes at spatial or temporal scales finer than those of the computational grid. The computational grid resolution is constrained by computer memory and time limitations on one hand, and by numerical stability and convergence constraints on the other.

Because solvers of two-dimensional and three-dimensional mobile-bed models generally have both implicit and explicit features, numerical stability generally requires that the time step be constrained by a Courant-type criterion. In most applications a horizontal grid scale on the order of 10 m implies a maximum time step on the order of 10 s. Although one could, in principle, work with much smaller spatial and temporal scales, this is generally impractical due to computer memory and processor limitations.

Therefore mobile-bed codes do not generally resolve turbulent motions of scales smaller than the order of 10 m or 10 s or bed forms smaller than the order of 10 m, for reasons of grid resolution alone. Even if the grid scales were sufficiently small to resolve such features, it is doubtful that the mathematical formulations or numerical procedures of models available as of this writing could resolve the flow separation and turbulent moment exchange associated with such features.

Comparison of suspended-sediment data with model predictions is subject to similar problems of reconciliation of scales. Figure 15-4 shows a comparison of measured and computed fine-sand profiles across a river at a particular transect. Although the suspended-sediment samples necessarily represent a certain time-averaging (on the order of

Fig. 15-4. Computed and measured suspended-sediment concentrations (fine sand).

several seconds) at a well-defined stationary vertical profile, one can still observe the kind of nonmonotonic behavior in the measured data that suggests the existence of large-scale variability (probably associated with large eddies or possibly with dune migration) that cannot be resolved by the numerical model. Therefore one cannot conclude, from this comparison alone, that the model’s suspended-sediment profiles are or are not correct in their detailed structure.

Similar attention was focused on the issue of the appropriate initial bed-material size distribution in the model, as has been discussed earlier in Section 15.10.4. In this study, dozens of grab-samples of bed material were available in the study reach, and additional grab-sample thalweg data was available from a previous study.

Clearly several of the measured size distributions, although undoubtedly representative of “the truth” at the time and location they were taken, were not representative of the general area of the river at the spatial scale resolvable by the model. These samples may have been representative of the portion of a dune from which they were taken, or perhaps of lenses of finer material moving through the system, but were clearly not representative of a quasi-equilibrium bed condition representative of most of the width of the river over several hundred meters of length. This conclusion was driven by the fact that the mobile-bed model generates excessive and unrealistic scour in the first few time steps if the initially imposed bed-material distribution is unrealistic, or not nearly in equilibrium, with the hydraulic characteristics of the river in that vicinity.

Of course the “satisfactory” or “true” initial bed-material size distribution is also dependent on the particular bed-sediment entrainment algorithm in the model. Does this

suggest that the “truth” in field data must also be interpreted in light of the model’s sediment-mechanics formulations?

The problem of reconciling the needs of field data collection with the needs of numerical models is not a new one. Even in one-dimensional modeling, the need for measurements of time-varying stages and discharges is still too seldom recognized when field data programs are designed and executed. Now that three-dimensional modeling has entered the realm of engineering practice, study managers and modelers must work together to ensure that data-collection efforts are aimed at collecting and/or processing data resolved at temporal and spatial scales that are meaningful to the model’s grid resolution. Judgments as to the validity and accuracy of numerical predictions must be conditioned by a realistic view of the scales and processes that a model can and cannot be expected to resolve, given its mathematical formulation and grid constraints. The “truth” is relative in this context: relative to the model’s framework, and to the accuracy of the field-data. With regard to the latter, it is important to keep in mind that just like model results, field data are also subject to errors in collection, analysis, and reporting, and thus must also be interpreted and assessed carefully in the context of their use in an overall modeling effort.

## 15.11 EXAMPLES

### 15.11.1 Introduction

The purpose of this section is to present a few examples of multidimensional mobile-bed modeling. These are necessarily based on the authors’ own experiences and are intended to illustrate the scope, challenges, and possibilities of such modeling and to give the reader a sense of the kinds of problems to be anticipated. Section 15.11.2 describes application of the three-dimensional mobile bed model CH3D-SED to an analysis of sediment dynamics at the Old River Control Complex on the lower Mississippi River. Section 15.11.3 describes the application of CH3D-SED to the study of river habitat restoration measures on the Leavenworth Bend of the Missouri River. Section 15.11.4 describes application of the two-dimensional mobile-bed model MOBED2 to the prediction of reservoir sedimentation in three flood-control reservoirs in Iowa.

### 15.11.2 Old River Control Complex, Mississippi River

**15.11.2.1 Background** The Old River Control Complex is located on the lower Mississippi River about 300 km upstream of New Orleans, in the state of Louisiana and adjacent to the state of Mississippi. Figure 15-5 shows the general layout of the site, which has an interesting and complex history as described by Tuttle (unpublished manuscript, 1998).

Prior to the fifteenth century, the Red River flowed generally parallel to the Mississippi, continuing independently

to the Gulf of Mexico. In the fifteenth century a westward meandering loop of the Mississippi broke into the basin of the Red River and captured it, also intersecting a south-flowing distributary of the Red currently known as the Atchafalaya River. Through time, and in response to both artificial cut-off construction and log-raft clearing, the Red came to flow directly into the Atchafalaya and henceforth to the Gulf of Mexico, but with a connecting channel to the Mississippi known as the Old River. Bidirectional flow occurred in the Old River according to hydrological and hydraulic conditions in the adjacent river systems.

After World War II, it became apparent that the increasing natural diversion of the Mississippi flow into the Atchafalaya channel through the Old River would begin to threaten the geomorphic viability of New Orleans as a deep-water port. Therefore, after extensive study and analysis involving Professor Hans Albert Einstein and others, it was agreed to seek a long-term flow distribution such that 30% of the “latitudinal” flow (i.e., the sum of the Red River and Mississippi River flows at the latitude of the Old River complex) would flow to the gulf through the Atchafalaya. This was to ensure the long-term geomorphic stability and navigational viability of both the Mississippi and Atchafalaya.

In 1959 the low sill structure and outflow channel (see Fig. 15-5) were constructed to achieve the 30 to 70% targeted flow split. However, during the Lower Mississippi flood of 1973, this structure was severely threatened and nearly failed due to scour and associated loss of a wing wall. Consequently, in 1986, the auxiliary structure (see Fig. 15-5) was constructed to obviate total reliance on the low sill structure to achieve the targeted flow diversion.

Recognizing the hydropower potential of the average 6-m head difference between the Mississippi and Atchafalaya, in 1977 a group of investors proposed construction of the Sidney A. Murray, Jr. Hydroelectric Station 2 km above the low sill structure (see Fig. 15-5). This 192-MW bulb-turbine facility was constructed in a New Orleans shipyard and towed up the Mississippi to the site, where it was sunk into place and completed in 1990. Since that time it has been operated successfully by the Louisiana Hydroelectric Corporation, in close coordination with the U.S. Army Corps of Engineers, to achieve the 30 to 70% target flow distribution in concert with the auxiliary and low sill structures. The facility passes an average discharge of about 2,800 m<sup>3</sup>/s.

Although the turbines were designed to pass a significant sand and silt load, the hydroelectric facility is located on a relatively sediment-poor location of the right descending bank of the Mississippi. Because long-term geomorphic stability of the lower Atchafalaya River requires a continuing supply of sediment from upstream, Louisiana Hydroelectric and the U.S. Army Corps of Engineers have been exploring ways of increasing the diversion of sands and silts from the Mississippi to the Atchafalaya in and around the Old River Control complex. The purpose of the study was to develop an understanding of the short- and long-term sediment dynamics

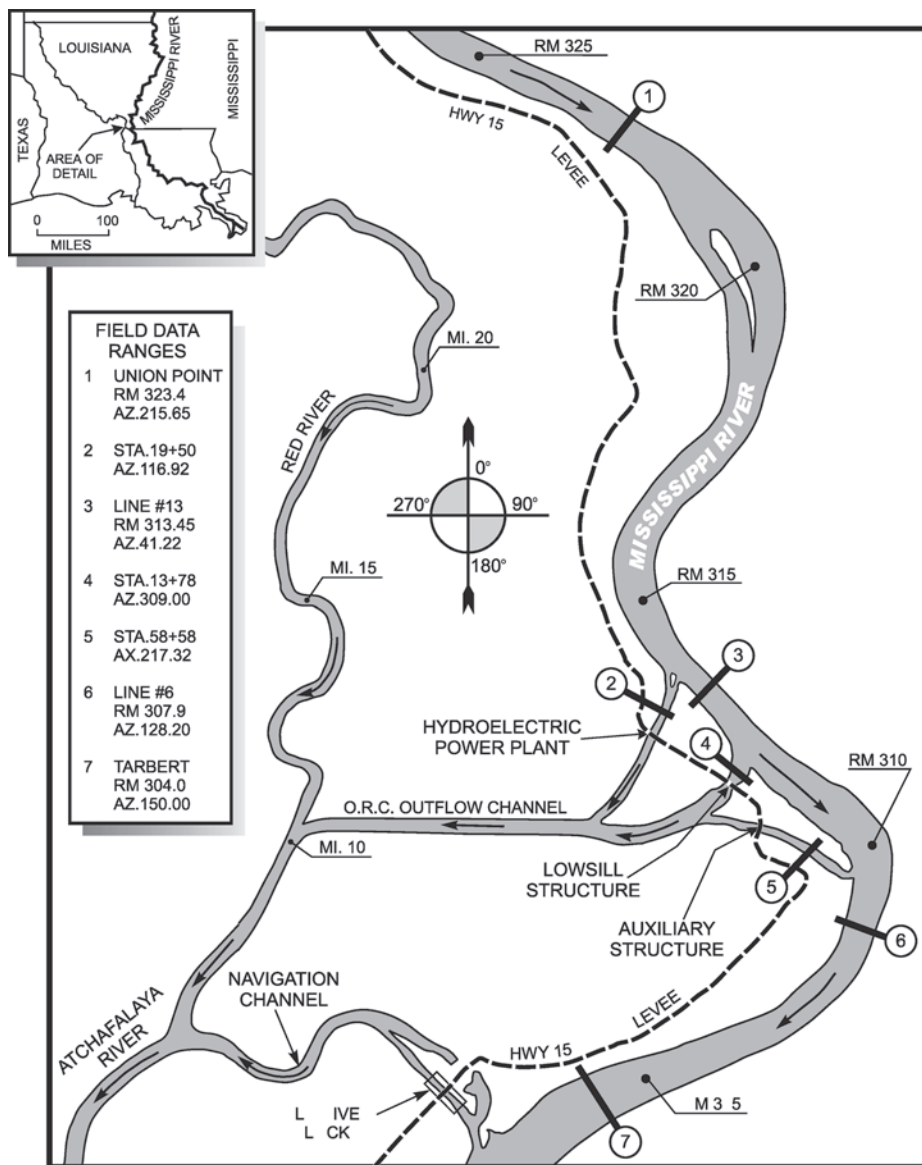

Fig. 15-5. Old River Control Complex, lower Mississippi River.

of the system, both locally and along extended downstream reaches of the Mississippi and Atchafalaya rivers.

Supported by extensive analysis of historical data and dedicated field campaigns to collect new hydraulic and sediment data, the project involved a detailed and comprehensive geomorphic study, the use of one-dimensional mobile-bed modeling for the study of long-term stability of the downstream reaches (see Chapter 14), and three-dimensional mobile modeling for the study of short-term sediment dynamics in the immediate vicinity of the complex. The overall objectives were to quantify the present diversion rate of Mississippi River sediment into the Atchafalaya River and identify possible structural or sediment-management strategies that could increase the diversion of suspended

and bed-load sediments through the hydroelectric complex into the Atchafalaya. The overall study is the subject of a comprehensive report (Catalyst-Old River Hydroelectric Limited Partnership d.b.a. Louisiana Hydroelectric Limited Partnership 1999).

**15.11.2.2 CH3D Modeling System** The CH3D modeling system has been described in some detail by Gessler et al. (1999). The code simulates unsteady free-surface three-dimensional (hydrostatic) hydrodynamics, constituent and sediment transport, and mobile-bed dynamics in natural waterways. In one time step, the code sequentially solves the hydrodynamic, constituent, and mobile-bed equations.

In the hydrodynamic solution, CH3D first solves the depth-averaged Reynolds approximation of the momentum

equations (Eqs. (15-14) and (15-15)) coupled with the depth-averaged mass-conservation equation (Eq. (15-9)) to yield the depth-averaged velocity and water-surface elevation on a two-dimensional grid. This solution is based on finite-difference approximations applied to a boundary-fitted, nonorthogonal curvilinear grid in the horizontal plane. The deviations from the depth-averaged velocity are then computed for each computational cell through solution of the momentum-conservation equations (Eqs. (15-12) and (15-13)), whereas the vertical-velocity component is obtained by solving the mass-conservation equation (Eq. (15-1)), all coupled with a  $k$ - $\epsilon$  closure for vertical momentum diffusion on a sigma-stretched vertical grid. These procedures for the hydrodynamic solution are described in more detail by Chapman and Johnson (1996) and Sheng (1983).

The mobile-bed algorithms have been described in detail by Spasojevic and Holly (1993). In the mobile-bed solution within one time step, the computations are based on a two-dimensional solution of the mass conservation equations for the channel bed (Eqs. (15-63) and (15-64)) and the three-dimensional advection-diffusion equation for suspended-sediment transport (Eq. (15-62)), both for any number of distinct sediment size classes. Auxiliary relations used for the system closure are discussed in Section 15.8.4 of this chapter. The sediment transport algorithms autonomously account for the movement of multiple size classes as either bed load or suspended load, with the exchange between these modes of transport and the bed being governed by local hydrodynamic conditions interacting with sediment properties.

**15.11.2.3 Field Data Campaign and Model Construction** In the ORCC study, an initial CH3D model data was constructed to the prototype dimensions of an existing coal-bed 1:120 scale undistorted outdoor hydraulic model at the Waterways Experiment Station, Vicksburg, Miss. This preliminary study was used to verify the overall behavior of the CH3D model for a range of prototype discharges and support design of the actual ORCC model data set.

During the 1998 hydrologic cycle seven field-data collection campaigns were organized. A morphology survey was conducted during January 1998. Field sediment and flow data were collected on (1) February 27 (reported Mississippi River discharge at Union Point was  $Q = 1,059,000$  cfs;  $29,989$  m<sup>3</sup>/s); (2) March 23 ( $Q = 1,082,000$  cfs;  $30,640$  m<sup>3</sup>/s); (3) April 10 ( $Q = 1,224,000$  cfs;  $34,661$  m<sup>3</sup>/s); (4) April 17 ( $Q = 1,178,000$  cfs;  $33,358$  m<sup>3</sup>/s); (5) May 8 ( $Q = 1,445,000$  cfs;  $40,919$  m<sup>3</sup>/s); (6) June 9 ( $Q = 739,000$  cfs;  $20,927$  m<sup>3</sup>/s); and (7) August 3 ( $Q = 573,000$  cfs;  $16,226$  m<sup>3</sup>/s). The collected data were used in conjunction with data available from other sources, to formulate the initial and boundary conditions for the three-dimensional Old River Control Complex model, to calibrate the model, and to verify the model results.

Detailed calibration and verification of the three-dimensional Old River Control Complex model is presented here, as well as a critical assessment of the model's simulation

results for the February 27, 1998, data set. Established calibration procedures and experience gained through simulations based on February 27 data were successfully used to make simulations of flow and sediment diversions for other data sets.

On February 27, 1998, field sediment and flow data were collected at six field-data ranges (Fig. 15-5): Range 1, the Mississippi River at Union Point; Range 2, the hydroelectric power plant (HPP) channel some distance upstream from the hydroelectric power plant; Range 3, the Mississippi River at Line 13; Range 5, the auxiliary structure channel some distance upstream from the auxiliary structure; Range 6, the Mississippi River at Line 6; and Range 7, the Mississippi River at Tarbert. The field data were not measured at Range 4, in the low sill structure channel, because the low sill structure was closed.

To obtain sediment data in a particular range, four verticals were chosen along the range. Twenty-four suspended-sediment samples were taken at the range, six point samples along each of the four chosen verticals. Also, four bed-sediment samples were collected at bed-surface locations corresponding to the same four chosen verticals. Suspended-sediment samples were processed to obtain vertical suspended-sediment concentration profiles by size class for each of the chosen verticals. Bed-sediment samples were processed to obtain bed-sediment size distribution at the bed-surface location of each vertical.

Flow data at a particular data range were obtained using an acoustic Doppler current profiler to measure the distribution of horizontal velocity vector intensities and directions across the range. The total water discharge at the range was obtained by integrating measured velocities across the range. To be consistent with sediment data, the distribution of horizontal velocity vector intensities and directions was reported only along the four chosen verticals, the same ones that were used for collecting suspended-sediment samples. Furthermore, reported vertical profiles of velocity vector intensities and directions were the result of ensemble averaging (Fagerburg 1998). Each velocity vector intensity and direction value, reported for a particular point on a particular vertical, is the average of the value at that particular point and five or eight surrounding points. Ensemble averaging, instead of time averaging, was introduced to eliminate significant randomness in measured velocities caused by ADCP high-frequency sampling (1–3 s per vertical).

All field sediment and flow data collected during the seven field data collection campaigns in 1998, including the February 27 data, can be found in the report of the Catalyst-Old River Hydroelectric Limited Partnership d.b.a. Louisiana wHydroelectric Limited Partnership (1999).

Certain data relevant to the Old River Control Complex model are available on a daily basis from sources other than the 1998 field-data collection effort. The Mississippi River discharges at Union Point and Tarbert, as well as the free-surface elevation at the Tarbert Landing gauge, are reported

daily. At the hydroelectric power plant, the low sill structure, and the auxiliary structure, free-surface elevations are measured and discharges computed on daily basis.

On February 27, 1998, the reported Mississippi River discharges at Union Point and Tarbert were 1,059,000 cfs (29,988 m<sup>3</sup>/s) and 870,000 cfs (24,636 m<sup>3</sup>/s), respectively. The calculated discharges at the hydroelectric power plant and the auxiliary structure were 162,000 cfs (4,587 m<sup>3</sup>/s) and 27,000 cfs (765 m<sup>3</sup>/s), respectively. The low sill structure was closed.

The three-dimensional model domain comprises (1) the Mississippi River between Union Point and Tarbert; (2) the channel between the Mississippi River and the hydroelectric power plant (HPP channel); (3) the channel between the Mississippi River and the low sill structure (low sill structure channel); and (4) the channel between the Mississippi River and the auxiliary structure (auxiliary structure channel) (Fig. 15-16).

The computational grid for the February 27 data has 344×49 points that lie in a horizontal plane and 10 points in a vertical direction, i.e., along the depth. However, for a complex domain such as the Old River Control Complex, the CH3D-SED computational grid covers an area larger than the actual model domain. In this case, the number of active computational points inside the model domain is 7,200 in the horizontal plane, with 10 points along the depth.

**15.11.2.4 Hydrodynamic Boundary and Initial Conditions** Hydrodynamic computations require either free-surface elevations or unit discharges as boundary conditions at all open boundaries. For the February 27 data, the open boundaries of the Old River Control Complex model are (1) the Mississippi River at Union Point as an upstream inflow boundary; (2) the Mississippi River at Tarbert as a downstream outflow boundary; (3) the hydroelectric power plant as an outflow boundary; and (4) the auxiliary structure as an outflow boundary. All other boundaries, including the closed low sill structure, are treated as impermeable boundaries.

It should be noted that available measured-velocity data did not support the imposition of measured unit discharges as a boundary condition at open boundaries, which would have been the ideal situation. For the Mississippi River at Union Point and Tarbert, measured velocities were reported only for four verticals along each of the respective data ranges, whereas there are 20 computational-grid verticals at each range. It was practically impossible to extrapolate data measured at four locations to 20 computational points, and still satisfy the total-discharge requirement, without using unfounded assumptions. Furthermore, in the HPP and auxiliary structure channels, velocities were not even measured at model boundaries, but rather at some distance upstream from the hydroelectric power plant and the auxiliary structure. Thus, when unit discharges were used as a boundary condition for the Mississippi River at Union, the total measured discharge was distributed across the flow so that the ratio

between total discharge and the particular unit discharge through a computational-cell face was the same as the ratio between the total cross-section area and the appropriate cell-face unit area. This commonly used approximation amounts to assigning constant depth-averaged velocities across the flow. The measured free-surface elevation was assigned as a downstream boundary condition for the Mississippi River at Tarbert, horizontal across the section.

A measured free-surface elevation seemed to be the logical choice for the outflow boundary condition at the hydroelectric power plant and the auxiliary structure. The alternative, unit outflow discharges, required using the constant depth-averaged velocity approximation to distribute the total discharge across the channel. However, using the free-surface elevation as an outflow boundary condition at the hydroelectric power plant and the auxiliary structure would have made modeling the proper flow diversion at these two locations very difficult. It would have required almost perfect bed morphology and bed-surface friction data, as well as a very advanced flow model, to reproduce the complex flow pattern caused by the flow diversion through the HPP and the auxiliary structure channels. Assignment of unit discharges as boundary conditions at the hydroelectric power plant and the auxiliary structure automatically achieved the desired flow diversion, but the model still needed to be calibrated to reproduce the proper free-surface elevations in respective channels. This task was also difficult, because the free surface in the HPP and the auxiliary channels is dictated by specific rating curves at the hydroelectric power plant and the auxiliary structure. The CH3D hydrodynamic computations do not include a rating-curve boundary condition. Thus, final runs of the model, with calibrated parameters for the HPP channel, were made with unit discharges as the HPP boundary condition, ensuring the exact HPP discharge.

For the auxiliary structure, approximated unit discharges, providing the proper flow distribution, were assigned as a boundary condition. The discharge through the auxiliary structure on February 27 was small as compared to other discharges throughout the model. Thus, velocities and free-surface elevation slope at the auxiliary channel were small, leading to a relatively simple calibration of free-surface computations.

Zero-flow initial conditions (i.e., horizontal free-surface elevation and zero-velocity field) were used for the hydrodynamic computations. The chosen combination of initial and boundary conditions (realistic discharges and/or free-surface elevations imposed on initially still water) is known to produce a disturbance (wave) that propagates back and forth throughout the flow domain. A stabilization period is required to allow the disturbance to eventually die out. Avoidance of transient dry-bed conditions and high Courant numbers associated with the arbitrary initial condition required careful treatment, and is not discussed further here. At the end of the flow-stabilization period, the flow approached a steady-state condition.

**15.11.2.5 Hydrodynamic Model Calibration and Verification** For the purpose of model calibration and verification, the results of the steady-state flow solution for the February 27 discharge were compared to available field data.

A flow-stabilization period of 10 h (2,400 15-s computational time steps) proved to be sufficient for the dissipation of the initially severe wave propagation in the domain. At the end of the flow-stabilization period, a steady-state flow solution was achieved.

The first series of calibration and verification runs was made with measured free-surface elevation as a boundary condition for the Mississippi River at Tarbert, and unit discharges (obtained by using the constant depth-averaged velocity assumption to distribute known total discharges across appropriate boundaries) as a boundary condition for the hydroelectric power plant, the auxiliary structure, and the Mississippi River at Union Point. The low sill structure was closed on February 27, 1998.

The goal of these runs was to achieve generally good agreement between the computed and measured data throughout the domain by globally calibrating the friction coefficient. The agreement between computed and known free-surface elevations was checked throughout the model domain (the Mississippi River at Union Point, the hydroelectric power plant, the low sill structure, and the auxiliary structure). Also, the agreement between computed and measured horizontal velocity vector intensities and directions was checked for all verticals at all data ranges.

The CH3D hydrodynamic-computations program module has two major physical parameters that can be determined through the calibration process: (1) the bed-surface friction coefficient and (2) the horizontal eddy-viscosity coefficient, used in conjunction with the boussinesq approximation for horizontal turbulent-diffusion terms. For both coefficients only an expected range of values can be estimated, because the exact values are unknown a priori.

Initially, a number of runs with different values for the eddy-viscosity coefficient were made. Changing the horizontal eddy-viscosity coefficient within the expected range of values, from 10 to 10,000  $\text{cm}^2/\text{s}$ , did not significantly

affect the computed hydrodynamic results. Thus, all subsequent hydrodynamic computations were made with an eddy-viscosity coefficient of 1,000  $\text{cm}^2/\text{s}$ . Considerably more effort was devoted to the spatial variability of the absolute roughness and consequent friction and manning coefficients in the model. This is described in detail in Catalyst-Old River Hydroelectric Limited Partnership d.b.a. Louisiana Hydroelectric Limited Partnership (1999).

Through the calibration process, it became apparent that the present CH3D hydrodynamics model could not fully reproduce the complex flow pattern in the HPP channel, especially in the channel's upstream portion. In general, the existing CH3D hydrodynamic model cannot fully reproduce strong secondary currents, due to the simplified horizontal turbulence model, but even more to the vertical hydrostatic pressure assumption, which implies parallel streamlines in a vertical direction. Thus, even with carefully calibrated friction and a corrected cross-section area, the model could not reproduce the exact flow diversion through the HPP channel when the measured free-surface elevation was used as the HPP boundary. However, the calibrated friction and the corrected morphology could still be used to improve HPP free-surface computations in the case when unit discharges were used as a HPP boundary condition. HPP unit discharges were obtained by using the constant depth-averaged velocity assumption to distribute known total discharge across the HPP boundary. The described unit-discharge boundary condition amounts to assigning known total discharges at the hydroelectric power plant, thus forcing the correct HPP flow diversion. Using the previously calibrated friction coefficient and adjusted cross-section area in the HPP channel, resulted in a computed HPP surface elevation that was only 9 cm lower than the measured one.

Table 15-3 shows the final comparison between computed and known free-surface elevations throughout the model domain. This should be indicative of reasonable expectations for the water-surface elevation calibration in a three-dimensional hydrodynamic model of this type. As previously stated, after each calibration run the agreement between computed and measured horizontal velocity-vector

**Table 15-3 Computed and Measured (or estimated) Free-Surface Elevations**

	Measured (or estimated) free-surface elevations	Computed free-surface elevations
Mississippi River at Union Point	15.58 m asl (51.1 ft) (estimated)	15.60 m asl (51.18 ft)
Hydroelectric power plant	14.82 m asl (48.6 ft)	14.73 m asl (48.33 ft)
Low-sill structure	14.91 m asl (48.9 ft)	14.95 m asl (49.05 ft)
Auxiliary structure	14.69 m asl (48.2 ft)	14.66 m asl (48.10 ft)
Mississippi River at Tarbert	14.38 m asl (47.17 ft)	14.38 m asl (47.17 ft) assigned boundary condition

intensities and directions was checked for all data verticals in all data ranges. Fig. 15-6 shows a sample of computed (at the end of the calibration process) and measured horizontal velocity-vector intensities and directions for the Mississippi River at Line 13.

The computation of velocities at Line 13 (Fig. 15-6) required additional calibration of the local Mississippi River model area immediately downstream from the HPP channel. Specifically, the Mississippi River navigation charts show the presence of a clay shelf next to the Mississippi River's right bank immediately downstream from the HPP channel. In that location, the Mississippi River's main flow leaves the right bank and crosses toward the left bank. This is reflected in velocities measured at line 13. Evidently, the present CH3D hydrodynamic model cannot properly reproduce the flow over and around the clay shelf, due to an oversimplified horizontal turbulence model. Thus, an engineering approximation was used. At the clay shelf area, the wall-shear stress was significantly increased to compensate for the poorly modeled flow around the shelf and the associated drag. An absolute roughness of 3 cm, corresponding to a friction coefficient  $C_d$  of 0.02, i.e., a Manning coefficient  $n$  of 0.066, for  $H = 10$  m, proved to be sufficient to achieve satisfactory agreement

between computed and measured velocities at line 13 (Fig. 15-6).

Fagerburg (1998) reported the existence of a strong reverse flow area along the right bank of the auxiliary structure channel. Fig. 15-7 shows the computed mid-depth velocity vector intensities and streamlines at the auxiliary structure channel, featuring the predicted reverse flow. However, although it is known that the turbulence model based on constant eddy viscosity can predict the strong reverse flow, it cannot correctly predict the size of the reverse flow area. This was confirmed when computed and measured horizontal velocity-vector intensities and directions in the auxiliary structure channel were compared. Range 4 (Fig. 15-6) in the auxiliary structure channel is located slightly upstream from the predicted reverse flow area shown in Fig. 15-7. However, measured horizontal velocity-vector directions show that, whereas velocities at verticals 2, 3, and 4 are generally oriented toward the auxiliary structure, velocities at vertical 1 (next to the right bank) are still generally oriented away from the structure. Thus, the model underestimates the size of the reverse-flow area.

At locations other than the Mississippi River at line 13 and the auxiliary structure channel, similar calibration procedures

Fig. 15-6. A sample of computed and measured velocities at line 13.

**Fig. 15-7.** Middepth velocity vector intensities and streamlines in the auxiliary structure channel.

produced generally good agreement between computed and measured horizontal velocity-vector intensities and directions.

It should be noted that the hydrodynamic-computations results were checked again after the sediment-model calibration and the sediment simulation runs. Results of the hydrodynamic computations at the end of the 10-h flow-stabilization period and at the end of the total flow and sediment simulation period of 34 h were virtually identical. The difference in free-surface elevations was 1 cm at Union Point and smaller everywhere else. The difference in velocity magnitudes at field-data verticals was less than 0.5%, and the difference in velocity angles at field-data verticals was around 0.1%.

**15.11.2.6 Model Sediment Size Classes** Suspended-sediment samples, collected on February 27, 1998, were processed to obtain suspended-sediment concentrations by size class. Grain-size analysis for suspended sediment showed the five size classes. These suspended-sediment samples generally contained a significant amount of silt and clay and fine sand (suspended-sediment size classes 1 and 2), some amount of very fine and medium sand (size classes 3 and 4), and very little coarse sand (size class 5).

Bed-sediment samples, collected on February 27, were also processed to obtain bed-sediment size distribution at the bed-surface. Grain-size analysis for bed sediment

featured the 18 size classes. These bed-sediment samples generally contained a significant amount of sediment with diameter smaller than 1 mm (bed-sediment size classes 1 to 9), and only a small percentage of sediment with diameter larger than 1 mm.

In addition, it is known that the HPP channel bed is covered with very coarse material (essentially cobbles), and that revetments along the Mississippi River near the Old River Control Complex comprise very coarse material.

Based on the above observations, the six size classes in Table 15-4 were chosen to represent the totality of natural sediment mixtures relevant to the Old River Control Complex model.

Size class 6 (referred to as gravel) was used to model the coarse material found in small amounts at the bed surface, and also the coarse material at the HPP channel bed and the revetment material. The characteristic sizes for the silt and clay and the gravel were not known in advance, and were determined during the model calibration. Characteristic sizes for sand size classes were obtained as geometric means of the diameter-range limits.

**15.11.2.7 Sediment Boundary Conditions** Sediment computations in CH3D-SED recognize three boundary types: sediment-inflow, sediment-outflow, and impermeable

**Table 15-4 Representative Size Classes for the Old River Control Complex Model**

Model size class	Diameter range (mm)	Characteristic diameter (mm)(geometric mean of diameter-range limits)	Corresponds to suspended-sediment size class	Corresponds to bed-sediment size class
1(silt and clay)	$D < 0.062$		1	1
2(very fine sand)	$0.062 < D < 0.125$	0.088	2	2–4
3(fine sand)	$0.125 < D < 0.250$	0.177	3	5–6
4(medium sand)	$0.250 < D < 0.500$	0.326	4	7–8
5(coarse sand)	$0.500 < D < 1.00$	0.707	5	9
6(gravel)	$D > 1.00$			10–18

boundaries. Boundary conditions are required only along sediment-inflow boundaries.

Boundary conditions for suspended-sediment computations are known vertical suspended-sediment concentration profiles for all size classes, assigned at each vertical along all sediment-inflow boundaries. For bed load, the formulations of CH3D-SED require assignment of a size-fraction distribution (featuring size fractions for all size classes) to each bed point along all sediment inflow boundaries. The assigned size-fraction distribution at each particular bed point must satisfy the basic requirement that the sum of all fractions must be equal to unity. This requirement, in conjunction with other sediment boundary conditions, determines the proper total number of sediment boundary conditions, because the bed-surface elevation computations do not require a boundary condition in the formulation of CH3D-SED. Boundary conditions for both suspended- and bed-sediment computations can be either constant or time-dependent.

Sediment computations also require declaring a potential reverse-flow boundary (a boundary where the flow could potentially change direction during the simulation) as a sediment-inflow boundary, and assigning the appropriate boundary conditions along it. Assigned boundary conditions are used only when the potential reverse-flow boundary becomes an actual inflow boundary and are ignored otherwise.

The only real potential reverse-flow boundary is a tidal boundary. However, any flow boundary with an imposed free-surface elevation as a boundary condition can theoretically become a reverse-flow boundary, depending on the variations in the imposed water level. When CH3D-SED code is used to model river flow, transitory waves at the beginning of the flow-stabilization period may actually cause reverse flow for a short period of time at such boundaries.

For the Mississippi River at Union Point, initial suspended-sediment data, obtained as described later, were also used as the suspended-sediment inflow boundary condition. The Mississippi River at Union Point is the only real sediment inflow boundary. The Mississippi River at Tarbert and the hydroelectric power plant with free-surface

elevation as a hydrodynamic boundary condition were identified as potential reverse-flow boundaries, and therefore declared as sediment-inflow boundaries. However, for the two potential reverse-flow boundaries, zero-concentration profiles were assigned as suspended-sediment boundary conditions, so that if momentary reverse flow occurred during the stabilization period, no suspended sediment would be advected into the domain through those normally outflow boundaries. The described suspended-sediment boundary conditions were kept constant for the duration of the simulation.

**15.11.2.8 Suspended-Sediment Initial Conditions** As an initial condition for suspended-sediment computations, vertical concentration profiles for all size classes must be defined for all verticals throughout the model domain, including outflow boundaries. Sediment data collected on February 27, 1998, were used to extract vertical suspended-sediment concentration profiles for all representative model size classes at all data-collection ranges and appropriate verticals.

Fig. 15-8(a) through 15-8(f) show a sample of measured suspended-sediment concentrations along four data verticals at Line 13. More specifically, Figs. 15-8(a) through 15-8(e) contain measured suspended silt and clay, very fine sand, fine sand, medium sand, and coarse sand concentrations, respectively. Fig. 15-8(f) contains measured total suspended-sediment concentrations.

Simultaneous inspection of measured suspended silt and clay concentrations for all data verticals in all data ranges shows a relatively modest variation in measured values. Similarly, measured vertical concentration profiles for suspended very fine sand do not show significant variation between different vertical locations. The same observations apply to measured vertical concentration profiles for suspended medium sand, as well as measured vertical concentration profiles for suspended coarse sand. Measured vertical concentration profiles for suspended fine sand are the only profiles showing relatively significant changes from one location to another.

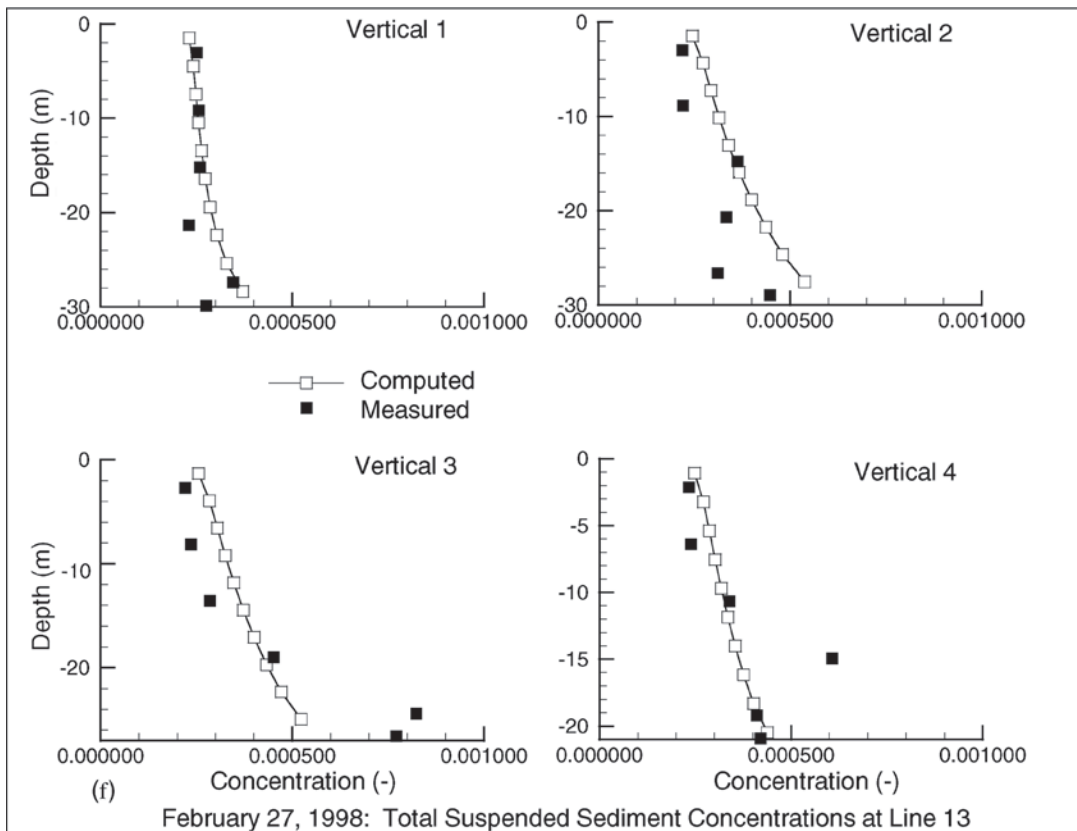

Fig. 15-8(f). Computed and measured suspended total concentrations at line 13.

The preceding observations supported the use of simple extrapolation to construct the initial condition for suspended-sediment computations. First, six suspended-sediment concentrations measured along a particular data vertical were used to construct a set of measured concentration profiles, one for each size class, corresponding to the appropriate computational grid vertical with ten computational points. Each constructed set of vertical concentration profiles was then assigned not only to the corresponding computational-grid vertical, but also to neighboring left and right grid verticals across the flow and grid verticals upstream and downstream from the corresponding grid vertical, until all computational verticals were assigned initial suspended-sediment data. The initial suspended-sediment distribution thus determined at the upstream model boundary, Union Point, was also assigned as a constant suspended-sediment boundary condition.

**15.11.2.9 Bed-Sediment Initial Conditions** As an initial condition for bed-sediment computations in CH3D-SED, initial size-fraction distributions and bed-surface elevations have to be defined for all bed-surface points throughout the domain, including outflow boundaries. In addition, bed-sediment computations in CH3D-SED require definition of initial bed-material characteristics below each bed-surface point in the model domain: (1) the initial active-layer (bed-surface layer) depth at a particular bed point; (2) the initial number of bed-sediment strata below a particular bed-surface point; and (3) the initial depth and size-fraction distribution for each stratum below a particular bed-surface point.

Flow-stabilization hydrodynamic computations, assuming a nonmovable bed, can successfully start up using exact but unrealistic zero-flow initial conditions (e.g., horizontal free-surface elevation and zero-velocity field). Fixed-bed hydrodynamic computations with simple zero-flow initial conditions and proper boundary conditions kept constant over a period of time yield an observed steady-state flow solution at the end of the flow-stabilization period.

Sediment computations, by contrast, initiated from the steady-flow hydrodynamic condition at the end of the flow-stabilization period, require initial conditions to be as close to reality as possible. With boundary conditions held constant over time, flow and sediment will eventually reach a balance, or state of equilibrium. But if the initial sediment conditions are unrealistic, then so will be the achieved solution. For example, if sediment computations are initiated in a flow with relatively high velocities (as observed on February 27, 1998), and if the assigned initial sediment condition assumes an unrealistically fine bed sediment for this flow rate, flow and sediment balance will still be achieved, but only after unrealistically excessive bed erosion (just as if one introduced a sudden large discharge into a channel with very fine material on the bed—the fine material would be removed very quickly). Thus determination of the appropriate initial bed-sediment size distribution comprises part of the model calibration process, as described below.

Sediment data collected on February 27, 1998, were initially used to extract size-fraction distributions at bed-surface

points corresponding to locations of data-collection verticals at all data-collection ranges.

Bed-material samples were not collected in the HPP channel, where the bed is predominantly covered with large cobbles. Thus, the initial size-fraction distribution for the HPP channel was assumed to comprise 100% of the model size class 6 (gravel), and 0% of all other size classes.

Table 15-5 shows measured size-fraction distributions at bed-surface points corresponding to four data verticals in the auxiliary structure channel. Bed material in the auxiliary structure channel does not contain sediment coarser than fine sand. The reason is probably a combination of generally small velocities in the auxiliary structure channel (due to the relatively small average discharge through the auxiliary structure) and the reverse flow in the upstream portion of the auxiliary structure channel. Measured size-fraction distributions (Table 15-6) were extrapolated and assigned as an initial condition throughout the auxiliary structure channel area.

Table 15-6 shows measured size-fraction distributions at bed-surface points corresponding to all data verticals at four data ranges along the Mississippi River. Silt and clay were virtually nonexistent on the bed throughout the domain, except for the bed-surface point corresponding to Vertical 1 at Line 13, where silt and clay make up one-half of the bed-surface sediment mixture. Bed-material samples generally contain less than 5% of very fine sand, but again there are a few exceptions where very fine sand makes up one-third of the bed-surface sediment mixture (bed-material samples corresponding to Vertical 1 at Line 13 and Vertical 4 at Line 6). Fine sand and medium sand were found in virtually all bed-sediment samples, but their percentage in the bed-surface sediment mixture varies from 0% to 89% for the fine sand, and from 0% to 77% for medium sand. Coarse sand was not found in six bed-material samples, but for the remaining ten samples its percentage in the bed-surface sediment mixture varies from 0 to 43%. Gravel was found only in the bed-material sample corresponding to Vertical 1 at Union Point. Vertical 1 at Union Point is the vertical closest to the right bank, and it is also close to the island next to the upstream boundary.

Based on bed-material samples collected on February 27, 1998, it could be generally concluded that the bed-material composition varies significantly within the studied portion of the Mississippi River. Experience showed that the assumption that a particular measured size fraction distribution is representative of a large surrounding area (as was done successfully with measured suspended-sediment concentrations) lead to unrealistic initial conditions for bed-sediment computations. For example, the assignment of the measured size-fraction distribution corresponding to Vertical 1 at Line 13 (with a large silt and clay fraction) to a large model domain lead to excessive erosion in the first few hours of the mobile-bed simulation.

This conclusion is supported by consideration of the Nordin and Queen (1989) study, which presents particle size distributions for several hundred bed-sediment samples collected along the Mississippi River thalweg

between Head of Passes and Cairo, Illinois. It includes 15 bed-material samples within the Old River Control Complex model domain. Relevant particle size distributions show similar variations in bed-material composition to those of the February 27, 1998, data. Samples containing a significant amount of silt and clay were also found, but seem to have been local phenomena, not representative of larger areas.

Thus, for the Old River Control Complex model, an average size-fraction distribution (Table 15-7), obtained by combining February 27, 1998, data and relevant Nordin and Queen (1989) data, was chosen to be representative of the default size-class distribution for the Mississippi River.

Initial size-fraction distributions for the Mississippi River were then obtained by assigning the default size-fraction distribution to all Mississippi River bed points, except for the local areas at and around the data-vertical locations, where measured (February 27, 1998) size-fraction distributions were assigned.

The initial thickness of the active (bed-surface) layer was assumed to be 5 cm throughout the model domain. Because no other information was available, a single very

thick stratum below the bed surface was initially assumed. The Mississippi River's default size-fraction distribution was initially assigned to all subsurface sediment below the Mississippi River's bed surface. The initial subsurface size-fraction distribution for the HPP and the auxiliary structure channels was assumed to be the same as the appropriate bed-surface size-class distribution.

Furthermore, measured size-fraction distributions at four union point verticals were extrapolated to neighboring points left and right across the flow and used as the bed-sediment boundary condition for the Mississippi River at Union Point. For the two potential reverse-flow boundaries (the Mississippi River at Tarbert and the hydroelectric power plant with free-surface elevation as the hydrodynamic boundary condition) the boundary size-fraction distribution was assumed to be 100% of the model size class 6 (gravel) and 0% of all other size classes. The described bed-sediment boundary conditions were held constant for the duration of the simulation.

**15.11.2.10 Physical Calibration Parameters** Calibration of the mobile-bed model comprised not only adjustment of the boundary and (especially) initial conditions, but also the adjustment of certain physical parameters associated with various terms in the auxiliary sediment equations used in CH3D-SED. For the sediment size classes that showed a significant presence in both suspension and at the bed surface (such as sand size classes), the bed-sediment erosion source and the near-bed concentration contain physical parameters that can be calibrated.

The sediment model uses an empirical relation to compute the concentration of near-bed sediment particles, detached from the bed and available either to be entrained into suspension, or to be moved near the bed (sliding, rolling, or saltating) as bed load. This near-bed concentration is evaluated at a certain distance  $a$  above the bed. The bed-sediment erosion source describes the entrainment of near-bed sediment particles into suspension. It is modeled as an upward mass-diffusion flux featuring a vertical-concentration gradient. The vertical-concentration gradient is computed using the difference between near-bed concentration, evaluated at distance  $a$  above the bed, and the suspended-sediment concentration, evaluated at distance  $a + \Delta a$  above the bed. The suspended-sediment concentration at distance  $a + \Delta a$  above the bed is obtained by extrapolating suspended-sediment concentrations computed at the two nearest computational points in suspension above the bed as described in Section 15.7.

Both near-bed distances  $a$  and  $a + \Delta a$  are input data calibration parameters. Their proper assignment ensures proper values for the near-bed concentration and erosion source terms. The near-bed distances  $a$  and  $a + \Delta a$  with assigned values of 8 and 2 cm, respectively, provided the most satisfactory computed concentrations for suspended very fine, fine, medium, and coarse sand.

For silt and clay (the size class that is present mainly in suspension as wash load and that has little contact with the bed

surface) adjustment of the bed-sediment erosion source and the near-bed concentration term has virtually no effect on the sediment model. For this finest size class, the fall-velocity term decisively influences the final suspended-sediment model results. The fall velocity appears in the advection-diffusion equation governing suspended-sediment transport, but also in the bed-sediment governing equations throughout the suspended-sediment deposition source term. The calibration of the fall-velocity term was based on the proper choice of the previously unknown characteristic grain diameter for the silt and clay size class. A characteristic silt and clay diameter of 0.01 mm proved to provide satisfactory suspended silt and clay concentrations throughout the model domain, except in the auxiliary structure channel.

**15.11.2.11 Model Calibration and Verification** The three-dimensional model was used to simulate sediment fate and behavior at the Old River Control Complex on February 27, 1998. The sediment simulation period was 1 day. Sediment computations were initiated after a 10-h flow-stabilization period. Thus, the total flow and sediment simulation period was 34 h. Sediment computations were performed using a computational time step of 15 s.

Model calibration included choosing physical calibration parameters as well as choosing initial and boundary conditions as described earlier. To verify the model, computed suspended-sediment concentrations, at the end of the sediment simulation period, were compared to suspended-sediment concentrations measured on February 27. Also, computed bed-sediment size-fractions distributions, at the end of the sediment simulation period, were analyzed and compared to the February 27, 1998, data as well as to the Nordin and Queen (1989) data. Finally, computed changes in bed-surface elevations were analyzed to ensure that the January 1998 morphology data were not severely distorted during the sediment simulation period.

Figures 15-8(a-f) show the comparison between the computed (at the end of a 1-day simulation period) and the measured suspended-sediment concentrations along four data verticals at Line 13. More specifically, Figs. 15-8(a-e) contain computed and measured suspended silt and clay, very fine sand, fine sand, medium sand, and coarse sand concentrations, respectively, whereas Fig. 15-8(f) contains computed and measured total suspended-sediment concentrations. For silt and clay (Fig. 15-8(a)), the model correctly reproduces the total depth-averaged concentration. For very fine sand and coarse sand (Figs. 15-8(b and e)) the model correctly reproduces both total depth-integrated concentration and concentration-profile shape. For fine sand (Fig. 15-8(c)) the model slightly overestimates the total depth-integrated concentration along Vertical 2 and underestimates the total depth-integrated concentration along Verticals 3 and 4. Medium-sand concentrations (Fig. 15-8(d)) are generally overestimated, but small when compared to fine sand concentrations, and do not significantly influence the total suspended-sediment concentrations at Line 13. Thus, the computed total

suspended-sediment concentration (Fig. 15-8(f)) is mainly influenced by the computed fine-sand concentration. The model slightly overestimates the total depth-integrated concentration along vertical 2 and underestimates the total depth-integrated concentration along verticals 3 and 4 at line 13. At locations other than the Mississippi River at line 13, same calibration procedures produced similar agreement between computed and measured suspended-sediment concentrations.

Model calibration and verification consisted primarily of detailed analysis of changes that the bed-surface elevations and bed-sediment size-fraction distributions underwent during the 1-day sediment simulation period.

Except for a few local spots, the total deposition and erosion varied between +10 cm and -10 cm throughout the model domain. This relatively moderate bed-elevation change indicates that the assigned initial sediment conditions were appropriate. Somewhat higher erosion, up to -20 cm, is observed in the Mississippi River close to the HPP channel, and may be attributed either to the local flow pattern or to the fine material assigned to the bed surface next to the right bank at line 13. Large deposition values, up to +50 cm, were observed within the local area next to the upstream boundary at Union Point. This large amount of deposition can be attributed to the high fine-sand concentration assigned as a boundary condition at Union Point.

The silt and clay fraction was initially assigned a zero value everywhere throughout the domain, except for the small area next to the right bank at line 13, and the auxiliary structure channel. The computed silt and clay fraction at the end of the 1-day simulation period is below 0.05 (or 5%) throughout the domain. The initially assigned fine material at line 13 was eroded, whereas the initially assigned fine material at the auxiliary structure channel remained.

The very fine-sand fraction was initially assigned a value of 0.01 (1%) everywhere throughout the domain, except at the Mississippi River areas where collected bed-sediment samples dictate different values. The very fine-sand fraction at the auxiliary structure channel was also assigned according to the measured data. The computed very fine-sand fraction at the end of the 1-day simulation period shows almost no change as compared to initial data, except that the very fine-sand was eroded from the Mississippi River bed at those few spots where the initial very fine-sand fraction was assigned a larger value.

The fine-sand fraction was initially assigned a default value of 0.45 (45%) everywhere throughout the domain except at the Mississippi River data ranges, in the HPP and the auxiliary structure channels, and at the location of revetments along riverbanks. In the auxiliary structure channel and at the Mississippi River data ranges, the fine-sand fraction was initially assigned measured values. In the HPP channel and at the locations of revetments along the riverbanks, the fine-sand fraction was initially assigned a zero value. The computed fine-sand fraction after the 1-day simulation varied between 0 and 0.9 (90%) throughout

the domain, depending on the location. A similar range of variation in the fine-sand fraction was also found in the February 27, 1998, data and the Nordin and Queen (1989) data. Small computed values of the fine-sand fraction generally coincide with the computed erosion areas. The largest computed values of the fine-sand fraction are found at and downstream of the Union Point area with the largest computed amount of deposition, and can be attributed to the high fine-sand concentration assigned as a boundary condition at Union Point. A slight computed increase of the initially zero fine-sand fraction in the HPP channel indicates a small computed amount of deposition of fine sand in the HPP channel. A computed increase in the fine-sand fraction along the left bank in the upstream portion of the auxiliary structure channel indicates the computed erosion of the initially assigned larger fractions of silt and clay and very fine sand.

The medium-sand fraction was initially assigned a default value of 0.45 (45%) everywhere throughout the domain except in the Mississippi River data ranges, in the HPP and the auxiliary structure channels, and at the location of revetments along riverbanks. In the auxiliary structure channel and in the Mississippi River data ranges, the medium-sand fraction was initially assigned measured values. In the HPP channel and at the locations of revetments along the riverbanks, the medium-sand fraction was initially assigned a zero value. The computed medium-sand fraction varies between 0 and 0.7 (70%) throughout the domain, depending on the location. A similar range of variation in the medium-sand fraction was also found in the February 27, 1998, data and the Nordin and Queen (1989) data. Small computed values of the medium-sand fraction coincide with the computed erosion areas. Small computed values of the medium-sand fraction are also found at and downstream of the Union Point area with largest amount of deposition, and can be attributed to the large amount of fine-sand deposition which is related to the high fine sand concentration values assigned as a boundary condition at Union Point. Large computed values of the medium-sand fraction at the mid- and downstream portions of the model domain are attributed to the fine-sand erosion in those areas. The slight increase of the initially zero medium-sand fraction in the HPP channel indicates a small amount of medium-sand deposition in the HPP channel.

The coarse-sand fraction was initially assigned a default value of 0.08 (8%) everywhere throughout the domain, except in the Mississippi River data ranges, in the HPP and the auxiliary structure channels, and at the location of revetments along riverbanks. In the auxiliary structure channel and at the Mississippi River data ranges, the coarse-sand fraction was initially assigned measured values. In the HPP channel and at the locations of revetments along the riverbanks, the coarse-sand fraction was initially assigned a zero value. The computed coarse-sand fraction varies between 0 and 0.4 (40%) throughout the domain, depending on the location. A similar range of variation in the coarse-sand fraction was also found in the February 27, 1998, data and the Nordin

and Queen (1989) data. Computed values of the coarse-sand fraction that are larger than the initially assigned values are generally attributed to the erosion of fine and medium sand.

Finally, the gravel fraction was initially assigned a default value of 0.01 (1%) everywhere throughout the domain, except in the Mississippi River data ranges, in the HPP and the auxiliary structure channels, and at the location of revetments along riverbanks. In the auxiliary structure channel and in the Mississippi River data ranges, the gravel fraction was initially assigned measured values. In the HPP channel and at the locations of revetments along the riverbanks, the gravel fraction was initially assigned a value of 1.0 (100%). The computed gravel fraction at the HPP channel is 10 to 15% below the initially assigned value, reflecting the small amount of fine and medium sand deposition in the HPP channel. The large computed gravel fraction (up to 80%) can also be found in the large-erosion areas. Evidently, in the large-erosion areas, all finer-than-gravel-size classes were gradually eroded, leading to the bed-surface armoring with gravel and preventing further erosion.

**15.11.2.12 Use of Calibrated Model** One of the primary objectives of the use of CH3D-SED in this study was to provide sediment rating curves, by size class, for flow in the ORCC structure channels and at Tarbert Landing. This was needed for study of the long-term stability of the Mississippi and Atchafalaya rivers below the ORCC with the hydropower facility in operation, using one-dimensional mobile-bed sediment transport simulation (HEC-6 model). An associated secondary objective was to determine the expected size distribution of sediment diverted from the Mississippi into the Atchafalaya through the various outlet structures.

For these purposes, the model as calibrated for the February 27 conditions as described above was first validated through application to three other flow events for which field data campaigns had been conducted; this resulted in no further adjustment of the bed roughness, eddy viscosity, or sediment parameters.

For each of these additional flows, which ranged from 573,000 to 1,178,000 cfs (16,226 to 33,358 m<sup>3</sup>/s), the CH3D-SED model was run to a short-term water and sediment steady state, and the amount and size distribution of sediment transport, both bed load and suspended load, through the hydropower installation and auxiliary structure and downstream of Tarbert Landing were determined from model results. The limited number of discharges tested were marginally sufficient to establish rating curves for the one-dimensional models, yet the flows that were tested provided invaluable and heretofore unavailable information on sediment dynamics in the vicinity of the structures. In the end, the overall study, based on three-dimensional modeling, one-dimensional modeling, geomorphic analysis, and direct analysis of field data, concluded that operation of the hydropower installation did not have a detectable or measurable effect on the long-term stability of the Mississippi and Atchafalaya rivers downstream of the complex.

As is invariably the case in application of computational hydraulics to prototype situations, an extremely valuable secondary benefit of the three-dimensional modeling effort was the understanding of, and insight into, the interaction among flow, sediment, bathymetry, and structures in the Old River Control Complex. A detailed modeling effort such as this one can be thought of as a magnifying glass that draws the attention of the investigators to the fine details of mobile-bed hydraulics in the system, forcing them to reconcile model response with field data observations in a way that sharpens and deepens their overall understanding of the system.

### 15.11.3 Leavenworth Bend, Missouri River

**15.11.3.1 Introduction** As part of the Missouri River Mitigation Program, the U.S. Congress has mandated 48,000 acres of habitat mitigation in Iowa, Nebraska, Missouri, and Kansas. As of this writing, this mandate was being significantly expanded to well over 100,000 acres. The Omaha and Kansas City Districts of the U.S. Army Corps of Engineers are seeking guidance as to how to achieve bendway mitigation with minimal adverse affect on the stability and viability of the navigation channel. The study is presented in detail in Spasojevic et al. (2001).

The objective of this work was to perform a three-dimensional mathematical-model study of free-surface hydrodynamics, sediment transport, and bed evolution, in order to analyze the Missouri River habitat restoration measures. The chosen sample location was Leavenworth Bend on the Missouri River between Omaha and Kansas City. The CH3D-SED code was used as the basis of the mathematical model. The model's domain includes the Missouri River from river mile 399.4 to river mile 405. Fig. 15-9 shows the overall layout of Leavenworth Bend.

Fig. 15-9. General layout of Leavenworth Bend, Missouri River.

**15.11.3.2 Field Data Campaigns** Two field data sets were used for model calibration and verification to ensure that model results reproduce as closely as possible the available prototype data. One field sediment and flow data set was collected within the study area during October 5 to 7, 1999, the other during June 9 to 10, 2000. Both October 1999 and June 2000 data sets contained ADCP (Acoustic Doppler Current Profiler) discharge and velocity measurements, water free-surface elevation measurements, suspended- and bed-sediment data, and bathymetry survey data. However, the conventional techniques used during the October 1999 data set collection revealed a need for improvements, which were implemented during the June 2000 data collection effort (see Spasojevic et al. 2001). Therefore, the October 1999 data set was used for initial model calibration and verification, whereas the improved June 2000 data were used for the final model calibration and verification.

The upstream model domain boundary was chosen to approximately coincide with Line 127 (Fig. 15-9). The downstream model domain boundary was chosen to approximately coincide with Line 142. All other boundaries were treated as impermeable. Because sufficiently detailed bathymetry data around both perpendicular and L-shaped dikes were difficult to obtain, the exact dike shapes and crest elevations were recovered from the COE 1994 Hydrographic Survey maps.

**15.11.3.3 Model Construction** Once the exact location of model-domain boundaries and the dike geometry had been established, the computational grid was generated. Following experimentation with several levels of the grid refinement, a relatively uniform grid was constructed throughout the domain, with an average computational cell chosen to be about  $10 \times 10$  m.

In the end, the computational grid had 22,947 so-called active points in a horizontal plane and 10 points in the vertical direction, i.e., along the depth. CH3D-SED uses a single-block computational grid, which, for a complex domain, covers an area larger than the actual model domain. The computational grid points inside the actual model domain are labeled “active,” whereas the rest of the points are labeled “inactive.” The size of the entire computational grid block was  $823 \times 33$  points in the horizontal plane, again with 10 points along the depth.

The model construction, revisited as part of the calibration process, included choosing the proper representation of dikes within CH3D-SED limitations. The code offers two possibilities for dike modeling. One is to use an internal boundary condition called a thin barrier, which applies to the computational-cell face. The cell face is assumed to be a thin membrane with zero flow in the perpendicular direction. Because the thin barrier must extend all the way to the free surface, this condition can apply to nonsubmerged dikes or portions of dikes. For submerged dikes or portions of dikes, the dike crest elevation can be directly assigned as input data.

Eventually, a combination of the two possibilities for dike representation was used. For clearly submerged portions of dikes, the crest elevation was directly assigned, which also provided the dike-volume representation. For nonsubmerged portions of dikes, the thin-barrier condition was used in combination with an assigned crest elevation. To avoid the potential small-depth problem, the assigned crest elevation was chosen to be clearly submerged, although still providing a correct representation of the dike volume.

**15.11.3.4 Boundary and Initial Conditions—October 1999 Event** Hydrodynamic computations require either a free-surface elevation or an elemental-discharge distribution across the flow as a boundary condition at an open boundary. The elemental-discharge distribution across the flow can be extracted from the ADCP velocity measurements. However, the October 1999 velocity data, collected with the moving-vessel ADCP, are not fully reliable, as discussed by Spasojevic et al. (2001). The more reliable June 2000 velocity data were only collected at four verticals across the flow, which is insufficient for extraction of the elemental-discharge distribution across the width of the channel. Furthermore, measured velocities are generally not available for the model’s prediction of future scenarios, such as the analysis of proposed habitat-restoration measures.

Thus, when an elemental-discharge distribution was used as a boundary condition, the total measured discharge was distributed across the flow using the assumption that the ratio between an elemental discharge and the maximum elemental discharge was the same as the ratio between the appropriate elemental area and the maximum elemental area, assuming that the maximum discharge corresponds to the maximum elemental area. This assumption amounts to forcing the depth-integrated velocities to be proportional to the corresponding flow depths. The assumption has been already tested elsewhere using ADCP velocity data and has proven to yield reasonable results.

The approximated elemental-discharge distribution was used as a boundary condition for the upstream inflow boundary at Line 127 (Fig. 15-9). The horizontal free-surface elevation was used as the boundary condition for the downstream outflow boundary at Line 142.

Suspended-sediment samples collected on October 5 to 7, 1999 were processed to obtain suspended-sediment concentrations by size class. Bed-sediment samples collected on October 5 to 7, 1999 were also processed to obtain bed-sediment size-class distributions at the bed surface.

Because of CPU time restrictions, it proved impractical to have more than three size classes in the model. Following considerable analysis, and based on early calibration runs, the three size classes in Table 15-8 were chosen to represent the natural sediment mixture in the model of the Missouri River at Leavenworth Bend.

**Table 15-8 Representative Size Classes for the Model of the Missouri River at Leavenworth Bend**

Model sediment size class	Diameter range (mm)	Characteristic diameter (mm)
Size class 1 (SC1)	$D < 0.074$	Determined in calibration
Size class 2 (SC2)	$0.074 < D < 0.420$	0.176
Size class 3 (SC3)	$0.420 < D < 3.360$	1.188

Even though it was obvious from field observation that there was appreciable sand content in suspension in Leavenworth Bend, the October 1999 suspended sediment data showed no sand size classes in suspension, even though the general shape of some of the fine-sediment vertical distributions bore a strong resemblance to the shape one would have expected for suspended sand. (Suspended fine-sediment concentrations are typically more or less constant over the flow depth. Suspended-sand concentration profiles typically resemble the theoretical profile (e.g., the Rouse profile), with highest concentrations close to the bed.)

After thorough analysis, it was concluded that the suspended-sediment sample measurements required double sampling, with one sample providing the proper total suspended-sediment concentration, and the other sample providing the proper size-class distribution. Double sampling was then used to collect the June 2000 suspended-sediment data.

Based on analysis of the field data, an approximate set of boundary and initial conditions for the October 1999 sediment computations was constructed. An average size class 1 concentration profile, with a concentration of 160 ppm constant over the flow depth, was assigned as the size class 1 initial condition throughout the domain. Zero-concentration profiles were assigned as an initial condition for size classes 2 and 3, again throughout the domain.

The measured suspended-sediment concentrations were also used to construct a set of vertical concentration profiles, one for each size class, at the location of each data vertical at the inflow sediment boundary (Line 127). Size class 1 profiles were constant over the depth, with average concentration values of 100, 175, 155, and 100 ppm, corresponding to verticals 1, 2, 3, and 4, respectively. Zero-concentration profiles were constructed for size classes 2 and 3. Each constructed set of vertical concentration profiles was then assigned not only to the corresponding computational-grid vertical, but also to neighboring grid verticals across the flow, until all computational verticals across the inflow sediment boundary were assigned a boundary suspended-sediment condition.

Because the free-surface elevation was used as a downstream boundary condition for flow computations, Line 142 was identified as a potential reverse-flow boundary and also defined as a sediment inflow boundary if the flow should reverse, which of course should not occur once initial-condition transients have settled down.

Bed-sediment data collected on October 5 to 7, 1999 were used to extract size-class percentage (or fraction) distributions at bed-surface points corresponding to locations of sediment data collection verticals at all sediment data collection lines (Fig. 15-9).

Size class 1 was seldom found at the bed surface. In addition, bed-sediment samples that contained size class 1 typically showed a very small amount of fine sediment (1–5%). Exceptions were a few samples with quite significant amounts (40–60%) of size class 1, such as Vertical 4 at Line 8, vertical 1 at Line 28, or Vertical 1 at Line 108. Such samples suggest the movement of fine-sediment lenses traveling through the system, typically close to the bank. The amount of size class 2 at the bed surface varied between 10 and 100%, whereas the amount of size class 3 at the bed surface varied between 0 and 90%. Except for its large variability, the bed-material data did not offer any specific clues on the spatial distribution of size classes 2 and 3, as related to different bathymetry or flow features.

Therefore, an average size-class fraction distribution, based on all the field data, was assigned as an initial condition for bed-sediment computations. This approach ensures the correct amount of bed material in the system, and allows for comparison between the computed and the measured spatial variation ranges for each size-class fraction. An average size-class fraction distribution, based on the data for four verticals at Line 127, was assigned as an inflow boundary condition for bed-sediment computations in CH3D-SED. The inflow bed-sediment boundary conditions were kept constant for the duration of the simulation.

The initial thickness of the active (bed-surface) layer was assumed to be 5 cm throughout the model domain. Because no other information was available, a single very thick stratum below the bed surface was initially assumed. The initial subsurface size-class percentage distribution was assumed to be the same as the appropriate bed-surface distribution.

**15.11.3.5 Model Calibration—October 1999 Event** The flow model was first built and calibrated without sediment. The computational time step for the flow computations was 5 s; this choice was dictated by the familiar Courant-number-related numerical stability criterion. Zero-flow initial conditions (i.e., horizontal free-surface elevation and zero-velocity field) were used to begin the flow computations. The chosen combination of initial and boundary conditions (realistic discharges and/or free-surface elevations imposed on initially still water) is known to produce a disturbance (wave) that propagates back and forth throughout the flow domain. A stabilization period is required to allow the disturbance to eventually die out. At the end of the

flow-stabilization period, a steady-state flow solution was achieved. A flow-simulation period of 12 h (8,640 f5-s computational time steps) proved to be sufficient to achieve a steady-state flow solution for a given set of boundary and initial conditions.

The major physical parameter in the CH3D hydrodynamic computations, to be determined through the calibration process, is the bed-surface friction coefficient. The CH3D flow-computations program module requires the absolute roughness as input data. The absolute roughness  $k$  determined through calibration runs had a value of 0.7 cm throughout the model domain. The appropriate friction coefficient  $C_d$  varied from 0.0124 for depth  $H = 5$  m to 0.0414 for  $H = 1$  m. The high absolute roughness and corresponding friction coefficients probably compensated for the simplifications in the CH3D hydrodynamic computations module, most of all the hydrostatic-pressure assumption. This assumption is ill suited for the strong secondary currents associated with almost 180° bend flow at Leavenworth Bend. Furthermore, the hydrostatic-pressure assumption does not allow for a detailed simulation of the near-field flow around dikes, which is mainly responsible for the formation of large turbulent structures and associated energy losses.

Analysis of the computed discharges showed that the model was capable of reproducing the steady-state flow condition, as defined by the average ADCP discharge, to an accuracy of 0.5%. also, as shown in Table 15-9, the

**Table 15-9 Measured and Computed Free-Surface Elevations for the October 1999 Event**

River mile	Free-surface elevation [m]	
	Measured	Computed
399.4	230.50	230.50 (b/c)
400.6	230.80	230.83
402.1 (d/s)	231.22	231.20
402.1 (u/s)	231.26	231.25
404.0	231.81	231.82
405.0	232.09	232.05

computed free-surface elevations showed good agreement with the measured ones.

However, computed velocities for the October 1999 event showed a fairly random pattern of agreement/disagreement with ADCP velocity measurements throughout the model domain. Fig. 15-10 presents a sample comparison of computed and measured velocities, in which significant data scattering is apparent.

The shift between measured and computed velocities in the figure appears randomly at other locations throughout the domain. As described in Spasojevic et al. (2001), the data scattering, associated with the moving-vessel ADCP velocity

**Fig. 15-10.** Sample of computed and measured velocities for October 1999 event.

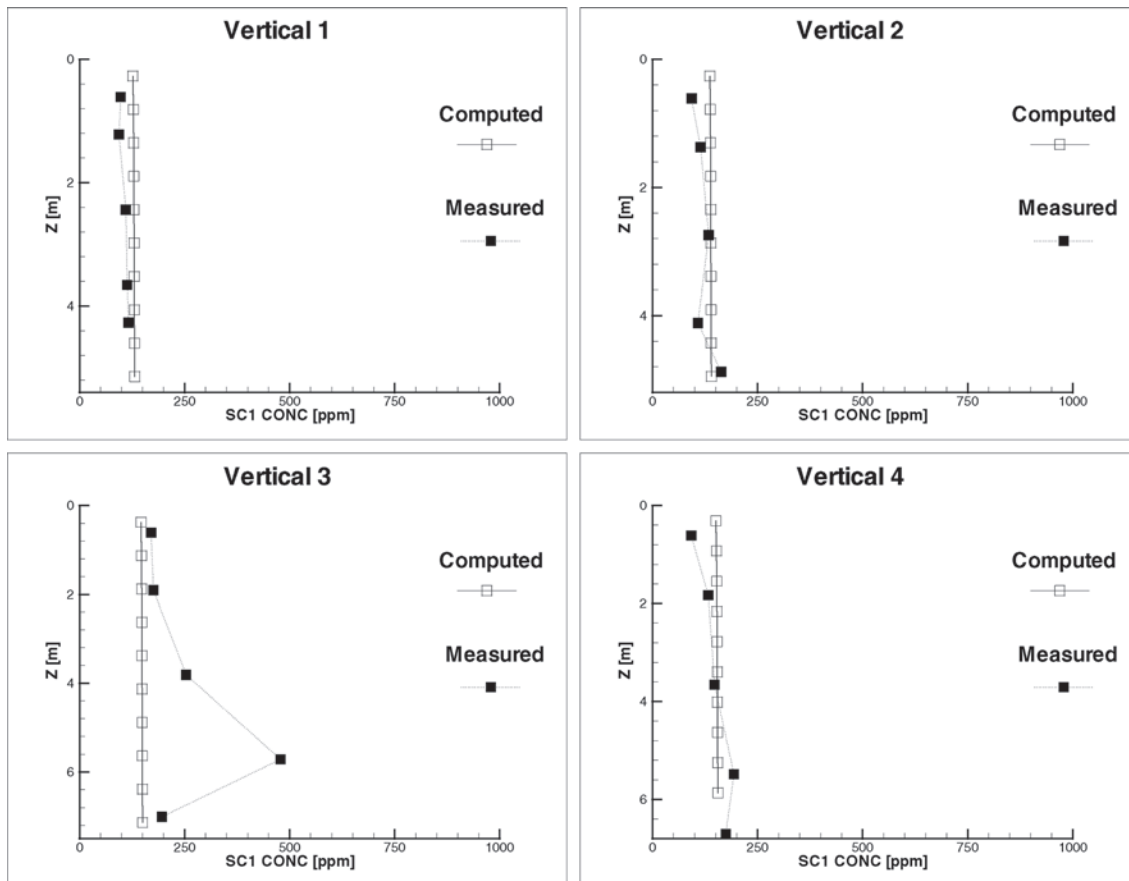

measurements, is caused by small-scale turbulence. Also, as shown in Spasojevic et al. (2001), the large-scale turbulence produces a random shift between the moving-vessel ADCP measurements and the proper mean-flow velocity profile. Thus, the disagreement between the computed and measured velocities in Fig. 15-10 can be attributed to the moving-vessel ADCP velocity measurements. This conclusion is further supported by the consistently fair agreement between computed and measured velocities for the June 2000 event as seen further on, when the stationary ADCP was used for collecting velocity data.

Sediment computations were initiated after a 12-h flow-stabilization period. A flow and sediment simulation period of one full day proved to be sufficient to achieve a quasi-equilibrium state between the flow and the sediment. The combined flow and sediment computations were made using a computational time step of 5 s, which was small enough to satisfy the stability condition associated with the suspended-sediment computations.

During the combined flow and sediment computations, the flow-model boundary conditions and physical parameters were kept the same as for the flow-only computations.

For the fine sediment of size class 1, the fall-velocity term had a decisive influence on the final suspended-sediment model results. The fall velocity appears in the advection-diffusion equation governing suspended-sediment transport, but also in the bed-sediment governing equations throughout the suspended-sediment deposition flux term. The calibration of the fall-velocity term was based on the proper choice of the previously unknown characteristic grain diameter for the fine sediment size class. A characteristic fine-sediment diameter of 0.015 mm proved to provide satisfactory suspended fine-sediment concentrations, but only for cases when the measured concentration profiles did not indicate the presence of sand in suspension.

Fig. 15-11 presents a sample of computed and measured suspended-sediment concentrations for the October 1999 event. Shown is a comparison between measured and computed suspended fine-sediment (size class 1) concentrations for all four sediment-data verticals at sediment data line 59. The measured size class 1 concentrations shown are also the total measured concentrations in suspension as described earlier.

**Fig. 15-11.** Sample of computed and measured suspended-sediment concentrations for October 1999 event.

Satisfactory agreement between measured and computed size class 1 concentrations was achieved only when measured concentration profiles had the usual fine-sediment profile characteristics (verticals 1, 2, and 3 in Fig. 15-10). The shape of the measured concentration profile for vertical 4 in the figure clearly suggests the presence of sand in suspension.

At the end of the 1-day flow and sediment simulation period, preceded by the 12-h flow-stabilization period, the flow and the sediment reached a quasi-equilibrium state. Except for some local spots, the total (cumulative) deposition and erosion at the end of the simulation period varied between +5 and -10 cm throughout the model domain. This moderate bed-elevation change indicated a reasonable choice of initial sediment conditions.

**15.11.3.6 Model Calibration—June 2000 Event** The June 2000 data set was used for the detailed model calibration. This data set includes ADCP discharge and velocity measurements, free-surface elevation data, suspended- and bed-sediment data, and bathymetry. The model domain boundaries and the computational grid were the same as for the October 1999 event.

**15.11.3.6.1 Flow Computations** All discharges computed from the June 2000 velocity data were within  $\pm 5\%$  of an average value. In addition, partial averages for multiple transect discharge measurements were within  $\pm 3\%$  of the average value. Therefore, an average discharge of 37,500 cfs, or approximately  $1,060 \text{ m}^3/\text{s}$ , was used to represent the quasi-steady-state flow situation observed during June 9 to 10, 2000.

The choice of the initial and boundary conditions, as well as the representation of dikes, was the same as defined during the October 1999 event modeling. The June 2000 flow-model calibration comprised further refining the friction coefficient.

Table 15-9 shows that the longitudinal free-surface elevation slope was fairly uniform during October 5 to 7, 1999 (about 1 ft/mi, or about 20 cm/km). However, the free-surface elevation data collected during June 9 to 10, 2000 showed a significant longitudinal-slope variation from one portion of the domain to another. Therefore, the absolute roughness  $k$  determined through calibration runs also had different values along the domain: 0.8 cm between river miles 399.4 and 400.6, 0.05 cm between river miles 400.6 and 402.1, 0.4 cm between river miles 402.1 and 404, and 0.8 cm between river miles 404 and 405. Again, the high absolute roughness in certain areas and corresponding friction coefficients probably compensated for the simplifications in the CH3D hydrodynamic module, in particular the hydrostatic-pressure assumption.

The computed discharges reproduced the steady-state flow condition, as defined by the average ADCP discharge, within 0.5%. Also, as shown in Table 15-10, the computed free-surface elevations showed good agreement with the measured ones, with somewhat larger discrepancies at river mile 402.1.

Computed velocities for the June 2000 event showed fairly good agreement with ADCP velocity measurements throughout the model domain. Fig. 15-12 presents a sample comparison of computed and measured velocities.

**15.11.3.6.2 Sediment Computations** The representative sediment size classes were the same as those chosen during the October 1999 event modeling (Table 15-8); the characteristic fine-sediment diameter was also taken to be the same as determined for the October 1999 event. Sediment initial and boundary conditions were also constructed following the procedure established during the October 1999 event modeling and discussed in the previous section. The model calibration included defining the physical parameters that were not calibrated during the October 1999 event modeling, notably due to the incomplete suspended-sediment data.

Measured suspended fine sediment (size class 1) concentrations were more or less constant over the depth. Furthermore, with only two or three exceptions, depth-averaged values of measured fine sediment concentrations varied between 90 and 120 ppm throughout the domain. Therefore, a concentration profile with a depth-constant value of 105 ppm was assigned as an initial condition for the fine-sediment concentrations at all computational points.

Measured suspended size class 2 concentrations showed rather large variation throughout the domain. The near-bed concentration generally varied between 0 and 300 to 400 ppm, but some data points showed concentrations an order of magnitude larger (up to 3,000 ppm). Furthermore, even though the measured size class 2 concentration profiles generally resembled the theoretical sand concentration profiles, several of them showed distinctly nonmonotonic behavior. An occasional spike in a measured sand-concentration profile could be attributed to the large turbulent structures (boils) carrying the high concentrations away from the bed. However, the two-spike profiles with maximum concentration about 3,000 ppm (dike 2, vertical 7) are more difficult to explain. This difficulty was obviated by simply assigning an average size class 2 profile with a near-bed concentration of

**Table 15-10 Measured and Computed Free-Surface Elevations for the June 2000 Event**

River mile	Free-surface elevation [m]	
	Measured	Computed
399.4	229.55	229.55 (b/c)
400.6	230.04	230.05
402.1 (d/s)	230.13	230.26
402.1 (u/s)	230.24	230.31
404.0	230.90	230.92
405.0	231.23	231.24

Fig. 15-12. Sample of computed and measured velocities for June 2000 event.

100 ppm as the initial condition for all computations points. This approach succeeded in initially introducing enough size class 2 sediment into suspension to let the sediment-flow interaction converge to the final computed size class 2 profiles.

Measured suspended size class 3 concentrations were generally close to zero, again with typically excessive exceptions, such as the near-bed concentration of 1,600 ppm at vertical 2 of Line 28. Neglecting these isolated exceptionally large measured concentrations, an average size class 3 profile with a near-bed concentration of 10 ppm was assigned as the initial condition to all computational points.

The actual measured suspended-sediment concentrations at Line 127 were used to construct a set of vertical concentration profiles, one for each size class, at the location of each data vertical at the inflow sediment boundary. Each constructed set of vertical concentration profiles was then assigned not only to the corresponding computational-grid vertical, but also to neighboring grid verticals across the flow, until all computational verticals across the inflow sediment boundary were assigned a boundary suspended-sediment condition.

It should be noted that the measured size class 2 concentrations at Line 127 in some cases contained excessive values. As a result of using the measured excessive concentrations

as the sediment inflow boundary, computations showed corresponding excessive deposition at and immediately downstream from the boundary. Thus, it was concluded that the excessive measured concentrations are probably a short-lived phenomena associated with transitory turbulent structures, and not characteristic of longer periods of time as resolved by the model. Consequently, the excessive concentrations at the boundary were replaced by average values, which led to moderate computed bed elevation changes in the first few hours of mobile-bed simulation.

Most bed-sediment samples did not contain size class 1. Those samples that did contain size class 1 typically showed a small amount of fine sediment (1–4%). Two bed-sediment samples that contained somewhat larger amounts of the fine sediment (around 15%) were collected next to the right bank at Line 8 (vertical 1) and behind Dike 1 (vertical 6). The data did not offer clear evidence of a fine-sediment lens traveling through the system. The amount of size class 2 at the bed surface varied between 3 and 96%, whereas the amount of size class 3 at the bed surface varied between 3 and 97%. Again, the bed-material data did not offer any specific clues on the spatial distribution of size classes 2 and 3, as related to different bathymetry or flow features, other than the inherent large variability and nonhomogeneity of the bed material. As an example, whereas the data shows a significant amount of

size class 2 upstream from Dike 1, the amount of the same size class upstream from Dike 2 is quite small.

Therefore, an average size-class fraction distribution, based on all collected data, was assigned as an initial condition for bed-sediment computations. Furthermore, because the June 2000 data did not contain any bed-sediment samples at Line 127 (the closest bed-sediment samples were collected at Line 108), the same average size-class fraction distribution was used as an inflow boundary condition for bed-sediment computations. Table 15-11 shows the size-class fraction distribution used as both initial and boundary conditions. The inflow bed-sediment boundary conditions were kept constant for the duration of the simulation.

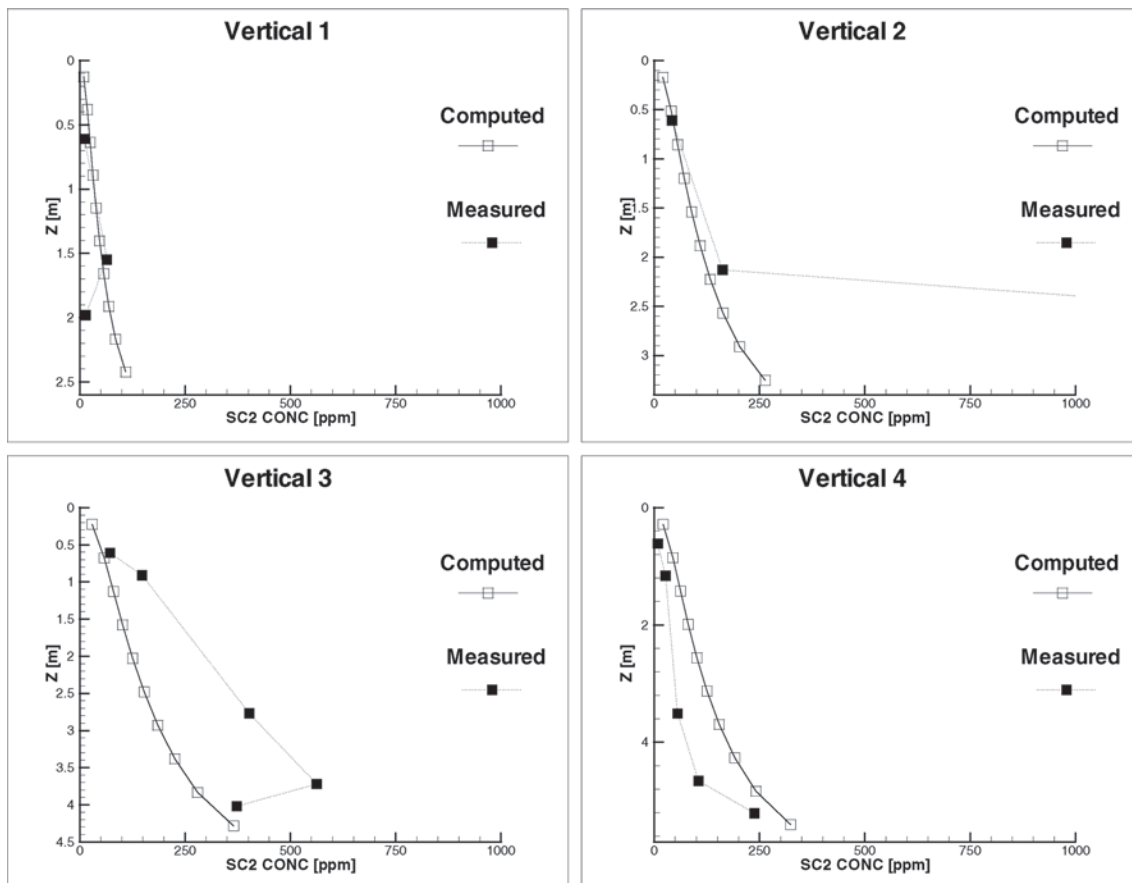

**Table 15-11 The Size-Class Fraction Distribution Used as Initial and Boundary Conditions, June 2000**

	Size-class fractions [-]		
	Size class 1	Size class 2	Size class 3
I/C and B/C	0.01	0.53	0.46

The initial thickness of the active (bed-surface) layer was assumed to be 5 cm throughout the model domain. Because no other information was available, a single very thick stratum below the bed surface was initially assumed. The initial subsurface size-class percentage distribution was assumed to be the same as the appropriate bed-surface distribution.

The near-bed distances  $a$  and  $a + \Delta a$  with assigned values of 1 and 3 cm, respectively, provided the most satisfactory computed suspended-sediment concentrations. Fig. 15-13 presents an example of computed and measured suspended-sediment concentrations for the June 2000 event. Shown is a comparison between measured and computed suspended size class 1 concentrations for all four sediment-data verticals at Line 28.

The agreement between the computed and measured fine sediment concentrations is quite good throughout the domain. Because the model cannot reproduce the large variation and sudden discontinuities of the size class 2 sediment concentration data, the calibration goal was to achieve an agreement between computations and measurements in an average sense. As shown in Fig. 15-13, computed size class 2 concentrations were occasionally overestimated at one and underestimated at another vertical, whereas the excessive

**Fig. 15-13.** Sample of computed and measured suspended-sediment concentrations for June 2000 event.

measured concentrations were simply ignored. The model also successfully reproduced the observed small size class 3 concentrations, although missing the few excessive measured values.

At the end of the one-day combined flow and sediment simulation period, preceded by the 12-h flow-stabilization period, the flow and the sediment reached a quasi-equilibrium state. Except for some local spots, the total (cumulative) deposition and erosion at the end of the simulation period varied between +10 and -10 cm throughout the model domain. This moderate bed-elevation change validates the reasonable choice of initial sediment conditions. As before, the spots with larger cumulative erosion and deposition found around dikes or close to banks are attributed to errors in the initial bathymetry.

The computed fine sediment (size class 1) fraction was practically zero throughout the domain. A small amount of the fine sediment, up to 2%, was computed at near-bank areas. The initially assigned size class 2 fraction was 0.53 (53%) throughout the domain. The computed size class 2 fraction at the end of the one-day simulation period, as shown in Fig. 15-14, showed a range of variation quite similar to the observed one. The depletion of size class 2 in the upstream portion of the model domain indicates insufficient supply of this size class through the inflow boundary, probably due to the approximate boundary conditions. The June

2000 data set did not contain enough information in that area. The most upstream data line with bed-sediment data is line 108, which had only two bed-sediment samples. The computed distribution of the size class 3 fraction throughout the domain was practically a mirror image of the size class 2 fraction distribution. Size class 3 also showed a variation range similar to the observed one.

**15.11.3.7 Use of Model to Study Proposed Habitat Restoration Measures** The complete model, as described in the previous sections, required quite extensive CPU time (2 to 2.5 times longer than real time on a state-of-the-art 2002 personal computer) for simulation runs. Due to the prohibitive CPU time, it was decided to extract a small portion of the complete model and apply the proposed habitat restoration modifications to this submodel. The submodel included approximately the area between data lines 28 and 48 (Fig. 15-9). The submodel computational grid, the bathymetry, and the dikes representation were kept the same as for the corresponding portion of the complete model. The total number of computational-grid cells for the submodel was  $121 \times 27$ . Figure 15-15 shows the submodel domain.

A proper transition from the complete model to the submodel could be achieved by using the entire set of the complete-model results as initial and boundary data for the submodel. However, this would require hot-start capability, unavailable in the CH3D-SED code as of this writing.

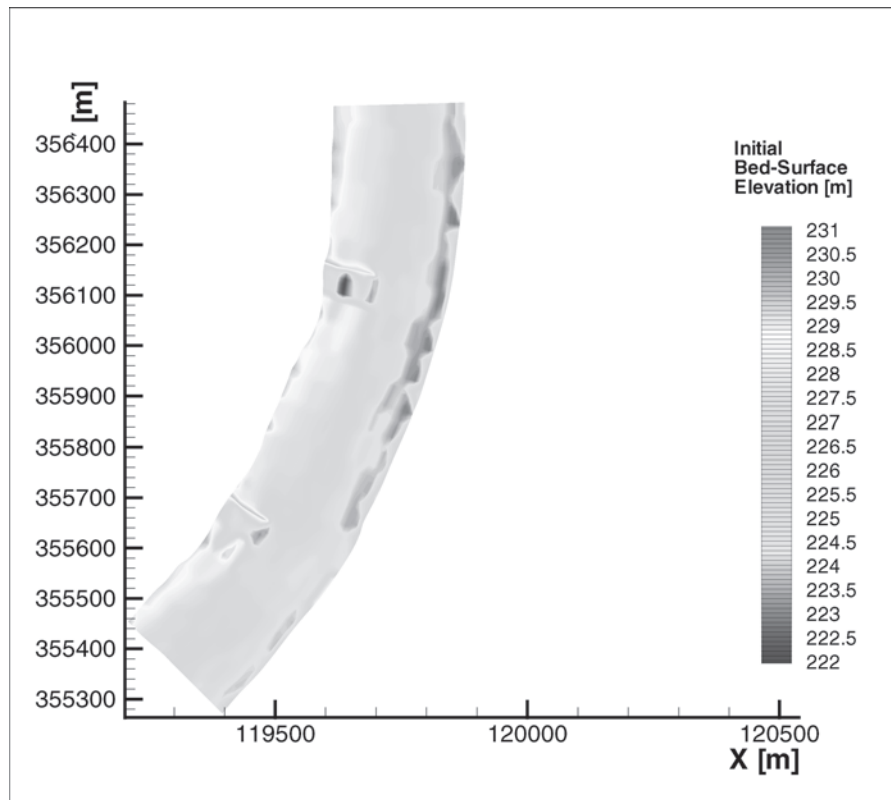

Fig. 15-14. Computed size class 2 fraction at the bed surface, June 2000 event.

**Fig. 15-15.** The submodel domain.

Therefore, boundary and initial conditions for the submodel computations were constructed based partly on the complete model simulations of the June 2000 event, and partly on the available June 2000 data within the submodel domain.

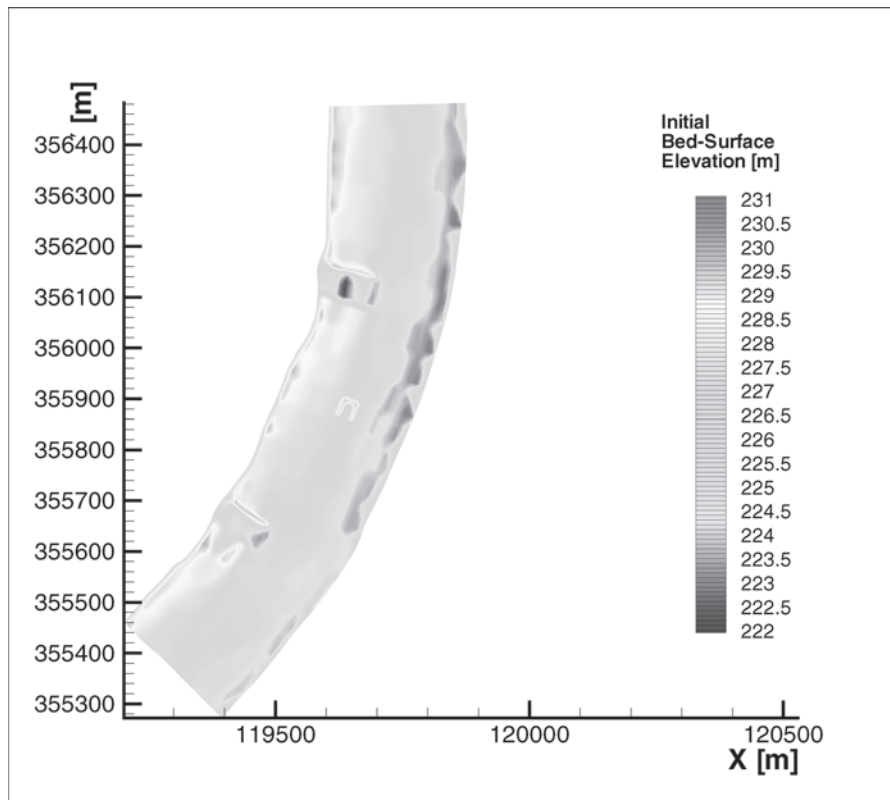

Boundary conditions for the submodel flow computations were the approximated elemental-discharge distribution at the upstream inflow boundary (Line 48, Fig. 15-9) and the free-surface elevation, extracted from the complete model results, at the downstream outflow boundary (Line 28, Fig. 15-9). Zero-flow initial conditions were used for the flow computations. The friction coefficient was kept the same as the friction coefficient for the corresponding portion of the complete model, defined during the calibration of the complete model.

Boundary conditions for the submodel sediment computations were suspended-sediment concentration profiles and bed-sediment size-class fraction distributions extracted from the complete-model results. Initial conditions for sediment computations were constructed based on the June 2000 data, available within the submodel domain. The sediment characteristic size classes and physical calibration parameters (fine-sediment characteristic diameter and near-bed distances  $a$  and  $a + \Delta a$ ) were kept the same as determined during the complete-model calibration.

The submodel produced discharges and free-surface elevations with the same accuracy as the complete model.

The computed submodel velocity and suspended-sediment concentration profiles showed the same agreement with the corresponding data as achieved with the complete model. However, the submodel cumulative erosion and deposition, as well as the size-class fractions at the bed surface, were not entirely the same as for the corresponding portion of the complete model. This suggests that the difference between the submodel and the corresponding portion of the complete model stems from the imbalance between initial and boundary conditions used for the small-model bed sediment computations. Thus, the submodel, and not the corresponding portion of the large model, was used as the reference for analyzing changes due to the proposed river-restoration modifications. The simulation period of five days was used for all submodel runs, both without and with modifications.

The first proposed modification included river widening and modifying the existing dikes into so-called rootless dikes. To widen the river, a channel, approximately 30 ft (9.14 m) wide and 10 ft (3.05 m) deep, was added along the concave bank. To modify the existing dikes into rootless ones, the near-bank portions of the existing dikes, approximately 30 ft (9.14 m) long, were removed. The cumulative bed-surface elevation changes after a 5-day simulation period for the submodel with the river widening and rootless dikes were compared with the same results for the submodel

**Fig. 15-16.** River widening with rootless dikes and far chevron.

without any modifications. The comparison shows almost no difference between the two cases. Both computations show no significant change in the bed-surface elevation next to the concave bank. The intermittent erosion and deposition in the main channel and around dikes is quite similar in both cases, suggesting minimal influence of the proposed change.

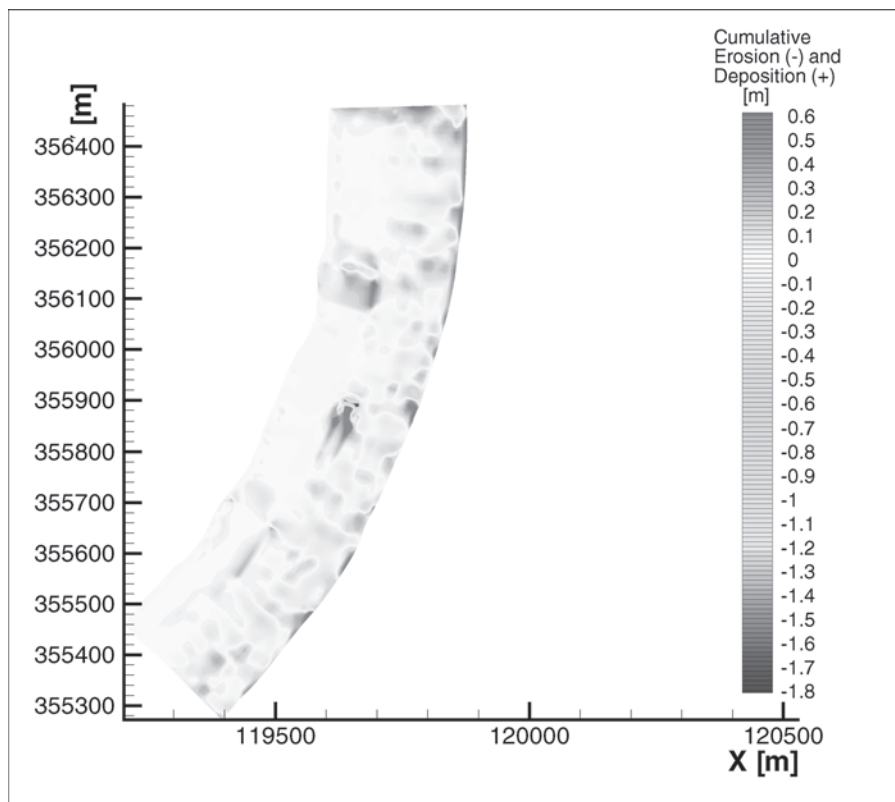

A second proposed modification was a so-called far chevron dike added to the original modification (river widening with rootless existing dikes), as shown in Fig. 15-16. The schematic chevron dike was about 120 ft long (36.6 m) and 120 ft (36.6 m) wide. Its upstream end was about 720 ft (219.4 m) downstream from the upstream existing dike (Fig. 15-16), whereas its downstream end was about 750 ft (228.6 m) upstream from the downstream existing dike. An imaginary mid-chevron line, approximately parallel to the riverbanks, was located about 370 ft (112.8 m) away from the right descending bank, i.e., about 430 ft (131.1 m) away from the left bank. The dike was submerged with the crest elevation 3 ft (1 m) below the water surface; i.e., its height varied between about 8 (2.4 m) and 10 ft (3.05 m).

Figure 15-17 shows the cumulative bed-surface elevation changes, after a 5-day simulation period, for the model with river widening, rootless existing dikes, and the added far chevron dike. The cumulative bed-surface elevation changes away from the dike are quite similar to those for the original modifications. The area where the far chevron was intro-

duced did not suffer any large erosion or deposition due to the initial modifications. Therefore, the computed local bed-surface elevation changes around the dike can be attributed to the dike alone. The maximum erosion immediately downstream from the dike was about 2.5 m. The eroded material was deposited further downstream, over a larger area with maximum deposition of about 1.4 m.

As a third proposed modification, a so-called close chevron dike was added to the original modification (river widening with rootless existing dikes). The schematic close chevron dike had the same dimensions as the far chevron dike. The near chevron was located on the same perpendicular section as the far chevron; i.e., its upstream end was about 720 ft (219.4 m) downstream from the upstream existing dike (Fig. 15-16), whereas its downstream end was about 750 ft (228.6 m) upstream from the downstream existing dike. The imaginary mid-chevron line was located about 280 ft (85.3 m) away from the right descending bank; i.e., the dike was about 90 ft (27.9 m) closer to the right bank than the far chevron. The dike was submerged with the crest elevation 3 ft (1 m) below the water surface.

The cumulative bed-surface elevation changes after a 5-day simulation period, for the model with river widening, rootless existing dikes, and the added close chevron dike, in the area away from the chevron were again quite similar to those for the initial modifications. The close chevron

**Fig. 15-17.** Cumulative erosion and deposition after a five-day simulation period: submodel with river widening, rootless dikes, and far chevron.

affected a smaller local area than did the far chevron. The maximum erosion immediately downstream from the dike was about 1.4 m. The eroded material was deposited further downstream, over a larger area with maximum deposition of about 0.8 m.

This example effectively demonstrates the power of a three-dimensional mobile-bed model to provide indications of the response of a mobile-bed river to modifications imposed upon it, even if CPU time restrictions (as of this writing) make it impossible to perform truly long-term simulations (e.g., one or more complete hydrographs). There is nothing in CH3D-sed or the model data set that would preclude doing simulations for part or all of one or more hydrographs, if the supporting computer hardware were one or more orders of magnitude faster than what was available as of this writing.

#### 15.11.4 Coralville, Saylorville, and Red Rock Reservoirs, Iowa

**15.11.4.1 Introduction** Two-dimensional mobile-bed models cannot capture the hydrodynamic and sediment processes associated with secondary flow, vertical acceleration around structures, etc. On the other hand, they offer the possibility of relatively long-term unsteady simulations when their

simplifying assumptions are appropriate for the problem under study. This can be illustrated through a summary description of the application of the MOBED2 two-dimensional mobile-bed program to the prediction of long-term sedimentation in the three major flood-control reservoirs of Iowa.

The mathematical and numerical basis for MOBED2 is described in Spasojevic (1988), and Spasojevic and Holly (1990a). This example is extracted from the report by Savic and Holly (1993).

The MOBED2 code comprises a numerical procedure for simulation of two-dimensional (plan view) unsteady interaction of sediment movement and hydrodynamics in natural watercourses. The basic governing equations for the flow are the momentum Eqs. (15-14) and (15-15) and the continuity Eq. (15-9). The basic sediment equations are the mass conservation equations for the channel bed (Eqs. 15-63) and (15-64) and the two-dimensional advection-diffusion equation for suspended-sediment transport (Eq. 15-71), both for any number of distinct sediment size classes. Auxiliary relations used for system closure are discussed in Sections 15.8.4 and 15.8.5 of this chapter. The tensor forms of the governing water and sediment equations in an orthogonal curvilinear system are used, permitting ready representation of the boundaries of natural watercourses. The entire code and associated numerical techniques are structured to avoid use of any

particular empirical relation until very late in the derivations. Therefore, the overall structure of the computation is independent of particular empirical expressions used to evaluate auxiliary relations, and thus they can be exchanged rather easily.

The hydrodynamic (depth-averaged Reynolds) equations are solved numerically using a split-operator procedure (momentum advection and diffusion steps had not yet been implemented in the code at the time of this project), and the resulting system of linear algebraic equations is solved by the alternative direction implicit method.

The sediment equations (including bed load for each size class and bed evolution) are solved simultaneously for each computational point using the Newton-Raphson method. Some of the important features of MOBED2 include the following:

The global set of sediment equations for all size classes, taken as a whole and solved simultaneously, describes the behavior of a mixture, including natural phenomena such as differential settling, armoring, and hydraulic sorting.

Sediment particles can move either in suspension or as bed load, depending on local flow conditions. Criteria for distinguishing between bed-load and suspended-sediment transport, as well as mechanisms defining exchange between the two, are incorporated into the code.

Sediment mixtures in natural watercourses are represented through a suitable number of discrete size classes.

Both the hydrodynamic and sediment equations are solved in a curvilinear coordinate system, which implies transformation of the governing equations in the real coordinates  $X$ – $Y$  of the so-called physical plane into the computational  $\xi$ – $\eta$  plane.

The goals of this study were to demonstrate the ability of MOBED2 to simulate unsteady water-sediment flow for the three Iowa reservoirs (Coralville, Saylorville, and Red Rock) and to provide a preliminary calibration of the data sets preliminary to transfer of the code and data sets to the sponsoring user, the Rock Island District of the U.S. Army Corps of Engineers.

**15.11.4.2 Data Sources and Model Construction** Topographical data came from two sources:

1. 1:24,000 U.S. Geological Survey topographic maps
2. U.S. Army Corps of Engineers Sedimentation Survey Reports

Because the computational-grid spacing was much denser than the spacing of the sedimentation survey sediment ranges (SR), an interpolation procedure, performed by University of Iowa GIS specialists, was used to obtain the computational-grid topology and topography. Numerous manual modifications of the data sets were performed in an iterative process, using the preliminary computation runs, to ensure correct numerical solution of the governing equations. This manual grid adjustment and refinement were a preliminary calibration of the model data sets.

The hydrologic data were provided by the Rock Island District of the U.S. Army Corps of Engineers. For the purpose of preliminary calibration the data were used to set inflow discharges and suspended sediment concentrations for the test runs. The most important data—regarding suspended-sediment size and bed-load size and distribution—were not available, and were thus assumed from Spasojevic (1988).

Specification of the two-dimensional plan-view grid is relatively simple for rectangular (or nearly rectangular) channels, and/or if the expected variations of free-surface elevations are small. However, in natural watercourses, any significant change of the free-surface level may notably change the plan-view contour of the flow domain. One approach to resolving this problem is to define the maximum model-domain contour based on the maximum expected free-surface level, and to treat the periodically dry areas of the model by a special procedure if the water level lowers significantly, so that the flow domain shrinks. However, at the time of this study, MOBED2 was not designed to cope easily with frequent and large changes in wetted and dry areas within the model domain. For this particular study, in which the Old River channels were permanently submerged below the dam-maintained reservoir elevation and the reservoir banks were relatively steep, it was possible to simulate extended periods of time with a single computational grid.

For the Iowa reservoir models, the downstream boundary was the dam itself, the impermeable side boundaries were determined by the maximum water levels, and the upstream boundaries were selected in consultation with Rock Island District engineers so that the major part of the sediment entrapped in the reservoir lay within the computational domain. The computational grid was specified to provide sufficiently detailed information on the studied reservoirs, yet not so detailed as to unnecessarily encumber the already time-consuming computations.

#### **15.11.4.3 General Boundary and Initial Conditions**

For initial conditions, MOBED2 requires known values or hydrodynamic and sediment quantities appropriate to the beginning of the simulation period: water-surface elevations and two-directional velocity fields for the hydrodynamic equations, and suspended-sediment concentration and distribution of the bed material for each size class and the initial bed elevation for the sediment equations.

Both inflow (upstream) and (outflow) downstream boundary conditions are required for the hydrodynamic computation. The outflow boundary condition can be a rating curve or a given discharge or free-surface elevation hydrograph, whereas the inflow boundary condition can be a discharge or free-surface elevation hydrograph only. For the sediment equations, boundary conditions are required only at inflow (hydrodynamic) boundaries, with prescribed evolution of suspended-sediment concentrations, bed-material distribution, and the bed elevation for each computational point across the inflow boundary.

The test cases for the preliminary calibration were selected to demonstrate the ability of the model to simulate two-dimensional unsteady water-sediment flow in the three Iowa reservoirs, that is, to show that the code can provide long-term simulations without numerical problems.

Accordingly, the test cases presented here were selected to treat a hypothetical hydrological situation, i.e., not to follow the strict details of a particular hydrological time-series. Moreover, even in a less hypothetical application of the models, it is suggested that only major flood events be simulated, i.e., those in which the majority of the sediment inflow occurs. (For example, one may simulate the important sedimentation features of a 50-year period by running only 100–200 months.) In addition to significant savings of CPU time, this helps to alleviate potential dry-bed problems (as explained earlier), because the large flood-flow discharges tend to correspond to the higher pool elevations for which the computational grids were laid out.

Initial data for the hydrodynamic computations required the initial distribution of both components of the depth-averaged velocity and the free-surface elevations. A zero-flow initial condition was assumed, implying a horizontal water level and a zero velocity field for the entire computational domain.

The hydrodynamic boundary condition along the upstream inflow boundaries was the distribution of unit discharge across the boundary. Because measured data for the flow distributions was not available, a reasonable estimate was obtained by distributing the total discharge across the upstream boundary in accordance with the cross-sectional area distribution. Imposition of the free-surface elevation along the dam cross section seemed to be an appropriate boundary condition at the downstream boundary, given the small velocities in the vicinity of the dam.

The sediment computations require representation of the natural sediment mixture in the reservoir by an appropriate number of size classes and their distribution. Measurements and analyses of size distributions for natural sediment mixtures in the Iowa reservoirs are extremely scarce, especially for the bed material. Therefore, the values from Spasojevic (1988) were used as a reasonable assumption for all three reservoirs. Only two size classes were chosen to simulate the natural sediment mixture. Size class 1 represents fine sediment capable of moving in suspension, whereas size class 2 represents coarser sediment mainly confined to the bed. A characteristic diameter of  $D = 0.0025$  mm, taken from the size-distribution curve for suspended sediment at the Marengo gauging station (Spasojevic 1988), was used as an equivalent diameter for size class 1, whereas a diameter of  $D = 0.6$  mm was used as the equivalent diameter for size class 2. It was assumed that, immediately after the dam was built, the bed consisted predominantly of coarser sediment (size class 2); thus, the initial active-layer size fractions were assigned to be zero for size class 1 and unity for size class 2. Initial bed elevations (as well as the entire geometry of the

model domain) were defined based on the original reservoir survey data.

The dam section was treated as an outflow boundary with zero bed-load flux during sediment computations. Imposed suspended-sediment concentrations (obtained from the data provided by the Rock Island District) defined the inflow boundary condition for the suspended sediment; a zero bed-load influx and constant bed elevations, were assumed to be appropriate upstream assumptions for the bed-load boundary conditions, given the lack of meaningful field data.

Ten-year periods were simulated for each of the reservoirs. The first year represented a schematic annual hydrological cycle to demonstrate that the code can perform under unsteady-flow conditions (see Fig. 15-18). The upstream hydrodynamic boundary condition was a schematic discharge hydrograph with a base of  $Q_{\min}$  and peak of  $Q_{\max}$ , whereas the similar schematic pool-elevation hydrograph determined the downstream boundary condition; the suspended-sediment concentration variations were assumed to correspond to the inflow hydrograph variations (Fig. 15-19). The remaining portion of the 10-year period was simulated with a constant discharge at the representative flood peak  $Q_{\max}$ , the maximum pool elevation  $Z_{\max}$ , and the maximum suspended sediment concentration  $C_{\max}$ , for each of the three reservoirs.

**15.11.4.4 Coralville Reservoir** The Coralville Reservoir is a flood-control impoundment located on the Iowa River near Iowa City, Iowa. The Coralville reservoir model represents the part of the reservoir from the Coralville Dam up to Sediment Range (SR) No. 21. To define the computational domain of the Coralville model, a flood situation with free-surface elevation around 217 m (roughly 712 ft) was adopted. For this condition the reservoir can be thought of as consisting of two parts with distinctly different hydraulic characteristics, as seen in Fig. 15-20. The part between Coralville Dam and the Curtis Bridge is relatively narrow, with the majority of the cross sections being either roughly trapezoidal or triangular in shape. The part between the Curtis Bridge and the upstream boundary is primarily a broad valley with dominant flood plains.

Fig. 15-20 shows the two-dimensional (plan-view) contour of the model domain, together with the orthogonal curvilinear computational ( $\xi-\eta$ ) grid constructed to fit the model domain. The total number of computational points was 2,937, with  $I = 267$  points in the  $\xi$ -direction (which is roughly the direction of the flow) and  $J = 11$  points in the  $\eta$ -direction (which is roughly the direction perpendicular to the flow).

As described earlier, a zero flow state, with horizontal free-surface elevations and zero flow field, was used for the hydrodynamic initial condition. The initial suspended-sediment concentration for size class 1 (fine sediment) was set to 100 ppm over the entire domain; for size class 2 (coarse sediment), a global zero concentration was assigned as an initial condition.

Fig. 15-18. Hydrodynamic boundary conditions for the test cases.

Fig. 15-19. Suspended-sediment boundary conditions for the test cases.

**Fig. 15-20.** Bed-elevation changes for Section  $I = 228$  of Coralville Reservoir for simulation times of  $t = 8.2$  and 11 years.

The maximum and minimum discharges of  $Q_{\max} = 300 \text{ m}^3/\text{s}$  (10,600 cfs) and  $Q_{\min} = 50 \text{ m}^3/\text{s}$  (1,765 cfs) for the upstream boundary condition (see Fig. 15-18) were selected in accordance with the historical hydrologic data. For the downstream boundary condition, free-surface elevations of  $Z_{\max} = 217 \text{ m}$  (712 ft) and  $Z_{\min} = 213 \text{ m}$  (698 ft) were selected, thus obviating possible dry-bed conditions, but still leaving the possibility to simulate pool-management operations during flood periods. The suspended sediment concentrations of  $C_{\max} = 1,000 \text{ ppm}$  and  $C_{\min} = 100 \text{ ppm}$  (Fig. 15-19) were considered to be a reasonable approximation for the purpose of preliminary calibration.

Two characteristic cross sections were chosen to present flow and sediment variables for this test simulation. Figures 15-21 to 15-24 show selected flow/sediment variables at cross section  $I = 228$  (corresponding approximately to sediment range SR-5), whereas Figs. 15-25 to 15-28 show cross section  $I = 7$  (close to sediment range SR-20). Cross section  $I = 228$  (i.e., range SR-5) is located in the narrow part of the reservoir, whereas cross section  $I = 7$  (SR-20) is in the wide inundation area upstream of Curtis Bridge.

The distribution of the unit discharge component in the flow direction ( $U_{\text{st}}$  discharge) across the section  $I = 228$  is presented in Fig. 15-19. As expected, larger discharges occur in the zones of larger depth, and the suspended-sediment concentration distribution (for size class 1, i.e., fine sediment)

roughly follows the  $U_{\text{st}}$  discharge pattern (Fig. 15-20). The bed deposition (shown in Fig. 15-21) reflects closely the suspended-sediment concentration distribution, because the deposition component of the suspended-sediment source term (which is the dominant source of bed deposition) is mainly governed by the depth-averaged concentrations and the flow field.

The picture is somewhat different for the section  $I = 7$ , where the wide cross section produced the velocity field less dominated by  $\xi$ -direction velocities, and where the influence of the upstream boundary was felt more strongly. The result was a more evenly distributed bed-deposition (Fig. 15-28), which is in general agreement with the observed field data.

Due to an effective Courant-number limitation, the hydrodynamic computational time step had to be limited to 1 h. This relatively small time step is impractical for simulation of slowly varying sediment movement. Sediment variables changed very little during 1 h; moreover, the sediment computations are extremely time-consuming, and a sediment time step of 1 h would have enormously increased the CPU time. For a slowly varying flow field the problem is circumvented by choosing a “global” time step (for sediment computations) to be much longer than the hydrodynamic one. Hence, within a single global time step, water computations are performed for several short “water” time steps, only the first and latest computed flow fields being used in sediment

computations. A global time step of 24 h was found to be an optimum value for the Coralville Reservoir model.

The CPU time required for the described 11-year simulation was around 200 h on a 486/33 MHz personal computer, using the Lahey 32-bit compiler; one would expect the same run to have taken only about 6 h on a state-of-the-art personal computer. (More iterations, and accordingly, more CPU time were needed for the unsteady part of the computations, i.e., for the first year of the simulation.) The storage memory requirements, beyond the 500K required for the program load module, were 1,650K for the Coralville model.

**15.11.4.5 Saylorville and Red Rock Reservoirs** The Saylorville and Red Rock reservoir model construction and operation followed the same general pattern as for the Coralville reservoir. Therefore in this section only brief descriptions of the physical situation and model grids are given.

The Saylorville Reservoir is located on the Des Moines River upstream of Des Moines, Iowa. The Saylorville Reservoir model represents the part of the reservoir from the Saylorville Dam up to Sediment Range (SR) No. 15. The computational domain of the model is defined for a flood situation, with pool elevation at 271.3 m (890 ft). Cross-section sediment range 1 is immediately upstream of the dam site, whereas Sediment Range SR-15 is close to the upstream boundary of the model domain. Fig. 15-29 shows the two-dimensional contour of the model domain and the computational grid. The total number of computational points was 1,144, with  $I = 104$  points in the  $\xi$ -direction (the direction of the flow) and  $J = 11$  points in the  $\eta$ -direction.

The Red Rock Reservoir is located on the Des Moines River, downstream of Des Moines, Iowa. The model represents the part of the reservoir from the dam up to Sediment Range (SR) No. 19. The computational domain of the model is defined for a flood situation, with the pool elevation at 237.75 m (780 ft). Cross-section Sediment Range 1 is upstream of the dam site, whereas Sediment Range SR-19 is close to the upstream boundary of the domain. Fig. 15-30 shows the contour of the model domain and the computational grid. The total number of computational points was 781, with  $I = 71$  points in the  $\xi$ -direction (the direction of the flow) and  $J = 11$  points in the  $\eta$ -direction.

**15.11.4.6 Summary** This two-dimensional example has been included primarily to point out the possibility—even in 1993, when this study was done—of making multi-year simulations to detect sedimentation trends subject to a succession of real or schematic hydrographs. As of this writing, it is not possible to envision such long-term simulations with three-dimensional models, even those based on the hydrostatic pressure assumption. As long as vertical accelerations and secondary flows are relatively unimportant to the problem under study, two-dimensional modeling offers a great deal of power at relatively low computational cost, and therefore is a viable tool within its known constraints.

## 15.12 CRITICAL ASSESSMENT OF STATE OF THE ART AND FUTURE PERSPECTIVES

As of this writing, two-dimensional (depth-averaged) fixed-bed modeling has reached a certain maturity and seen moderate use. But after a promising beginning, development of two-dimensional (depth-averaged) mobile-bed modeling has taken a back seat to three-dimensional. Meanwhile, three-dimensional fixed-bed modeling is rapidly becoming an effective engineering tool, and its mobile-bed counterpart is receiving considerable developmental attention and enjoying some success in practical engineering use.

It is unfortunate that development and application of two-dimensional (depth-averaged) mobile-bed modeling has become somewhat of an orphan in the rush to develop three-dimensional tools. Two-dimensional modeling, although unable to resolve mobile-bed responses closely related to secondary flow, detailed water and sediment dynamics around structures, and other three-dimensional effects, still offers the possibility of making truly long-term simulations in a way that is currently unthinkable with three-dimensional models. To exploit this potential fully, two-dimensional models need to be based on unstructured or nonorthogonal curvilinear structured grids, have robust wetting and drying capability for application to multiyear hydrologic series, and include both bed-load and suspended-load transport mechanisms in a nonuniform sediment environment.

In both two- and three-dimensional modeling, there is the issue of structured versus unstructured grids. Structured grids (usually nonorthogonal curvilinear and associated with finite-difference methods) are not well suited to grid refinement around local areas of interest or adjacent to hydraulic structures, but are generally attractive for their minimization of computational time (and thus their enabling of longer-term simulations and/or finer resolution of nonuniform sediment). Structured grids (e.g., finite-element or finite-volume, usually associated with flux-based methods) offer great flexibility in grid refinement around structures and local features of interest and lend themselves well to dynamic adaptive refinement, at the cost of relatively high demands on computer resources. Although it is tempting to believe that continuing rapid increases in computer processor speed and parallel systems will eventually make the speed advantages of structured grids irrelevant, experience has shown that this is unlikely to be the case. Indeed, it is always desirable to use a finer grid resolution, adopt more sediment size classes, run for longer periods, or test a greater number of cases, i.e., to push the limits of practical CPU time with whatever numerical tool is being used. It is likely that there will continue to be partisans of, and real needs for, both structured and unstructured modeling systems into the foreseeable future.

Another issue of importance as of this writing is that of fully three-dimensional versus quasi-three-dimensional

**Fig. 15-29.** Numerical grid for Saylorville Reservoir.

(i.e., hydrostatic) hydrodynamic modeling as a framework for mobile-bed models. Experience has shown that water and sediment movement in the immediate vicinity of structures (e.g. submerged dikes and bridge piers) can be correctly represented only if vertical acceleration components are explicitly taken into account, i.e., only if the model explicitly includes the vertical momentum equation. Quasi-three-dimensional models, in which the vertical momentum equation is replaced by the hydrostatic pressure assumption, offer the considerable

advantage of orders of magnitude decreases in computational time (the solution essentially comprises a two-dimensional one followed by application of the three-dimensional water continuity equation to recover vertical velocities). At the present time, truly unsteady simulations of any significant duration cannot be performed using full three-dimensional models, whereas they are becoming feasible with models based on the hydrostatic pressure assumption, as described in the examples of the previous section. In time, increases of computing speed

**Fig. 15-30.** Numerical grid for Red Rock Reservoir.

may obviate the need to use the hydrostatic pressure assumption. For the near- to mid-term, however, the best situation is to have the option of using fully three-dimensional modeling to obtain steady-state solutions including the best possible detail of flow around structures; or to use quasi-three-dimensional hydrostatic modeling to obtain unsteady simulations for prototype time periods of the order of days to weeks. Future three-dimensional developmental efforts should be based primarily on the full nonhydrostatic equations, even though at the present time this appears to exclude unsteady simulation for practical reasons.

The preceding paragraphs deal with dimensionality (two-dimensional, quasi three-dimensional, fully three-dimensional), and structured/unstructured grid issues. An equally important issue is related to the basic mathematical formulation of noncohesive sediment processes and their interaction with the flow. One can argue that this is not a subject for mathematical modelers because the basic understanding of physical processes, which is a basis for mathematical formulations, typically comes from experimental work. However, authors believe that there is a need for mathematical modelers to become more involved in guiding experimental programs that can be focused on the need to improve basic sediment formulations for computational models. Today's finest flow and sediment models, with features such as fully three-dimensional computation, unstructured and adaptive grids, and advanced turbulence models, may easily choke on imperfect, and often stale, formulations of sediment processes.

Even the advection-diffusion equation with the fall-velocity term, typically used as the governing equation for

suspended-sediment processes, brings up many questions. Is there a better formulation for the fall velocity of multiple particles in a moving fluid than typically used relations developed for a single particle in quiescent water? What are the real values of the turbulent Schmidt number  $\sigma_\epsilon$ , relating the sediment mass-diffusivity coefficient  $\epsilon_s$  to the turbulent eddy viscosity  $\nu_t$ , which even some of the most sophisticated contemporary models assume to be equal to unity? What are the consequences of the assumption that the velocity of suspended-sediment particles is the same as that of the fluid for the accuracy of the suspended-sediment advection-diffusion equation? Or alternatively, what is the effect of an experimentally demonstrated lag between the fluid and suspended-sediment particle velocities on an overall sediment quantity such as the total suspended-sediment load?

Additional difficult questions arise concerning mathematical formulation of bed and near-bed processes. Even though one can talk about several prevailing alternative conceptual models of bed processes, as of this writing there is still no generally accepted unified theory for conceptual and mathematical formulation of these processes. In this area there is even more need for communication and coordination between researchers involved in sediment-related numerical and experimental work. One example concerns the issue of bed-form-related flow roughness. It is tempting to expect that computational grids will eventually become fine enough to resolve the details of bed forms, so that the flow and sediment equations themselves can capture their effects on flow and sediment processes. But this may never occur, and until it does, it may still be necessary to bring empirical representations of bed-form

effects on flow and sediment processes into two- and three-dimensional models. Another example concerns the fact that practically all bed-load formulas are developed from steady equilibrium conditions, whereas most models operate in an unsteady nonequilibrium environment. In general, unsteady-flow effects on sediment processes are seldom addressed in experimental work in a way that can be used to improve sediment modeling. This is all the more true when one considers the complicating factor of nonuniform sediment mixtures in the natural environment.

Especially important and difficult is the question of interaction between suspended-sediment and bed and near-bed processes. Prevailing modeling approaches, most of which rely on an empirical near-bed concentration in one way or another, simply bypass the role of near-wall turbulent events on sediment entrainment and deposition. Even though considerable experimental work on such events has been carried out, some of it including sediment, the results cannot be used in present mathematical models, partly because of CPU limitations and limits to model resolution in space and time, not to mention the stochastic nature of these processes. Therefore there is still a large gap between detailed experimental knowledge of turbulent events, including sweeps and streaks, and formulations that can be used effectively in the existing mathematical-modeling context of relatively coarse computational grids.

As challenging the disciplines of two- and three-dimensional noncohesive mobile-bed modeling are, there is a growing need for development of equivalent cohesive capability. Indeed, contaminants in waterways are most often associated with (sorbed to) fine silts and clays, whose cohesive properties are extremely difficult to capture in entrainment and deposition relations. Yet the need to study the transport and fate of contaminated sediment in waterways subject to exceptional hydrological events or disasters is likely to be a major driving force in the development and application of mobile-bed models in the coming decades. Cohesive sediment processes appear to be far less susceptible to rational analysis than their noncohesive counterparts, and numerical formulation of the mechanisms of exchange of sediment-borne contaminants among the multiple transport media (dissolved, suspended, bed, subsurface, etc.) is in its infancy and quite problematic. Contaminant-sediment capability should be a high developmental priority in current and future two- and three-dimensional modeling systems.

Can the model be separated from its developer? In the early days of one-dimensional unsteady-flow models, it was axiomatic that one would be naïve to consider making effective use of a code without having the telephone number of its developer close at hand. To some extent, that remains true today of one-dimensional mobile-bed models, though many organizations have achieved a certain autonomy in the use of HEC-6 (one-dimensional mobile-bed) without needing to consult with its developer on a

regular basis. Such autonomous use is not yet possible for some one-dimensional mobile-bed codes such as the authors' CHARIMA, which still require as much art as science for effective use.

Two- and three-dimensional mobile-bed modeling has not achieved, as of this writing, the maturity that would allow general use of most codes by engineers not in reasonably close contact with the code developer. However, the authors expect that such codes will fairly rapidly mature to enable generalized use by nonspecialists, or at least by specialists not in direct contact with the developers. An important reason for this anticipated acceleration to maturity has to do with the relative roles of science and art in one-, two-, and three-dimensional mobile-bed modeling.

In one-dimensional mobile-bed modeling, the highly heterogeneous processes of sediment entrainment, deposition, bed-load movement, etc. must be described for the cross section as a whole as functions of bulk channel properties such as average velocity, overall discharge, average depth, bulk shear stress, and average bed-material composition in the section. As much art as science is needed in selecting channel properties, and indeed in locating cross sections, in the effective use of one-dimensional models for engineering studies. The code developer is generally the one who is best positioned to combine science with art in extracting viable and useful results from a one-dimensional model.

In two- and three-dimensional mobile-bed models, the mathematical formulations of sediment processes are localized to a particular point on or above the bed, and thus need only be related to the hydrodynamic and bed-material conditions at that point. To be sure, there is still some art in knowing which relations are most appropriate for the area under study, and in relating local processes to depth-averaged hydrodynamic and sediment properties in the two-dimensional domain. But the higher the dimensionality of the model, the more local are the numerical formulations, and local formulations fall more into the realm of science than art. It may appear that multidimensional models are still heavily dependent on empirical auxiliary relations and calibration (as in the examples of Section 15.11). Yet these localized relations and calibrations have a much more physical/scientific basis than their counterparts in one-dimensional modeling, and thus are far more likely to support reliable model use in situations for which the model was not specifically calibrated. To the extent that this is true, the role of the model developer, and his or her skill in teasing the best information and behavior out of cross-sectional properties, becomes less important in enabling use of the model by engineers who are not closely associated with its development. Still, the most effective use of any mobile-bed model comprises close collaboration between model developer and user.

What should be the priorities for further two- and three-dimensional model development? In the authors' view, the

areas of greatest weakness at present are threefold: (1) inability to capture large temporal scales of change (e.g., seasons if not years) due to the sheer computational time burden of such complex computations; (2) inability to resolve subgrid scale processes, such as dune movement, due to computer speed and memory limitations; and (3) continuing inadequate descriptions of physical processes such as particle entrainment, deposition, and mixing. Weaknesses (1) and (2) will (presumably) progressively disappear as computational resources and speed continue their astounding rate of progress. Weakness (3) will not disappear simply because more powerful computers become available. There is a continuing need for research and development efforts focused on laboratory and field experiments specifically designed to improve the physical-process formulations adopted in numerical models. It is perhaps ironic that the rush to replace physical hydraulic investigations with numerical modeling, in both applications and research, has deprived numerical modelers of what they most need—improved understanding of some of the most complex physical processes on earth.

## CHAPTER 16

# *Turbulence Models for Sediment Transport Engineering*

*D. A. Lyn*

### 16.1 INTRODUCTION

In problems of civil engineering interest, sediment transport invariably occurs under turbulent-flow conditions. Traditional discussions (*ASCE Manual 54*; see also Chapter 2) of turbulence models have, however, been mainly restricted to the problem of determining the vertical distribution of suspended sediment in the simplest case of uniform channel flow over a plane bed. Since the appearance of *ASCE Manual 54* in 1975, there have been considerable advances in our understanding and hence modeling of complex turbulent flows, and these might be expected to have a positive impact on approaches to practical problems in sediment transport. In general, the scope of the problems that can be studied has been broadened substantially, and a larger range of engineering problems can be tackled with reasonable success. The more traditional basic questions have proven more refractory and progress in answering them has been correspondingly limited. Nevertheless, with ever-growing computational capabilities and the proliferation of commercial computational fluid dynamics (CFD) software packages, numerical modeling with turbulence models will in the foreseeable future become an increasingly important engineering tool in dealing with sediment transport problems. Hence, a basic familiarity with such models, their theoretical bases, and their limitations will be useful.

The present chapter describes the standard turbulence models currently being applied to problems involving sediment transport, focusing on so-called two-equation models, but also discussing more briefly simpler models that might be used judiciously for special problems, as well as more advanced models that may find more practical application in the future. In most applications thus far, the turbulence model has been taken without modification from fields where the use of these models is more solidly established, but where possibly important features unique to sediment transport are absent. The standard features, assumptions, and limitations of turbulence models are discussed in a number

of monographs (Rodi 1993; Hallbäck et al. 1996; Chen and Jaw 1998; Wilcox 1998; Piquet 1999; Durbin and Petterson Reif 2001), as well as review articles (Launder 1984; Speziale 1991; Hanjalic 1994; Rodi 1995; Speziale 1996; Launder 1996; Spalart 2000), but, except for the review by the ASCE Task Committee on Turbulence Models in Hydraulic Computations (1988) and the works of Rodi, hydraulic or sedimentation engineering applications have not received much attention (see, however, the brief review by Lane 1998). General references on multiphase flows are also available (e.g., Crowe et al. 1998) that discuss aspects relevant to turbulent particulate flows, often, however, with gas-solid or bubbly flows in mind. Although the present chapter will necessarily rely heavily on these works, it will elaborate issues that may be of particular relevance to sediment-transport engineering applications. Turbulence modeling, especially for the very complicated problem involving sediment transport, is an extensive field undergoing continual development, and the present chapter can only serve as an introduction to the subject, targeted at a sedimentation engineering audience. For the most part, the discussion is restricted to classical problems in sediment-transport mechanics, emphasizing noncohesive uniform-sized sediment. The important case of depth-averaged models, in which complicating issues other than but closely related to turbulence modeling arise, is covered briefly in an appendix.

### 16.2 TURBULENCE, MODELS, AND PARTICULATE FLOWS

Before the mathematical models used to describe the behavior of turbulent flows in general and sediment-laden flows in particular are stated, a discussion of qualitative aspects introduces basic concepts, motivations, and terminology. Much use will be made of scaling arguments and dimensional analysis involving length scales and time scales (or velocity scales, because a combination of length and

time scales will define a velocity scale). These characteristic quantities associated with physical processes provide a measure of size and of duration. Turbulent flows exhibit a broad and continuous range of length (and time) scales corresponding loosely to the size of “eddy” motions or “eddies.” The analogy between turbulent and molecular transport, although deficient in many respects, has been important in the development of turbulence models, and it will be helpful to consider the similarities and differences between the two types of transport.

### 16.2.1 Qualitative Features of Turbulent Flows and Modeling Implications

In attempting to define turbulence, Tennekes and Lumley (1972) list several essential features. The instantaneous flow quantities at a point of a turbulent flow, such as velocity and pressure, fluctuate irregularly in time in such a way as to preclude predictability, except possibly in a statistical “averaged” sense. Instead of attempting to solve the complete exact governing equation, which is not feasible for practical problems, the engineer resorts to describing the flow by suitably averaged equations involving at most second-order moments, such as variances. Because the influence of higher-order statistics is presumed to be weaker, the modeler is permitted greater flexibility in formulating models of correlations involving higher-order terms (Launder 1996).

As a consequence of the averaging operation, detailed flow information is lost that may still have important transport effects, for which models, preferably simple and of wide applicability, must be developed. This much-greater effectiveness in mixing or greater “diffusivity” compared to laminar flows is the feature of turbulent flows that is often of most practical interest. The ratio of turbulent diffusivity (viscosity in the context of momentum transfer) to molecular diffusivity may be several orders of magnitude, which can be qualitatively understood in terms of the much larger length scales involved in the former compared to the latter. As a result, turbulent diffusive transport may be of comparable importance to or, in some cases, may even dominate advective transport, and the effective modeling of turbulent transport becomes essential to reliable predictions of overall transport. Turbulence models have therefore focused on predicting the effects of the large-scale motions responsible for the enhanced diffusivity.

Even though the main flow features of engineering interest, and hence the (time-)averaged equations, may be well approximated as being one- or two-dimensional, instantaneous turbulent fluctuations are essentially three-dimensional in that they are nonzero in all spatial directions. Moreover, turbulence characteristics will vary in at least one, and possibly all spatial directions; i.e., the turbulence is inhomogeneous. The characteristics in each coordinate direction also may differ from one another; i.e., the turbulence is anisotropic.

The modeling of strongly inhomogeneous and anisotropic features requires greater effort, both theoretically and computationally, and still is the subject of intensive research. The search for simpler models has often been based on assumptions of local homogeneity and isotropy, such that, in a sufficiently small volume in the flow region of interest, spatial variations and anisotropic effects may be neglected. The simple models, however, may not yield reliable results for flows far from the isotropic and homogeneous ideal.

A flow becomes turbulent at sufficiently high Reynolds number,  $R = UL/\nu$ , where  $U$  and  $L$  are appropriate velocity and length scales, and  $\nu$  is the fluid kinematic viscosity. In alluvial channel flows,  $R$ , based on an average velocity and the flow depth,  $h$ , can attain quite large values, because of the large length scale ( $h$ ) involved. As a result, not only is the flow turbulent, but it is a high- $R$  turbulent flow, a characteristic that has been exploited in turbulence modeling. Two aspects of high- $R$  flows have been implicitly incorporated into most turbulence models (Launder 1996). The first is the empirical observation of high- $R$  similarity, in which many practically important characteristics of high- $R$  turbulent flows are largely insensitive to variations in  $R$ , or equivalently to the effects of molecular viscosity. This has implications for suspension flows, because it is known that the effective (molecular or small-scale) viscosity of a suspension may vary with the suspension concentration. For dilute suspensions, however, this effect is irrelevant as far as high- $R$  turbulent flows are concerned, because viscous effects are unimportant in regions away from (smooth) solid boundaries. The second is that, at high  $R$ , turbulence at the smallest scales is considered locally isotropic, not being strongly influenced by the mean flow or the anisotropic large-scale turbulent motions. In smooth-channel flows, e.g., in the laboratory, however, viscous effects may be important in the near-bed region because the local  $R$  is low, and high- $R$  model assumptions need to be reexamined. In sediment-transport applications with fine sands, viscous effects may also need to be considered in particular problems, such as the formation of ripples (Richards 1980).

In the shear flows of primary interest in hydraulic engineering, turbulent fluctuations or “kinetic energy,” which is more precisely defined later (Eq. (16-5)), may be viewed as being produced or extracted from the mean flow by the interaction of the fluctuations with large-scale mean velocity gradients. On the other hand, the fluctuations are also seen as being dissipated at the smallest scales by the action of viscosity. The process by which the energy is produced and then eventually dissipated, essentially through the stretching of vortices, is often conceptually pictured as a cascade, in which large-scale eddying motions undergo continual transformation into motions on smaller and smaller scales. Fluctuating vorticity, which accompanies this cascade, is a defining feature of turbulence. In spite of the fact that dissipation is effected through fluid viscosity, the rate of dissipation of turbulent kinetic energy, denoted by  $\epsilon$ , is controlled

by the largest scales. Changes in fluid viscosity influence the scale on which dissipation occurs, but do not affect  $\epsilon$ , consistent with the high- $R$  similarity already mentioned. The importance of the large scales in determining  $\epsilon$  will be reiterated throughout this chapter. When production and dissipation are in approximate balance, i.e., a local equilibrium is established, this may permit model simplification. On the other hand, strongly nonequilibrium turbulence, like strongly anisotropic turbulence, will present problems for simple turbulence models.

### 16.2.2 Length and Time Scales in Turbulent Sediment-Transport Problems

A familiarity with the relevant length and time (or velocity) scales is important in the discussion of turbulent flows and models. Turbulence scales characteristic of the bulk flow are usually taken to be the average or maximum velocity and the flow depth or boundary layer thickness, with time and length scales on the order of at most minutes and tens of meters, respectively. For flows where the turbulence is primarily generated by boundary shear, the shear velocity,  $u_*$ , which characterizes the local boundary shear stress,  $\bar{\tau}_b$ , since  $u_* \equiv \sqrt{\bar{\tau}_b/\rho}$ , ( $\rho$  is the fluid density), plays a particularly important role as a velocity scale. The smallest scales of turbulence are those associated with viscous dissipation of eddies, and hence are characterized by  $\nu$  and  $\epsilon$  (with dimensions of energy per unit mass per unit time,  $[L^2/T^3]$ ). The Kolmogorov scales, the smallest length and time scales in turbulent flows, are determined from these variables as  $\eta_K = (\nu^3/\epsilon)^{1/4}$  and  $\tau_K = (\nu/\epsilon)^{1/2}$ , respectively, with typical values of  $O(1 \text{ mm})$  and  $O(0.05 \text{ s})$ .

A comparison of turbulence scales with scales of interest in sediment-transport engineering, which may span a very wide range, provides a preliminary assessment of the importance of effects on turbulence and serves as a guide to appropriate turbulence models. Morphological time scales over which changes of engineering significance in erodible boundaries occur may be on the order of months or even years. The migration speed of bed forms is much smaller than bulk-flow velocities, and so is associated with correspondingly much longer time scales. Flood hydrographs in rivers and the corresponding sedimentographs or flow reversals in estuaries occur on time scales of hours or days. Because of the large disparities in time scales, such “long”-time-scale unsteady phenomena should not interact strongly with “short”-time-scale turbulence-generating (or-dissipating) mechanisms, and hence turbulence models developed for steady-state problems should be adequate; i.e., deficiencies in predictive abilities are likely due to other than unsteady effects. The possibly different needs of sediment transport and flow predictions need to be pointed out. Because sediment transport may occur over relatively long time scales, detailed flow features may have important implications for sediment transport, and yet, from the narrow point of view

of the gross flow, be unremarkable. Further, this does not address possible difficulties arising when problems involving large-scale unsteadiness are *deliberately* simplified and modeled as being steady. In problems involving shorter time (or length) scales, e.g., oscillatory waves with periods on the order of seconds, possible unsteady effects on turbulence may not be so easily dismissed. Because laboratory measurements play such an important role in verifying (and calibrating) turbulence models, it should also be emphasized that important length and time scales in the laboratory may differ from those in the field, and effects that may be small or negligible in the field may assume greater importance in small-scale laboratory experiments, and vice versa.

Particle length and time scales merit further discussion, because these may be comparable to turbulence scales, and so conducive to potentially strong interaction with turbulence. A characteristic length scale of a sedimenting particle is its size,  $d$ , and its time scale may be taken as the time required for it to respond to fluid velocity fluctuations,  $\tau_p$ . A simple estimate of the latter is  $\tau_p \sim w_s/[g(s-1)/s]$ , where

- $w_s$  = terminal settling velocity;
- $g$  = the acceleration due to gravity, and
- $s = \rho_s/\rho$  = relative density of the sediment.

The ratio of  $\tau_p$  to a turbulence time scale is often termed a Stokes number, denoted as  $St$ ; e.g., the Stokes number based on the Kolmogorov time scale is  $St_K \equiv \tau_p/\tau_K$ . For fine to medium sands,  $d/\eta_K = O(1)$  and  $St_K = O(10^{-1})$ , suggesting that these sands will follow all but the highest frequency fluctuations. For noticeable effects on the bulk flow, it might be expected that a sufficiently large suspension volume concentration,  $c$ , is necessary. A length scale indicative of concentration would be an interparticle separation distance,  $l_s \sim d/c^{1/3}$ , which for moderate values of  $c = O(10^{-3})$  would lie in a range,  $\approx 10d$ , comparable to smaller turbulence scales.

### 16.2.3 Turbulence in Particulate Flows

The qualitative features of suspension-free or clear-water turbulent flows should also apply to turbulent suspensions transporting solid particles, at least if the suspension is sufficiently dilute, i.e., for  $c$  sufficiently small. What level of  $c$  characterizes a dilute suspension? Lumley (1973) has argued on the basis of the neglect of particle-particle interaction that  $c$  should not exceed  $O(10^{-3})$ , which also has been suggested by Elghobashi (1994). For problems in sediment-transport engineering, this is often satisfied over much, though not necessarily all, of the flow region of interest. In particular, in the important near-bed region, the dilute assumption is suspect, and a dense-phase flow may need to be considered.

Particles in a suspension are discrete and dispersed throughout the flow. Because the trajectories of specific individual particles are generally of no interest to the sediment transport engineer, a continuum or two-fluid treatment

of a suspension flow is attractive. The discrete particles are considered to constitute a continuum like the carrier fluid, and hence to be governed by equations of motion very similar to the equations of fluid flow. This can be achieved (just as in the case of the carrier fluid) by averaging over a representative volume containing a sufficiently large number of particles, but it also requires that the length scale,  $\mathcal{L}_v$ , of the representative volume be sufficiently small compared to important flow length scales. When combined with the dilute-suspension assumption, this requirement places a rather severe restriction on such a modeling approach. For a fine sand,  $d = 0.2$  mm; at  $c = 10^{-3}$ , this implies that  $\mathcal{L}_v = O(1$  cm), which is certainly much larger than  $\eta_K$ , and, for laboratory flows, even becomes comparable to the largest scales. Thus, like much else in turbulence, the frequently used continuum models, though often effective for engineering purposes, can be difficult to justify with any semblance of rigor.

In the simplest models, encompassing the large majority of models, the particles or, in continuum models, the particulate phase is assumed to behave, like a dye, as a passive scalar, in that it does not influence the flow dynamics. At what level of  $c$  can this “one-way” coupling be justified? In a rough classification, Elghobashi (1994) suggests that  $c < 10^{-6}$  for one-way coupling. This seems overly stringent, particularly in the parameter range more relevant to (aqueous) sediment transport, where density ratios are  $O(1)$ , but it does indicate that the usual neglect of the effects of the particulate phase on turbulence, sometimes termed turbulence modulation (or modification), should not be so casually assumed. The problem of modeling the two-way coupling, in which the particulate phase may significantly affect the flow, remains an active research topic, though mainly outside of the sediment-transport literature (e.g., Elghobashi and Abou-Arab 1983; Elghobashi and Truesdell 1993; Boivin et al. 1998). As will be discussed below, the main effect of sediment on the flow that has been considered within the sediment-transport literature is that analogous to density stratification stemming from vertical variation in particle concentration.

#### 16.2.4 Aims and Scope of Modeling

Wilcox (1998) has defined an ideal turbulence model as one that “should introduce the minimum amount of complexity while capturing the essence of the relevant physics.” For the sediment-transport engineer, this may be interpreted as implying that a useful prediction can be obtained reliably for a reasonable expenditure of effort. Much of the following will be concerned with describing relatively complex models requiring not only possibly lengthy numerical solution but also possibly extensive data collection to specify boundary/initial conditions and for model validation. It should not necessarily be assumed that the additional effort in formulating and setting up more complex models will always result in commensurate improvements in predictions. The incomplete understanding

of turbulence without particles already sets an upper limit on what can be achieved in the modeling of the more complex problem of turbulence with particles. Similarly, limitations on our predictive ability may be set by our incomplete understanding of the most basic problems of sediment transport, such as the specification of bed load or an equilibrium bed concentration, which are needed in specifying boundary conditions.

### 16.3 THE REYNOLDS-AVERAGED EQUATIONS

The traditional modeling approach based on Reynolds averaging is likely to remain dominant for practical hydraulic problems. An instantaneous quantity of interest,  $f(\mathbf{x}, t)$ , which may be a velocity component,  $u_i$ , or a sediment concentration,  $c(\mathbf{x}, t)$ , is decomposed into an averaged, e.g.,  $\bar{f}$ , and a random or at least unpredictable fluctuating component,  $f'$ . Here,  $\mathbf{x} = x_i$ ,  $i = 1, 2, 3$ , denotes the position vector, and  $t$  denotes the time variable. Where convenient, the identifications  $(x_1, x_2, x_3) = (x, y, z)$  and  $(u_1, u_2, u_3) = (u, v, w)$  will be made, where  $x$  is taken to be in the stream-wise direction,  $z$  in the vertical direction, opposite to the direction of gravity (or approximately in the direction away from the bed), and  $y$  in the horizontal direction perpendicular to  $x$  and  $z$ . For steady flows, the averaging can be performed over time,

$$\bar{f}(\mathbf{x}) = \lim_{T_{\text{avg}} \rightarrow \infty} \frac{1}{T_{\text{avg}}} \int_0^{T_{\text{avg}}} f(\mathbf{x}, t) dt, \quad (16-1)$$

where  $T_{\text{avg}}$  denotes the time period over which the averaging is performed. In the case of unsteady flows, an ensemble average can be taken over different realizations of conceptually the same flow, such as experiments repeated under the same conditions. For steady flows, averaging over an ensemble and averaging over time may be assumed to be equivalent and to yield the same results. Though, in Eq. (16-1),  $T_{\text{avg}}$  is formally taken as going to infinity, in practice it is sufficient that  $T_{\text{avg}}$  be much longer than any relevant turbulence time scale, but much shorter than any time scale over which the flow might be considered unsteady (Lumley and Panofsky 1964; Wilcox 1998).

#### 16.3.1 The General Flow Equations

With the averaged continuity equation, the general three-dimensional Reynolds-averaged Navier-Stokes (RANS) equations for an incompressible fluid may be conveniently written in Cartesian tensor notation (for those unfamiliar with this notation, a brief introduction is given in Appendix I to this chapter) as

$$\frac{\partial \bar{u}_j}{\partial x_j} = 0 \quad (16-2a)$$

$$\begin{aligned}
\frac{D\bar{u}_i}{Dt} &= \frac{\partial \bar{u}_i}{\partial t} + \frac{\partial (\bar{u}_i \bar{u}_j)}{\partial x_j} \\
&= -\frac{1}{\rho_{\text{ref}}} \frac{\partial \bar{p}}{\partial x_i} + \frac{\partial}{\partial x_j} \left( -\overline{u'_i u'_j} + \frac{\mu}{\rho_{\text{ref}}} \frac{\partial \bar{u}_i}{\partial x_j} \right) + \bar{F}_i
\end{aligned}
\quad (16-2b)$$

where

$p$  = pressure;  
 $\rho_{\text{ref}}$  = reference fluid density; and  
 $\mu$  = molecular dynamic viscosity.

The term  $\bar{F}_i$  represents a force per unit mass, i.e., an acceleration. Here, the summation convention is followed, where repeated roman alphabetic subscripts indicate summation over all values of the subscript. For particle-free flows,  $\bar{F}_i$  might be the gravitational body force, such as  $g_i$ , the component of gravitational acceleration in the  $i^{\text{th}}$  coordinate direction.

In the context of suspension flows,  $\bar{F}_i$  would represent interaction forces exerted on the fluid by the particles. Frequently, the effect of sediment on the flow is modeled in a manner analogous to that of a variable-density fluid. A locally averaged density,  $\rho_m$ , for the suspension can be defined as

$$\begin{aligned}
\rho_m(\mathbf{x}, t) &= \rho_s c(\mathbf{x}, t) + \rho[1 - c(\mathbf{x}, t)] \\
&= \rho[1 + (s - 1)c(\mathbf{x}, t)].
\end{aligned}
\quad (16-3)$$

The Boussinesq approximation, which neglects inertial effects due to a variable (suspension) density, and includes only buoyancy effects, can then be invoked, with the result (using  $\rho_{\text{ref}} = \rho$ ) that

$$\bar{F}_i = g_i \frac{(\bar{\rho}_m - \rho)}{\rho} = g_i (s - 1) \bar{c}. \quad (16-4)$$

To what extent the application of Eqs. (16-2) to suspensions can be justified is debatable, but if the suspension is sufficiently dilute, then Eqs. (16-2) should at least approximately hold. Whether the dominant interaction force between fluid and solid phases can be effectively modeled with a variable-density buoyancy term as in Eq. (16-4) is more controversial. Simplified forms of Eqs. (16-2) are often used; e.g., for primarily horizontal flows, the shallow-water-wave assumption of hydrostatic pressure distribution in the vertical direction is frequently invoked (see the discussion of spatially averaged flows in Appendix II).

The basic closure problem following from the adoption of the Reynolds averaging procedure arises because of the appearance, on the right-hand side of Eq. (16-2b), of the correlation terms,  $-\overline{u'_i u'_j}$ . These result from the averaging of the nonlinear advection term,  $\bar{u}_i \bar{u}_j$ . As expressed in Eq. (16-2b),  $-\overline{u'_i u'_j}$  is not known a priori and consequently, Eqs. (16-2) are not closed and cannot be solved as is. The

**Fig. 16-1.** Steady uniform flow without sediment in a wide channel on a slope  $\theta$ .

nine elements of  $-\overline{u'_i u'_j}$  may be interpreted as representing effective stresses and hence  $-\overline{u'_i u'_j}$  is termed the (kinematic) Reynolds stress tensor. The three diagonal terms,  $-\overline{u'_1 u'_1}$ ,  $-\overline{u'_2 u'_2}$ ,  $-\overline{u'_3 u'_3}$ , are interpreted as normal stresses, while the off-diagonal terms are interpreted as shear stresses. In general, the diagonal terms are all different in value, and hence turbulence is anisotropic. One of the most important parameters describing turbulence is obtained from the sum of the diagonal terms, namely, the turbulent kinetic energy,

$$k \equiv \frac{1}{2} \overline{u'_i u'_i} = \frac{1}{2} (\overline{u'_1 u'_1} + \overline{u'_2 u'_2} + \overline{u'_3 u'_3}). \quad (16-5)$$

The Reynolds stress tensor is symmetric, so that only six of its nine terms (the diagonal terms and the three off-diagonal terms,  $\overline{u'_1 u'_2}$ ,  $\overline{u'_1 u'_3}$ ,  $\overline{u'_2 u'_3}$ ) are independent. Together with the four primary unknowns (the three mean velocity components,  $\bar{u}_i$  and the mean pressure,  $\bar{p}$ ), the six independent Reynolds stresses form a total of ten unknown variables, whereas Eqs. (16-2) provides only four equations. Turbulence modeling provides closure of the system by formulating sufficient additional equations, algebraic or differential, that specify  $-\overline{u'_i u'_j}$ , in terms of already existing variables.

*Example.* In the following, the special case of a steady uniform plane-bed flow in an infinitely wide channel (Fig. 16-1) will be used recurrently as a simple illustration of the use of the model equations discussed. These illustrations will be set apart from the main text. In this special case,  $\bar{u}_2 = \bar{u}_3 = 0$ ,  $\partial/\partial t \equiv \partial/\partial x_1 \equiv \partial/\partial x_2 \equiv 0$ . Equation (16-2a) is therefore satisfied automatically, and Eq. (16-2b) is reduced to

$$0 = \frac{\partial}{\partial x_3} \left( -\overline{u'_1 u'_3} + \frac{\mu}{\rho_{\text{ref}}} \frac{\partial \bar{u}_1}{\partial x_3} \right) + g \sin \theta \quad (16-6a)$$

$$0 = \frac{\partial}{\partial x_3} \left( -\overline{u'_2 u'_3} \right) \quad (16-6b)$$

$$0 = \frac{1}{\rho_{\text{ref}}} \frac{\partial \bar{p}}{\partial x_3} + \frac{\partial}{\partial x_3} \left( -\overline{u'_3 u'_3} \right) - g \cos \theta. \quad (16-6c)$$

This involves five unknowns ( $\bar{u}_1$ ,  $\bar{p}$ ,  $\overline{u'_1 u'_3}$ ,  $\overline{u'_2 u'_3}$ ,  $\overline{u'_3 u'_3}$ ) with only three equations. From Eq. (16-6b) and the boundary

condition at the bottom,  $-\overline{u'_2 u'_3}$  is found to be identically zero, and from Eq. (16-6c), the pressure distribution may be treated as hydrostatic because  $\partial(\overline{u'_3 u'_3})/\partial x_3$  is small. Interest is therefore focused on Eq. (16-6a), which still involves two unknowns,  $\overline{u'_1}$  and  $\overline{u'_1 u'_3}$ , and therefore is not closed.

### 16.3.2 Equation(s) for the Sediment Model

The basic flow equations, the continuity and Navier-Stokes equations describing (fluid) mass and momentum conservation, may be considered exact at least for a pure fluid, and very plausible for the fluid phase in a dilute suspension. In contrast, much remains unclear as far as the basic governing equations for sediment are concerned. Unlike “molecular” scalars like temperature or salinity, sediment constitutes a separate physical phase, the motion of which may not necessarily be the same as the motion of the fluid. The large bulk of the work on sediment transport modeling has been based on a continuum approach, similar to that taken with a molecular species. In analogy with the treatment of the latter, only a sediment mass conservation equation is taken, without mention of sediment momentum conservation equation. To further complicate the picture, the discrete nature of the solid phase permits an alternative (Lagrangian) modeling approach, in which the motion of individual particles is tracked. Thus, even before any attempt at the modeling of turbulent transport of sediment, the choice and justification of even the basic sediment equations must be addressed.

**16.3.2.1 The Continuum Approach** The continuum or two-fluid approach treats the discrete solid phase as a continuum, described by a possibly spatially and temporally varying local (either point or depth-averaged or cross-sectionally averaged) sediment concentration,  $c(\mathbf{x}, t)$ . A differential conservation equation is then heuristically derived, which governs the temporal evolution and/or the change in spatial distribution of  $c$ . Most commonly, the sediment is treated in a manner analogous to a molecular species, assuming that the particulate phase moves with the fluid, with, however, a special model for particle settling, which is characterized solely by a constant settling velocity,  $w_s$ . In problems where sediment heterogeneity may play an important role, the problem may be attacked by modeling different size classes, such that the  $\alpha^{\text{th}}$  size class would be characterized by its own settling velocity,  $(w_s)_\alpha$ . The standard Reynolds-averaged model equation describing the conservation of sediment in the  $\alpha^{\text{th}}$  size class is thus written as

$$\begin{aligned} \frac{D\bar{c}_\alpha}{Dt} &= \frac{\partial \bar{c}_\alpha}{\partial t} + \frac{\partial (\bar{u}_j \bar{c}_\alpha)}{\partial x_j} \\ &= \frac{\partial (-\overline{u'_j u'_s})}{\partial x_j} + \frac{\partial [(w_s)_\alpha \bar{c}_\alpha]}{\partial z} + \bar{R}_\alpha. \end{aligned} \quad (16-7)$$

Here, the summation convention is not applied with repeated Greek subscripts ( $\alpha$ ). The source (sink) term,  $\bar{R}_\alpha$ , represents a reaction or transformation term, such as might be considered in cases involving particle coagulation, breakup, or entrainment from a heterogeneous bed, that may cause a change in the concentration of particles in any given size class. From Eq. (16-7), the settling term (the second term on the extreme right-hand side) might also be viewed as a somewhat special reaction term for a molecular species. The total solid-phase volume concentration,  $\bar{c}$ , can be obtained by summation as

$$\bar{c} = \sum_{\alpha} \bar{c}_\alpha. \quad (16-8)$$

In spite of its wide use and its intuitive physical interpretation and hence appeal, the theoretical basis of Eq. (16-7) deserves further examination. The questions surrounding the continuum approximation have already been discussed in Section 16.2.3. Even if a continuum model is adopted, the question remains of whether it suffices to formulate only a mass conservation equation for sediment, or whether a more consistent two-phase flow approach including not only sediment kinematics but also sediment dynamics is necessary. The latter would necessitate an equal treatment of the continuous solid phase with its own momentum conservation equation. In particulate flows, it is empirically observed that, even with the settling velocity taken into account, the mean particle velocity differs from the fluid velocity (e.g., Muste and Patel 1997), such that the implicit assumption of Eq. (16-7) of equal particle and fluid velocities is clearly violated. The velocity difference for aqueous suspensions of small sand particles is however generally small,  $O(w_s)$ , and so it is not clear if and when a detailed treatment of sediment dynamics would be required. A general discussion of the theoretical basis of two-phase flow models is given by Drew (1983) and Crowe et al. (1998). In practical sediment transport computations, the latter approach has rarely been taken, though two-phase flow models have been proposed (Drew 1975; McTigue 1981; Kobayashi and Seo 1985; Greimann et al. 1999; Hsu et al. 2003) and simple cases, such as uniform flow over a plane bed, have been analyzed. Subtle differences from the conventional approach can lead to confusion (see, e.g., the discussion between Celik 1982 and McTigue 1982); whereas Eq. (16-7) is conventionally interpreted as a *kinematic* sediment conservation equation, the two-phase modeler may view it (or at least its simplified form in the uniform-flow case) as resulting from a *dynamic* momentum balance. The main difficulty in the two-phase flow approach, however, is similar to that of turbulence closure, in that modeling assumptions regarding the interaction between phases must be made to close the governing system of equations, but these are often impossible to confirm experimentally in any detail.

**16.3.2.2 The Settling Velocity in a Turbulent Suspension** Even if Eq. (16-7) is accepted as an intuitively plausible model for describing sediment transport, it remains

to specify  $w_s$ . The simplest choice of  $w_s$ , which therefore has been the most popular, is that corresponding to the settling of an isolated equivalent-spherical particle in a stagnant fluid of infinite extent, and formulae for this are available (see Chapter 2, where other effects on  $w_s$ , such as those due to shape, are discussed). In a turbulent suspension, however, these assumptions are not strictly satisfied. For the present chapter, the effects due to concentration and turbulence (already discussed in *ASCE Manual 54*) are relevant. Presumably, if the dilute assumption implicit in the standard models is valid, then effects of concentration are likely negligible (though the effect of preferential particle clustering in a turbulent flow (Wang and Maxey 1993) might need to be considered). On the other hand, numerical simulations (Wang and Maxey 1993) have shown an effect of turbulence on  $w_s$ , with  $w_s$  increasing by as much as 40% over the fall velocity in a stagnant fluid. Unfortunately, these results have been obtained for small heavy particles ( $d < \eta_K$ , and  $s \gg 1$ ) in homogeneous isotropic turbulence, which is not in the parameter range of greatest interest in sediment transport applications.

Since the publication of *ASCE Manual 54*, experimental studies of settling velocities of particles in water have been few. Boillat and Graf (1981; 1982) conducted experiments of spherical particle settling in stagnant water and in an approximately homogeneous turbulent flow for a range of particle Reynolds numbers,  $200 \leq w_s d/\nu = R_p \leq 20,000$ , which for typical particle parameters would correspond to the size range of coarse sands and larger. The observed drag coefficients,  $C_D$ , which can be simply related to  $w_s$ , in the stagnant-water case were consistently larger than those given by the standard drag curve for spheres. Relative to the stagnant-water  $C_D$ , the turbulent-flow  $C_D$  was generally reduced, corresponding to a larger  $w_s$ , though an increased  $C_D$ , corresponding to a smaller  $w_s$ , was often observed when  $R_p \approx 2,000$ . Although it was argued that both the intensity and the length scale of the turbulence influence  $C_D$ , a simple dimensionless correlation could not be found. In a similar study, Yang and Shy (2003) examined a range of smaller  $R_p < 40$ , and observed increases in  $w_s$  (relative to still-water values) with increasing  $St_K$  with a maximum increase of up to 7% for  $St_K \approx 1$ , but also found that decreases might occur for much larger  $St_K$ . The limited experimental evidence should be regarded with some caution, but does indicate that the use of a  $w_s$  based on stagnant-fluid condition may involve uncertainties of  $O(10\%)$ . Moreover, since most practical applications involve inhomogeneous turbulence, such that the settling particle is constantly adjusting to a changing turbulence environment, the practical implications of such results remain to be explored.

**16.3.2.3 Lagrangian Models** In this approach, the motion of individual particles is determined by writing a model equation of motion for an individual particle:

$$m_p \frac{d(u_i)_p}{dt_p} = (F_i)_p. \quad (16-9)$$

The subscript,  $p$ , refers to a particle quantity; hence,  $(u_i)_p$  is the instantaneous velocity of a particle,  $m_p$  is mass, and  $(F_i)_p$  denotes the sum of forces acting on the particle. In a popular variant of the Basset-Boussinesq-Oseen (BBO) equation for a spherical particle of radius  $a$ , the forces are modeled as

$$\begin{aligned} (F_i)_p = & m_p \underbrace{\left[ \frac{3}{8} \frac{C_D}{a_s} \{ (u_i)_f - (u_i)_p \} | (u_i)_f - (u_i)_p | \right]}_I \\ & + m_f \underbrace{\left[ \frac{d(u_i)_f}{dt} \right]}_{II} + \underbrace{\frac{1}{2} m_f \left[ \frac{d(u_i)_f}{dt} - \frac{d(u_i)_p}{dt_p} \right]}_{III} \\ & + 6a^2 (\pi \rho \mu)^{1/2} \underbrace{\int_{t_{p0}}^{t_p} \frac{d[(u_i)_f - (u_i)_p]/d\tau}{\sqrt{t_p - \tau}} d\tau}_{IV} \\ & + \underbrace{(m_p - m_f) g_i}_V \end{aligned} \quad (16-10)$$

including (I) a drag force (i.e., in the direction of relative velocity), (II) forces due to fluid pressure gradient and viscous stresses, (III) virtual mass forces, (IV) the Basset force due to unsteady relative acceleration, and (V) gravitational forces (Hinze 1975; Elghobashi and Truesdell 1993; Frey et al. 1993). In Eq. (16-10), the subscript  $f$  refers to a fluid quantity,  $C_D$  is the drag coefficient, and  $d(u_i)_f/dt$  is the total instantaneous acceleration of the fluid as seen by the particle at  $(x_i)_p$ . The BBO equation is intended for a single isolated particle, and cannot be rigorously justified outside of the Stokes regime (Clift et al. 1978). Lift forces, i.e., those acting in a direction normal to the relative velocity, may also be important, but are more difficult to model because they may arise from different mechanisms, such as shear and particle rotation (Clift et al. 1978; Stock 1996). Wiberg and Smith (1985; 1989) proposed a model for saltating particles, neglecting the Basset force and direct viscous forces but including an empirical expression for a lift force stemming only from shear. The possible importance of other lift mechanisms was also discussed. A similar study by Sekine and Kikkawa (1992) argued, however, that, at least for saltation, lift forces are negligible. For the case where  $s \gg 1$ , frequently encountered in the literature on two-phase flows, terms (II), (III), and (IV) are negligible, but for the conditions of interest in aqueous sediment transport, where  $s = O(1)$ , a priori neglecting any one of these terms is difficult to justify generally. Rigorous applications to turbulent flows require additional restrictions, including  $d/\eta_K \ll 1$  (Maxey 1993; Elghobashi 1994; Stock 1996).

A solution of Eq. (16-9) can then be used to determine the trajectory,  $(x_i)_p$ , of the particle by integrating

$$\frac{d(x_i)_p}{dt_p} = (u_i)_p - (Z_{u_i})_p, \quad (16-11)$$

where  $(Z_{u_i})_p$  is a random velocity-fluctuation term that models the stochastic motion of particle, if  $(u_i)_p$  is assumed to be entirely deterministic.

In addition to the question of the settling velocity in turbulent flows dealt with in the preceding subsection, two other main classes of problems have been studied with the Lagrangian approach. The question of the diffusivity of solid particles in a turbulent flow relative to the diffusivity of fluid particles is a classical problem, discussed by Lumley (1973) and Hinze (1975), and more recently by Squires and Eaton (1991) and Mei and Adrian (1995). An early review in a more specifically sediment hydraulic context was given by Alonso (1981). These studies are of some relevance because they illuminate theoretically one of the empirical parameters in the transport models to be discussed later, namely the turbulent Schmidt number,  $(\sigma_p)_s$ , for turbulent diffusion of solid particles. The turbulent Schmidt number is defined and discussed in greater detail in Section 16.4.1.3. Under rather restrictive idealized assumptions, they predict that the particle diffusivity is less than or equal to the fluid diffusivity (i.e.,  $(\sigma_p)_s \geq 1$ ) for sedimenting particles. Unfortunately, the experimental evidence is somewhat equivocal regarding this prediction.

The other major class of problems that have been examined by means of Lagrangian models is the saltation of particles and the resulting bed load (e.g., van Rijn 1984b; Wiberg and Smith 1985). Typically, simplified versions of Eq. (16-10) were used. Rather more problematic, Eqs. (16-9) to (16-11) were integrated with time-averaged models of the fluid velocity instead of an instantaneous velocity, and did not include any stochastic component. It is not clear that the averaged, much less the instantaneous, trajectory of a particle in a turbulent flow can be predicted from such a procedure, but such a Lagrangian approach may provide an alternative more physically based starting point for developing bedload formulae. In a somewhat different application, Frey et al. (1993) computed the steady flow in a model sedimentation tank, and, based on this flow field, studied particle transport using Eqs. (16-9) to (16-11), including a stochastic component. Some of their results are given in Section 16.5.2.

### 16.3.3 Auxiliary Equations: Boundary Conditions—Introductory Discussion

The governing equations for the flow and the sediment (Eqs. (16-2) and (16-7)) form a system of partial differential equations that requires a specification of boundary conditions on the entire boundary of the domain being considered. Conditions at inlet and outlet boundaries are problem-dependent, and, for practical computations, are best based on laboratory or field measurements. If these are not available,

then the problem of specifying these boundary conditions may be alleviated by choosing the boundaries of the computational domain sufficiently far from the region of greatest interest, such that the computational results in this region are not sensitive to exact details of the inlet and outlet conditions. For special problems, spatially periodic conditions in which inlet and outlet conditions are identical may be reasonable.

A boundary condition of special interest in sediment-transport problems is that at the bed, or at a solid boundary. The standard condition at a solid boundary, namely zero velocity, remains applicable to the instantaneous velocity, as well as to the mean and the fluctuating components. Because of the dominance of viscous effects, the elements of the Reynolds stress tensor tend to zero as the solid wall is approached. Although these wall conditions are undisputed, difficulties arise in its implementation in practical computations. For high- $R$  problems, large gradients occur in the region adjacent to the solid boundary, and hence lead to difficulties in numerical resolution. For the rough-boundary flows of most interest in sediment transport, the detailed geometric representation of the rough wall is not feasible, and a fictitious boundary is used for modeling purposes, so that an exact bed boundary condition is not necessarily helpful. As might be expected from the preceding discussion of the uncertainties in the modeling of suspended sediment transport, an exact boundary condition on the sediment concentration at the bed is not available. The deformability of the bed/boundary due to an erodible bed introduces a further complication, such that if the details of the bed forms and their motion are of interest, then, just as in the case of the water surface, an additional boundary condition is required. In most applications, however, a simplified approach is taken in which bed details, whether small-scale sand-grain roughness or large-scale bed form, are ignored, and only their effect on the bulk flow is modeled.

The other boundary of special interest is the water surface. In most cases, a simplified approach is taken in which the water surface is treated as a rigid, i.e., nondeformable, shear-free plane lid, the location of which is known a priori. This is often implemented by treating the water surface as a plane of symmetry, with zero applied shear, analogous to the centerline of a pipe flow. In steady flows, this approximation can be justified when the appropriate Froude number is small and the direct effect of spatial variations in water surface elevations is negligible. If the water surface is treated more exactly as a free, i.e., deformable, surface, then the computational effort will be much more significant. In addition to a dynamic boundary condition, a kinematic boundary condition needs to be satisfied. These conditions per se are not unique to turbulent flows, and so are not discussed further here; the reader is referred to Liggett (1994) for details. Turbulence at a water surface, however, differs from that at a pipe centerline, so that if the effects of free-surface turbulence are of interest, then special models of free-surface turbulence may be required, even when a rigid-lid approximation is made.

In sediment transport applications, interest is usually focused on the near-bed region rather than on the free-surface region, and so detailed turbulence modeling of the latter is generally not necessary.

## 16.4 TURBULENCE CLOSURE MODELS

### 16.4.1 The Boussinesq Eddy-Viscosity Model

The turbulence closure problem arises because of the presence of the Reynolds stress tensor,  $-\overline{u'_i u'_j}$ , in the governing flow equations (Eq. (16-2)). Further, the effectiveness of turbulent transport relative to molecular transport has been remarked as perhaps the most important characteristic of turbulence for engineering purposes. The analogy between molecular and turbulent diffusivity has played a pervasive, some would say pernicious, role in turbulence modeling, but before this analogy is explicitly made, the basic features of molecular diffusive transport are recalled.

**16.4.1.1 Molecular Transport of Momentum** Consider a pure-shear steady laminar flow (Fig. 16-2), in which only a single component of velocity is nonzero and varies only in one coordinate direction,  $\mathbf{u} = (u_1(x_3), 0, 0)$ . The only nonzero shear stress is

$$\tau_{13} = \tau_{31} = \mu \frac{du_1}{dx_3} = \nu \frac{d(\rho u_1)}{dx_3}. \quad (16-12)$$

This constitutive equation (for a Newtonian fluid) relates the only nonzero shear stress *linearly* to the strain rate (here simply the velocity gradient) through the transport coefficient,  $\mu$ , or its kinematic variant,  $\nu = \mu/\rho$ , which are *properties* of the *fluid*. Equation (16-12) is an example of a gradient-transport model, in which a flux, here the shear stress, which can be interpreted as a (negative) momentum flux, is related to a gradient of the quantity being transported, here the momentum per unit volume, i.e.,  $\rho u_1$ .

At the molecular level, this shear stress or momentum flux is effected by molecules in random motion. If the instantaneous fluctuating velocities of molecules in the  $x_1$  and  $x_3$  directions are denoted as  $u_1''$  and  $u_3''$ , then the shear stress can also be written as  $\tau_{12} = \rho \overline{u_1'' u_3''}$ , exactly analogously to a Reynolds shear stress. Moreover, for ideal gases, a rigorous result can be obtained for  $\nu$  using kinetic theory, namely,

Fig. 16-2. Laminar shear flow.

$$\nu \propto u_{th} \mathcal{L}_{mfp} \quad (16-13)$$

where

$u_{th}$  = average molecular thermal velocity and  
 $\mathcal{L}_{mfp}$  = molecular mean free path, i.e., the average distance a molecule travels before a collision with another molecule.

This motivates an analogous treatment of turbulent transport, which is effected by random fluid motion rather than random molecular motion. Equation (16-13), however, can only be justified if the length scale over which  $u_1$  varies is much larger than  $\mathcal{L}_{mfp}$  and the time scale of the mean flow (measured by  $(du_1/dx_3)^{-1}$ ) is much longer than molecular time scales (measured by  $(u_{th}/\mathcal{L}_{mfp})^{-1}$ ). This is evidently satisfied for the case of molecular transport, but, as will be argued below, the equivalent condition is clearly not satisfied in the case of turbulent transport.

**16.4.1.2 The Eddy Viscosity** For multidimensional problems, the analogy between molecular and turbulent transport can be expressed in a general form as

$$\begin{aligned} -\overline{u'_i u'_j} &= \nu_t (2\bar{S}_{ij}) - \frac{2}{3} k \delta_{ij} \\ &= \nu_t \left( \frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right) - \frac{2}{3} k \delta_{ij} \end{aligned} \quad (16-14)$$

which will be termed the Boussinesq eddy-viscosity model (BEVM), where  $\nu_t$  denotes a (kinematic) turbulent eddy viscosity. An expanded version of Eq. (16-14) is given in Appendix I as Eq. (16-79). The mean strain-rate tensor

$$\bar{S}_{ij} = \frac{1}{2} \left( \frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right) \quad (16-15)$$

and the Kronecker delta tensor  $\delta_{ij}=1$  for  $i=j$  and  $\delta_{ij}=0$  for  $i \neq j$ . Eq. (16-14) specifies the Reynolds stress tensor in terms of gradients of the mean flow, and thus makes progress in closing the system, Eq. (16-2). It remains to specify  $\nu_t$ , which is no longer a fluid property like its molecular counterpart,  $\nu$ , but rather depends on the local flow state. Hence,  $\nu_t$  will in general vary spatially within a flow and differ in different types of flows even with the same fluid.

The term,  $(2/3)k\delta_{ij}$ , is necessary for consistency with the definition of the turbulent kinetic energy (Eq. (16-5), since the sum  $\overline{u'_i u'_j} = 2k$ ), and acts as an effective pressure. When Eq. (16-14) is substituted into Eqs. (16-2), this term can be absorbed into the pressure-gradient term. Hence, even though  $k$  appears explicitly in Eq. (16-14), it does not necessarily have to be determined independently.

*Example.* When Eq. (16-14) is applied to a steady plane uniform flow, the only relevant elements of  $-\overline{u'_i u'_j}$  are obtained as

$$-\overline{u'_1 u'_3} = \nu_t \frac{\partial \bar{u}_1}{\partial x_3} \quad (16-16a)$$

$$-\overline{u'_2 u'_3} = \nu_t \frac{\partial \bar{u}_2}{\partial x_3} \quad (16-16b)$$

$$-\overline{u'_3 u'_3} = 2\nu_t \frac{\partial \bar{u}_3}{\partial x_3} - \frac{2}{3}k \quad (16-16c)$$

thereby yielding for momentum conservation

$$\begin{aligned} 0 &= \frac{\partial}{\partial x_3} \left[ (\nu_t + \nu) \frac{\partial \bar{u}_1}{\partial x_3} \right] + g \sin \theta \\ &= \frac{\partial}{\partial x_3} \left( \frac{\bar{\tau}_{13}}{\rho_{\text{ref}}} \right) + g \sin \theta \end{aligned} \quad (16-17a)$$

$$0 = -\frac{\partial}{\partial x_3} \left( \frac{\bar{P}}{\rho_{\text{ref}}} \right) - g \cos \theta \quad (16-17b)$$

In Eqs. (16-17), the conditions,  $\bar{u}_2 = \bar{u}_3 = 0$ ,  $\nu = \mu/\rho_{\text{ref}}$  have been used, an effective pressure has been redefined as  $\bar{p} = \bar{P} + (2/3)\rho_{\text{ref}}k$ , and  $\bar{\tau}_{13} = \rho_{\text{ref}}(\nu_t + \nu)(\partial \bar{u}_1/\partial x_3)$ . To solve for  $\bar{u}_1$ , a specification for  $\nu_t$  is still needed. Equations (16-17) can be integrated over  $x_3$ , and, with the imposition of the condition that, at  $x_3 = 0$ ,  $\bar{\tau}_{13} = \rho_{\text{ref}}u_*^2$ , where  $u_* = \sqrt{gh \sin \theta}$  is the shear velocity, and at the free surface,  $x_3 = h$ ,  $\bar{\tau}_{13} = 0$ , the following result is obtained:

$$\frac{\bar{\tau}_{13}}{\rho_{\text{ref}}} = u_*^2 \left( 1 - \frac{x_3}{h} \right) \quad (16-18a)$$

$$\approx -\overline{u'_1 u'_3} \quad (16-18b)$$

where the second relation assumes a region sufficiently far from the bed that molecular viscous effects are negligible. Equations (16-18) already point to  $u_*$  as the appropriate scale for the turbulent velocity fluctuations in wall-bounded flows.

**16.4.1.3 The Eddy Diffusivity and the Turbulent Schmidt Number** A close analogy holds between the viscous transport of momentum and the diffusive (molecular) transport of heat or a solute species. In laminar flows, both momentum and mass diffusion are typically assumed to follow a gradient-transport law, with constant transport coefficients that are properties of the fluid and, in the case of mass transport, of the solute. The ratio of the molecular kinematic viscosity to the molecular diffusivity, termed the Schmidt number and denoted as  $\sigma$ , is necessarily constant, depending again only on the carrier fluid and the solute.

With the analogies between laminar and turbulent transport of momentum, and between mass and momentum transport, the extension of Eq. (16-14) to mass (sediment) transport applications in turbulent flows is naturally motivated. Unlike momentum, which is a vector, mass or concentration is a scalar. The turbulent mass fluxes are therefore assumed to follow a gradient-transport law of the form

$$\overline{u'_j c'} = -\epsilon_c \frac{\partial \bar{c}}{\partial x_j} = -\frac{\nu_t}{\sigma_t} \frac{\partial \bar{c}}{\partial x_j} \quad (16-19)$$

where the eddy diffusivity,  $\epsilon_c$ , is specified as being proportional to the turbulent kinematic viscosity,  $\nu_t$ . The turbulent Schmidt number,  $\sigma_t$ , is defined as the ratio of the turbulent eddy viscosity to the turbulent diffusivity of the relevant transported scalar,

$$\sigma_t = \frac{\nu_t}{\epsilon_c} \quad (16-20)$$

In traditional sediment transport hydraulics, the reciprocal of  $\sigma_t$ , denoted as  $\beta_s$ , is more often encountered; i.e.,  $\epsilon_s = \beta_s \nu_t = [1/(\sigma_t)_s] \nu_t$ . Unlike its laminar counterpart,  $\sigma_t$  will not depend solely on fluid and species properties, but, like  $\nu_t$ , may in general depend on local flow conditions. It is usually assumed to be constant spatially, though the justification for this is based more on convenience and ignorance than on theory. Another complication arises from the anisotropy of particle diffusivity for sedimenting particles, whereby vertical diffusivity differs from horizontal diffusivity (Lumley 1973). Further, because the large-scale transport and mixing effected by turbulent eddies is relatively insensitive to the transported quantity, whether momentum, heat, or mass,  $\sigma_t$  is  $O(1)$  in contrast to  $\sigma$ , which may vary widely, e.g., for salt in water,  $\sigma = O(10^3)$ . A strict interpretation of the Reynolds analogy between momentum and mass turbulent transport would imply  $\sigma_t = 1$ .

The appropriate turbulent Schmidt number for sediment,  $(\sigma_t)_s = 1/\beta_s$ , has been much debated, and various prescriptions have been given (see the discussion in Davies 1995). Most studies (e.g., Li and Davies 1996; Olsen and Kjellesvig 1999; Wu et al. 2000) have simply chosen  $(\sigma_t)_s = 1$ , implicitly assuming the strict Reynolds analogy. Such a choice could plausibly be justified if  $d/\eta_K$  and  $w_s/u_*$  were sufficiently small. On the other hand, for a molecular scalar, e.g., an average value of  $\sigma_t = 0.7$  is given by Launder (1978). For boundary-layer flows, which may be particularly relevant to the channel flows of sediment transport, the model of Rotta (1964) prescribes a  $\sigma_t$  varying from 0.9 in the near-wall region to a value of 0.5 toward the outer edge of the boundary layer.

The estimation of  $(\sigma_t)_s$  from measurements is still problematic. Its basic definition (Eqs. 16-19) relies on local estimates of sediment and momentum fluxes that require estimation of gradients from noisy and often sparse point measurements. Consequently, these estimates can be erratic, but have the advantages that no additional model assumptions need to be made and a spatially variable  $(\sigma_t)_s$  is allowed. Traditionally,  $\beta_s$  has been estimated by assuming specific velocity and concentration profiles for uniform sediment-laden flows over a plane bed and fitting these to measured profiles in uniform sediment-laden flow. Such an integral approach results in smoother estimates but rests on

dubious profile assumptions. Unfortunately, these different approaches may yield quite disparate estimates. An estimate of  $\beta_s$  based on fitting to a Rouse-type profile may be significantly *smaller* than an estimate based on local gradients.

Based on the flume studies of Coleman (1970), in which sediment diffusivity was estimated from local gradients, van Rijn (1984c) proposed that

$$(\beta_s)_{vR} = 1 + 2 (w_s/u_*)^2, \quad 0.1 < w_s/u_* < 1 \quad (16-21)$$

Two aspects of the Coleman data deserve mention: (1) the relatively small width-to-depth ratio ( $< 3$ ) raises questions regarding the effects of secondary currents, and (2) the lack of an equilibrium sand bed raises doubts regarding the extent to which the flows studied were actually “saturated,” and therefore applicable to real equilibrium-bed cases. One version of the earlier model of Einstein and Chien (1954) related the fitted Rouse exponent,  $Z_R$ , to  $(Z_R)_{\text{ref}} \equiv w_s/\kappa u_*$ , and can be expressed as

$$(\beta_s)_{E-C} = \exp \left[ \frac{(Z_R)_{\text{ref}} C_{E-C}}{\sqrt{\pi}} \right] + (Z_R)_{\text{ref}} C_{E-C} \operatorname{erf} \left[ \frac{(Z_R)_{\text{ref}} C_{E-C}}{\sqrt{\pi}} \right] \quad (16-22)$$

with

$$C_{E-C} = \ln 1.3.$$

Both relations satisfy  $(\sigma_t)_s \leq 1$ , and  $(\sigma_t)_s \rightarrow 1$  as  $w_s/u_* \rightarrow 0$ .

Local estimates of  $(\sigma_t)_s$  from uniform flows over a plane equilibrium beds are plotted in Fig. 16-3a; a large scatter is evident. The data of Cellino and Graf (1999) are interesting as an example of direct measurements of momentum and sediment fluxes using acoustic Doppler techniques. Their values, however, seem excessive (values in the region  $z/h < 0.4$  consistently exceed 3, and so are not plotted) and remains to be independently supported. Experimental evidence for spatial variation in  $(\sigma_t)_s$  is particularly strong in the Barton and Lin (1955) and Cellino and Graf (1999) data, with  $(\sigma_t)_s$  decreasing toward the

**Fig. 16-3.** (a) Local estimates of  $(\sigma_t)_s$  for uniform flow over a plane equilibrium bed as a function of relative distance,  $z/h$ , from the bed:  $\circ$ , Cellino and Graf (1999,  $u_*/w_s = 0.27$ , Run SAT S015);  $\blacksquare$ , Lyn (1988,  $u_*/w_s = 0.73$ , Run EQ2565);  $\blacktriangle$ , Lyn (1988,  $u_*/w_s = 0.45$ , Run EQ1665);  $\square$ , Barton and Lin (1955,  $u_*/w_s = 0.52$ , Run 31);  $\triangle$ , Barton and Lin (1955,  $u_*/w_s = 0.36$ , Run 36). (b) Averaged (over  $0.1 < z/h < 0.5$ ) values of  $(\sigma_t)_s$  as a function of  $u_*/w_s$ :  $\triangle$  Barton and Lin (1955);  $+$ , Coleman (1970),  $\blacksquare$ , Lyn (1988).

free surface, a variation consistent with the already-mentioned Rotta model for a flat-plate boundary-layer flow. Though scatter clouds the issue, the data, especially in the practically important near-bed region, point to the possibility of  $(\sigma_t)_s > 1$ , contrary to both Eqs. (16-21) and (16-22). For a spatially varying  $(\sigma_t)_s$ , the question of its dependence on  $u_* / w_s$  becomes complicated. The Lyn (1988) data generally indicate an increase in  $(\sigma_t)_s$  with increasing  $u_* / w_s$ , whereas the Barton and Lin (1955) data exhibit the opposite tendency. The two studies, however, cover somewhat different ranges of  $u_* / w_s$ , and so the observed trends may not be entirely inconsistent.

As a simplification, the modeler may elect to use a constant averaged value of  $(\sigma_t)_s$ . Figure 16.3b shows values of  $(\sigma_t)_s$  (averaged over  $0.1 \leq y/h \leq 0.5$ , because this region carries the bulk of the suspended sediment) for different values of  $u_* / w_s$ . Also plotted are curves corresponding to Eqs. (16-21) and (16-22) (for the latter, a value of  $\kappa = 0.4$  has been assumed). The different behavior of  $(\sigma_t)_s$  with respect to  $u_* / w_s$  in the different studies discussed above can still be seen in the averaged quantities. The van Rijn model not surprisingly agrees well with the Coleman data on which it was based. The behavior of the Einstein–Chien model, which was based on traditional fitting to a Rouse profile, relative to the van Rijn model is also expected in that integral estimates of  $\beta_s$  based on the Rouse profile will generally yield values closer to unity than local estimates (assuming a clear-water value of  $\kappa \approx 0.4$ ).

The preceding was concerned only with uniform flows homogeneous in the streamwise direction. In nonuniform flows, even more complications may be expected. That the appropriate value of  $(\sigma_t)_s$  may vary not only with distance from the wall but also in the streamwise direction was observed by Celik and Rodi (1988), who simulated the experiments of Jobson and Sayre (1970) and found that better predictions were achieved with different values of  $(\sigma_t)_s$  at different streamwise stations. Ouillon and le Guennec (1996), simulating the same experiment, showed that the  $\bar{c}$ -profiles nearer the inlet can even be well predicted by choosing  $(\sigma_t)_s = \infty$ , i.e., without any turbulent transport. They also found that agreement with measurements was improved by choosing different values of  $(\sigma_t)_s$ , ranging from 0.6 to 1, depending on the type of flow-bed interaction, i.e., on whether deposition to or entrainment from the bed was occurring. In practical computations with the  $k$ - $\epsilon$  model to be described, and where  $(\sigma_t)_s$  is interpreted more as a model-tuning parameter that might compensate for model deficiencies and hence might be model-dependent, then experience indicates that  $(\sigma_t)_s \leq 1$  (or  $\beta_s \geq 1$ ) will yield better results, though a definitive conclusion is still to be reached.

In view of the difficulties associated with specifying  $(\sigma_t)_s$ , alternative approaches that avoid it altogether or attempt to specify it more completely might be sought. The conceptual model of Lyn (1988) does not rely on an eddy-diffusivity model and hence does not require a  $(\sigma_t)_s$ , but makes quite restrictive similarity assumptions that apply only in simple flows such as uniform plane-bed flows. Two-phase-flow

models, such as that of Greimann et al. (1999), may offer some guidance, because an explicit expression for  $(\sigma_t)_s$  in terms of local flow and suspension parameters can be derived, though other constant(s) may need to be specified. A second-order model (a brief introductory discussion of second-order modeling is given in Section 16.4.7) for sediment concentration could also conceivably do without an eddy-diffusivity model. This would, however, not only likely require specifying *other* model “constants” but even in second-order turbulence models for single-phase flows, isotropic-turbulent-viscosity models with turbulent Schmidt numbers remain popular for numerical reasons (see the discussion in Lien and Leschziner 1994).

*Example.* For the simple uniform-flow case, Eq. (16-7) with Eq. (16-19) reduces to

$$\begin{aligned} 0 &= \frac{\partial(w_s \bar{c})}{\partial z} + \frac{\partial(-\overline{w'c'})}{\partial z} \\ &= \frac{\partial(w_s \bar{c})}{\partial z} + \frac{\partial}{\partial z} \left( \frac{\nu_t}{\sigma_c} \frac{\partial \bar{c}}{\partial z} \right) \end{aligned} \quad (16-23)$$

where  $u'_3$  and  $x_3$  have been rewritten as  $w'$  and  $z$ , respectively. This can be integrated once, and, with the imposition of a no-flux condition at the water surface, yields the familiar

$$-\overline{w'c'} + w_s \bar{c} = \frac{\nu_t}{(\sigma_t)_s} \frac{d\bar{c}}{dz} + w_s \bar{c} = 0 \quad (16-24)$$

As with the momentum equations, a complete solution awaits a specification of  $\nu_t$  (and  $(\sigma_t)_s$ ).

#### 16.4.2 The Specification of the Eddy Viscosity: Zero-Equation Models

A kinematic viscosity (or diffusivity) may be considered as a product of a velocity scale,  $u$ , and a length scale,  $\mathcal{L}$ . A prescription of  $\nu_t$  will in general involve specifying these two scales in terms of quantities, either already known or for which equations are already available. The additional equations governing these scales may be formulated either as algebraic equations or as differential transport equations, and hence eddy-viscosity models have conventionally been classified as zero-, one-, or two-equation models depending on the number of differential transport equations used in specifying  $u$  and  $\mathcal{L}$ .

**16.4.2.1 Constant-Eddy-Viscosity Models** Not surprisingly, the oldest turbulence models are zero-equation models, because the computational requirements are least severe. The simplest of these assume that the turbulent velocity and length scales, and hence the eddy viscosity, are effectively constant over the entire flow region of interest. The main difficulty then is the choice of an appropriate value. Calibration with measurements, possibly combined with

dimensionally based scaling arguments to extend the range of application, is recommended. In fully developed wall-bounded wide channel flows, a common choice involves the product of the shear velocity and the depth,  $\nu_t \propto u_* h$ . For depth-averaged models (see Appendix II), this choice for a constant horizontal eddy viscosity is often justified as the result of integrating the classic parabolic mixing-length eddy-viscosity model, discussed below, which gives the proportionality constant as  $\kappa/6$ , where  $\kappa$  is the von Kármán constant. Observed horizontal diffusivities tend to indicate a larger proportionality constant (Fischer et al. 1979), and so, for practical computations, calibration is recommended. This simplest of models is unlikely to be successful where flow details strongly influenced by turbulence, e.g., separation and reattachment, are of primary interest; where turbulence plays a secondary role, this may prove to be an economical if limited model.

**16.4.2.2 Mixing-Length Models** The classic zero-equation model, which remains important in current discussions of turbulence in sediment-laden flows, is the mixing-length model. Originally introduced within the context of simple turbulent shear layers by Prandtl (1925), the mixing length,  $\mathcal{L}_m$ , may be motivated in a scaling of turbulent velocity fluctuations with mean velocity gradients as  $u', w' \sim \mathcal{L}_m \partial \bar{u} / \partial z$ , where  $u'$  is the velocity fluctuation in the dominant streamwise direction,  $w'$  the corresponding fluctuation in the ( $z$ ) direction across the shear layer. In this way, with the only significant correlation term  $\overline{u' w'} \sim [\mathcal{L}_m (\partial \bar{u} / \partial z)]^2 \sim \nu_t (\partial \bar{u} / \partial z)$ , and with a choice of the velocity scale as  $Y = \mathcal{L}_m \partial \bar{u} / \partial z$ , the eddy viscosity can be specified as

$$\nu_t = \mathcal{L}_m \mathcal{U} = \mathcal{L}_m^2 \frac{\partial \bar{u}}{\partial z}. \quad (16-25)$$

To close the model, it remains only to specify  $\mathcal{L}_m$ . Physically,  $\mathcal{L}_m$  may be thought of as the size of a typical turbulent eddy at any given location. In a simple shear flow with a single dominant velocity gradient,  $\mathcal{L}_m$  can usually be related to a length scale across the shear layer (in the  $z$ -coordinate direction). In the important case of channel flows, this might be chosen as proportional to the distance  $z$  from the bed in the near-bed (“inner”) region, i.e.,  $\mathcal{L}_m \propto z$ , or the flow depth,  $h$ , in the “outer” bulk-flow region, i.e.,  $\mathcal{L}_m \propto h$ .

For plane uniform flows, with  $\mathcal{L}_m \propto z$  or  $\mathcal{L}_m = \kappa z$ , where the von Kármán constant,  $\kappa$ , is the proportionality constant, and also  $\tau_{13} \approx \rho u_*^2$  (from Eq. 16-18 in the near-bed region and neglecting viscous effects), the momentum equation in the streamwise direction becomes

$$-\overline{u' w'} = \nu_t \frac{d\bar{u}}{dz} = \left( \kappa z \frac{d\bar{u}}{dz} \right)^2 = u_*^2. \quad (16-26)$$

The specification of  $\nu_t$  has thus closed the system of equations, permitting a solution for the velocity profile. Simplification and then integration of Eq. (16-26) yield the well-known logarithmic law for the velocity profile in the near-bed region

(see Chapter 2). In spite of the apparent relation to molecular transport, a detailed mechanistic analogy between turbulent and molecular transport cannot be sustained. As previously noted, a key assumption of molecular momentum transport is that the relevant length scale for molecular viscosity, the mean free path, is much smaller than the length scale over which the strain rate or velocity gradient is defined. On the other hand,  $\mathcal{L}_m$  is of the same order of magnitude as the length scale over which the velocity gradient is defined, and hence the mixing length model cannot be justified by analogy with molecular transport. As has been emphasized by Tennekes and Lumley (1972), the success of the mixing-length model results from the existence of a single dominant velocity and a single dominant length scale, from which an eddy viscosity can be unambiguously formulated from dimensional considerations. In this case,  $u_*$  and  $z$  are identified as the relevant velocity and length scales, and consequently,  $\nu_t \propto u_* z$ , which when substituted in to Eq. (16-26) also reproduces the logarithmic velocity profile.

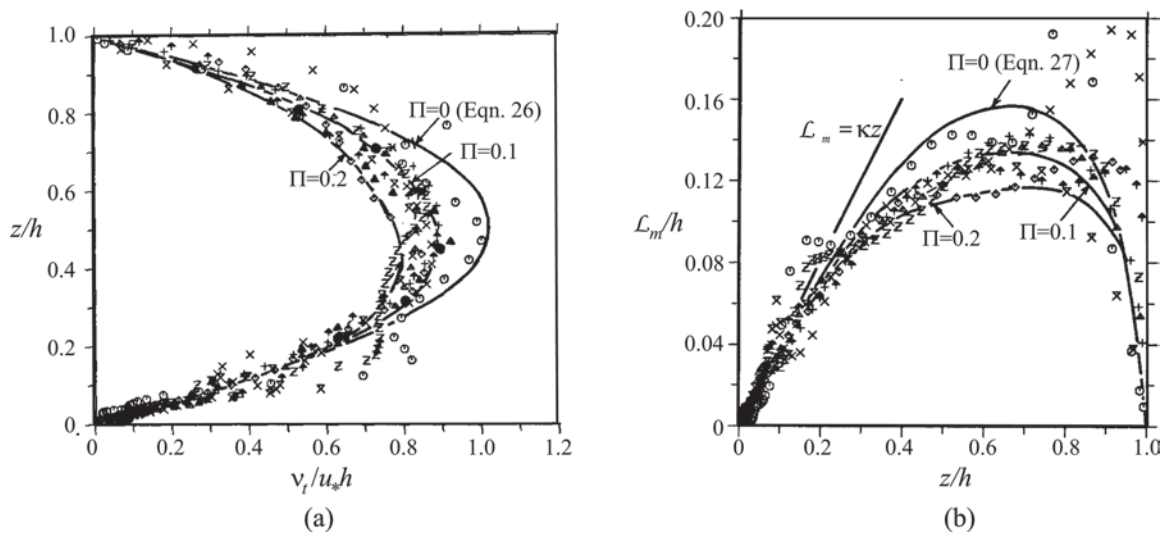

The specification,  $\nu_t = \kappa u_* z$ , can only be justified for the near-bed region (but outside of the viscous region). This exemplifies the problem of defining the turbulent length scale in a mixing-length model. Multiple length scales are important in a channel flow; e.g., the viscous length scale,  $\nu/u_*$ , in the viscous sublayer, and the flow depth,  $h$ , in addition to  $z$ , and the classic mixing-length model of  $\mathcal{L}_m \propto z$  can be applied only in the intermediate layer, where the local length scale is dominant. To develop an expression for  $\nu_t$  that may be extended to the outer region, a somewhat circular approach is conventionally taken. Equation (16-26) is first extended to  $\nu_t (\partial \bar{u} / \partial z) = u_*^2 (1 - z/h)$ . The logarithmic velocity profile is taken as an empirical observation, such that  $\partial \bar{u} / \partial z = u_* / \kappa z$ . It follows then that

$$\nu_t = u_*^2 \left( \frac{1 - z/h}{d\bar{u}/dz} \right) = \kappa u_* z (1 - z/h) \quad (16-27)$$

which is the classic parabolic eddy viscosity for open-channel flows, on which the traditional Ippen-Rouse suspended sediment concentration profile (see Chapter. 2) is based. The measurements of Nezu and Rodi (1986) agree reasonably well with this expression, though agreement could be improved with a more appropriate velocity model (Fig. 16-4(a)) through the addition of a wake component, characterized by a wake coefficient,  $W$ , to the logarithmic velocity profile. Equation (16-27) is also the basis of the constant-eddy-viscosity depth-averaged models, since depth-averaging of Eq. (16-27) yields  $\kappa u_* h/6$ . With similar reasoning, the following expression for the mixing length,  $\mathcal{L}_m$ , can be obtained:

$$\mathcal{L}_m = \kappa z [1 - (z/h)]^{1/2} \quad (16-28)$$

Again, measurements show reasonable agreement with Eq. (16-28) (Fig. 16-4(b)). Equation (16-27) has also been applied to unsteady oscillating boundary flows under waves,

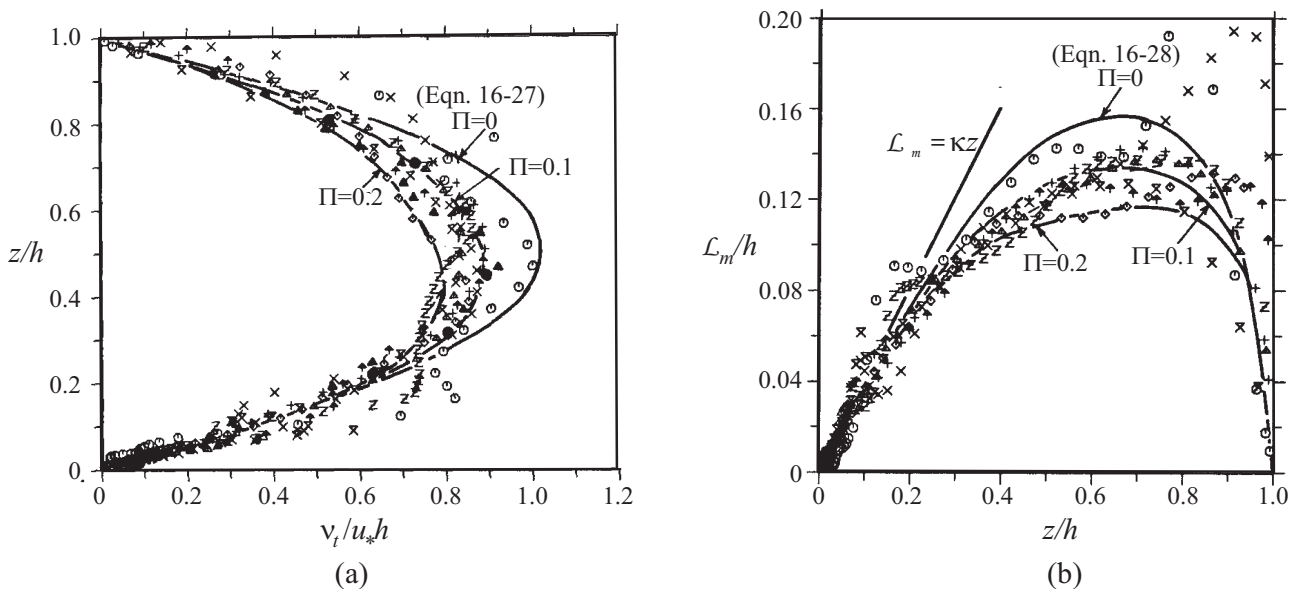

**Fig. 16-4.** (a) Nondimensional eddy viscosity,  $\nu_t/u_*h$ , and (b) mixing length,  $\mathcal{L}_m/h$ , in a clear-water flow in a straight open channel (adapted from Nezu and Rodi 1986). Symbols are measurements; lines are theory based on a model mean velocity profile, incorporating a log-law and a wake component, with  $\Pi$  being the wake coefficient in the model velocity profile.

with  $u_*$  and  $h = \delta_w$ , where  $\delta_w$  is the wave boundary layer thickness, both of which are allowed to vary in time (Fredsoe et al. 1985).

**16.4.2.3 Turbulence Modulation and the Stably Stratified-Flow Analogy** The effect of the suspension on the turbulent flow, sometimes termed turbulence modulation or modification, has been discussed extensively since the experimental work of Vanoni (1946), which showed a distinct steepening of the velocity profile in sediment-laden flows compared to

profiles in clear-water flows. The traditional approach has been to model this effect by a reduced mixing length, via a reduced  $\kappa$ , and to develop a correlation for  $\kappa$ , e.g., as a function of a ratio of the energy required to suspend particles to the total energy dissipated by the flow (Einstein and Chien 1955). Figure 16-5 compares the eddy viscosity and mixing length for clear-water and suspension flows, plotted in semilogarithmic coordinates to emphasize the near-bed region. There is much scatter, but the evidence, if any, for a reduced eddy viscosity and mixing length

**Fig. 16-5.** (a) Nondimensional eddy viscosity,  $\nu_t/u_*h$ , and (b) mixing length,  $\mathcal{L}_m/h$ , in a sediment-laden flow in a straight open channel (estimated from the data of Lyn 1988; open symbols: clear-water flow, filled symbols: sediment-laden flow).

is primarily in the inner region. The results of Cellino and Graf (1999) for a case with a smaller sand size and heavier load indicate a more substantial reduction in eddy viscosity over a more extensive region.

Only two models explicitly using the mixing-length approach are here discussed. Like the traditional model, both may be interpreted as resulting in a reduced mixing length, but whereas the traditional model assumes a constant proportional reduction over the entire depth, the two models propose a reduction dependent on local suspension conditions, either on the local concentration (van Rijn 1984c) or the local concentration gradient (Smith and McLean 1977). The van Rijn model modifies the standard eddy viscosity for flows without sediment,  $(\nu_t)_0$ , by a function,  $\phi$ , dependent on the local mean suspended sediment concentration,  $\bar{c}$ , to obtain an eddy viscosity for a suspension,  $(\nu_t)_s$ , as follows:

$$(\nu_t)_s = \phi(\nu_t)_0 = \left[ 1 - 2 \left( \frac{\bar{c}}{c_0} \right)^{0.4} + \left( \frac{\bar{c}}{c_0} \right)^{0.8} \right] (\nu_t)_0 \quad (16-29)$$

where  $c_0$  is the maximum possible volumetric sediment concentration, taken to be 0.65. The physical basis for Eq. (16-29) is obscure, and van Rijn (1984c) admitted that it “does not give optimal agreement for the entire profile,” conjecturing that the expression for  $\phi$  is “somewhat too simple.”

*Example.* As has been noted, an analogy between a sediment-laden flow and the flow of a variable-density fluid has been drawn frequently by numerous researchers (e.g., Barenblatt 1953; Lumley 1973). For uniform flow, with variations only in the vertical, the effective density of the suspension,  $\rho_m$  (Eq. 16-3), decreases away from the bed as  $\bar{c}$  decreases with increasing  $z$ . Vertical turbulent momentum transport is therefore inhibited relative to the non-stratified (neutral) case because fluid of vertically varying density displaced from its original elevation experiences a restoring buoyancy force acting to return it to its original elevation: i.e., the flow is stably stratified. The reduced vertical transport results in a velocity profile steeper than the neutral case, which, as noted above, is observed in sediment-laden flows. The analogy is attractive not only for its intuitive appeal, but also because it allows the application of results from a large literature on turbulent, stably (thermally or saline) density-stratified flows in atmospheric and oceanographic applications (Monin and Yaglom 1971; Turner 1973).

Smith and McLean (1977) proposed a density-stratified-flow model for sediment-laden flows, in which the effective mixing length is reduced, but, unlike the van Rijn model, the reduction is correlated with a suspension (gradient) Richardson number,  $Ri_s$ , defined as

$$Ri_s = - \frac{g}{\rho_{\text{ref}}} \frac{\partial \rho_m / \partial z}{(\partial \bar{u} / \partial z)^2} = - g(s-1) \frac{\partial \bar{c} / \partial z}{(\partial \bar{u} / \partial z)^2} \quad (16-30)$$

where  $\rho_{\text{ref}}$  has been taken to be  $\rho$ . Barenblatt (1996) has suggested that  $Ri_s$  be called the Kolmogorov number. As will become clearer below, for stable stratification,  $Ri_s > 0$  can be interpreted as being proportional to the ratio of the local rate of energy expenditure needed to overcome a stable stratification and the local rate of production of  $k$  (similar to the traditional Einstein–Chien (1955) model). In the Smith–McLean model,

$$(\nu_t)_s = \left[ 1 - \alpha_m \left\{ \frac{\epsilon_s}{(\nu_t)_s} \right\} Ri_s \right] (\nu_t)_0 \quad (16-31)$$

where  $\alpha_m$  is a model constant. Here,  $\epsilon_s / (\nu_t)_s$  is seen as equivalent to  $1 / (\sigma_t)_s$ , but, contrary to the usual practice where  $(\sigma_t)_s$  is assumed constant in space (e.g., as in the van Rijn model),  $\epsilon_s / (\nu_t)_s$  can be expressed as a spatially varying function in terms of other model parameters. Villaret and Trowbridge (1991) analyzed the performance of this model (actually a perturbation solution of this model, since, for most of the laboratory flows examined,  $Ri_s \ll 1$ ) in fitting an extensive series of laboratory measurements from various studies. They found some support for the stratified-flow model, but their results indicate that  $\alpha_m$  might vary considerably, detracting from one of the main advantages of this model.

In contrast to the traditional approach, in which the solution for the velocity profile is effectively decoupled from the solution for the suspended sediment concentration profile, both the van Rijn and the Smith–McLean models require a fully coupled treatment, in which the relevant momentum and sediment equations are solved simultaneously. These two models may be expressed respectively as follows:

#### Van Rijn model:

$$[(\nu_t)_0 \phi] \frac{d\bar{u}}{dz} = u_*^2 \left( 1 - \frac{z}{h} \right) \quad (16-32a)$$

$$[(\beta_s)_{vR} (\nu_t)_0 \phi] \frac{d\bar{c}}{dz} = - w_s \bar{c} \quad (16-32b)$$

#### Smith–McLean model:

$$\begin{aligned} (\nu_t)_s \frac{d\bar{u}}{dz} &= (\nu_t)_0 \left[ 1 - \alpha_m \left\{ \frac{\epsilon_s}{(\nu_t)_s} \right\} Ri_s \right] \frac{d\bar{u}}{dz} \\ &= u_*^2 \left( 1 - \frac{z}{h} \right) \end{aligned} \quad (16-33a)$$

$$\varepsilon_s \frac{d\bar{c}}{dz} = (v_t)_0 \left[ 1 - \alpha_s \left\{ \frac{\varepsilon_s}{(v_t)_s} \right\} \text{Ri}_s \right] \frac{d\bar{c}}{dz} \quad (16-33b)$$

$$= -w_s \bar{c}$$

where  $\alpha_s$  is another model constant.

A comparison of the predictions of the van Rijn and Smith-McLean models with two measured velocity and concentration profiles for flows under equilibrium-bed (capacity or saturated) conditions is given in Fig. 16-6. The experimental parameters are given in Table 16-1. In these computations, different models of  $(v_t)_0$  were used. The  $(v_t)_0$  of van Rijn (1984b) was used for the van Rijn model, whereas the  $(v_t)_0$  of Villaret and Trowbridge (1991) was used for the Smith-McLean model. Bottom boundary conditions were based on measured velocity and concentration, and  $\alpha_m$  and  $\alpha_s$  were taken as 6.9 and 9.2, as specified in McLean (1992). According to the classification scheme of Soulsby and Wainwright (1987), based on  $u_*$  and  $d$ , both of the experiments should exhibit some stratification effects ( $u_* \approx 4$  cm/s and  $d_{50} \approx 0.18$ – $0.19$  mm). Estimates of local flux Richardson numbers from the measurements indicate values exceeding  $O(0.01)$  in both experiments. Both models perform reasonably well for both the velocity and concentration data of Barton and Lin, although slight systematic deviation of the data from predictions might be seen. The van Rijn model does somewhat better in predicting concentrations than the Smith-McLean model, which underestimates concentrations in the outer flow ( $z/h = O(1)$ ), due to the reduced mixing caused by stable stratification. The Barton-Lin data were used in the calibration of the van Rijn model, and so good performance might be expected. Both models do comparatively poorly for the Lyn velocity data, which exhibit a much more pronounced deviation from the log-law profile that is, however, confined to the near-bed region. At the measured concentration values, both models predict profiles quite close to the classic log-law profile. Hence when the measured velocity at the lowest point is imposed as a boundary condition, there is notable disparity between measured and predicted profiles. Nevertheless, the Lyn concentration data are quite well reproduced by the Smith-McLean model, whereas the van Rijn model predictions are substantially in error, attributable to the overly large  $\beta_s$  value given by Eq. (16-21) and the associated enhanced vertical sediment transport.

The problem of predicting the velocity and concentration profiles in a suspension flow over a nominally plane bed is still largely unresolved. Two other related aspects of uniform sediment-laden flows over plane beds shed light on appropriate models, namely flow resistance, e.g., parameterized by a friction factor,  $f_{DW}$ , and the root mean square of vertical velocity fluctuations,  $\sqrt{w'^2}$ . In their purest (and simplest) form, the stably stratified-flow models predict

**Table 16-1 Experimental Parameters for Equilibrium Plane-Bed Flows**

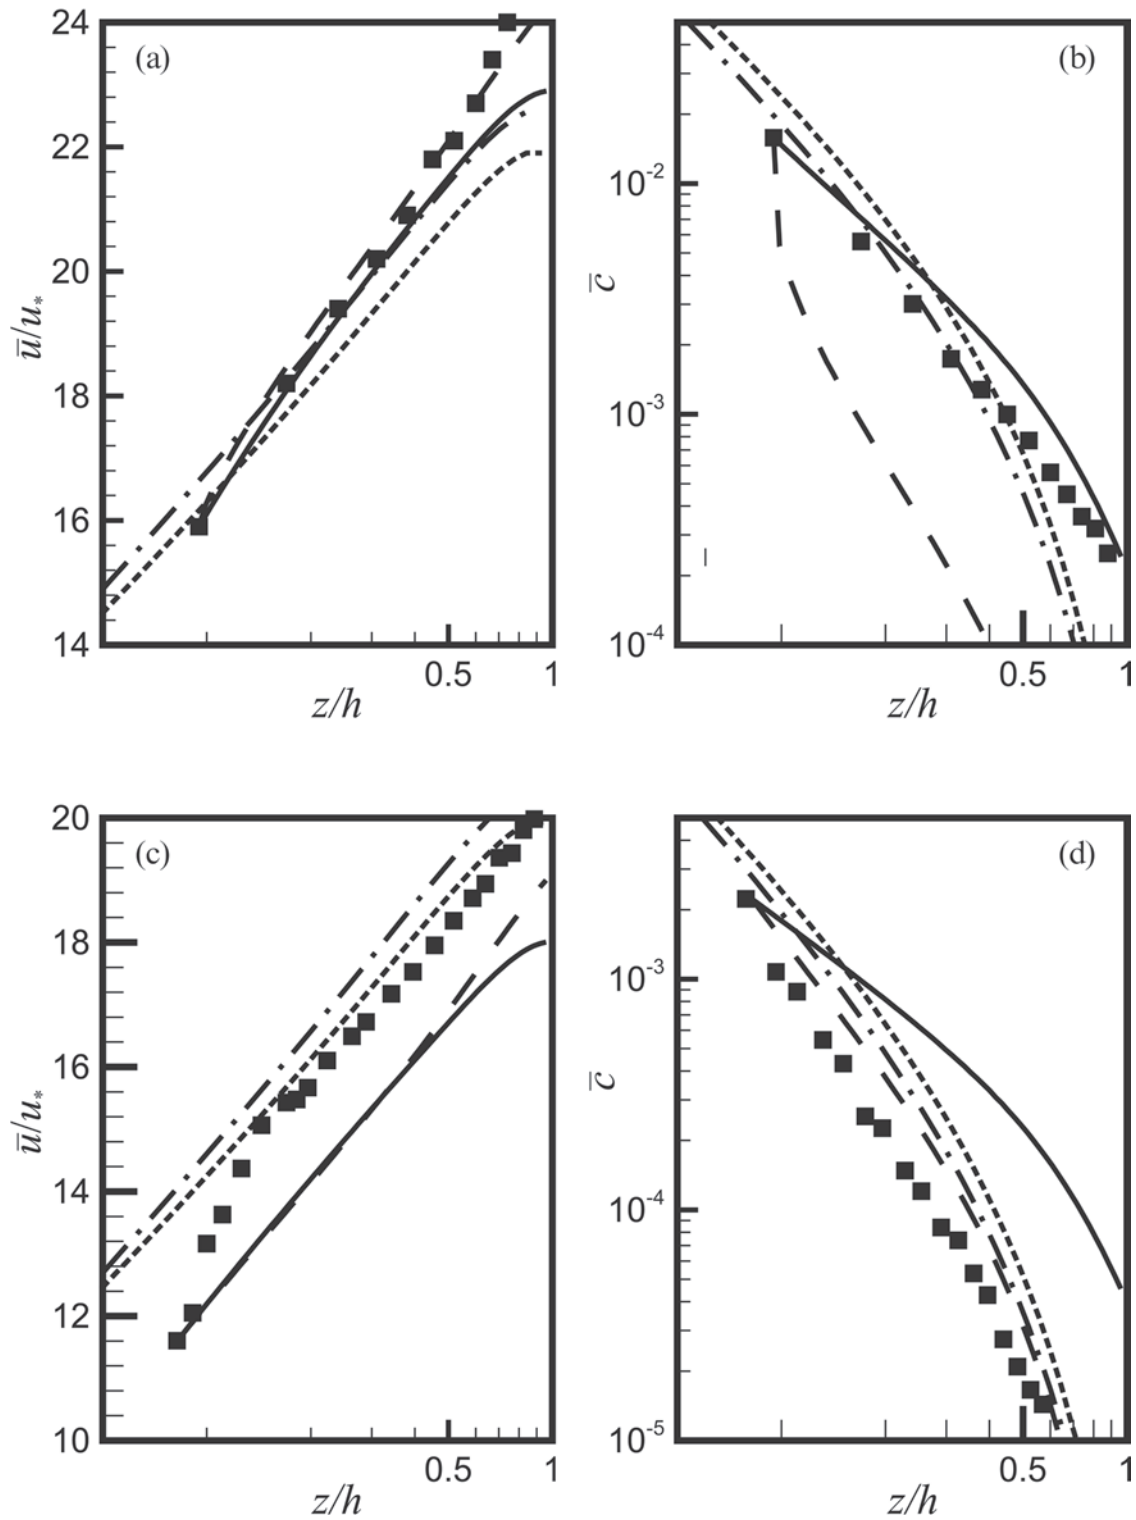

Parameter	Barton and Lin (1955) Run 36	Lyn (1988) Run 1957EQ
Median sediment size, $d_{50}$ (mm)	0.18	0.19
Depth, $h$ (cm)	16.2	5.7
Shear velocity, $u_*$ (cm/s)	5.6	3.95
$\bar{c}(z/h = 0.1) (\times 10^{-3})$	3.1	1.1
Slope, $S (\times 10^{-3})$	2.10	2.95
$R_* = u_* h / \nu (\times 10^3)$	9.1	2.3
$F = U / \sqrt{g h_0}$	0.21	0.90

a decrease in  $f_{DW}$  (e.g., Itakura and Kishi 1980; McLean 1992) and a reduction in  $\sqrt{w'^2}$  in suspension flows. The choice of an appropriate benchmark or reference for comparison is important, because, unlike stratification due to temperature or salinity, density stratification in sediment-laden flows may be only one of several factors influencing flow characteristics. In the case of flow resistance, if the basis of comparison is a clear-water flow of the same depth and a roughness height equal to the *median grain size*,  $d_{50}$ , as is commonly done in clear-water flows, then the empirical evidence argues *against* this prediction of the stably stratified flow models (see the discussion below of boundary conditions for further details). In the case of  $\sqrt{w'^2}$ , the laser-Doppler studies of Lyn (1993) and Bennett et al. (1998) indicate either no significant effect or indeed the opposite effect, namely, a slight increase in, contrary to that expected from stably stratified-flow analogies. On the other hand, Cellino and Graf (1999), using an acoustic Doppler technique, did observe a marked reduction in  $\sqrt{w'^2}/\mu_*$ , and so the experimental evidence is at present inconclusive. Measurements of turbulence characteristics in the most interesting flow region, i.e., the near-wall region, in a sediment-laden flow over a plane sand bed in equilibrium with the suspension present very difficult challenges to all experimental techniques, and hence any such measurements should be considered with some caution.

The stably stratified flow analogy has been discussed here within the context of mixing-length models, but similar comments would also apply to the more sophisticated models discussed below, since they, as will be seen, may often be simplified to essentially mixing-length models for uniform-flow problems.

**16.4.2.4 Limitations of Mixing-Length Models** The success of the mixing-length model rests on the dominance of a single velocity and a single length scale, which also, as will be seen below, reflects a local equilibrium between production and dissipation of turbulent kinetic energy.

**Fig. 16-6.** Comparison of model predictions for steady uniform sediment-laden flows of (a) and (c) dimensionless velocity,  $\bar{u}/u_*$ , and (b) and (d) concentration,  $\bar{c}$ . Data (filled symbols) in (a) and (b) from Barton and Lin (1955), Run 36; data in (c) and (d) from Lyn (1988), Run 1957EQ. — : van Rijn model; - - - : Smith-McLean model; ... : standard  $k-\epsilon$  model; - · - :  $k-\epsilon$  model including buoyancy.

In multidimensional problems with strong spatial variation in more than one coordinate direction, the mixing-length model will likely perform poorly. Generalizations of Eq. (16-25) to multidimensional flows have been proposed, but the practical difficulty of specifying  $\mathcal{L}_m$  for complicated flows remains. Nonequilibrium problems where history/transport effects are important will also present difficulties because of the time required to relax to an equilibrium state, which introduces another time (or velocity) scale into the problem. On the other hand, a great deal of practical experience has been accumulated with such models in a wide variety of problems, the computational demands are attractive, and reasonable predictions can be obtained with some degree of experience and judgment on the part of the modeler. The problem of turbulence modulation does illustrate the fundamental weakness of mixing-length models (as well as other more sophisticated models) in that the appropriate mixing length when the flow is sediment-laden is not clear, even for the simplest case of a fully developed uniform wall-bounded flow.

### 16.4.3 The Specification of the Eddy Viscosity: One-Equation Models

An algebraic specification of the eddy viscosity, as in zero-equation models, may be interpreted as implicitly assuming a local equilibrium where  $v_t$  is determined entirely by local flow conditions. Nonequilibrium effects imply that the flow characteristics at a point may be significantly affected by the history of fluid parcels passing through that point. Zero-equation turbulence models are poorly suited to model such effects in any general way. An alternative approach seeks to include these effects in a differential rather than algebraic specification of the velocity scale, the length scale, or both. In one-equation models, a single differential equation for a turbulence quantity is formulated in addition to the momentum equations. Most frequently, the quantity chosen is the turbulent kinetic energy,  $k$ , the square root of which provides a velocity scale.

#### 16.4.3.1 The Equation for Turbulent Kinetic Energy

An exact equation for  $k$  can be derived from the Navier-Stokes equations (Hinze 1975; Kundu 1990):

$$\begin{aligned} \frac{Dk}{Dt} &= \frac{\partial k}{\partial t} + \frac{\partial(\bar{u}_j k)}{\partial x_j} \\ &= -\frac{\partial}{\partial x_j} \left( \frac{1}{2} \overline{u'_i u'_i u'_j} + \frac{1}{\rho_{\text{ref}}} \overline{u'_j p} - 2\nu \overline{u'_i s'_{ij}} \right) \\ &\quad + P_k - \epsilon + G_k \end{aligned} \quad (16-34)$$

where

$$s'_{ij} = (\partial u'_i / \partial x_j + \partial u'_j / \partial x_i) / 2 \text{ fluctuating strain-rate tensor.}$$

The rate of production,  $P_k$ , of  $k$  by the interaction of the Reynolds stresses with the mean strain rate is given by

$$\begin{aligned} P_k &= -\overline{u'_i u'_j} S_{ij} = -\overline{u'_i u'_j} \left[ \frac{1}{2} \left( \frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right) \right] \\ &= -\overline{u'_i u'_j} \frac{\partial \bar{u}_i}{\partial x_j} \end{aligned} \quad (16-35)$$

(see Appendix I, Eq. (16-82) for an expanded version of Eq. (16-35)). The rate of dissipation,  $\epsilon$ , of  $k$  by viscosity can be expressed as

$$\begin{aligned} \epsilon &= 2\nu \overline{s'_{ij} s'_{ij}} \\ &= \frac{\nu}{2} \overline{\left( \frac{\partial u'_i}{\partial x_j} + \frac{\partial u'_j}{\partial x_i} \right) \left( \frac{\partial u'_i}{\partial x_j} + \frac{\partial u'_j}{\partial x_i} \right)} \\ &= \nu \overline{\left( \frac{\partial u'_i}{\partial x_j} + \frac{\partial u'_j}{\partial x_i} \right) \frac{\partial u'_i}{\partial x_j}}. \end{aligned} \quad (16-36)$$

The last term in Eq. (16-34),  $G_k$ , represents any other source or sink of  $k$  that may be due to additional forces, e.g., due to the presence of particles. If buoyancy effects are important, then

$$G_k = (G_k)_\rho = \frac{g_i}{\rho_{\text{ref}}} \overline{u'_i \rho'}. \quad (16-37)$$

The ratio  $(G_k)_\rho / P$  is termed the flux Richardson number. If, as has been assumed in several models, the sole effect of particles in suspension on the  $k$ -budget is analogous to that caused by buoyancy, then

$$\frac{g_i}{\rho_{\text{ref}}} \overline{u'_i \rho'} = g_i (s - 1) \overline{u'_i c'}. \quad (16-38)$$

Because Eq. (16-34) contains extra correlation terms (the triple velocity correlation,  $\overline{u'_i u'_i u'_j}$ , and the pressure-velocity correlation,  $\overline{u'_j p'}$ , as well as  $\epsilon$ ) that are not known, it is not immediately useful. For a one-equation model based on Eq. (16-34), the length scale,  $\mathcal{L}$ , is specified algebraically, and so the extra correlation terms must be expressed in terms of  $k$  and/or  $\mathcal{L}$  for a closed system of equations. The terms involving the triple velocity and pressure-velocity correlations are interpreted as turbulent “diffusive” transport terms that do not increase or decrease the overall level of  $k$  but only redistribute  $k$  over the flow region of interest. A diffusion model for these terms together can be motivated, namely,

$$\frac{1}{2} \overline{u'_i u'_i u'_j} + \frac{1}{\rho_{\text{ref}}} \overline{u'_j p'} = -\frac{\nu_t}{\sigma_k} \frac{\partial k}{\partial x_j} \quad (16-39)$$

where the turbulent Schmidt number for  $k$ ,  $\sigma_k$ , is defined by Eq. (16-39) and is usually assumed constant. The model for the rate of dissipation (sink) term,  $\epsilon$ , is obtained from a dimensional scaling argument as

$$\epsilon = c_D \frac{k^{3/2}}{\mathcal{L}} \quad (16-40)$$

with  $c_D$  an empirically determined model constant. With these model choices, the inclusion of a buoyancy effect for suspensions, and the neglect of the viscous diffusive term (justifiable for high- $\text{Ri}$  applications), the equation for  $k$  becomes

$$\begin{aligned} \frac{Dk}{Dt} &= \frac{\partial k}{\partial t} + \frac{\partial(\bar{u}_j k)}{\partial x_j} \\ &= \frac{\partial}{\partial x_j} \left( \frac{v_t}{\sigma_k} \frac{\partial k}{\partial x_j} \right) + v_t \left( \frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right) \frac{\partial \bar{u}_i}{\partial x_j} \\ &\quad - g_i (s-1) \frac{v_t}{(\sigma_t)_s} \frac{\partial \bar{c}}{\partial x_i} - c_D \frac{k^{3/2}}{\mathcal{L}} \end{aligned} \quad (16-41)$$

where the standard eddy viscosity (Eq. (16-14)) or diffusivity (Eq. (16-19)) model has been applied to eliminate the Reynolds stress term,  $-\overline{u'_i u'_j}$ , and the buoyancy flux term,  $\overline{u'_i c'}$ . In this form, the ratio,  $(G_k)_\rho/P$ , becomes proportional to the gradient Richardson number,  $\text{Ri}_s$ , already introduced in the discussion of zero-equation models. The solution of Eq. (16-41) for  $k$  provides the required  $\mu$ , and so  $v_t$  is evaluated as

$$v_t = c'_\mu \sqrt{k} \mathcal{L} \quad (16-42)$$

where  $c'_\mu$  is a model constant. The choice of  $c_D$  and  $c'_\mu$  is constrained by the requirement for consistency in the case of local equilibrium, as will be elaborated below.

**16.4.3.2 Local Equilibrium and Mixing-Length Models** In Eq. (16-34) or (16-41), the left-hand side of the equation and the diffusive term (the first term on the right-hand side of the equation) represent the transport terms that become important in nonequilibrium problems. In cases where these effects may be neglected, i.e., those for which the mixing-length model might be appropriate, Eq. (16-41) reduces to

$$\begin{aligned} 0 &= P_k + (G_k)_\rho - \epsilon \\ &= v_t \left( \frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right) \frac{\partial \bar{u}_i}{\partial x_j} \\ &\quad + g(s-1) \frac{v_t}{(\sigma_t)_s} \frac{\partial \bar{c}}{\partial z} - c_D \frac{k^{3/2}}{\mathcal{L}}. \end{aligned} \quad (16-43)$$

*Example.* For the plane uniform-flow case, Eq. (16-43) becomes

$$\begin{aligned} P_k + (G_k)_\rho &= \epsilon \quad \text{or} \quad v_t \left( \frac{d\bar{u}}{dz} \right)^2 + g(s-1) \frac{v_t}{(\sigma_t)_s} \frac{\partial \bar{c}}{\partial z} \\ &= c_D \frac{k^{3/2}}{\mathcal{L}} \end{aligned} \quad (16-44)$$

which, together with Eq. (16-42), becomes

$$\begin{aligned} v_t &= \sqrt{\frac{(c'_\mu)^3}{c_D}} \mathcal{L}^2 \frac{d\bar{u}}{dz} \left[ 1 - \frac{1}{(\sigma_t)_s} \text{Ri}_s \right]^{1/2} \\ &= (v_t)_0 \left[ 1 - \frac{1}{(\sigma_t)_s} \text{Ri}_s \right]^{1/2} \end{aligned} \quad (16-45)$$

where

$(v_t)_0$  = eddy viscosity in the absence of buoyancy effects.

If  $\text{Ri}_s = 0$ , then Eq. (16-45) reproduces the standard model. If  $\mathcal{L}$  is taken as  $\kappa z$ , then for consistency with the mixing-length model, the constants  $c'_\mu$  and  $c_D$  must be chosen so that  $(c'_\mu)^3/c_D = 1$ , and cannot be chosen independently. For nonzero but small  $\text{Ri}_s$ ,  $[1 - \text{Ri}_s/(\sigma_t)_s]^{1/2}$  can be expanded in a power series in  $\text{Ri}_s$ , and a relationship of the same form as Eq. (16-31) is obtained. The inclusion of buoyancy effects adds another relevant velocity (or length) scale, e.g.,  $\sqrt{g(s-1)\mathcal{L}^2(\partial \bar{c}/\partial z)}$ , to the problem, and so introduces an ambiguity into the mixing-length model, which, as was argued above, relies on the dominance of a single velocity and a single length scale. An interesting alternative approach was taken by Barenblatt (1953; reported in Monin and Yaglom 1971 and in Barenblatt 1996), who sought similarity solutions to Eq. (16-44). With  $k \sim u_*^2$ ,  $\mathcal{L} \sim z$ , and  $v_t \sim \sqrt{k} \mathcal{L} \sim u_* z$ , these could be found when  $\bar{c} \sim 1/z$  and  $\partial \bar{u}/\partial z \sim 1/z$ , equivalent to a constant  $\text{Ri}_s$ , though the implications, practical or theoretical, of this result remain unclear.

#### 16.4.3.3 Applications of a One-Equation Model

Because of their intermediate nature between the simpler zero-equation model and the more complete two-equation model, one-equation models not making the local-equilibrium assumption have not been as commonly used in hydraulic or sediment-transport engineering as either of the other two model types. Two examples may, however, be cited. In a study of sand-wave evolution due to sediment transport, Johns et al. (1990) applied a quasi-two-dimensional model based on Eqs. (16-41) and (16-42) including buoyancy effects. Nonequilibrium transport effects might be expected because of the streamwise spatial variations in flow over bed

forms. All turbulent Schmidt numbers were assumed to be unity, whereas  $c_D = (c'_\mu)^3 = 0.15$ , with  $c'_\mu = 0.53$ . The length scale was determined from a von Kármán type relationship (see the discussion in Rodi 1993),

$$\mathcal{L} = \frac{-\kappa \sqrt{k} / \mathcal{L}}{d(\sqrt{k} / \mathcal{L}) / dz} \quad (16-46)$$

which is not algebraic, but is not specified by means of a partial differential transport equation. Some of their numerical results are briefly mentioned in Section 16.5.1. The second example is due to Li and Davies (1996), who were interested in predicting sediment transport in combined wave-current flows. In this case, nonequilibrium effects might be expected because of the unsteadiness in problems with surface waves. The stratification analogy was also made, so that  $(G_k)_\rho$  was included. The variable  $(\sigma_r)_s$  was assumed to be unity, but  $\sigma_k = 1.37$ , while  $c_D = (c'_\mu)^3 = 0.097$ , corresponding to  $c'_\mu = 0.46$ . Wilcox (1998) reported on early one-equation models with values of  $c_D$  taken in the range from 0.07 to 0.09 and with  $c'_\mu = 1$ , where Rodi (1993) indicated that the product  $c'_\mu c_D \approx 0.08$ . The length scale, motivated by Eq. (16-28), was given by

$$\mathcal{L} = \left(1 - \frac{z}{h}\right)^{1/2} \kappa \sqrt{k} \left(z_0 k_0^{-1/2} + \int_{z_0}^z k^{-1/2} d\eta\right) \quad (16-47)$$

where  $z_0$  is a bottom roughness scale. Some results with this model will be given in Section 16.5.4. Further developments of this model are sketched in Villaret and Davies (1995) and tested on even simpler steady unidirectional flows, with still rather mixed results, as will be seen in Section 16.4.7. Both Eqs. (16-46) and (16-47) differ from classic mixing-length specifications and attempt to incorporate information obtained in the solution of  $k$  in the specification of  $\mathcal{L}$ , so that  $\Lambda$  can vary in both space and time depending on flow conditions, as characterized by the local value of  $k$ . In particular, buoyancy effects that affect  $k$  will therefore also affect  $\mathcal{L}$ .

**16.4.3.4 Limitations of One-Equation Models** The current verdict on one-equation models in comparison to mixing-length models remains rather negative in that the improvements in predictions tend to be rather marginal (Bradshaw 1997; Wilcox 1998). As with the mixing-length model, the main problem lies in the length-scale specification, which becomes increasingly difficult in complex flow problems. In both of the above examples, the length-scale specification was guided by results for a plane-bed uniform-flow case; in more complicated flows, the specification is more difficult to motivate. This problem can be circumvented by formulating a transport equation directly for the eddy viscosity, rather than for  $k$ , such that a second equation for the length scale is not necessary. The model of Spalart and Allmaras (1992; see also the discussion in Spalart 2000), following this logic, has revived interest in one-equation

models for aeronautical problems, but does not seem to have been adopted so far in hydraulics or sediment transport, and so is not discussed further.

#### 16.4.4 The Specification of the Eddy-Viscosity: Two-Equation Models

If the logic leading to the development of the  $k$ -equation is followed, then the problem of determining the relevant length scale can be resolved by formulating an additional transport equation for a quantity that would, possibly in combination with  $k$ , provide a length scale. Rodi (1993) has noted that any quantity of the form  $k^m \mathcal{L}^n$ , where  $m$  and  $n$  are arbitrary exponents, would lead to dimensionally consistent equations of the same form. The presence of  $\epsilon$  in the  $k$  equation as an unknown variable leads naturally to its choice as the quantity for which a transport equation is developed. An exact equation for  $\epsilon$  can be derived from the Navier-Stokes equations, but its dominant correlation terms are impossible to measure in the laboratory (though they could be evaluated from results of numerical simulations), so model proposals cannot rely on experimental observations for guidance (Launder 1984; Wilcox 1998). Further, because viscous dissipation occurs on the smallest scales, the relevance of the exact terms for specifying  $\mathcal{L}$  is questionable, which is characteristic of the larger energy-carrying scales that determine the level of overall dissipation (recall the qualitative discussion of dissipation in Section 16.2.1). It has therefore been conventionally preferred to formulate a surrogate equation for  $\epsilon$  along the lines of the  $k$ -equation, based primarily on dimensional analysis and appropriate asymptotic behavior, e.g., in the ideal case of homogeneous high- $R$  turbulence (Launder 1984). The strict identification of  $\epsilon$  with the rate of dissipation of  $k$ , however, becomes more tenuous.

**16.4.4.1 The Equation for  $\epsilon$**  The standard model equation for  $\epsilon$ , incorporating the eddy viscosity model and, as usual, neglecting viscous transport terms in high- $R$  flows, is thus of the form

$$\begin{aligned} \frac{D\epsilon}{Dt} &= \frac{\partial \epsilon}{\partial t} + \frac{\partial(\bar{u}_j \epsilon)}{\partial x_j} \\ &= \frac{\partial}{\partial x_j} \left( \frac{\nu_t}{\sigma_\epsilon} \frac{\partial \epsilon}{\partial x_j} \right) + P_\epsilon - D_\epsilon + G_\epsilon \end{aligned} \quad (16-48)$$

where  $\sigma_\epsilon$  is the turbulent Schmidt number for the diffusive transport of  $\epsilon$ . The production-of-dissipation term,  $P_\epsilon$ , is necessary because, if  $k$  is being produced and the level of  $k$  increases in time, then the level of  $\epsilon$  must also increase in order ultimately to limit the level of  $k$ . A simple model of  $P_\epsilon \propto P_k$  may therefore be motivated, but for dimensional consistency, a multiplicative factor of  $\epsilon/k$ , which may be interpreted as a turbulence frequency, is needed, such that

$$\begin{aligned}
P_\epsilon &= c_{1\epsilon} \frac{\epsilon}{k} P_k \\
&= c_{1\epsilon} \left( \frac{\epsilon}{k} \right) \left[ \nu_t \left( \frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right) \right] \frac{\partial \bar{u}_i}{\partial x_j}
\end{aligned} \quad (16-49)$$

where

$c_{1\epsilon}$  = a model constant.

The destruction-of-dissipation term,  $D_\epsilon$ , is similarly modeled as

$$D_\epsilon = c_{2\epsilon} \left( \frac{\epsilon}{k} \right) \epsilon = c_{2\epsilon} \frac{\epsilon^2}{k} \quad (16-50)$$

where

$c_{2\epsilon}$  = another model constant.

Like the corresponding term in the  $k$ -equation, the last term in Eq. (16-48),  $G_\epsilon$ , reflects the effect on  $\epsilon$  of other forces or strains. In the case of buoyancy effects,  $G_\epsilon = (G_\epsilon)_\rho$ , the modeling of which, however, still remains open. That a term similar to  $P_\epsilon$  but proportional to  $(G_\epsilon)_\rho$  is desirable is commonly accepted, particularly where buoyancy production is concerned, i.e., in *unstable* stratification. Rodi (1993) recommended that

$$(G_\epsilon)_\rho = c_{1\epsilon} \frac{\epsilon}{k} [(G_k)_\rho (1 + c_{3\epsilon} R i_s) + c_{3\epsilon} R i_s P_k] \quad (16-51)$$

where

$c_{3\epsilon}$  = yet another model constant.

More often (Burchard and Baumert 1995; Chen and Jaw 1996), a simpler model for  $(G_\epsilon)_\rho$ , which can be viewed as a special case of Eq. (16-51) for horizontal flows, is applied:

$$(G_\epsilon)_\rho = c_{1\epsilon} c_{3\epsilon} \frac{\epsilon}{k} (G_k)_\rho \quad (16-52)$$

**16.4.4.2 The Standard  $k$ - $\epsilon$  Model and the Closure Constants** The buoyancy-extended  $k$ - $\epsilon$  model consists of Eq. (16-41) with the original  $\epsilon$  rather than its model,  $k^{3/2}/\mathcal{L}$ , and Eq. (16-48). With  $u = \sqrt{k}$  and  $\mathcal{L} = k^{3/2}/\epsilon$ , this yields

$$\nu_t = c_\mu \sqrt{k} \left( \frac{k^{3/2}}{\epsilon} \right) = c_\mu \frac{k^2}{\epsilon} \quad (16-53)$$

with  $c_\mu$ , a further model constant. In total, the standard model without buoyancy extensions requires five model constants: the two coefficients in the source and sink terms of the  $\epsilon$  equation,  $c_{1\epsilon}$  and  $c_{2\epsilon}$ , the coefficient,  $c_\mu$ , in the eddy viscosity specification, and the turbulent Schmidt numbers for  $k$  and  $\epsilon$ ,  $\sigma_k$

and  $\sigma_\epsilon$ . The first three are chosen to agree with experimental observations in special (asymptotic) flow cases where the model equations simplify, such as equilibrium shear layers (where  $P_k = \epsilon$ ), grid-generated wind-tunnel turbulence (where  $P_k = 0$  and diffusive terms are zero), and the log-law region in wall-bounded flow (where  $P_k \approx \epsilon$  and other terms are negligible). The remaining constants,  $\sigma_k$  and  $\sigma_\epsilon$ , were tuned or calibrated to a variety of flows. The standard values for the  $k$ - $\epsilon$  model constants are given in Table 16-2, together with the value of the von Kármán constant,  $\kappa$ , resulting from the use of the standard constants. The range in values of  $\kappa$  may be surprising, though there have been some recent discussions on this topic (see, e.g., the review of Patel 1998). Other values of the closure constants have been suggested based on other considerations. From the case of homogeneous shear flows, Tennekes (1989) has offered an interesting scaling argument based on the special case of homogeneous shear flows for the choice,  $c_{1\epsilon} = 3/2$ , which is very close to the standard value for the various models in Table (16-2). Similarly, theoretical models for grid-generated turbulence at high  $R$  (Speziale and Bernard 1992) suggest, in spite of experimental evidence to the contrary, that  $c_{2\epsilon} = 2$ , which has been adopted in some models. Nevertheless, because the first three constants are generally tuned to the same types of flows, their values shown in Table 16-2 are quite similar. The values of the closure constants are *not* independent, and changes in one constant may for consistency require changes in other constants, similar to what was seen earlier for one-equation models.

Because of the prominence of the stratified-flow analogy in sediment-transport literature, the closure constant,  $c_{3\epsilon}$ , merits special discussion, which will be limited to the simpler model of Eq. (16-52). In the unstable case, where the density gradient is positive in the direction opposite to gravity, which might be assumed in models of sediment dumping or inflows, turbulence is generated by negative buoyancy,  $(G_k)_\rho > 0$ , and  $c_{3\epsilon} > 0$ . In this case, there seems to be general agreement with the value of  $c_{3\epsilon} = 1$  (Rodi 1987; Burchard et al. 1998). For the more common case of stable stratification, which is of greater interest in sediment transport in alluvial channels, there is substantial variation in values used, with even the sign being in dispute. Baumert and Peters (2000) listed nine different choices ranging from  $-1.4$  to  $1.45$ , with the most common choice being  $c_{3\epsilon} = 0$ , but generally non-negative. Chen and Jaw (1998), who give an extended discussion of turbulent buoyant flows, recommended values in the range from  $1$  to  $1.33$  (note that the notation for  $c_{3\epsilon}$  may vary; what is denoted here as  $c_{1\epsilon} c_{3\epsilon}$  is denoted in Chen and Jaw as  $c_{3\epsilon}$ ). A theoretical argument based again on the special case of strictly stationary ("full equilibrium") homogeneous stably stratified shear flows has been advanced by Burchard and Baumert (1995) for a negative value and the value of  $-1.4$  was proposed (note that this value is given for a  $k$ - $\epsilon$  model with nonstandard choices of the other closure constants, so caution is advised in using this value with the standard model). Needless to say, a standard choice of  $c_{3\epsilon}$

**Table 16-2 Effective<sup>a</sup> Closure Constants for the Standard  $k$ - $\epsilon$ , the RNG  $k$ - $\epsilon$ , the  $k$ - $\omega$ , and the Mellor-Yamada (M-Y) Models, together with the Corresponding Value for the Von Kármán Constant,  $\kappa$**

Model	$c_\mu$	$c_{1\epsilon}$	$c_{2\epsilon}$	$\sigma_k$	$\sigma_\epsilon$	$\kappa$
Standard	0.09	1.44	1.92	1.0	1.3	0.43
RNG	0.085	1.42	1.68	0.72	0.72	0.39
$k$ - $\omega$	0.09	1.56	1.83	2.2	0.41	
M-Y <sup>b</sup>	0.095	1.6	2	2	2	0.40

<sup>a</sup>The  $k$ - $\omega$  and Mellor-Yamada models differ in formulation from the  $k$ - $\epsilon$  model, and hence the closure constants for the different models cannot be considered as exactly equivalent.

<sup>b</sup>This refers to the Mellor-Yamada level 2 1/2 model for non-density-stratified flows, with the stability functions of Galperin et al. (1988).

has not as yet been established, and some sensitivity analysis with respect to its value is recommended.

That the closure coefficients satisfy constraints established in special asymptotic cases of homogeneous flows or flows in local equilibrium is certainly necessary; that they then should apply to flows far from the asymptotic conditions assumes, as Wilcox (1998) has remarked, that the model possess a degree of universality that may be grossly optimistic. The possibility that the closure constants may be functions of local dimensionless parameters reflecting the deviation of conditions from the asymptotic cases is naturally motivated (Hanjalic 1994; Bradshaw 1997). In near-wall models (Launder 1984, 1996; Patel et al. 1985; Wilcox 1998) that must deal with viscous effects, the closure constants are commonly assumed to vary with a local turbulent Reynolds number. For stratified flows, the Mellor-Yamada models discussed below propose what might be interpreted as a  $c_\mu$  varying with Richardson flux numbers. For highly nonequilibrium flows, the closure constants might be taken to vary with  $(P_k/\epsilon) - 1$  (or more simply,  $P_k/\epsilon$ ), which is a measure of the distance from local equilibrium (see also the discussion in Rodi 1993). A more systematic theoretical justification for the last two proposals can be based on algebraic stress models, which will also be dealt with below.

#### 16.4.5 The Treatment of Boundary Conditions and Auxiliary Model Equations

The following is restricted to boundary conditions at the bed and at the free surface. The conventional approach to dealing with the condition at a solid surface, namely, through the use of so-called wall functions, is outlined. For sediment-transport problems, the difficulty of specifying a boundary condition for the sediment conservation equation, Eq. (16-7), must also be confronted. Because the boundary condition on Eq. (16-7) is conventionally not applied at the bed, Eq. (16.7) only treats suspended load (see Chapter 2 for a definition), and so if total load is of interest, then a

bed-load relationship is also required. If further a mobile erodible bed is to be simulated, then an additional equation for the bed evolution, similar to a dynamic equation at a free surface, must be included.

**16.4.5.1 The Treatment of the Near-Bed Region: Flow and Turbulence** The problems of imposing an exact-flow boundary condition have been discussed previously. The solution most commonly applied is the so-called wall functions approach, based on an equilibrium model for the near-wall flow, and the wall boundary conditions are imposed, not at the wall, but at a level outside of the viscous region. The traditional local-equilibrium model,  $P_k = \epsilon$  and  $d\bar{u}/dz = u_*'/\kappa z$ , is assumed to apply in a constant-shear-stress layer, where the boundary conditions are to be imposed, with the result that the necessary boundary conditions for  $\bar{u}_i$ ,  $k$ , and  $\epsilon$  are expressed as

$$\begin{aligned} \frac{V_w}{u_*'} &= \frac{1}{\kappa} \ln \frac{z_w u_*'}{\nu} + B(d_r^+), \\ k_w &= \frac{u_*'^2}{c_\mu^{1/2}}, \quad \epsilon_w = \frac{u_*'^3}{\kappa z_w} \end{aligned} \quad (16-54)$$

where the  $w$ -subscript refers to the level where the boundary conditions are imposed,  $V_w$  is the magnitude of the velocity, with direction opposite to that of the shear stress, and  $B$ , the integration constant in the log-law velocity profile, is a function of the roughness Reynolds number,  $d_r^+ \equiv u_*' d_r / \nu$  where  $d_r$  is an equivalent roughness height. Various specifications of  $B$  are available; one due to Cebeci and Bradshaw (1977) and used by Wu et al. (2000) can be expressed as

$$\begin{aligned} &\frac{B_s - B}{B_s - B_r + (1/\kappa) \ln d_r^+} \\ &= \begin{cases} 0, & d_r^+ < 9/4, \text{ (smooth),} \\ \sin \left[ \frac{\pi}{2} \frac{\ln(4d_r^+/9)}{\ln 40} \right], & 9/4 \leq d_r^+ < 90, \text{ (transitionally rough),} \\ 1, & 90 \leq d_r^+, \text{ (fully rough)} \end{cases} \end{aligned} \quad (16-55)$$

Equation (16-55) is an interpolation formula for  $B$ , with  $B_s$  and  $B_r$  being the well-known integration constants in the log-law profile for hydraulically smooth and rough flows, taken to be 5.2 and 8.5. A slight inconsistency is noted in that Eq. (16-55) presumably is based on  $\kappa = 0.41$ , whereas the standard  $k$ - $\epsilon$  model constants are based on  $\kappa = 0.43$ .

This single-layer wall-function approach can be extended by the use of multilayer models, in which different functional forms for  $k$ ,  $\epsilon$ , and  $V_w$  are assumed in each layer (e.g., in Cheong and Xue 1997). In Eq. (16-54),  $u_*$  is to be determined as part of the solution, but this is accomplished via a momentum balance in the near-wall region. To be consistent with this equilibrium model, the nearest boundary point in the computational grid should be placed in a region where the log-law is presumed valid, e.g.,  $z_w u_* / \nu \gtrsim 40$  for a smooth wall or  $z_w / d_r \gtrsim 2$  for a rough wall, though mild violations of these conditions do not seem to affect results significantly.

Several questions arise in the application of this traditional approach to treating the near-wall region. The log-law profile does not necessarily always hold in wall-bounded flows, e.g., in the recirculation region of separated flows of interest in flows over bed-forms. Measurements in smooth-walled backward-facing-step flows (Devenport and Sutton 1991; Jovic and Driver 1995), confirmed by direct numerical simulations (Le et al. 1997), also show that when the log-law profile first becomes reestablished, the associated constant is not necessarily the same as that ( $B_s$ ) in an equilibrium wall-bounded flow. From the particular perspective of sediment-transport problems,  $z_w$  may be located in a high-concentration region, where particle-particle interactions are strong, and Eq. (16-54) can hardly be justified. Even if this is avoided by a judicious choice of  $z_w$ , the classic question of the appropriateness of the log law and/or the constancy of  $\kappa$  in a sediment-laden flow, discussed previously in Section 16-4.2.3, reappears. A related issue is the appropriate choice of wall roughness height,  $d_r$ . On a fixed (nonerodible) nominally plane bed characterized by homogeneous roughness in a flow without sediment, the choice of  $d_r$  is straightforward, namely, the equivalent median sand size,  $d_{50}$ . Experimental evidence indicates that, even on a nominally plane bed, flow resistance is *increased* in a sediment-transporting flow compared to an equivalent fixed-bed clear-water flow. While the deviation from the classic log-law profile may have contributed significantly to this increased flow resistance (Lyn 1991), an interpretation or parameterization in terms of an effective roughness height much larger than  $d_{50}$  is widely accepted in practice. Van Rijn (1982) listed six widely varying prescriptions for the effective roughness height for flow over plane alluvial beds, finally recommending an average value of  $3d_{90}$  (see also Chapter 2). An alternative approach (Smith and McLean 1977; Dietrich 1982; Wiberg and Rubin 1989; see also Chapter 2), better

known in coastal and oceanographical applications and in some respects more physically based, proposes a roughness height parameter that may be interpreted in terms of a saltation height, and hence may vary with both particle *and* flow parameters. The difficulties become more acute when bed forms are present and the details of the bed geometry are not simulated. In this case, not only must an effective roughness height *including* the form resistance of bed forms be given, the choice of the level at which the flow boundary conditions are to be imposed also becomes much more problematic. Although crude specifications, e.g., the van Rijn (1984c) proposal used by Wu et al. (2000), are available, these leave much to be desired.

In the turbulence-modeling literature, the development of low-Reynolds-number corrections to the standard  $k$ - $\epsilon$  model, primarily with the aim of obviating the use of wall functions, has attracted much attention (Launder 1984, 1996; Patel et al., 1985; Chen and Jaw 1998; Wilcox 1998). Here, low Reynolds number refers to the near-wall flow, where the local Reynolds number, based on the distance to a wall, becomes small, indicative of the increasing importance of viscous effects. Because of the complications noted above in sediment-transport problems, the advantages of such a more sophisticated treatment of the boundary becomes debatable.

**16.4.5.2 Boundary Conditions for the Sediment Equation** The condition on the suspended sediment concentration,  $\bar{c}$ , at the free surface is invariably a no-flux condition; in contrast, the condition at the bed or the near-bed region remains a vexing problem. In a manner similar to the wall-function approach to the flow boundary conditions, the bottom boundary condition for sediment is imposed at a level above the bed. This is already familiar from the traditional Ippen-Rouse profile, for which the boundary condition is usually applied at a reference level above the bed,  $z = z_b$  (see Chapter 2). An “equilibrium” concentration condition,

$$\bar{c}|_{z=z_b} = \bar{c}_{eq} \quad (16-56)$$

has often been chosen (e.g., Li and Davies 1996; Olsen and Kjellesvig 1999), where an equation similar to that which might be traditionally used to close the Ippen-Rouse profile would be used for  $\bar{c}_{eq}$ . Alternatively, a net vertical sediment flux per unit area,  $J_{s,b}$ , might be defined at  $z = z_b$ :

$$J_{s,b} = w_s (E_s - \bar{c}_b) \quad (16-57)$$

where

$E_s$  = entrainment concentration and  
 $\bar{c}_b$  = local concentration at  $z = z_b$ .

With  $w_s$  known and  $\bar{c}_b$  part of the solution for  $\bar{c}$ , the only quantity to be externally specified is the entrainment concentration,  $E_s$ . Somewhat similarly to the treatment of flow quantities, a local-equilibrium hypothesis can be motivated in which the flow entrains as much as it possibly can (Celik and Rodi 1988), such that  $E_s = \bar{c}_{eq}$ , for which, as noted already, several prescriptions are available. A condition essentially equivalent to Eq. (16-57) can be expressed as a diffusive-flux condition (e.g., Murray et al. 1991) in which the combination  $w_s E_s$ , is termed a pickup function, which is then empirically obtained (e.g., van Rijn 1984a). Other variants of Eq. (16-57) and their practical implementation are discussed in Chapter 15. A somewhat different formulation has been adopted in unsteady sediment transport in coastal engineering applications (e.g., Hagatun and Eidsvik 1986; Davies et al. 1997; Savioli and Justesen 1997b) in which

$$\bar{c}|_{z=z_b} = \max(\bar{c}_{eq}, \bar{c}_{ws}) \quad (16-58)$$

where

$\bar{c}_{eq}$  = equilibrium bed concentration associated with the time-varying ('instantaneous') bed shear stress, whereas

$\bar{c}_{ws}$  = concentration if only a settling flux (i.e., independent of the bed shear stress) is imposed.

Equation (16-58) aims to model a lag between settling and entrainment, such that the suspension is not always in equilibrium with the time-varying bed stress, e.g., during periods of small bed shear stress, when settling might dominate. This can also be modeled in Eq. (16-57), and so the advantage of Eq. (16-58) compared to Eq. (16-57) is not clear. Savioli and Justesen (1997b) suggested that  $\bar{c}_{ws}$  is not only due to a settling flux, but also affected by turbulent diffusion; details were, however, not given, and some tuning was found necessary.

The question remains at what level this "bottom" boundary condition is to be imposed. As may also be said of the flow boundary conditions, this level should be located at or possibly above the lower limit of the applicability of the field equations (in this case, the advection-diffusion for sediment, Eq. (16-7)), but this remains controversial. The traditional bed-load formulae proposed in the sediment-transport literature, e.g., for a reference or equilibrium concentration, have been calibrated at specific levels, which have not necessarily been chosen with the needs of modern computational fluid dynamics or turbulence models in mind. For example, for flows over plane beds, the classic Einstein total-load model specifies the lower limit of the suspended load at  $z_b = 2d_{50}$ , with  $\bar{c}|_{z=z_b}$  taken from the Einstein bed-load model (see Chapter 2). On the other hand,  $z_b = 2d_{50}$  may not be consistent with the local equilibrium model assumed in the flow boundary conditions, or even with the validity of the

field equations. The reference level for the bottom concentration boundary condition need not be located at the same level as the flow boundary conditions (Wu et al. 2000), but the two types of boundary conditions must be formulated in a consistent manner, which may place constraints on the near-bottom grid.

Bed forms complicate the issue of boundary conditions. If individual bed forms are modeled, then conditions similar to Eq. (16-57) (or even Eq. (16-56)) could conceivably be imposed, though the local equilibrium assumption (and hence  $\bar{c}_{eq}$ ) would be difficult to justify in the vicinity of the separated flow region. In all fairness, however, such an approach may be said to be equally justified (or unjustified) as the log-law velocity profile wall-function model imposed on the flow. If, as in most practical computations, individual bed forms are *not* modeled and hence details of the near-bed flow are sacrificed for simplicity, then, if Eq. (16-57) or Eq. (16-56) is imposed, then these conditions should be interpreted cautiously because, when a fictitious plane bed is assumed, they implicitly invoke spatial averaging. The application of equations for  $\bar{c}_{eq}$  based on plane-bed flows is thus rather questionable, and alternative specifications of  $\bar{c}_{eq}$  based on flows over bed forms, which might vary sensitively with bedform characteristics, should be considered. The fictitious level at which the sediment boundary condition is to be imposed becomes even more difficult to specify in this case.

**16.4.5.3 Bed-Load Transport and Erodible-Bed Modeling** If the total load is of interest, or if a mobile erodible bed is to be modeled, then a bed-load model is necessary. In the present context, the bed-load region may be defined as that below the level at which the bottom sediment boundary condition is imposed. The turbulence model and the flow and transport computations discussed above are directly concerned only with suspended load, and, in most if not all models, only indirectly affect bed-load transport through the estimate of the bed shear stress,  $\bar{\tau}_b$ . Conventional bed-load formulae in most models were developed for use in problems where only bulk quantities such as  $\bar{\tau}_b$  were available. An interesting attempt to incorporate information about turbulence characteristics into bed-load models has been reported by Mendoza and Shen (1988). For flow models using wall functions (Eq. (16-54)), the turbulence quantities,  $k_w$  and  $\epsilon_w$ , are defined in terms of  $\bar{\tau}_b$ , and so, unless  $z_b$  is chosen to be significantly higher than  $z_w$ , the turbulence model will still only affect bed load through  $\bar{\tau}_b$ .

For modeling of the erodible bed, a conservation equation for the overall bed-material load, including the effect of deformation and temporal evolution of the bed, is formulated, typically in the form of an Exner equation (see Chapter 2 and particularly Chapter 15 for an extensive discussion) relating changes in bed elevation to spatial variations in total load. Alternatively, because the suspended load is presumably already modeled (e.g., by Eq. (16-7)), a bed-load conservation equation can be formulated. A simple form of such an equation can be expressed as

$$\begin{aligned} \frac{\partial}{\partial t} [(1-p)z_{\text{bed}} + (\bar{c}|_{z=z_b} z_b)] \\ + \frac{\partial Q_{sbx}}{\partial x} + \frac{\partial Q_{sby}}{\partial y} = -J_{s|b} \end{aligned} \quad (16-59)$$

where

- $p$  = porosity of the bed;  
 $z_{\text{bed}}$  = elevation of the bed;  
 $z$  = height measured from the local bed elevation, such that  $z_b$  is the thickness of the bed-load layer; and  
 $Q_{sbx}$  and  $Q_{sby}$  = volumetric sediment flux or discharge in the bed-load layer in the Cartesian coordinate directions  $x$  and  $y$ .

The sediment concentration in the bed-load layer has been assumed constant in Eq. (16-59) with a value equal to  $\bar{c}|_{z=z_b}$ . This storage term involving  $\bar{c}|_{z=z_b}$  is often omitted as being negligible compared to the transport terms involving  $Q_{sbx}$  and  $Q_{sby}$ . Equation (16-59) can be considered an equation for the unknown  $z_{\text{bed}}$ , but involves  $Q_{sbx}$  and  $Q_{sby}$ , which need to be specified in terms of known quantities. A local-equilibrium assumption is usually made, wherein these are related to traditional bed-load transport functions, incorporating appropriate coordinate transformations (Wu et al. 2000). More sophisticated erodible-bed models, such as those that attempt to include nonequilibrium effects (Armanini and di Silvio 1998) have been proposed in the wider sediment-transport context. Similarly, the very practical problem of modeling the exchange of heterogeneous sediment between the bed and the flow is not addressed but receives extensive attention in Chapter 15. At the present stage of model development, these issues are only indirectly affected by the turbulence model and will not be dealt with further here.

*Example.* For the horizontally homogeneous unsteady case, the complete  $k$ - $\epsilon$ -model system of equations, including buoyancy effects only in the  $k$ -equation but neglecting viscous diffusion, may be written as

$$\frac{\partial \bar{u}}{\partial t} = \frac{1}{\rho} \frac{\partial \bar{p}}{\partial x} + \frac{\partial}{\partial z} \left( v_t \frac{\partial \bar{u}}{\partial z} \right) \quad (16-60a)$$

$$\begin{aligned} \frac{\partial k}{\partial t} = \frac{\partial}{\partial z} \left( \frac{v_t}{\sigma_k} \frac{\partial k}{\partial z} \right) + v_t \left( \frac{\partial \bar{u}}{\partial z} \right)^2 \\ + g(s-1) \left[ \frac{v_t}{(\sigma_t)_s} \frac{\partial \bar{c}}{\partial z} \right] - \epsilon \end{aligned} \quad (16-60b)$$

$$\begin{aligned} \frac{\partial \epsilon}{\partial t} = \frac{\partial}{\partial z} \left( \frac{v_t}{\sigma_\epsilon} \frac{\partial \epsilon}{\partial z} \right) \\ + c_{1\epsilon} \frac{\epsilon}{k} \left[ v_t \left( \frac{\partial \bar{u}}{\partial z} \right)^2 \right] - c_{2\epsilon} \frac{\epsilon^2}{k} \end{aligned} \quad (16-60c)$$

$$\frac{\partial \bar{c}}{\partial t} = \frac{\partial}{\partial z} \left[ \frac{v_t}{(\sigma_t)_s} \frac{\partial \bar{c}}{\partial z} \right] + \frac{\partial (w_s \bar{c})}{\partial z} \quad (16-60d)$$

Together with the relationship for  $v_t$ , Eq. (16-53), and an equation for  $\bar{p}$ , the system is closed with four equations in four unknowns,  $\bar{u}$ ,  $\bar{c}$ ,  $k$ , and  $\epsilon$ . For an oscillatory flow (further discussed in Section (16-5.4)),  $\bar{p}$  would be related to an imposed free-stream velocity by a Bernoulli equation. For a steady mean flow down a plane inclined at an angle  $\theta$ , the transient terms are zero and the pressure-gradient term can be replaced by a gravitational-force term,  $g \sin \theta$ .

The results of two  $k$ - $\epsilon$  computations, one with and one without buoyancy effects included in the  $k$ -equation (but  $c_{3\epsilon} = 0$ ), for the same two steady laboratory flows previously examined with the van Rijn and Smith-McLean models are shown in Fig. (16-6). The boundary conditions imposed were standard (Eqs. (16-54) with the van Rijn value of  $d_r = 3d_{90}$ , Eq. (16-61), Eq. (16-56) imposed at  $z_b = 3d_{90}$ , and  $(\sigma_t)_s = 1$ ) for the two computations. Thus, unlike the previous computations with the van Rijn and Smith-McLean models, which “benefited” from the measurements being used as boundary conditions, the present computations are complete predictions. The velocity predictions for the standard  $k$ - $\epsilon$  model agree well with measurements in both cases for the outer flow, but a tendency to overestimate velocities closer to the boundary is noted, very apparent for the Lyn data, but also seen in the Barton-Lin data. The flow boundary conditions are the same in the buoyancy-extended model, leading to predictions of larger velocities and smaller concentrations compared to the standard model because of a reduced eddy viscosity/diffusivity. In both cases, this leads to a deterioration in agreement with the velocity data, though the concentration predictions are improved. This does not necessarily imply a virtue or deficiency in the buoyancy-extended  $k$ - $\epsilon$  model as such. Much of the credit for the good agreement or blame for the discrepancies should not necessarily be attributed to the turbulence model as such but to the boundary conditions and the choice of model parameters (the choice of  $d_r$  and  $\bar{c}_{\text{ref}}$  and  $(\sigma_t)_s$ ). Viewed from this perspective, the differences between the predictions of the mixing-length models and the two-equation models are not as large as might at first be thought. As already pointed out, for the simple uniform-flow case, the  $k$ - $\epsilon$  model reduces to the mixing-length model because of local equilibrium. Thus, a comparison of the two types of models should focus on differences in predicted slopes rather than predicted values because the latter are

directly affected by boundary conditions. Not surprisingly, the predicted slopes of the two types of models are quite similar. The case of uniform flow over a flat bed is perhaps the simplest case of sediment-laden flow, and so is not a particularly stringent test of a turbulence model. Figure (16-6) shows what might be achieved with a  $k$ - $\epsilon$  model under the best of circumstances—in more complicated flows, larger discrepancies might be encountered.

**16.4.5.4 Free-Surface Conditions** The free surface is often treated as a symmetry plane, exactly analogous to the centerline of a pipe, such that, in the absence of wind shear, fluxes across the surface are set to zero. The turbulence in the vicinity of a free surface differs, however, from that in the vicinity of a pipe centerline due to a damping of vertical velocity fluctuations and a consequent flattening of turbulent eddies, somewhat similar to that occurring at a rigid wall. The resulting reduction in length scale has been modeled by imposing a condition on  $\epsilon$  at the free surface, namely,

$$\epsilon_{fs} = \frac{k_{fs}^{3/2}}{c_{fsc} h}, \quad (16-61)$$

where  $k_{fs}$  is the turbulent kinetic energy at the free surface and  $c_{fsc}$  is a constant, with a recommended value of 0.43 (Celik and Rodi 1988; Wu et al. 2000). Equation (16-61) which may be compared with the corresponding condition at the bed, reduces the length scale at the free surface relative to the situation when a simple symmetry condition is imposed. Celik and Rodi (1984, 1988) also proposed a direct reduction in  $v_t$  through a reduction in  $c_\mu$  by a factor depending on a surface damping function and the ratio  $\rho/\epsilon$ .

#### 16.4.6 Deficiencies of the Boussinesq Eddy-Viscosity and $k$ - $\epsilon$ Models and Some Alternatives

The weaknesses of the Boussinesq eddy-viscosity (BEVM) and  $k$ - $\epsilon$  models are discussed, and several alternative two-equation models developed to remedy some of these weaknesses are described. Because these have not yet been as widely adopted, only a select sample will be discussed here, and only rather briefly. The  $\epsilon$ -equation, not surprisingly, has been the focus of modeling, either being entirely replaced or modified by additional terms. As noted above, an equation for any generic “length-scale” quantity of the form  $k^m \mathcal{L}^n$ , can form the basis for a two-equation model, and the two models discussed below that differ in form from the  $k$ - $\epsilon$  model may be interpreted in terms of particular choices of  $m$  and  $n$ . The  $k$ -equation is usually retained, with either no modification or only such modification as to make it consistent with the new or revised length-scale equation.

**16.4.6.1 Weaknesses of the Boussinesq Eddy-Viscosity and  $k$ - $\epsilon$  Models** It was noted in connection with mixing-length models that nonequilibrium and anisotropic turbulence would cause problems. To a perhaps distressingly large extent, this remains true even when the BEVM model

is coupled with the more sophisticated  $k$ - $\epsilon$  model. Like the mixing-length model, the BEVM model was motivated primarily by thin shear flows, and the BEVM model usually performs well in predicting the important fluxes across shear-dominated flows. Fluxes in the other directions may not be so well predicted (Haroutunian and Engelman 1993). Flows in which differences in normal stresses are important, i.e., highly anisotropic flows, will pose difficulties for the standard models. These may include problems where turbulence-generated secondary currents play an important role, e.g., flows in compound channels. When extra strains, such as buoyancy forces, or when rapid changes in strain are imposed, model performance may also deteriorate (Wilcox 1998). As evident from the preceding sections, the effects of buoyancy may be relevant to suspension flows. Even if buoyancy is not accepted as the dominant mechanism for turbulence modification in sediment-laden flows, it may be argued on general physical grounds that the responsible mechanism is related to sedimentation in a gravitational field, and hence is expected to have an anisotropic effect on the flow field.

These deficiencies can be traced to the assumption of isotropy inherent in the BEVM, to the use of only scalar quantities,  $k$  and  $\epsilon$ , to characterize the turbulence, and to the specification of the linear relationship between  $\overline{u'_i u'_j}$  and only the mean strain rate. Because of the extent of model assumptions in the development of the  $\epsilon$ -equation, it has been the subject of much criticism, with modifications or alternatives often being proposed. As noted previously, the use of wall-functions has also been criticized because they tend to be justified only under fairly limited conditions. From the specific sediment-transport point of view, whether the stratification model and the assumed log-law wall-function model are appropriate remains unclear. Although much has been said of the anisotropic nature of real turbulent flows, the possible anisotropy of diffusive transport of settling particles even in isotropic turbulence should also be mentioned.

**16.4.6.2 The  $k$ - $\omega$  Model** The  $k$ - $\omega$  model, associated with Wilcox (and discussed at length in his 1998 book), is perhaps the major alternative to the  $k$ - $\epsilon$  model as far as two-equation models for engineering applications are concerned. It is based on an equation for  $\omega$ , which is interpreted as a frequency scale proportional to  $\epsilon/k$ , the rate of dissipation per unit turbulent kinetic energy:

$$\begin{aligned} \frac{d\omega}{dt} &= \frac{\partial \omega}{\partial t} + \frac{\partial (\bar{u}_j \omega)}{\partial x_j} \\ &= \frac{\partial}{\partial x_j} \left( \frac{v_t}{\sigma_\omega} \frac{\partial \omega}{\partial x_j} \right) + c_{1\omega} \frac{\omega}{k} P_k - c_{2\omega} \omega^2 \end{aligned} \quad (16-62)$$

Whereas the  $\epsilon$ -equation in the  $k$ - $\epsilon$  model may be interpreted as an equation for  $k^{3/2} \mathcal{L}^{-1}$ , i.e.,  $m = 3/2$  and  $n = -1$ , the

$\omega$ -equation corresponds to an equation for  $k^{-1/2} \mathcal{L}$ , or  $m = -1/2$  and  $n = 1$ . With the additional model relations

$$\epsilon = c_{kw} k \omega \quad \text{and} \quad v_t = \frac{k}{\omega} \quad (16-63)$$

the  $k$ - $\omega$  model is completely specified. Like the  $k$ - $\epsilon$  model, there are five closure coefficients,  $c_{k\omega} = 0.09$ ,  $c_{1\omega} = 5/9$ ,  $c_{2\omega} = 3/40$ , and the two turbulent Schmidt numbers,  $\sigma_k = 2 = \sigma_\omega$ . A frequently cited advantage of the  $k$ - $\omega$  model for wall-bounded flow applications is that, without the need to use wall-functions, integration to the wall is feasible. For the transitionally rough-wall flows of most interest in sediment-transport applications, the boundary conditions to be applied at the bed are the no-slip conditions for the velocity components, together with

$$k = 0, \quad \omega = u_*^2 S_r / \nu \quad (16-64)$$

where  $S_r$  is a parameter, analogous to  $E_r$  for the  $k$ - $\epsilon$  model (Eq. 16-55), that is correlated with the wall roughness, namely,

$$S_r = \begin{cases} (50/d_r^+)^2, & d_r^+ < 25 \\ 100/d_r^+, & d_r^+ \geq 25. \end{cases} \quad (16-65)$$

With the specification, Eq. (16-65) and boundary conditions, Eq. (16-64) the  $k$ - $\omega$  model reproduces the standard log-law for transitionally and fully rough flows for parallel or nearly parallel flows of a homogeneous fluid, such as clear-water boundary-layer or channel flows. Importantly, however, unlike the wall-functions approach, log-law behavior is *not* explicitly imposed on the flow. Yoon and Patel (1996) note that a fine grid close to the wall is necessary because of large spatial gradients. This does not imply that the flow very near the wall is being resolved, because individual roughness elements are not modeled; hence, the results very near the wall must be interpreted cautiously because the solution is only physically meaningful at some distance from the modeled wall. In addition to Wilcox (1998), Patel (1998) discusses the performance of the  $k$ - $\omega$  and  $k$ - $\epsilon$  models for wall-bounded flows in general, and, for rough walls in particular. Because it avoids explicitly assuming a log-law velocity profile at the wall, it may be advantageous in separated flows where it is known that the log-law profile does not hold in recirculating regions. Nevertheless, in a study of the backward-facing-step flow, Speziale and Thangam (1992) concluded that, at least for this flow, the use of wall functions does not entail major errors in spite of flow separation. The problems peculiar to sediment-transport applications discussed before, such as the appropriate roughness height in sediment-laden flows or dealing with bed forms, not to mention the question of turbulence modification, still need to be addressed. A well-known

weakness of the  $k$ - $\omega$  model is its extreme sensitivity to free-stream boundary conditions, and so it should not be applied without modifications to flows with interfaces between turbulent and nonturbulent flows, e.g., boundary-layer flows, free shear flows. For alluvial-channel flows, this should be of little concern, but may require more consideration in the coastal or lacustrine context.

**16.4.6.3 The RNG Model** Since its introduction by Yakhot and Orszag (1986), the renormalization group (RNG or RG) approach to developing turbulence models has attracted much attention (Speziale and Thangam, 1992; Yakhot and Orszag 1992), as well as skepticism (McComb 1990; Hanjalic 1994; Bradshaw 1997). The standard  $k$ - $\epsilon$  model is apparently derived, with only changes in the values of the closure coefficients (see Table 16-2) and, in its latest version, the addition of a term involving the mean strain rate  $\epsilon$ -equation, namely,

$$G = (G_\epsilon)_{RNG} = -c_\mu \frac{\epsilon^2}{k} \left[ \frac{\eta^3 (1 - \eta/\eta_0)}{1 + c_{RNG} \eta^3} \right] \quad (16-66)$$

where  $\eta = S k/\epsilon$ , and the two additional model constants,  $\eta_0 = 4.38$ , obtained from an analysis of homogeneous shear flow, and  $c_{RNG} = 0.015$ , the value of which was chosen to match a von Kármán constant,  $\kappa = 0.39$  (a value of  $c_{RNG} = 0.012$  would yield  $\kappa = 0.4$ ).

A formidable, even impenetrable theory notwithstanding, the RNG results rely on an asymptotic perturbation argument for a small parameter, but the argument is then applied with a finite (not small) value of that parameter. On one hand, this is similar to the standard procedure of determining the closure constants from simple flows and applying the model to complex flows (see the discussion in Section 16-4-4); on the other hand, the claims to theoretical rigor and superiority vis-à-vis the standard procedure suffer accordingly. Although the RNG approach points to the necessity of an additional term in the  $\epsilon$ -equation when  $S$  is large, the particular form of  $(G_\epsilon)_{RNG}$  given in Eq. (16-66) is *not* directly derived from the RNG approach, and constitutes another possible weak point in the RNG model. Because  $\eta \propto \sqrt{P_k}/\epsilon$ , the additional term,  $(G_\epsilon)_{RNG}$ , can also be interpreted as  $c_{2\epsilon}$  being a function varying with  $P_k/\epsilon$  rather than being a constant as in the standard  $k$ - $\epsilon$  model. This recalls the earlier discussion concerning the possibility of the closure constants being made dependent on dimensionless parameters reflecting deviations from the conditions prevailing in the simple calibration flows. In practice, the RNG  $k$ - $\epsilon$  model has led to improved predictions in some flows, particularly those in which massive separation has occurred (Lien and Leschziner 1994; Kim and Patel 2000), but not in others (Hanjalic 1994; Lien and Leschziner 1994). Whether it represents a viable general alternative to the standard  $k$ - $\epsilon$  model (or the  $k$ - $\omega$  model) remains to be established.

In their usual implementation, both the  $k$ - $\omega$  and the RNG version of the  $k$ - $\epsilon$  models retain the BEVM assumption, so

that the deficiencies, notably the linear stress-strain rate relationship and the insensitivity to normal stresses and anisotropy stemming from it, still remain. Possible turbulence modulation effects from the presence of particles do not seem to have yet received much, if any, attention in the application of either the  $k-\omega$  or the RNG models. Although neither model has been as extensively tested as the conventional  $k-\epsilon$  model, their availability in commercial computational fluid dynamics codes will likely stimulate increased use in the future.

**16.4.6.4 The Mellor-Yamada (or  $k-k\mathcal{L}$  Model) Length-Scale Equation** Mellor and Yamada (1982) describe a hierarchy of turbulence closure models ranging from a full second-moment model (level 4) to a local-equilibrium model (level 2). The intermediate level  $2\frac{1}{2}$  model is described in the next section. Unlike the  $k-\epsilon$  model, Mellor-Yamada models eschew the  $\epsilon$ -equation in favor of either a simple algebraic specification of the length scale, or more generally, an equation directly for the turbulence length scale,  $\mathcal{L}$  or equivalently of a quantity  $R = 2k$ . Although it can be written for more general flows (Mellor and Herring 1973; Rodi 1987), it is often expressed in a form aimed at boundary-layer applications (Mellor and Yamada 1982):

$$\begin{aligned} \frac{DR}{Dt} &= \frac{\partial R}{\partial t} + \frac{\partial(\bar{u}_j R)}{\partial x_j} \\ &= \frac{\partial}{\partial z} \left[ \frac{(v_t)_0}{\sigma_R} \frac{\partial R}{\partial z} \right] + \mathcal{L} c_{1R} [P_k + (G_k)_\rho] \\ &\quad - c_{2R} (2k)^{3/2} \left[ 1 + c_{3MY} \left( \frac{\mathcal{L}}{\kappa L_z} \right) \right] \end{aligned} \quad (16-67)$$

such that only diffusive transport in the vertical  $z$  direction is included. The basic eddy viscosity  $(v_t)_0 = (2k)^{1/2}\Lambda$ , whereas the length scale,  $L_z$ , is in general specified externally by an integral. For boundary-layer flow near a wall, the integral simplifies to  $L_z = z$ , the distance from the wall. The closure constants are  $\sigma_R = 5$ ,  $c_{1R} = 1.8$ ,  $c_{2R} = 0.06$ ,  $c_{3MY} = 1.33$ . The last term,  $\mathcal{L}/(\kappa L_z)$ , is necessary for matching the von Kármán constant in the log-law velocity profile. The dissipation term in the  $k$ -equation is  $\epsilon = c_{2R}(2k)^{3/2}/\mathcal{L}$ . As usual, a wall-functions approach may be applied in imposing conditions at a solid boundary. An interesting feature of Eq. (16-67) is the choice of the coefficient of the buoyancy term, equivalent to  $c_{3\epsilon}$  in the  $k-\epsilon$  model. The choice of unity, tentatively made by Mellor and Yamada (1982), seems to have become the standard in subsequent work, and has not aroused any debate comparable to that surrounding  $c_{3\epsilon}$ .

Equation (16-67) falls within the class of models, sometimes termed  $k-k\mathcal{L}$  (Wilcox 1998), that began with the work of Rotta (1951), who derived an equation for the integral of the two-point correlation function, which can serve to

define a length-scale. Within the classification of length-scale equations in terms of  $k^m \mathcal{L}^n$ , Eq. (16-67) has  $m = 1$ ,  $n = 1$ . Somewhat similar length-scale equations have been applied by Sheng and Villaret (1989) and Huynh Thanh and Temperville (1991) for sediment-transport application. Although widely used in geophysical applications, possibly because of its attention to stratification effects, the superiority of Eq. (16-67) to the  $\epsilon$ -equation in practical engineering computations is controversial. Speziale (1991), for example, concludes that it does not offer any significant advantages over the standard  $\epsilon$ -equation.

## 16.4.7 More Sophisticated Models

For the foreseeable future, practical computations of flows involving sediment transport will be dominated by the standard  $k-\epsilon$  model, possibly including buoyancy extensions or other ad hoc corrections, or alternative two-equation models, coupled with the advection-diffusion equation for the sediment concentration, Eq. (16-7). Nevertheless, more advanced models continue to be developed, and some have already found or may eventually find their way into leading-edge practice. The two-phase approach to dealing with suspension flows and possible modifications to the  $k-\epsilon$  model is very briefly discussed. Nonlinear  $k-\epsilon$  models are examined as a possible solution to modelling effects of anisotropy and extra strains. The present state-of-the-art in turbulence modeling for practical computations lies in second-moment closure models, and so these are briefly outlined, though primarily with the aim of deriving simpler algebraic stress models.

**16.4.7.1 Two-Phase Flow Turbulence Models** The two-phase nature of a suspension flow presents special problems not only for the modeling of the turbulence, but also for the formulation of basic continuity and momentum equations, and the frequent appeal to the stratification analogy deserves greater scrutiny than it has received. Several two-phase flow descriptions of the sediment-transport problem have been given (Drew 1975; McTigue 1981; Kobayashi and Seo 1985; Lamberti et al. 1991; Greimann et al. 1999), but because they have only considered the simplest case of uniform flat-bed flow, they have typically resorted to simple mixing-length closures. Turbulence modification was either ignored or treated via a stratification analogy. The formulation of general numerical models for turbulent two-phase flows and the fundamental problems of averaging and turbulence closure have been reviewed by Crowe et al. (1996). The two-phase formulation starts with separate continuity and momentum equations for each phase, where correlations modeling the kinematic and dynamic interaction between phases already present closure problems (in addition to the turbulence closure problem), which may not be amenable to the standard BEVM approach (Elghobashi 1994). Elghobashi and Abou-Arab (1983) derived two-phase  $k-\epsilon$  equations and proposed appropriate closures, with

applications to particulate jet flows. The exact  $k$ -equation is found to consist of 38 terms (this may be compared with the 8 terms in Eq. (16-34)), and rather drastic surgery is required to obtain closure. Interestingly, a buoyancy term does *not* explicitly appear in their formulation, though presumably the effect is implicitly captured in correlations involving the instantaneous slip between the two phases. Because of the abstract nature of the concept of interpenetrating continua, experimental determination of correlations or confirmation of detailed predictions is difficult or even impossible, except possibly in numerical simulations.

The near-bed bed-load region poses additional problems because particle-particle interactions become important or dominant, and a dense-phase (as opposed to a dispersed dilute-phase) flow model is necessary. In a single-phase flow approach based on Eq. (16-7), these problems are entirely avoided by using a bed-load transport model that bridges the immobile bed and the suspended-load region where Eq. (16-7) is applied. It is debatable to what extent the traditional views of turbulence can be applied to this region. The possibility of applying granular-fluid models to deal with this dense-phase region has been explored by a number of investigators (Hanes and Bowen 1985; Lamberti et al. 1991; Villaret and Davies 1995).

*Example.* Villaret and Davies (1995) reported simulations with a two-phase flow model, presumably a version of that described by Simonin (1991). The model incorporates granular-fluid concepts, suspension-induced buoyancy effects, and a low- $R$  model for the near-wall flow, in a  $k$ - $\epsilon$  model framework. Figure 16-7 shows the results, including those from simulations with an enhanced version of the Li-Davies one-equation model discussed previously, including buoyancy effects. All of the cases studied did *not* involve an equilibrium bed. The predictions of both models with respect to the velocity profiles agree quite well with measurements, and are clearly superior to the clear-water velocity profiles (the basis of the standard  $k$ - $\epsilon$  wall-functions). The simpler one-equation model seems, however, to perform as well as or only marginally worse than the more sophisticated two-phase  $k$ - $\epsilon$  model, at least where experimental evidence is available. Larger discrepancies between concentration predictions and measurements can be seen, and the superiority of one or the other model is not clearly established. The simpler one-equation model did benefit from having a measured concentration as its bottom concentration boundary condition, whereas only the depth-averaged concentration was imposed on the two-phase flow model. The comparison suggests that, even for this simplest case of sediment-laden flows, even a very sophisticated model may not necessarily lead to significantly better predictions. Further, improved boundary conditions may play a more important role in better predictions than additional sophistication in turbulence modeling, at least at the present stage of model development.

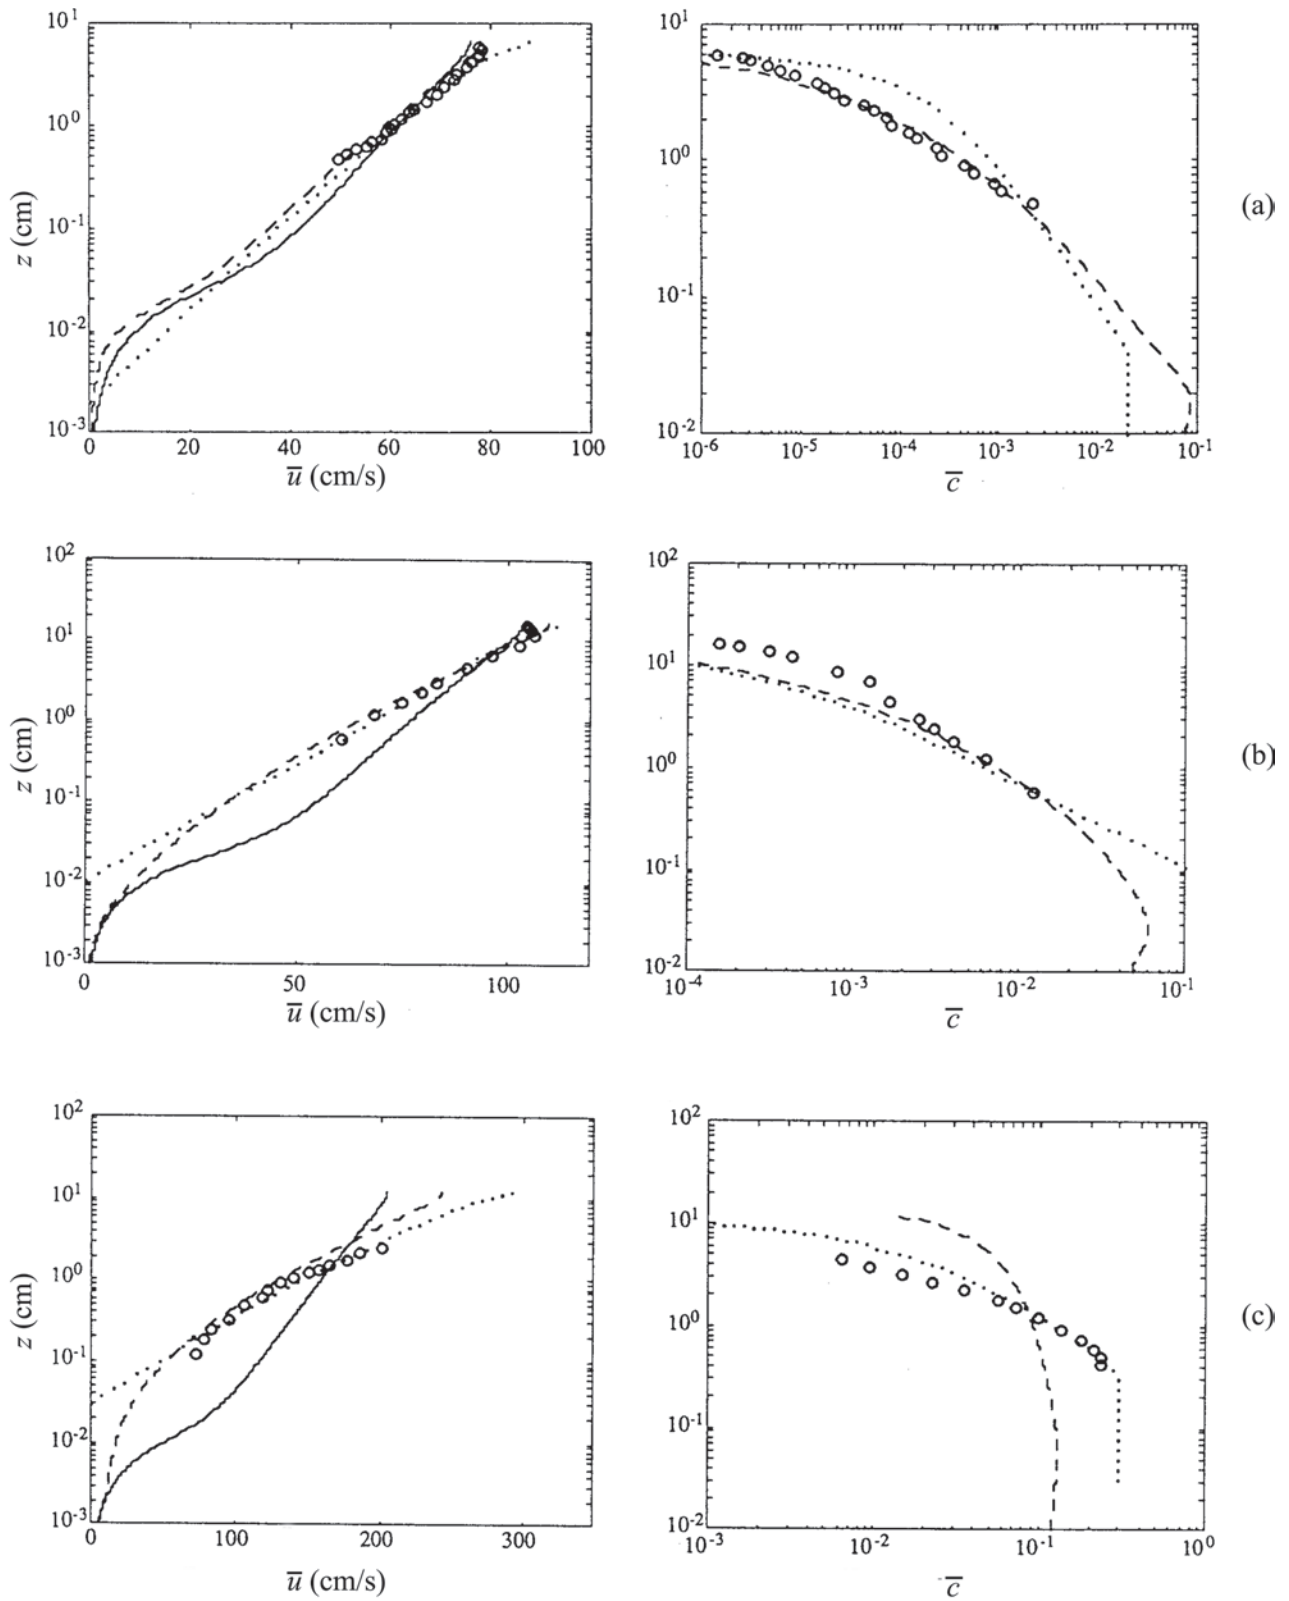

Hsu et al. (2003) reported predictions using a dilute two-phase-flow  $k$ - $\epsilon$  model, which did not include either dense-phase or, at least explicitly, stratification effects, and

so provides a contrast to the two-phase-flow model described in Villaret and Davies (1995). An approximate theoretical solution that agreed with a numerical solution of the resulting model near the bed suggested that effects on the velocity (and also the concentration) profile are  $O(\bar{c})$ . This seems too weak in general to explain observations, and may indicate that dense-phase and/or stratification effects need to be included.

**16.4.7.2 Nonlinear  $k$ - $\epsilon$  Models** The Boussinesq eddy viscosity model (Eq. (16-14)), relating the Reynolds stress *linearly* to the mean strain rate, analogously to that applied to a Newtonian fluid in laminar flows, is considered one of the major weaknesses of standard turbulence models. Nonlinear constitutive models, analogous to considering turbulent flow as a non-Newtonian fluid, have been proposed as a relatively simple remedy (Speziale 1987, 1996; Launder 1996; Wilcox 1998). An example is a model developed by Craft et al. (1993), which assumes that

$$\begin{aligned}
 -\overline{u'_i u'_j} = & \left( \nu_t S_{ij}^* - \frac{2}{3} \delta_{ij} k \right) \\
 & - \nu_t \frac{k}{\tau} \left[ c_{1n} \left( S_{ik}^* S_{kj}^* - \frac{1}{3} S_{kl}^* S_{ij}^* \delta_{ij} \right) \right. \\
 & + c_{2n} \left( \Omega_{ik}^* S_{kj}^* + \Omega_{jk}^* S_{ki}^* \right) \\
 & + c_{3n} \left( \Omega_{ik}^* \Omega_{jk}^* - \frac{1}{3} \Omega_{lk}^* \Omega_{li}^* \delta_{ij} \right) \Big] \\
 & - c_{4n} \nu_t \frac{k^2}{\tau^2} \left[ c_{4n} \left( S_{ki}^* \Omega_{lj}^* + S_{kj}^* \Omega_{li}^* \right) S_{kl}^* + c_{5n} \right. \\
 & \times \left( \Omega_{il}^* \Omega_{lm}^* S_{mj}^* + S_{il}^* \Omega_{lm}^* \Omega_{mj}^* - \frac{2}{3} S_{lm}^* \Omega_{mn}^* \Omega_{nl}^* \delta_{ij} \right) \\
 & \left. + c_{6n} S_{ij}^* S_{kl}^* S_{kl}^* + c_{7n} S_{ij}^* \Omega_{kl}^* \Omega_{kl}^* \right]. \quad (16-68)
 \end{aligned}$$

The first bracketed group of terms is the standard BEVM, whereas the second and third bracketed groups are respectively quadratic and cubic terms in  $S_{ij}^* = 2S_{ij}$  and a rotation tensor,  $\Omega_{ij} = \partial \bar{u}_i / \partial x_j - \partial \bar{u}_j / \partial x_i$ . There are seven additional closure coefficients,  $c_{1n}, \dots, c_{7n}$ . Although the nonlinear constitutive relationship is much more complicated than the Boussinesq model, such a generalization is computationally attractive, because it still permits the use of two-equation models. Apsley et al. (1997) have argued that the early quadratic model of Speziale (1987), although sensitive to anisotropy, is insensitive to flow curvature, which requires at least a cubic model. They also point out that the physical interpretation of nonlinear models that are postulated solely on a formal basis is tenuous, and that the closure coefficient in the viscosity relationship,  $c_{\mu}$ , will in general need to be made a function of the strain-rate and rotation tensors. An alternative, more physically based approach to developing nonlinear models simplifies second-moment closure models discussed below.

**Fig. 16-7.** Comparison of velocity ( $\bar{u}$ ) and concentration ( $\bar{c}$ ) predictions (Villaret and Davies 1995) and measurements of uniform-flow case: (a) data of Lyn (1988), (b) data of Coleman (1981), and (c) data of Einstein and Chien (1955). Symbols: measurements, — : clear-water prediction; — — : two-phase  $k-\epsilon$  model prediction; . . . : one-equation model prediction.

**16.4.7.3 Second-Moment Closure and Algebraic Stress Models** The original problem posed by the Reynolds averaging of the Navier-Stokes equations is the appearance of unknown Reynolds stress terms. Whereas eddy-viscosity models attempt to relate these unknown terms to the mean fields via constitutive equations and thus resolve the turbulence closure problem, a more direct approach might be considered, namely directly deriving equations for the elements of the Reynolds stress tensor. This approach leads to higher-order correlation terms, which, however, could then be subjected to the type of modeling applied to the lower-order terms in eddy-viscosity models. This forms the theoretical basis of Reynolds stress (RS) or second-moment closure (SMC) models. The equation for  $\overline{u'_i u'_j}$  can be written as

$$\begin{aligned} \frac{D(\overline{u'_i u'_j})}{Dt} &= \frac{\partial(\overline{u'_i u'_j})}{\partial t} + \frac{\partial[\overline{u_i}(\overline{u'_i u'_j})]}{\partial x_i} \\ &= P_{ij} + G_{ij} + D_{ij} + \Pi_{ij} - \epsilon_{ij} \end{aligned} \quad (16-69)$$

where  $D_{ij}$  denotes diffusive transport terms,

$$P_{ij} = -\overline{u'_i u'_l} \frac{\partial \overline{u_j}}{\partial x_l} - \overline{u'_j u'_l} \frac{\partial \overline{u_i}}{\partial x_l} \quad (16-70)$$

represents the production of  $\overline{u'_i u'_j}$  through interaction of the turbulence with the mean strain rate,  $G_{ij}$  the production of  $\overline{u'_i u'_j}$  by other forces or strains,  $\Pi_{ij}$  the pressure-strain term, and  $\epsilon_{ij}$  the term representing the viscous dissipation of the Reynolds stresses. If the effects of buoyancy are modeled, then

$$\begin{aligned} (G_p)_{ij} &= \frac{1}{\rho_{\text{ref}}} (g_i \overline{\rho' u'_j} + g_j \overline{\rho' u'_i}) \\ &= (s-1)(g_i \overline{c' u'_j} + g_j \overline{c' u'_i}) \end{aligned} \quad (16-71)$$

where the second equality invokes the suspension density relation. Besides the basic sediment conservation equation, transport equations for the second-moment quantities involving  $c'$  such as  $\overline{u'_i c'}$  and  $\overline{c'^2}$ , are also formulated. The resemblance between Eq. (16-69) and the exact equation for  $k$  is not coincidental, since the latter can be derived from the former.

Because the RS model approach solves for each element of the Reynolds stress tensor, and not simply  $k$ , anisotropic flow features *should* be better handled. RS models also have the advantage that the production terms, both from shear and from extra strains, are exact, and so flow aspects strongly influenced by such extra strains should be more rationally modeled. This does not of course necessarily extend in a straightforward way to particulate flows, for which the basic models for the momentum equations are still being debated,

though, if the stratification analogy is accepted, the effects of simple stratification should be better modeled. In practice, as will be seen in the next section, the promise of RS models has not yet been satisfactorily fulfilled (see also the general discussion of Bradshaw 1997 and that of Patel 1997 in the context of curvature effects). Apart from the difficulty of modeling the pressure-strain term,  $\Pi_{ij}$ , conventional RS models still use (1) the problematic  $\epsilon$ -equation, (2)  $k^2/\epsilon$  for the effective diffusion coefficient for diffusive transport terms, and (3) wall-functions at solid boundaries. Several computations using RS models will be reviewed in Section 16.5.

Although the full second-moment closure offers the promise of resolving some of the well-known problems of two-equation models, the computational demands are much more severe. If only the flow is considered, up to six additional partial differential equations must be solved for a three-dimensional simulation, and if the transport of a scalar, such as a sediment concentration, is also desired, then this may add up to four more partial differential equations, over and above what a two-equation model requires. A further practical problem, especially with sediment transport, is the specification of boundary conditions. The difficulties involved in specifying a bottom boundary condition for  $\bar{c}$  have been discussed already; for an RS model, additional conditions on other second-moment quantities involving  $c$  must also be imposed. For such reasons, an intermediate approach may be sought in which Eq. (16-69) is simplified, such that  $\overline{u'_i u'_j}$  may ultimately be specified algebraically without the need for solution of partial differential equations. Various algebraic stress (AS) models can be obtained depending on the simplifying assumptions made.

The simplest model makes a local equilibrium assumption in which transport terms in Eq. (16-69) are neglected, and  $\overline{u'_i u'_j}$  is determined from the equation

$$P_{ij} + G_{ij} + \Pi_{ij} - \epsilon_{ij} = 0. \quad (16-72)$$

This is the basis of the well-known Mellor-Yamada level  $2\frac{1}{2}$  model (Mellor and Yamada 1982), widely used in ocean modeling and more sporadically in hydraulic and coastal engineering (Blumberg et al. 1992; Davies et al. 1997). A feature of this model, absent in the standard or buoyancy-extended  $k$ - $\epsilon$  models, but common to AS models including AS  $k$ - $\epsilon$  models, is that the closure coefficients (such as  $c_\mu$  in  $k$ - $\epsilon$  models and the stability functions  $S_M$  in Mellor-Yamada models) associated with the effective eddy diffusivities for momentum and for buoyancy depend on local dimensionless parameters, such as a gradient Richardson number. Comparisons of the predictions of the Mellor-Yamada level  $2\frac{1}{2}$  model and other models have been made by Rodi (1987), and more recently by Burchard and Baumert (1995) and Baumert and Peters (2000), for stratified flows. A variant of the Mellor-Yamada level  $2\frac{1}{2}$  model was used by Sheng and Villaret (1989) to study the effect of sediment-induced stratification on erosion of cohesive sediments. Although

the results showed that such stratification could significantly affect erosion, detailed comparisons of flow predictions with experimental data were not given.

The AS model  $k-\epsilon$  due to Rodi (1976; 1993) assumes that the sum of the history and transport terms for  $\overline{u'_i u'_j}$  is proportional to the corresponding terms for  $k$ , with the proportionality factor being  $\overline{u'_i u'_j}/k$ , which is not constant. The resulting specification for  $\overline{u'_i u'_j}$  can be written as

$$\overline{u'_i u'_j} = k \left[ \frac{2}{3} \delta_{ij} + \frac{(1-c_{1A})\{P_{ij} - (2/3)\delta_{ij}P_k\} + (1-c_{2A})\{G_{ij} - (2/3)\delta_{ij}G_k\}}{P_k + G_k - (1-c_{3A})\epsilon} \right] \quad (16-73)$$

with the three additional closure coefficients  $c_{1A}$ ,  $c_{2A}$ ,  $c_{3A}$ . AS models share some similarities with nonlinear eddy viscosity models, and may be interpreted as a special class of nonlinear models for  $\overline{u'_i u'_j}$ . Lien and Leschinger (1994) have argued that, being based on simplifications of the full RS models, they have a stronger physical basis than general nonlinear models in which the relationship between stress and stress is only formally postulated. Mendoza and Shen (1990) applied this model in a study of clear-water flow over nonerodible dunes, and some results are given in Section 16.5.1.

From a similar though rather more involved analysis, involving a number of additional approximations, an analogous specification for concentration flux term,  $\overline{u'_i c'}$  can be given,

$$-\overline{u'_i c'} = \frac{k}{\epsilon} \left[ \frac{\overline{u'_i u'_j} \left( \frac{\partial \bar{c}}{\partial x_j} \right) + (1-c_{2c}) \overline{u'_i c'} \left\{ \left( \frac{\partial \bar{u}_i}{\partial x_j} \right) - 2c_{3c} (k/\epsilon) g_i (s-1) \left( \frac{\partial \bar{c}}{\partial x_j} \right) \right\}}{c_{1c} + \{(P_k + G_k - \epsilon)/2\epsilon\}} \right] \quad (16-74)$$

with additional constants,  $c_{1c}$ ,  $c_{2c}$ , and  $c_{3c}$ . Launder (1996) notes that, in wall-bounded flows where transport effects are not important, AS models yield results similar to RS models (which does not necessarily mean correct results) for  $\approx 60\%$  of the computational effort, but warns that the performance in free turbulent flows is much less satisfactory. As with other aspects of stratified-flow models, the values proposed in the literature for  $c_{1c}$ ,  $c_{2c}$ , and  $c_{3c}$  (e.g., Launder 1984; Rodi 1993; Chen and Jaw 1998) have been based on data from thermally stratified flows; to what extent, if at all, these are applicable to sediment-laden flows is still an open question. Velocity-sediment-concentration correlations are rather ill-defined experimentally, and, in any case, extremely difficult to measure.

*Example.* For a steady uniform plane flow, the algebraic stress model for the flow only (excluding buoyancy effects) can be expressed as

$$0 = g \sin \theta + \frac{\partial(-\overline{u'w'})}{\partial z} \quad (16-75a)$$

$$0 = \frac{\partial}{\partial z} \left( \frac{\nu_t}{\sigma_k} \frac{\partial k}{\partial z} \right) - \overline{u'w'} \frac{\partial \bar{u}}{\partial z} - \epsilon \quad (16-75b)$$

$$0 = \frac{\partial}{\partial z} \left( \frac{\nu_t}{\sigma_\epsilon} \frac{\partial \epsilon}{\partial z} \right) + c_{1\epsilon} \frac{\epsilon}{k} \left( -\overline{u'w'} \frac{\partial \bar{u}}{\partial z} \right) - c_{2\epsilon} \frac{\epsilon^2}{k} \quad (16-75c)$$

$$\overline{u'^2} = \frac{2}{3} k \left[ 1 + \frac{2(1-c_{1A}) \{ -\overline{u'w'} (\partial \bar{u} / \partial z) \}}{-\overline{u'w'} (\partial \bar{u} / \partial z) - (1-c_{3A}) \epsilon} \right] \quad (16-75d)$$

$$\overline{v'^2} = \frac{2}{3} k \left[ 1 - \frac{(1-c_{1A}) \{ -\overline{u'w'} (\partial \bar{u} / \partial z) \}}{-\overline{u'w'} (\partial \bar{u} / \partial z) - (1-c_{3A}) \epsilon} \right] \quad (16-75e)$$

$$\overline{w'^2} = \frac{2}{3} k \left[ 1 - \frac{(1-c_{1A}) \{ -\overline{u'w'} (\partial \bar{u} / \partial z) \}}{-\overline{u'w'} (\partial \bar{u} / \partial z) - (1-c_{3A}) \epsilon} \right] \quad (16-75f)$$

$$\overline{u'w'} = \frac{(1-c_{1A})k \{ -\overline{w'^2} (\partial \bar{u} / \partial z) \}}{-\overline{u'w'} (\partial \bar{u} / \partial z) - (1-c_{3A}) \epsilon} \quad (16-75g)$$

Again, with the  $\nu_t$ -relationship, Eq. (16-53), the system is closed, with seven equations for the seven unknowns,  $\bar{u}$ ,  $k$ ,  $\epsilon$ , and the four nonzero components of the Reynolds stress tensor,  $\overline{u'^2}$ ,  $\overline{v'^2}$ ,  $\overline{w'^2}$ , and  $\overline{u'w'}$ . That the algebraic stress model can reflect anisotropy is seen in the difference between the expression for  $\overline{u'^2}$  and  $\overline{w'^2}$ , with the latter being smaller, as is experimentally observed. Interestingly,  $\overline{u'^2}$  and  $\overline{w'^2}$  are predicted to be equal, which does not agree with measurements, which indicate that  $\overline{u'^2} > \overline{w'^2}$ . This incorrect behavior is also produced by the Mellor-Yamada level 2½ model (Mellor and Yamada 1982). The sum of the normal stresses is also seen to yield  $2k$ , as should be the case. Equation (16-75g) can also be expressed in a form consistent with a BEVM, i.e.,  $-\overline{u'w'} = c_\mu (k^2/\epsilon) (\partial \bar{u} / \partial z)$ , with, however,  $c_\mu$  being a function of  $P/\epsilon$  (Rodi 1993), a characteristic of AS models wherein the model constants of the standard  $k-\epsilon$  model are found to vary with local parameters, such as  $P/\epsilon$  or  $Ri_f$ .

## 16.5 APPLICATIONS OF TURBULENCE MODELS TO PROBLEMS RELATED TO SEDIMENT TRANSPORT

In this section, six applications relevant to sediment transport are described in rather more detail. The limited number

of applications necessarily reflect the biases and interests of the author, though studies were chosen to illustrate the capabilities/limitations of turbulence models to simulate different flow features, and where available, to compare the performance of different models. In the following, unless otherwise specified, simulations were performed with the standard  $k-\epsilon$  model without buoyancy, the free surface was not modeled (the rigid-lid approximation was invoked), and the turbulent Schmidt number for sediment, is  $(\sigma_s)_s = 1/\beta_s = 1$ . Four of the six problems involve the simulation of sediment transport, the cases without sediment being a study of flow over bed-forms and a study of flow within model vegetation, both of which exhibit aspects of some relevance to sediment transport modeling. In four cases, the bed is assumed fixed. Even in those cases with sediment transport and with an erodible bed, it is helpful to examine simulations of the corresponding case without sediment and with a fixed bed to investigate possible model deficiencies in a simpler problem. Without the added complications of sediment and a movable bed, the results for the simpler problem of flow over fixed beds provide an upper bound on what can be achieved by turbulence models, as far as the flow is concerned. The first four involve two-dimensional (one-dimensional when horizontal homogeneity is assumed) simulations, whereas, in the last two, three-dimensional computations were undertaken. In both erodible-bed simulations, an Exner equation is applied to determine the temporal evolution of the bed. Experimental data for comparisons have mainly been obtained in laboratory studies, because these offer more detail and control than can usually be achieved in field studies. In two instances, however, field observations were used for comparison.

Cautionary notes must be sounded in comparing the results of numerical simulation with experimental measurements. This concerns, on the one hand, the effects due entirely to numerical choices, such as mesh resolution and treatment of advection, and those due to the turbulence model. The earliest studies and likely most field studies may be criticized for the use of overly coarse numerical grids, often combined with overly diffusive numerical techniques. By the same token, experimental observations may also be contaminated by extraneous features, such as those due to side walls. In the following, the discussion will not dwell on either numerical or experimental shortcomings, though these should be kept in mind.

### 16.5.1 Flow Over Bed Forms

Bed forms (a definition sketch is given in Fig. 16-8) are ubiquitous in alluvial channels and have posed some of the most challenging problems for those interested in predicting sediment transport. An understanding of flow over bed forms is a prerequisite for reliable transport predictions. The flow over fixed two-dimensional nonerodible bed forms has been studied experimentally (Raudkivi 1963; van Mierlo and de Ruiter 1988; Lyn 1993; McLean et al. 1994; Bennett

and Best 1995; Cellino and Graf 2000). A comprehensive list of experimental work before 1995 is given in Bennett and Best (1995). Before the discussion of fixed-bed flows without sediment, however, the early work of Mendoza and Shen (1988) should be pointed out, in which not only flow but also sediment transport over dunes were simulated using an RS model, with however somewhat limited comparisons to measurements.

With separation, recirculation, and reattachment as prominent features, this flow shares similarities with the classic backward-facing step flow that has become a benchmark of turbulent flow simulation (for a recent study comparing the performance of various turbulence models, see Lien and Leschziner 1994). The quasi-periodic spatial pattern offers, however, simplifications as well as complications. On the one hand, a suitably defined outer flow may be less sensitive to details of bed geometry, somewhat analogously to the effective sand-grain roughness, which justifies to some extent the frequent approximation of treating the bed as being planer but with increased effective roughness (the main difficulty being that the flow region influenced by the bed forms may constitute a substantial fraction of the flow depth). On the other hand, the reattached flow will not have had sufficient time to approach an equilibrium state before separation occurs again, which contrasts with the typical backward facing-step flow, used in test cases, in which an equilibrium boundary-layer or fully developed channel flow separates.

The pioneering small-scale experiment of Raudkivi (1963) has been the subject of several studies, including those by Johns et al. (1990) using their one-equation model (see Section 16-4.3.3), by Mendoza and Shen (1990) with the AS model of Rodi (1976), by Sajjadi and Aldridge (1995) with one-equation,  $k-\epsilon$  and RS models, and by Cheong and Xue (1997) with a  $k-\epsilon$  model with a correction term for streamline curvature. The one-equation models have so far proved to be clearly inadequate, reproducing poorly the recirculation region in the mean velocity profile. The Sajjadi and Aldridge (1995) results with a one-equation model also largely over-predicted the magnitude of  $\overline{u'w'}$ . Some results of Mendoza and Shen (1990), in what seems to be the only study with an AS model (basically that of Rodi 1974), are shown in Fig. 16-9. Quite good agreement of predicted and measured velocity profiles is obtained, and even  $\overline{u'w'}$ , as well as bed shear

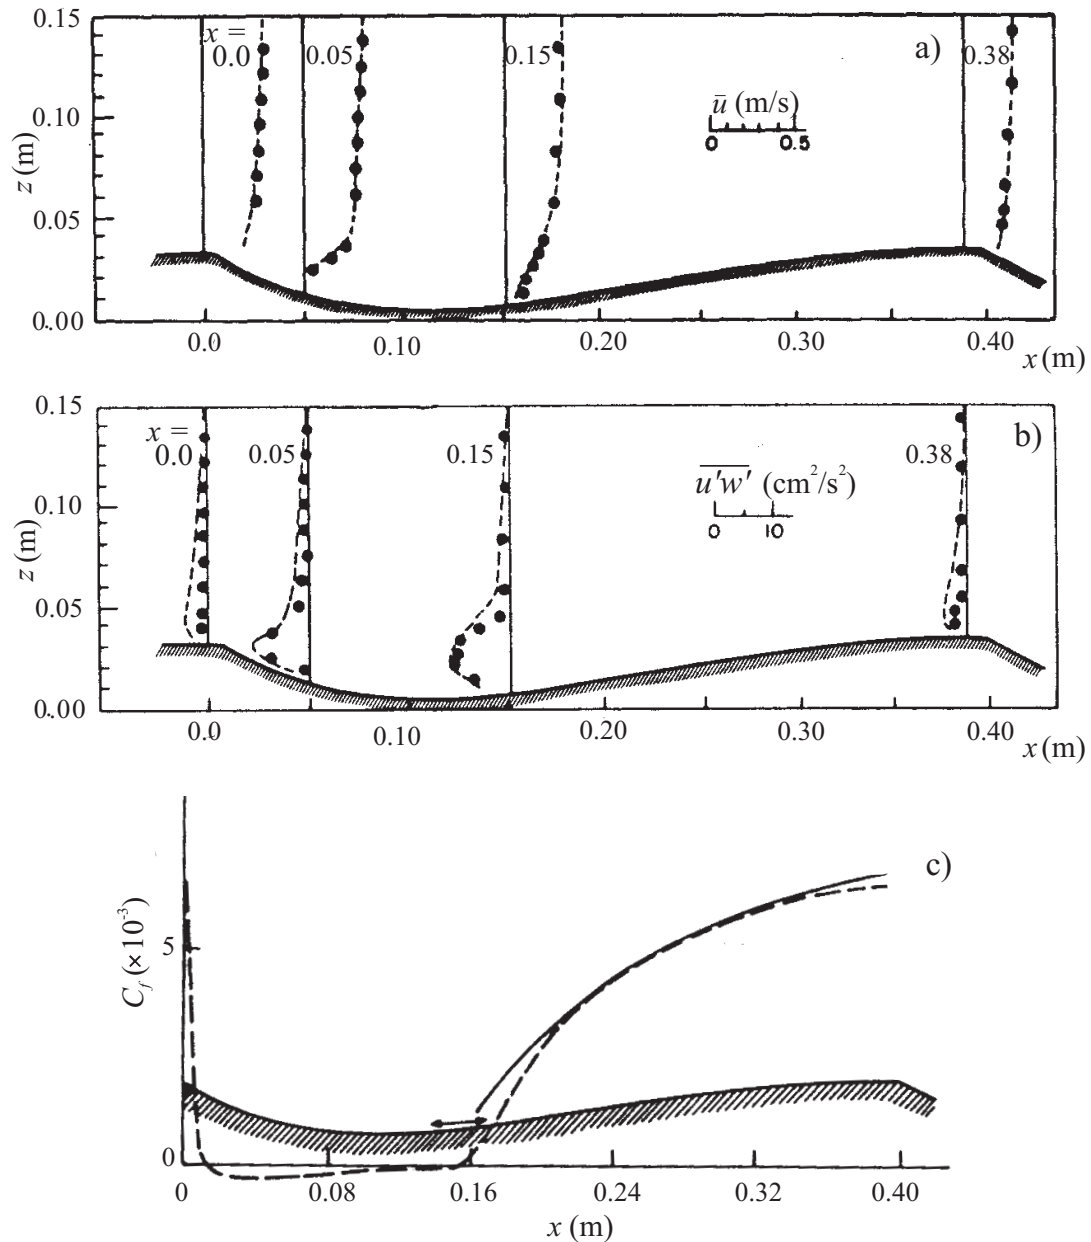

Fig. 16-8. Definition sketch for dune flow.

**Fig. 16-9.** Predictions of  $\bar{u}$ ,  $\overline{u'w'}$ , and  $C_f$  with an AS  $k-\epsilon$  model:—(Mendoza and Shen 1990); symbols and --- (measurements of Raudkivi 1963).

stresses, is quite well reproduced, though some deficiencies are seen, somewhat surprisingly, in regions away from the reattachment point. To a certain extent, this good performance is also found in the Sajjadi and Aldridge (1995) simulations of this case with  $k-\epsilon$  and RS models, in contrast to results of more recent studies for other flows, as discussed below. This difference may be explained by the experimental parameters of this particular case, which, as seen in Table 16-3, are quite

distinct from those of the other studies, but might also be due to the limitations of the experimental techniques.

Yoon and Patel (1996) simulated experiment T6 of van Mierlo and de Ruiter (1988) with a  $k-\omega$  model, whereas Cheong and Xue (1997) computed the experiment T5 with a  $k-\epsilon$  model (Johns et al. (1990) also studied T5 with their one-equation model, but its performance was similar to that already seen for the Raudkivi case). In spite of some

**Table 16-3 Experimental Parameters for Flow over Bed Forms**

Parameter	Raudkivi (1963; 1966)	van Mierlo de Ruiter (1988)		McLean et al. (Run 2, 1994)

differences between the two flows, T5 and T6, the two simulations are compared in Fig. 16-10. A three-layer wall-function approach at the bottom boundary was applied by Cheong and Xue, whereas the  $k-\omega$  rough-wall model (Eq. 16-64) was used by Yoon and Patel. The latter report a reattachment length,  $L_r$ , in agreement with the measured value, compared to a smaller than measured value (about 20% in the case of the standard  $k-\epsilon$  model and 10% in the case of the  $k-\epsilon$  model with curvature correction) predicted by Cheong and Xue. The prediction of the bed shear stress,  $\bar{\tau}_b$ , by the  $k-\omega$  model seems notably better, but Yoon and Patel reestimated  $\bar{\tau}_b$  from the velocity profile data based on  $d_r = 1.6$  mm rather than accepting the values provided by van Mierlo and de Ruiter, which assumed  $d_r = 2.6$  mm based on plane-bed measurements. In spite of the good prediction of  $\bar{\tau}_b$  and the fair agreement with regards to  $L_r$ , the results of Yoon and Patel *underestimated* overall flow resistance by 20%. This is likely associated with the poor performance of *both* models in predicting the peak Reynolds shear stress,  $-\overline{u'w'}$ , in the separated shear layer, which is markedly underpredicted. This differs from the experience in the backward-facing-step flow problem, where even the standard  $k-\epsilon$  model predicts reasonably well the value if not the location of the peak  $-\overline{u'w'}$  (Lien and Leschziner 1994), again pointing to subtle but important differences between this flow and the flow over periodic bed forms. An unfortunate characteristic of the van Mierlo and de Ruiter study is that, due to limitations of their optical system, measurements were taken at a location that was relatively far from the flume centerline, such that three-dimensional effects may have played some role.

Because these above studies examined different flows with various numerical grids and techniques, assessing the performance of turbulence models is made difficult. A comparison of four models for the same flow (Run 2 of McLean et al.

1994) with the same grid and numerical solver is given in Fig. 16-11. The computational domain and dune geometry are shown in Fig. 16-11(a). Periodic boundary conditions were imposed at the inlet and outlet, and the rigid-lid approximation was made. The commercial FLUENT (Version 6.0) code was used with second order upwind discretization on a  $321 \times 91$  (x,y) grid. A roughness height of 1.5 mm was assumed, and an enhanced near-wall model, which, grid permitting and if appropriate, attempts to resolve through to the viscous sublayer by appropriate blending functions and/or a two-layer model, was chosen.

The largest differences in the predicted bed shear stresses (Fig. 16-11(b)) are seen in the region upstream and in the neighborhood of the reattachment point. As seen in other studies, the  $k-\epsilon$  model significantly underpredicts  $L_r$ , with a slight improvement being achieved with the RNG modification. The  $L_r$  predicted by the  $k-\omega$  model is approximately the same as that in the earlier Yoon and Patel (1996) study, which, in view of the similarity of the experimental parameters, is not surprising. This, however, exceeds the observed  $L_r$  by  $\approx 10\%$ . The RS model underpredicts  $L_r$  by a similar amount, and tends to yield a flatter variation for the reattached internal boundary layer. Because of uncertainties in the estimation of bed shear stress, only a single representative point relatively far from the reattachment point is shown in Fig. 16-11b. All model predictions agree reasonably well with the measurement point in this region.

The results on mean velocity and Reynolds shear stress (Figs. 16-11(c and d)) indicate that the relative performance of a model can be quite variable depending on the region. In general, the standard  $k-\epsilon$  model fares the poorest, due in part to and consistent with its worst prediction of the reattachment point. In contrast, the  $k-\omega$  and RS models, which

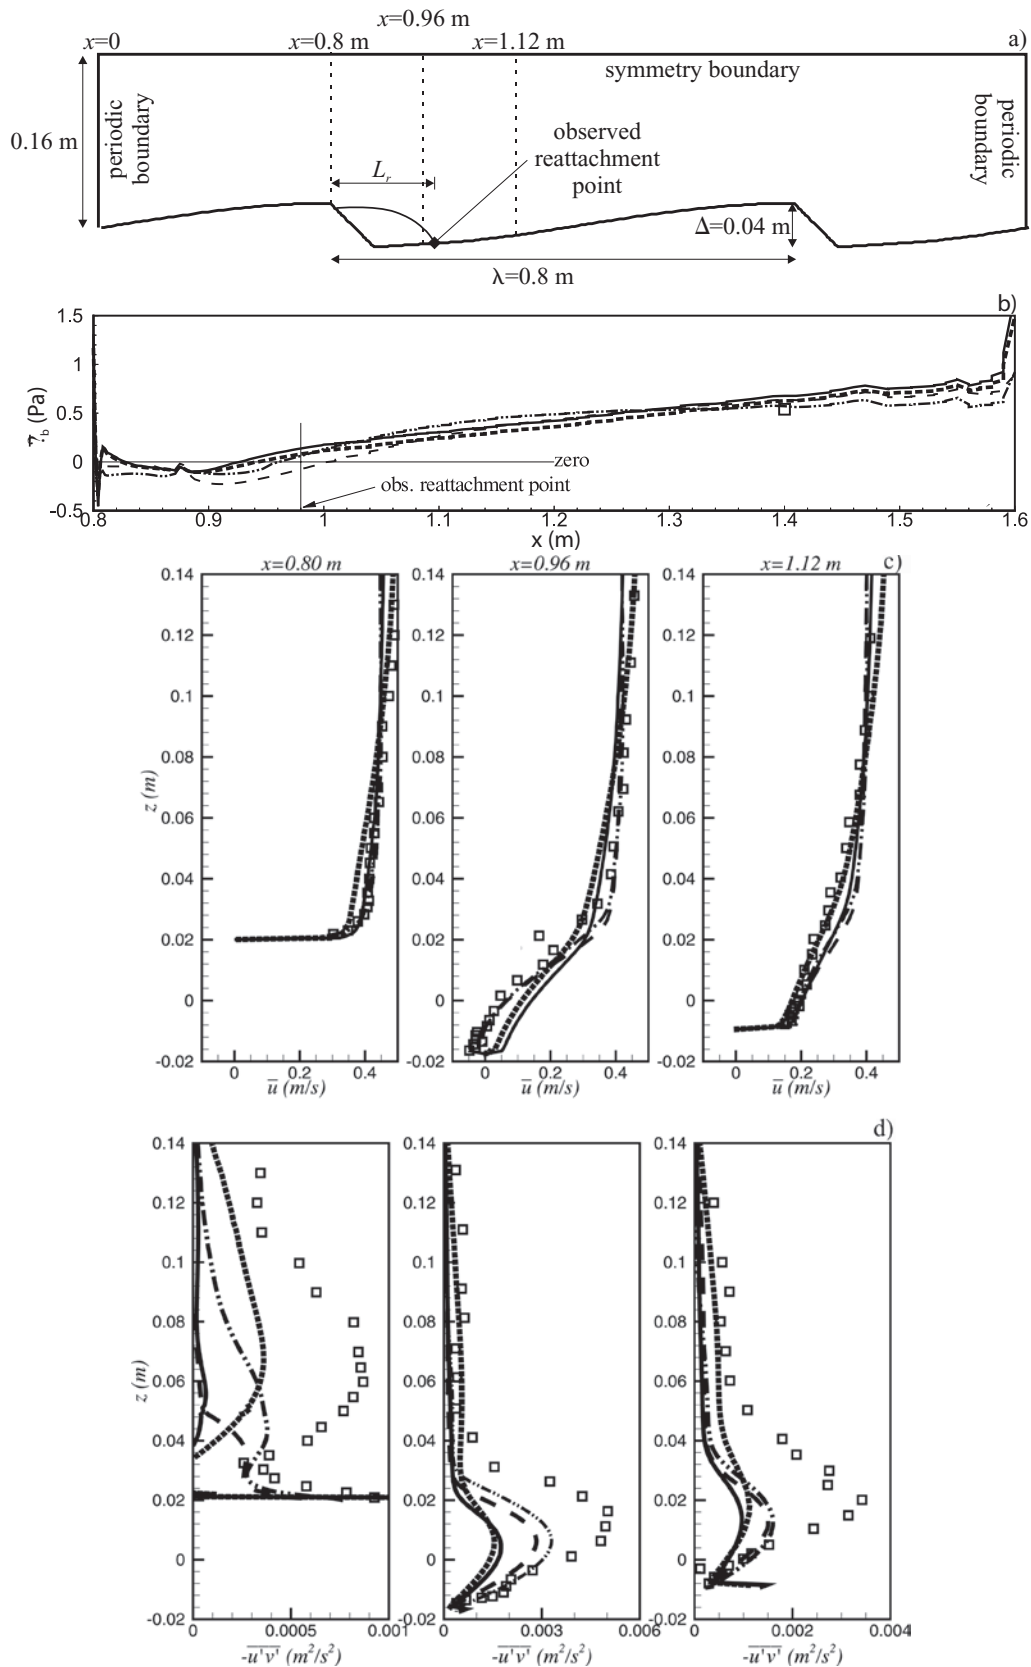

**Fig. 16-10.** Comparison of  $k-\omega$  results (Yoon and Patel 1996; note that  $z'$  is measured from the bed) (a), (b), (c), (d) with  $k-\epsilon$  model (Cheong and Xue 1997) (e), (f), (g) for van Mierlo and de Ruiter experiments, T6 and T5, respectively.

had best predicted the reattachment point, perform best, but only in the near-bed region. All models substantially underpredicted the peak  $-\overline{u'w'}$  associated with the separated shear layer. The RS model consistently performed the best in this regard, but could be in error by more than 50%. This conclusion is consistent with that found in previous studies of the van Mierlo and de Ruiter cases. In the upper half of the flow, however,  $-\overline{u'w'}$  was substantially underpredicted by all except the RNG  $k-\epsilon$  model. Somewhat surprisingly, the RNG  $k-\epsilon$  model did best in the upper half of the flow, particularly with respect to the prediction of  $-\overline{u'w'}$ . This behavior is rather at odds with previous studies, such as those shown in Fig. 16-10, where even an overprediction of  $-\overline{u'w'}$  in this region is seen in the results of Yoon and Patel (1996).

### 16.5.2 Flow and Transport in Sedimentation Tanks

Sedimentation tanks are standard equipment in water-treatment plants for the removal of suspended solids. From a broader perspective, lakes and estuaries may be viewed as naturally occurring sedimentation tanks. Turbulent transport in sedimentation tanks or clarifiers may significantly influence their removal performance and hence their reliability. In the present context, this sediment-laden flow presents an example, like turbidity currents, where sediment-induced buoyancy effects may be most clear-cut, and hence where buoyancy extensions to flow and turbulence models may be required. On the other hand, a major simplification compared to the problem of flows in alluvial channels is the negligible

**Fig. 16-11.** Comparison of four model predictions for the same flow (Run 2 of McLean et al. 1994) using the same numerical grid and scheme: (a) definition sketch, computational domain, and flow geometry; (b) bed shear stress predictions; (c) velocity profiles; (d) Reynolds shear stress profiles; where — is the  $k-\epsilon$  model, --- is the  $k-\omega$  model, ... is the RNG  $k-\epsilon$  model, and -·-·- is the Reynolds stress model. Symbols are measurements (or estimates from measurements).

role played by the near-bottom transport and hence the bottom boundary condition for the sediment equation. In this respect, the performance of the turbulence model is more precisely tested (in isolation from the other elements of the transport model) because only suspended load, which is directly related to the turbulence model, is of concern. Various computational studies have examined the flow and transport characteristics in clarifiers, ranging from the early constant eddy-viscosity models of Larsen (1977) and Imam et al. (1982) to the buoyancy-extended  $k$ - $\epsilon$  model of Devantier and Larock (1987) to an AS  $k$ - $\epsilon$  model in Zhou et al. (1994), with reviews of modeling issues by Krebs (1995) and Matko et al. (1996). Only two cases will be discussed in this section, those of Lyn et al. (1992) and Frey et al. (1993), who simulated the conditions listed in Table 16-4.

Lyn et al. (1992) applied a buoyancy-extended  $k$ - $\epsilon$  model with  $c_{3\epsilon} = 0$  to predominantly stably stratified horizontal flows. Even at relatively low particle concentrations, suspension-induced buoyancy effects may be significant because of small velocities and hence low shear. The problem of non-uniform-sized particles was dealt with by considering different size classes and solving Eq. (16-7) for each size class. That a solution for  $\epsilon$  is obtained in a  $k$ - $\epsilon$  model was exploited by developing a simple model for flocculation due to turbulent shear, such that the particle concentration in each size class may change not only by deposition but also by flocculation. A zero-diffusive-flux-concentration ( $\partial c / \partial z = 0$ ) condition was imposed at the bottom, under the assumption that reentrainment of deposited sediment does not occur. Results from simulations including and not including sediment-induced buoyancy effects of an actual (tertiary) clarifier are shown in Fig. 16-12. The actual inlet configuration is a series of square jets at the same elevation, and hence the details of the three-dimensional inlet flow cannot be captured by the two-dimensional model. Nevertheless, significant difference in streamline pattern depending on

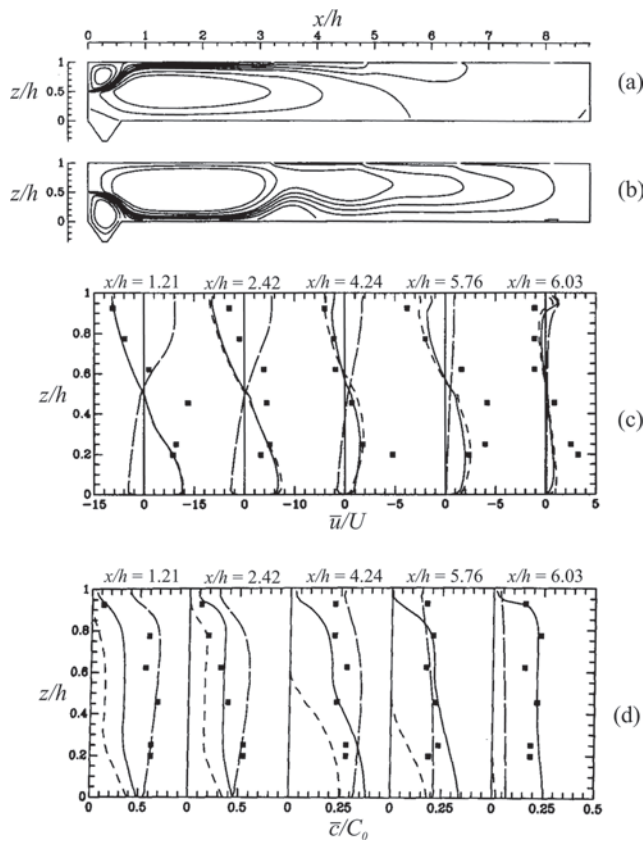

whether buoyancy effects are or are not included in the model is clearly seen, and comparison with the velocity measurements lends support to the significance of buoyancy effects, though only fair agreement between predicted and observed mean horizontal velocities was achieved. The importance of simulating different sediment size classes when buoyancy effects are included is seen in the comparison with concentration measurements. Because of the presence of small size fractions in the influent, a notable suspended solids concentration is still observed even toward the end of the tank. Interestingly, the concentration predictions, including the effects of different size classes, but without the effects of buoyancy, are found to be, somewhat fortuitously, in reasonable agreement with measurements in spite of obvious discrepancies in the corresponding flow predictions.

When Frey et al. (1993) applied a  $k$ - $\epsilon$  model in determining the steady-state flow field, they evaluated the removal efficiency of the clarifier, i.e., the ratio of influent to effluent particle concentration, not by the conventional advection-diffusion equation for the sediment concentration (Eq. (16-7)), but by a Lagrangian model, along the lines of Eqs. (16-9) and (16-10). They also more consistently included a random velocity component to simulate the random motion of particles. In their flow model, the rigid-lid approximation, which could be justified from their very small Froude numbers (Table 16-4), was not made, but buoyancy effects were not included. Fig. 16-13 compares their predictions for the flow field and removal with measurements in a laboratory model experiments with non-uniform-sized particles. Although substantial discrepancies between predicted and measured flow profiles can be seen in the inlet region, surprisingly good agreement is obtained for the predicted particle deposition (Fig. 16-13, the area numbers referring to streamwise stations at which deposited sediment was measured) and the effluent concentration, rather similarly to the previous case. Reasonable prediction

of derived overall quantities, such as sediment load, need not imply that detailed flow quantities are well reproduced, and caution is advised in evaluating numerical simulations based solely on derived quantities.

### 16.5.3 Flow in Vegetated Regions

With increased interest in the hydraulics of wetlands, interest in predicting flow and transport in vegetated areas has grown. Since it would be impractical to model the details of flows through vegetation (Fig. 16-14), questions regarding the appropriate averaging procedure may be raised. In this respect, the problem of predicting the average flow through vegetation resembles the two-phase flow problem in that, in addition to the modeling of turbulence, even the basic momentum balance as well as its effect

**Fig. 16-13.** Comparison of measurements in a model sedimentation tank with predictions of the  $k$ - $\epsilon$  model (Frey et al. 1993): (a) horizontal velocity,  $\bar{u}$ , and turbulent kinetic energy,  $k$  (symbols are measurements; — — — are predictions); (b) deposition of material at different streamwise stations (shaded bars are measurements; open bars are predictions); (c) effluent particle concentration relative to influent particle concentration as a function of particle diameter (shaded bars are measurements; open bars are predictions). Adapted with permission.

on turbulence characteristics, must be modeled. The usual practice adds a suitably parameterized force term modeling averaged drag forces to the momentum equation (Tsujimoto et al. 1991; Naot et al. 1996), somewhat analogous to the buoyancy-force term if the stratification analogy is invoked for sediment-laden flows. Lopez and Garcia (2001) have pointed out that this approach does not directly deal with the effects of dispersion associated with the spatial averaging process (see the discussion of

**Fig. 16-14.** Flow-through model (cylindrical) of nonemergent vegetation: (a) plan view, (b) profile view.

spatially averaged models in Appendix II to this chapter), but ultimately they resorted to the usual practice in their numerical modeling. In this subsection, for clarity, angle brackets will be used to denote variables that are spatially averaged over the horizontal plane.

Provided a model for the momentum equations has been chosen, the modeling of the effect of the vegetation on the turbulence follows essentially the same reasoning as in the development of the standard  $k$ - $\epsilon$  equations. If  $F_i$  denotes the additional force (per unit mass) term for modeling the effect of vegetation, then a production term,  $G_v = c_{vk} F_i u_i$ , is added as a source to the  $k$ -equation, and a balancing production term,  $(G_v)_\epsilon = c_{v\epsilon} (\epsilon/k) G_v$ , is added to the  $\epsilon$ -equation (Tsujimoto et al. 1991; Naot et al. 1996;

Lopez and Garcia 2001). As in previous discussions,  $c_{vk}$  and  $c_{v\epsilon}$  denote model constants, and again, for consistency with the limit of local equilibrium,  $c_{vk}$  and  $c_{v\epsilon}$  are related and cannot be chosen independently. There remains some debate as to the appropriate value of  $c_{vk}$ , which has been taken to be 0.07 by Tsujimoto et al. (1991) and Naot et al. (1996), and to be 1 by Burke and Stolzenbach (1983) and by Lopez and Garcia (2001). As noted by Lopez and Garcia, provided that  $c_{vk}$  and  $c_{v\epsilon}$  are chosen to satisfy the local-equilibrium-limit constraint, the predictions of the eddy viscosity,  $\nu_t$ , may not be particularly sensitive to the particular value of  $c_{vk}$ .

Lopez and Garcia applied one-dimensional (horizontal homogeneity of the spatially averaged flow was assumed)

**Fig. 16-15.** Comparison of measurements (symbols; interpolated lines to aid visualization) and simulation (heavy lines) results for spatially averaged quantities in flow-through model of nonemergent (Lopez and Garcia 2001) (a) mean velocity (—  $k$ - $\epsilon$  model, ....  $k$ - $\omega$  model, (b) Reynolds shear stress; (c) streamwise turbulence intensity (—  $k$ - $\epsilon$  model with  $c_{vk} = c_{v\epsilon} = 1$ , ....  $k$ - $\epsilon$  model with  $c_{vk} = c_{v\epsilon} = 0$ ).

$k$ - $\epsilon$  and  $k$ - $\omega$  models, with a varying closure coefficient,  $c_\mu$ , derived from an algebraic stress model, to the case of flow-through nonemergent vegetation without sediment. The results are shown in Fig. 16-15, compared with their own measurements, which were obtained with cylinders of diameter  $D = 0.64$  cm and height  $h_p = 12$  cm modeling plants. The parameter  $a_c \equiv D/(\lambda_x \lambda_y) = 1.09/\text{m}$  is used to characterize the areal density of the cylinders, where  $\lambda_x$  and  $\lambda_y$  are the center-to-center cylinder separations in the  $x$  and  $y$  directions. The mean velocity,  $\langle \bar{u} \rangle$ , is noticeably overpredicted by the  $k$ - $\epsilon$  model in the region above the model vegetation (Fig. 16-15a), which the authors attributed to the effect of three-dimensional motions that are not captured by the one-dimensional model. This by itself seems an inadequate explanation because the actual flow is also three-dimensional within the model vegetation, where the agreement between measurements and predictions is rather better. Similar to the two-phase flow, an incomplete model of the effects of vegetation might have contributed to the discrepancies, though the abrupt change from a vegetated region to vegetation-free region probably played a role. Both models predict similar Reynolds shear stress distributions (only the  $k$ - $\epsilon$  predictions are shown), which agree well with the data.

An evaluation of model performance regarding the predictions of  $k$ , in this case of the streamwise turbulence intensity, is bound up with the question of the appropriate value of the model constants  $c_{vk}$  and  $c_{ve}$  (whether  $O(1)$  or close to zero). A comparison was made of two model predictions obtained with the  $k$ - $\epsilon$  model (similar results were obtained with the  $k$ - $\omega$  model), one assuming that  $c_{vk} = c_{ve} = 0$ , the other assuming that  $c_{vk} = 1$  and  $c_{ve} = c_{1\epsilon}$ , with  $\langle \sqrt{u'^2} \rangle$ . The predictions of the former are clearly in closer agreement with the data. Lopez and Garcia, however, argue but do not confirm experimentally that if dispersive effects were included (see Appendix II for a discussion of dispersive effects), as they should be, then the latter predictions would likely be closer to reality.

#### 16.5.4 Oscillatory Flows with Sediment Transport over a Plane Bed

The previous cases examined flows that may be assumed steady in the mean. The effects of unsteadiness may play an important role in the case of sediment transport under waves, where short time scales, such as wave periods, are comparable to important turbulence time scales. The general topic of unsteady turbulent internal flows is reviewed by Brereton and Mankbadi (1995). Problems of sediment transport under waves are discussed broadly in Fredsoe (1993), and with particular attention to unsteady models in Davies (1995). Sediment transport in oscillatory flow over a plane bed has attracted much attention as a fundamental building block to the solution of the more general practical problem. The avail-

**Fig. 16-16.** Oscillatory flow: (a) U-tube laboratory channel; (b) profile view of flow in test section.

ability of standard experimental datasets (Jensen et al. 1989, referred to subsequently as JSF; Ribberink and Al-Salem 1994, and 1995, referred to subsequently as RA; Lodahl et al. 1998) makes possible detailed comparison of model predictions with measurements and evaluation of different models. These laboratory studies are performed in a U-tube channel with a closed and an open leg, with the unsteadiness being produced by an oscillating piston in the closed leg of the channel (Fig. 16-16). Under plane-bed (otherwise termed sheet-flow when the bed is erodible) conditions, horizontal homogeneity can be assumed, thus simplifying the problem in that only diffusive (in the vertical direction) transport need be considered, together with the unsteady terms. The experimental conditions for the two cases to be discussed are given in Table 16-5. In both cases, the free-stream flow is purely sinusoidal with zero mean flow; one is a clear-water flow over a fully rough fixed bed, where as the other involves suspended sediment over an erodible but plane transitionally rough bed.

Justesen (1991) compared the performance of the  $k$ - $\epsilon$  and a one-equation model (with  $\mathcal{L} = \kappa z$ ) for the JSF clear-water data at various phases,  $\phi = \omega t$ . The results (Fig. 16-17) suggest that the  $k$ - $\epsilon$  is somewhat superior to the one-equation model, at least with this simple specification of  $\mathcal{L}$ , but both models yield predictions in reasonable agreement with the measurements for the mean velocity and the bed shear stress, and as might be expected less so for the turbulence quantities. Agreement tends to deteriorate during the deceleration phase,  $\phi \gtrsim \pi/2$ , possibly indicating difficulties analogous to those encountered for turbulent boundary layers with adverse pressure gradients. Jensen et al. (1989) observed that the (ensemble) mean velocity profile follows a log law at each phase over much of the period, and indeed, for the rough boundary, estimated the bed shear stress from the log-law profile (hence, the good model predictions of bed shear stress are perhaps expected). Thus, since its behavior is so similar to that of a steady wall-bounded flow (over much of the period), and without the massive separation characteristic of the flow over bed forms and the inlet flow into sedimentation tanks, the oscillatory clear-water flow over a rough boundary is comparatively not a severe test of turbulence models, except possibly in the neighborhood of flow reversal ( $\phi = 0$  and  $\phi = \pi$ ).

Sana and Tanaka (2000) investigated various near-wall low-Reynolds-number  $k$ - $\epsilon$  turbulence models for oscillatory clear-water flows over a smooth bed. They compared

**Table 16-5 Experimental Parameters for Oscillatory Flows over Plane Beds**

Parameter	Jensen et al. (1989) (JSF, test 13)	Ribberink and Al-Salem (1995) (RA, condition 3)
Median sediment size, $d_{50}$ (mm)	n/a	0.21
Wave period, $T$ (s)	9.7	7.2
Freestream velocity amplitude, $U_m$ (m/s)	2.0	1.7
Freestream particle excursion amplitude, $a_{fs}$ (m)	3.1	2.0
Equivalent roughness, $d_r$ (mm)	0.84	0.52
$R = U_m a_{fs} / \nu$ ( $10^6$ )	6.2	3.4
$R_* = (u_*)_{\max} d_r / \nu$	84	n/a

their predictions with results of direct numerical simulations, thus avoiding uncertainties associated with experimental measurements. As in Justesen (1991), they found that velocity profiles and wall shear stresses were generally well predicted, with weakness during deceleration. Turbulence quantities, such as  $k$  and  $-\overline{u'w'}$ , tended to be less well predicted. As noted previously, the application of low-Reynolds-number near-wall models may be rather limited in sediment-transport problems characterized by rough erodible beds.

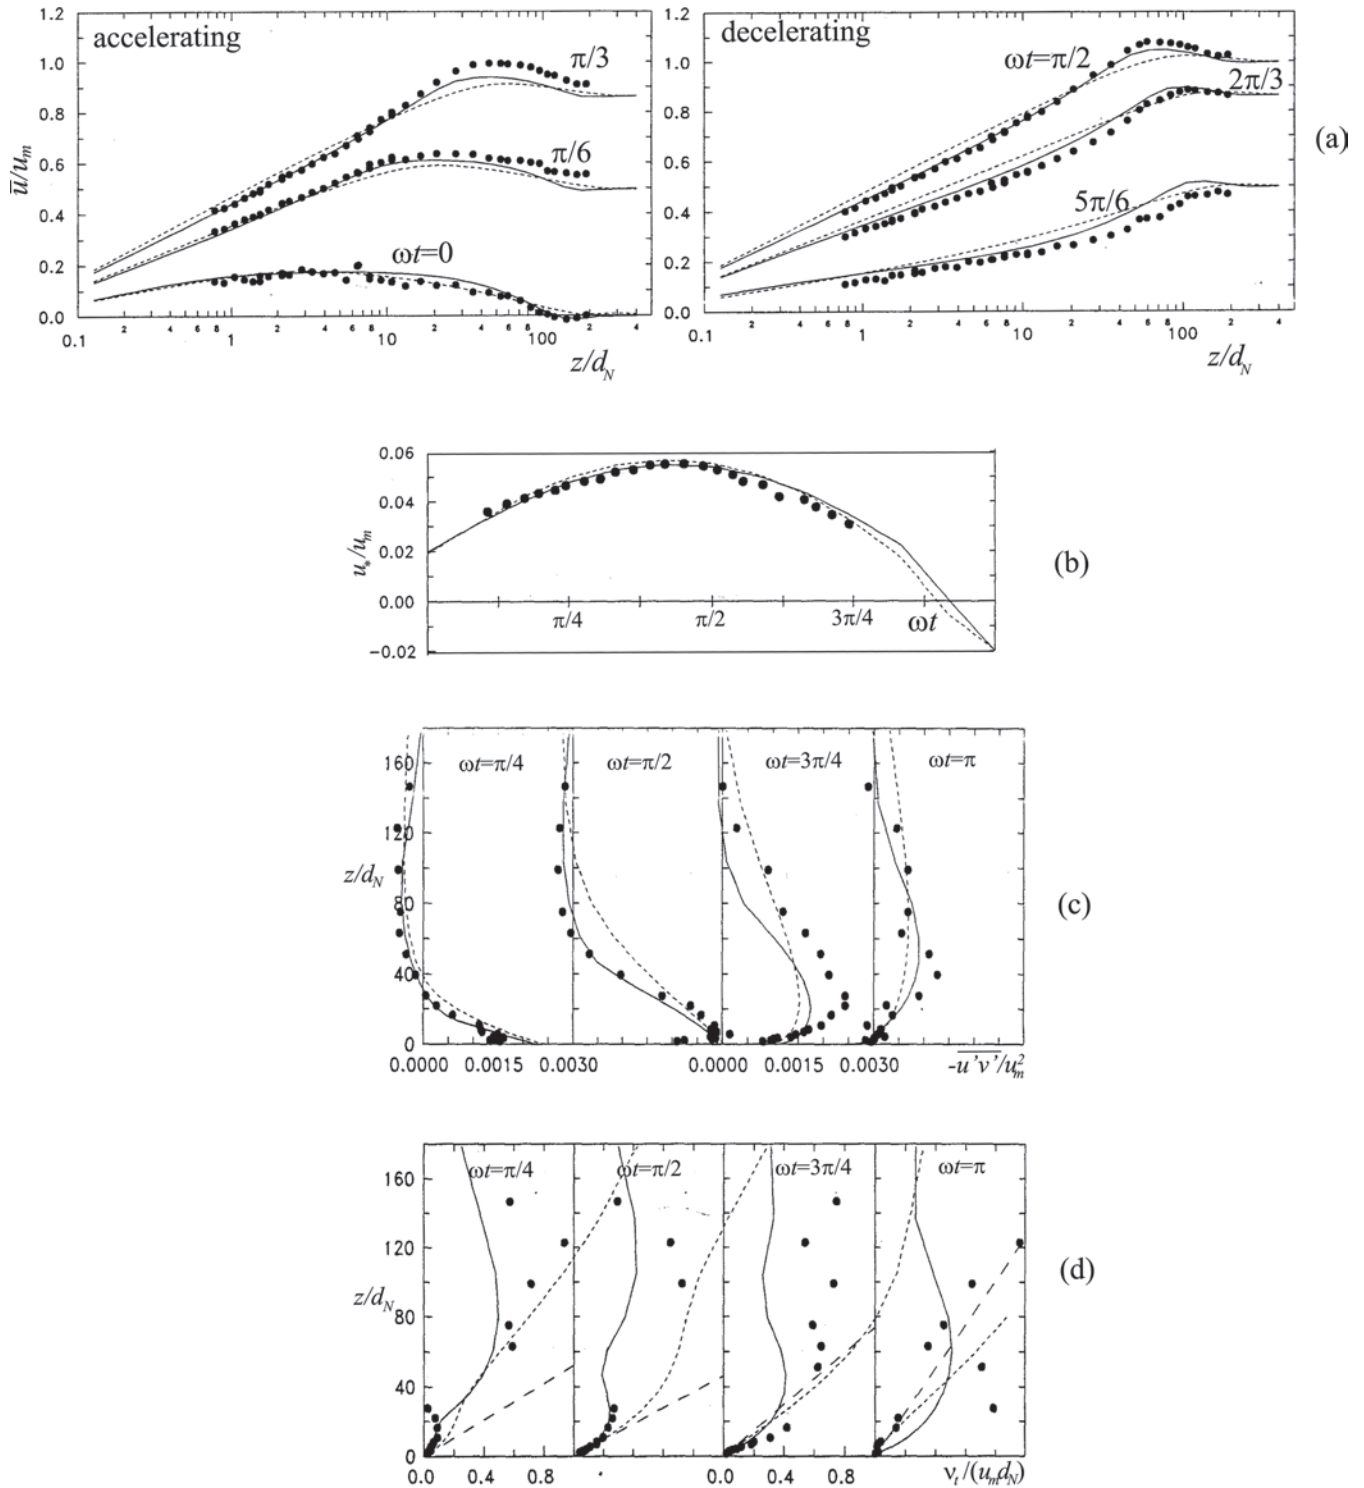

Various simulations of the flow studied by Ribberink and Al-Salem (1995) have been reported. Savioli and Justesen (1997a) applied a standard  $k$ - $\epsilon$  model, with a bottom concentration condition formulated in terms of a reference concentration, though effectively a flux condition (see discussion in Section 16.4.5.2). Four different models were tested in Davies et al. (1997): (1) a simple mixing-length model ( $\mathcal{L}_m = -\kappa z$ ), (2) a zero-equation eddy-viscosity model based on an unsteady generalization of Eq. (16-27), (3) an enhanced version of the one-equation model of Li and Davies already mentioned, and (4) a two-equation model of Huynh Thanh and Temperville (1991) that seems similar to the Mellor-Yamada level  $2\frac{1}{2}$  model. The one-equation and two-equation models incorporate the effect of buoyancy. The bottom concentration boundary condition was essentially the same in all four models, except for the mixing-length model, namely an equilibrium but time-varying reference concentration, though some allowance is made for sediment settling. Three of the four models assumed  $(\sigma_r)_s = 1$ , the exception being the two-equation model, where  $(\sigma_r)_s$  was variable. Brors and Eidsvik (1994) performed an RS model simulation, including buoyancy effects, with a bottom boundary concentration rather similar to that in the Davies et al. study.

The predictions of suspended sediment concentration at various distances from the bed are compared in Fig. 16-18. The simple mixing-length model is clearly inadequate, but the other models examined by Davies et al. are more comparable

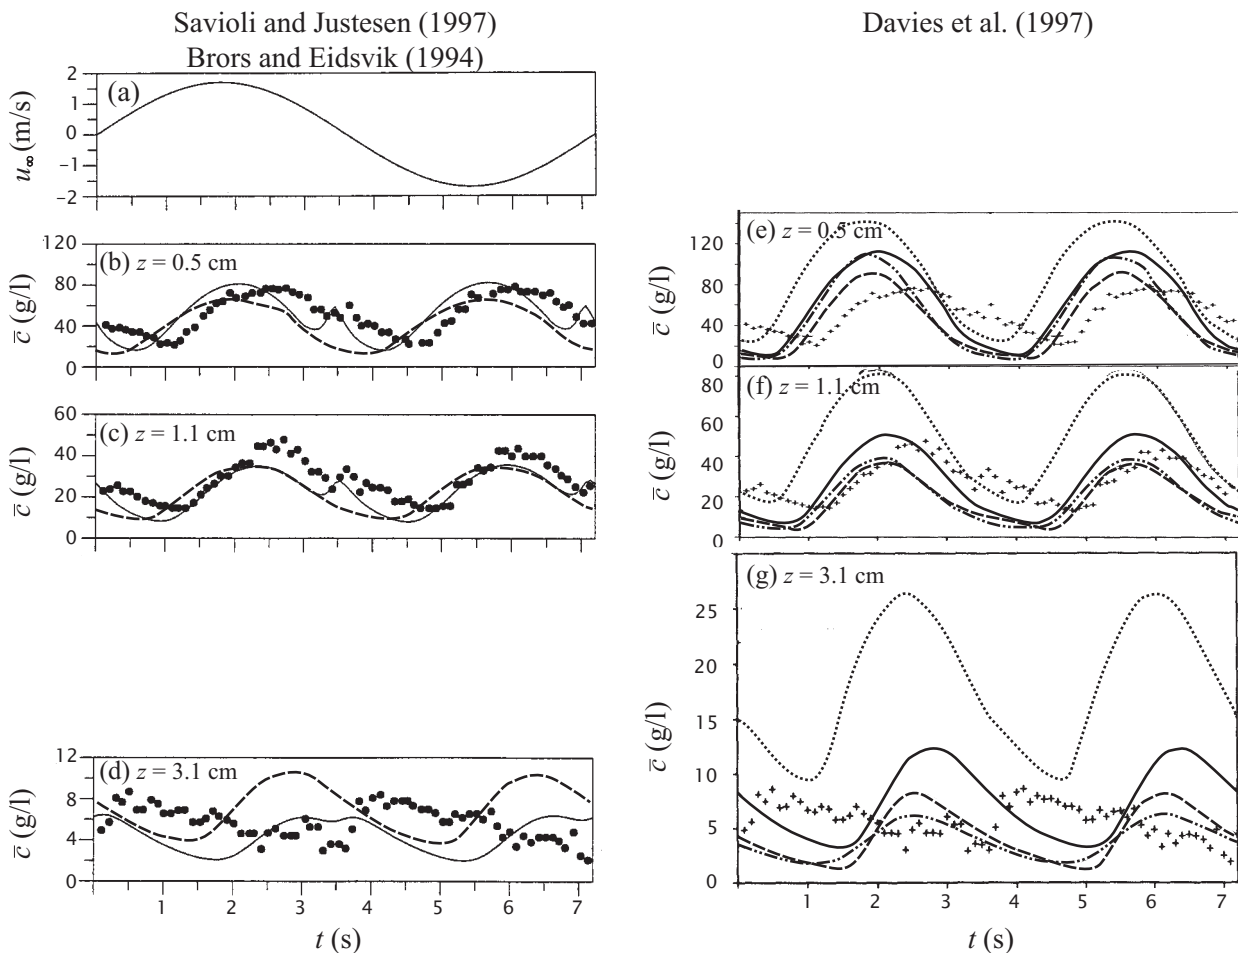

in predictive performance. All model predictions suffer from poor phase behavior, which tends to worsen as the distance from the bed increases. This contrasts with the good phase prediction seen earlier with respect to the bed shear stress in clear-water flows. In terms of concentration amplitude, the two-equation models, particularly that of Savioli and Justesen (the observed secondary peak when the flow velocity approaches zero is reproduced, whereas this is absent in the other predictions), performed somewhat better, though the eddy-viscosity model did surprisingly well. The performance of the RS model is not markedly better than that of the other models (again excepting the simple mixing length model), and is arguably worse than the  $k$ - $\epsilon$  results of Savioli and Justesen. This better performance of the Savioli-Justesen model may, however, not necessarily be attributable to the turbulence model as such, but rather to the bottom boundary condition, as argued by Savioli and Justesen (1997b). Although Ribberink and Al-Salem (1995) suggested that sediment-induced buoyancy effects might play an important role, Li and Davies (1996) concluded that turbulence damping effects predicted by the one-equation model were observed to be small, and that the representation of turbulence damping may be incomplete. The models including buoyancy effects did not especially distinguish themselves. Davies et al. (1997) attribute the discrepancy in phases to convective effects, though how these might arise in a horizontally homogeneous flow or how they may be different from history effects is not clear. Unfortunately, no predictions of flow characteristics was presented (the discussion by Ribberink and Al-Salem 1995 also was perfunctory with regard to velocity and turbulence statistics), and so whether the flow predictions were any better could not be assessed.

### 16.5.5 Flow and Transport in a Channel Bend

Natural channels often exhibit a sinuous or meandering longitudinal plan form, and hence flow and transport in

**Fig. 16-17.** Case of sinusoidally oscillating flow over a plane bed without sediment (Justesen 1991): profile predictions and measurements of (a) velocity,  $\bar{u}/U_m$ , (b) shear velocity,  $u_w/U_m$ , (c) Reynolds shear stress,  $-\bar{u}'w'/U_m^2$ , (d) eddy viscosity,  $\nu_t/(U_m d_N)$ ,  $U_m$  a maximum imposed velocity;  $d_N$  is the Nikuradse equivalent sand-bed roughness; symbols are measurements of Jensen et al. (1989) and Sumer et al. (1987); — is  $k$ - $\epsilon$  model; --- is one-equation model. Adapted with permission.

Adapted with permission.

bends are of interest to the sediment-transport community (see Chapter 8, which is devoted to various aspects of this topic). The flow is three-dimensional, with some of the basic aspects of sediment transport strongly influenced or even wholly determined by the action of relatively small secondary currents. The main secondary currents result from the opposing centrifugal and pressure forces. The importance of turbulence is more uncertain. Streamline curvature, measured by a radius of curvature,  $R$ , is known to have an effect, disproportionately large relative to the size of the curvature terms in the governing equations, on turbulent flow and transport (Patel and Sotiropoulos 1997). The question remains as to their importance relative to the pressure gradient terms, particularly in localized regions, such as regions near the banks. Further, even if its importance

with regard to the gross flow may be minor, its importance for long-term sediment transport, e.g., bank erosion, might be quite significant, and so good predictions of such flow details may be desirable for sediment rather than purely for flow aspects. Two recent experimental studies are suitable for detailed comparisons with numerical predictions (Hicks et al. 1990; Blanckaert and Graf 2001), in that not only mean but also turbulence quantities were obtained, but only the former has so far been the subject of a published simulation. Whereas Hicks et al. (1990) studied the simpler flow over a fixed smooth bed, the other two experimental studies to be dealt with, that of Thorne and Raïs (1983), a field study, and that of Odgaard and Bergs (1988), a laboratory study, investigated flows over an erodible bed, hence with mobile bed forms. In both cases, however, bed-load transport was

**Fig. 16-19.** (a) Definition sketch (plan view) of stream (Fall River, Colorado) simulated, (b), (c), and (d) predicted (dashed lines with shaded region) and measured (solid lines) lateral velocity at sections 2, 4, and 6. dominant. The important parameters of the three cases are summarized in Table 16-6.

Only three-dimensional or quasi-three-dimensional models will be discussed since the focus is on turbulence models. Ghanmi et al. (1997) applied a generalized mixing-length closure to simulating the flow in the Fall River in Colorado,

the site of the field study of Thorne and Raïs. A fixed bed, a hydrostatic pressure distribution (hence, this is a quasi-three-dimensional model), and a Manning friction relationship were also assumed. Within the bends, at Sections 2 and 6, there is reasonable *qualitative* agreement in the prediction of the secondary currents, though clear quantitative

**Table 16-6 Experimental Parameters for Flows in a Bend**

Parameter	Thorne and Raïs (1983)		Odgaard and Bergs (1988)	Hicks et al. (1990) (Run A6)
	Section 2	Section 6		
Experiment type	field		laboratory	laboratory
Bed conditions	migrating dunes		migrating dunes	smooth
Median sediment size, $d_{50}$ (mm)	mixed sand		0.30	n/a
Mean radius of curvature, $R_c$ (m)	11.0	13.5	13.1	3.66
Mean depth, $h$ (m)	0.41	0.44	0.15	0.062
Width, $B$ (m)	6.7	8.25	2.44	0.86
Discharge, $Q$ (m <sup>3</sup> /s)	1.7	1.7	0.15	0.022
$B/R$	0.61	0.61	0.19	0.23
$h/R$	0.037	0.033	0.011	0.017

discrepancies may be seen, even with the spatially sparse set of measurements (Fig. 16-19). In the straight reach connecting the two successive bends, at Section 4, there are *qualitative* discrepancies in the predicted and observed flow directions. This may indicate that the simple mixing-length model leads to an overly quick relaxation of the flow, such that the simulated flow out of the bend has little or no memory of the bend. The authors give a long list of possible reasons for the disagreement with measurements, though surprisingly the use of an overly simple turbulence model (or even an overly coarse numerical grid) is not mentioned.

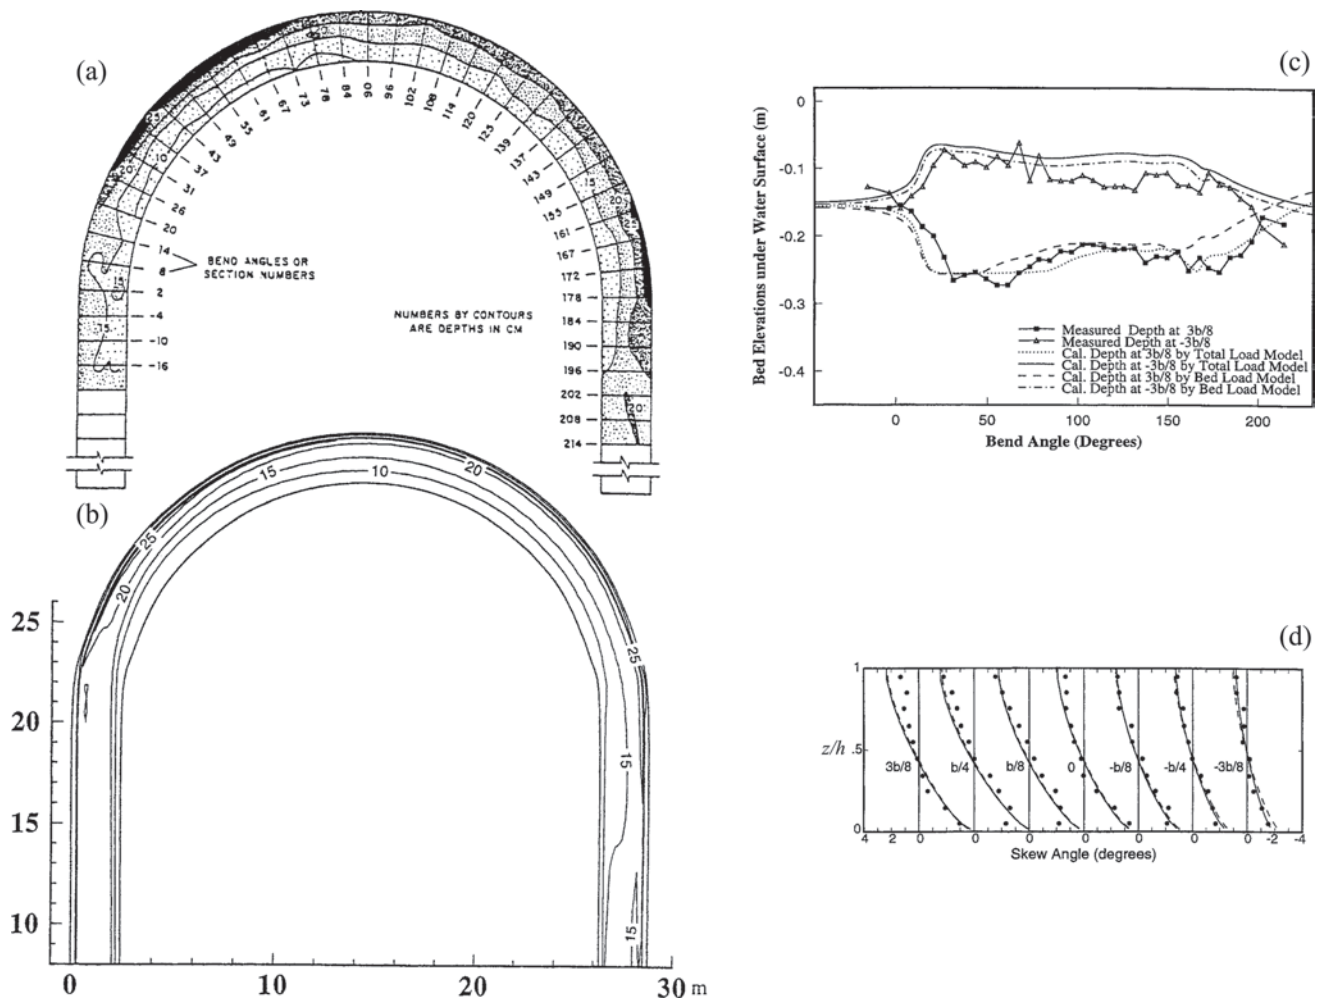

The more detailed laboratory measurements of Hicks et al. (1990) for the simpler fixed-bed problem with a sloping outer bank and a vertical inner bank allow a more precise evaluation of flow prediction. Ye and McCorquodale (1998) reported a full three-dimensional simulation, including a free-surface model, of this case. The  $k-\epsilon$  model was augmented by corrections to incorporate the effects of curvature and anisotropy near boundaries. The results, for the lateral velocity and turbulence intensity (Fig. 16-20), show quite good agreement with measurements at the different sections along the bed. Significant discrepancies are confined to regions near the free surface, near the outer sloping bank, and, perhaps surprisingly, at the bend entrance for the mean lateral velocity. To some extent, the better agreement may be attributed to the more precise laboratory measurements, though the use of the more sophisticated two-equation turbulence model probably contributed. Ye and McCorquodale also compared the predictions of the modified and the standard  $k-\epsilon$  model, and the differences were relatively minor, so the particular corrections for curvature and boundary-induced

anisotropy do not appear to have led to large improvements in predictions.

The erodible-bed laboratory study of Odgaard and Bergs (1988) has been tackled by Wu et al. (2000) in a model incorporating free-surface and erodible-bed models, as well as suspended (though for this particular case, suspended load was practically negligible) and nonequilibrium bed-load models. Typical of erodible-bed models, the sediment model is segregated from the flow model, so that the flow field is first computed, starting for example from an initially guessed bed geometry, then the sediment transport is estimated, and then the bed is adjusted, and the procedure is iterated until an equilibrium bed is attained. Because in the experiment, migrating dunes were observed, the equilibrium bed in the computations, which did not consider bed-form details, must be interpreted in terms of a temporal average. In Fig. 16-21, some computational results are compared with the laboratory measurements. The local flow depths and the equilibrium lateral bed profiles were reproduced fairly well (Figs. 16-21(a-c)). The velocity skew angle (Fig. 16-21(d)), i.e., the angle between the point velocity and the depth-averaged velocity, which characterizes the strength of the lateral velocity relative to the streamwise velocity and hence gives information regarding the relative importance of the secondary currents, was also relatively well predicted. The erodible-bed case was also examined in a simpler three-dimensional model by Shimizu et al. (1990) using the zero-equation parabolic eddy viscosity model (Eq. 16-27), and reasonable predictions of bed topography for a scale model of the Ishikari River were obtained. This raises the question of whether a two-equation model is necessary to predict gross changes in bed levels reliably in the bends of

**Fig. 16-20.** (a) Definition sketch of channel simulated, predicted (solid line), and measured (symbols), (b) lateral velocity,  $\bar{v}$ , and (c) lateral turbulence intensity,  $\sqrt{v'^2}$ , at different sections. Predictions, Ye and McCorquodale (1998); measurements, Hicks et al. (1990).

**Fig. 16-21.** Comparison of measurements (Odgaard and Bergs 1988) and predictions (Wu et al. 2000) in flow through a 180° bend: (a) measured and (b) predicted contours of water depth, (c) streamwise variation of bed elevations at two lateral positions, (d) streamwise averaged (along paths of constant radius) skew angles.

erodible-bed channels, even if detailed flow characteristics are not necessarily reproduced well.

### 16.5.6 Local Scour around a Circular Bridge Pier

The last application to be considered, local scour around a bridge pier (Fig. 16-22), shares many aspects of the flow and sediment transport discussed in the preceding subsections. As with the flow in bends, interest focuses on the (localized) erosion of the bed, and hence a model of a deformable bed is necessary. The smaller length scales involved, combined with strong three-dimensional features, would seem to pose a more difficult problem for turbulence models. Flow separation and even unsteady large-scale motions, e.g., due to vortex shedding in the wake, will also contribute to difficulties in flow simulation. Local scour occurs as the sediment transport capacity is locally enhanced due to a localized change in the

flow field, e.g., in the presence of a structure, causing sediment to be entrained into the flow, resulting in scour or erosion of the bed (or bank) in a localized area. This section will only consider the classic problem of scour around a circular bridge pier. Traditional discussions of this problem (Raudkivi 1990, or the two chapters 10 and 11 in this volume) have focused on developing correlations of the maximum scour depth with upstream hydraulic conditions, pier geometry, and perhaps sediment parameters. With the notable exception of Melville and Raudkivi (1977), detailed measurements of flow characteristics have only recently appeared (Dargahi 1989; Ahmed and Rajaratnam 1998). Several simulations have nevertheless been reported, mostly, however, without any detailed comparison with experimental measurements of flow and sediment comparable to those in the preceding subsections. Two of the cases to be considered simulated only the flow, without modeling the scour process itself, one over a plane bed, the other over a scour hole approximated as the

**Fig. 16-22.** Definition sketch of flow around a cylindrical bridge pier (adapted from Raudkivi 1990). Adapted with permission.

frustum of a cone (therefore radially symmetric about the cylinder axis), whereas the final case included an erodible-bed component, though in the simpler case of clear-water (zero sediment transport upstream of pier) scour. The experimental conditions of the three cases are summarized in Table 16-7. Only three-dimensional computations will be discussed.

Using an eddy-viscosity turbulence model (a Smagorinsky model, often used in large-eddy simulations; see discussion in the next section), with, however, a rigid-lid free-surface, Tseng et al. (2000) performed an unsteady computation of the fixed-plane-bed flow studied experimentally by Dargahi (1989). Because unsteadiness could be modeled, they were able to simulate the periodic vortex shedding occurring in the wake of the cylinder, predicting a shedding frequency of 0.34 Hz compared with a measurement of 0.32 Hz. The measured and predicted bed shear stresses ( $T_0$  is the upstream bed shear stress, and the cylinder center is located at  $x/D = 0$ ) along the streamwise line of symmetry are compared in Fig. 16-23(a). The maximum magnitude is well predicted, though its location is slightly displaced upstream. Unfortunately, comparisons with flow characteristics (velocity and turbulence intensity) were not reported, even though these were measured. The equilibrium-scour flow experiment of Melville and Raudkivi (1977) was simulated by Richardson and Panchang (1998), who tested both a mixing-length and an RNG model. They reported that whereas the latter “appeared to provide a qualitatively more realistic field downstream of the pier, the results of both simulations were largely similar.” Because the details of the bed geometry,

particularly those in the cylinder wake, were not available, they assumed a somewhat unrealistic scour hole geometry of a frustum of a cone concentric with the cylinder. The velocity magnitudes at a distance of 2 mm from the bed are of interest because they are expected to be closely correlated with bed shear stresses, and a comparison of predictions and measurements is given in Fig. 16-23(b). Because of likely differences in actual and modeled bed geometries downstream of the cylinder, only results upstream of the cylinder are of interest. Qualitative similarities are seen in an elongated and narrow low-velocity region at the rim of the scour hole and a high-velocity region at an  $\approx 70^\circ$  angle from the streamwise symmetry axis. A high degree of uncertainty is associated with these early measurements using thermal anemometry in a highly turbulent recirculation region where such techniques are known to be deficient. An earlier computation by Mendoza-Cabral (1993) with a  $k-\epsilon$  model of plane-bed experiments of Melville and Raudkivi (1977) also noted discrepancies between predictions and measurements and attributed these to both experimental uncertainties and deficiencies in turbulence closure.

The erodible-bed case with sediment transport was treated in a decoupled iterative manner by Olsen and Melaaen (1993), who solved alternately the steady flow field with a  $k-\epsilon$  model, and then the sediment equations, which included both a suspended-load (modeled by Eq. (16-7)) and a bed-load component, adjusting the bed elevation in the vicinity of the cylinder to ensure sediment conservation in the near-bed region. At the bed, the concentration was specified.

**Table 16-7 Experimental Parameters for Flow around a Circular Bridge Pier**

Parameter	Melville and Raudkivi (1977)	Dargahi (1989)	Olsen and Melaaen(1993)
Bed conditions	Fixed plane bed (roughness, $d_r = 0.36$ mm)	Equilibrium bed (sand)	Equilibrium bed (plastic particles)
Median sediment size, $d_{50}$ (mm)	n/a	0.30	3 ( $s = 1.04$ )
Cylinder diameter, $D$ (m)	0.051	0.15	0.75
Upstream depth, $h_0$ (m)	0.15	0.20	0.33
Upstream velocity, $u_0$ (m/s)	0.25	0.26	0.067
$R = u_0 D / \nu$ ( $10^3$ )	37.5	39	50
$F = u_0 / \sqrt{gh_0}$	0.21	0.19	0.04

A comparison between measured and computed scour-hole dimensions (Fig. 16-23(c)) showed good agreement. This work was later extended to treat the time-varying scour process in a more realistic manner including unsteady flow and transport as well as a free surface, and the resulting model is more fully described by Olsen and Kjellesvig (1999). While detailed comparisons with flow measurements were not made, the predicted maximum scour depth agreed well with traditional empirical formulae. These encouraging results indicate that the simulations can yield useful engineering results, but whether details of the flow field and the concentration field were predicted well remains to be established.

## 16.6 DISCUSSION

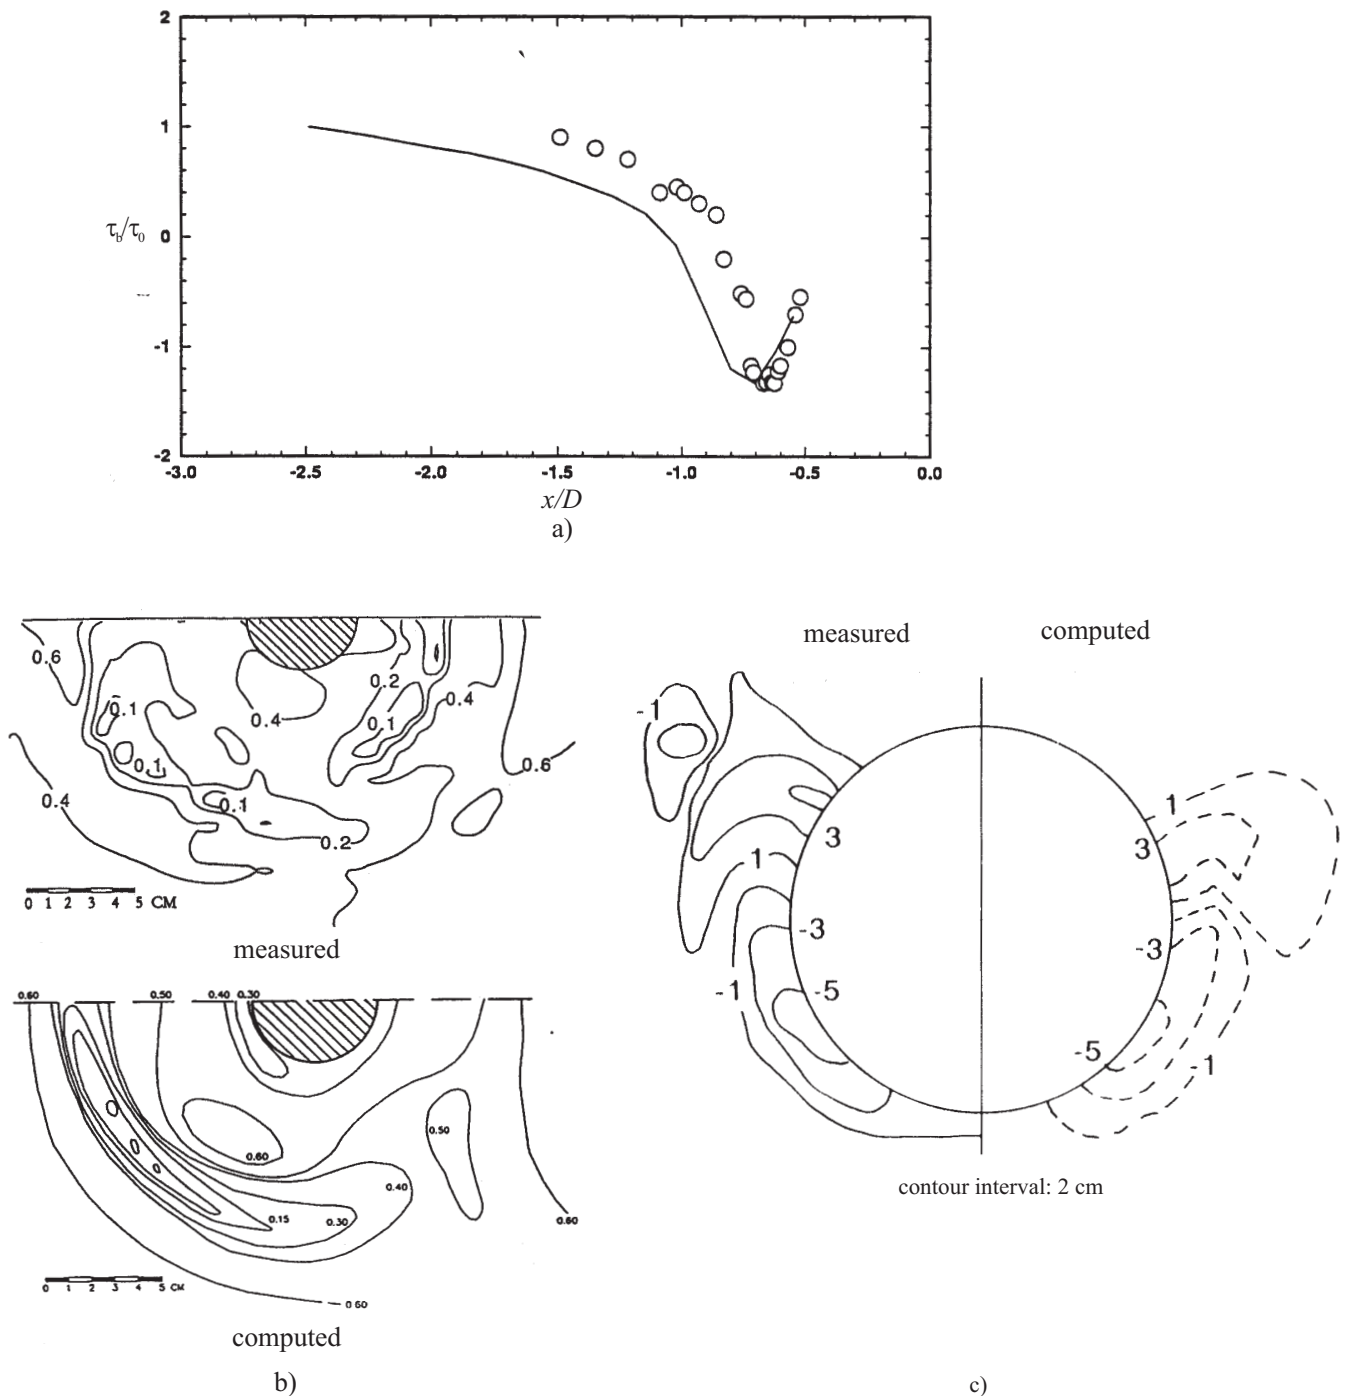

In the preceding sections, the rudiments of turbulence closure models have been described, with particular emphasis on application to problems in sediment transport. Models of varying degrees of sophistication are available, ranging from the simplest constant-eddy-viscosity model through to two-equation models and beyond, and each class of models can, when applied judiciously, provide useful tools for predicting flow and transport. Except in the section on more advanced models, discussion has been restricted to standard models, because these are the most likely to be encountered in the literature, and also most likely to be available in commercial CFD software packages (though these have not particularly catered to those interested in sediment transport). Other models, e.g., CH3D-SED, developed for the U. S. Army Corps of Engineers (Gessler et al. 1999), in which only the vertical diffusivity is computed from a  $k$ - $\epsilon$ -type model, and constant horizontal diffusivities are user-specified, may be understood as variants of the standard models, subject to the same or even more limitations, since these have been adapted for a particular class of applications. Although turbulence models have received the bulk of the

attention, these should be recognized as only one element of a flow and transport simulation, and therefore as only one source among others of errors in prediction.

### 16.6.1 Considerations in the Assessment and Choice of Models

A model should give useful predictions for reasonable effort. In the hands of skilful practitioners, useful predictions can be made with the simplest of models, judiciously complemented by additional empiricism. More complicated models should be adopted when there is reasonable expectation that these bring an increase in accuracy and reliability at least commensurate with the greater effort, which is not necessarily only computational, required. The latter is not always the case, and the point of diminishing returns might be at a rather low level of model sophistication. Qualitative understanding of the specific flow problem is valuable in assessing the importance of the various physical processes contributing to sediment transport and in choosing an appropriate model. What constitutes a reasonable effort is, however, continually changing as advances in computational power are made. Whereas at the time of publication of *ASCE Manual 54*, a one-dimensional model was the limit of what could be expected, at the present time, a fairly complete transport simulation of a steady two-dimensional problem with a two-equation model can be routinely performed with commonly available computer resources. In the not-too-distant future, three-dimensional models may foreseeably become the norm. Another consideration in choosing a more sophisticated model is the possible greater demands in terms of data input for initial and boundary conditions, and for calibration of model parameters.

Traditional prediction methods for one-dimensional cross-sectionally averaged sediment transport are notoriously inaccurate, with measures of merit for prediction typically formulated in terms of the fraction of predictions within 100%

**Fig. 16-23.** Flow around a cylindrical bridge pier: (a) Smagorinsky eddy-viscosity model predictions (—, Tseng et al. 2000) of normalized bottom shear stress ( $T_0$  = upstream bed shear stress) compared with the measurements (symbols) of Dargahi (1989); (b) RNG model predictions (Richardson and Panchang 1998) and measurements (Melville and Raudkivi 1977) of near-bed (2 mm from bed) velocity magnitudes; (c)  $k-\epsilon$  model predictions and measurements of local scour (Olsen and Melaaen 1993). Adapted with permission.

of the observed values. It is important to recognize that several elements of traditional methods may be imbedded in the models discussed in this chapter in boundary conditions and model parameters, such as the effective roughness height, the equilibrium concentration at a reference elevation, or a sediment-transport function. Errors and uncertainties associated with these elements carry over to predictions made with numerical simulations incorporating sophisticated turbulence models. The turbulence model is directly concerned only with suspended load, and only indirectly affects bed-load transport through the estimate of the shear stress at the bed. Particularly in computations of flows over bed forms, where these are not simulated directly, heavy reliance is placed on traditional results. Here it might be mentioned that one of the classic problems of traditional sediment transport, that of determining the stage or depth of flow for given discharge, channel, and sediment characteristics, has to a large extent been avoided in flow simulations, which frequently assume the depth to be known and apply a rigid-lid model for the free surface. Thus, if the depth must be known prior to the simulation, a rather curious situation could arise in which a traditional method is applied to determine the depth, with all of the uncertainties inherent in such an estimate. Similarly, the determination of whether bed forms are present in any given flow, and if so, their dimensions, so that the specifications of flow and sediment bottom boundary conditions can be done, may rely on traditional procedures. Thus, it would be overly optimistic to expect that the use of sophisticated turbulence models will result in large gains in prediction accuracy and reliability over the entire range of sediment transport problems. Computational fluid dynamics, coupled with turbulence models, has permitted a considerably wider range of sediment transport problems, including multidimensional problems, to be tackled in much greater detail successfully, i.e., with about the same level of accuracy that has been achieved with traditional methods for simple one-dimensional problems. While this may seem disappointing, it should be realized that the problems often could not be tackled at all, so that a prediction within 100% could represent considerable improvement. Nevertheless, the point should be made that the largest errors may be associated with the model elements taken over from traditional methods, rather than with the choice of turbulence models.

The choice of model dimensionality, whether a one- or two- or even three-dimensional modelling approach is taken, may have important implications for the choice of turbulence models. A three-dimensional model at this time may eliminate from consideration more sophisticated turbulence closures due to the computational effort required, so it becomes important to weigh whether increased dimensionality may be more important than a more sophisticated turbulence model. At the same time, if three-dimensional effects on turbulence are strong, then simple turbulence models may be difficult to justify because appropriate length and velocity scales are unknown, and a two-equation model would be attractive. A depth-averaged model (see Appendix II as well as Chapter 15)

might be considered as a workable compromise if the primary turbulence-producing motions of interest are in the horizontal "plane." For steady flows in a channel, with a dominant flow direction and flow separation and reverse flow either absent or not important, a zero-equation model is certainly worth considering as a first step; if the results indicate that important expected flow features one missing or conversely unexpectedly present, a more sophisticated model might be considered for further study. The place of one-equation models is rather questionable; although their limitations vis-à-vis two-equation models are clear, their superiority compared to the zero-equation model is debatable. Of the two-equation models, the  $k-\epsilon$  model remains the standard, being the most widely used and hence the most widely tested. This does not mean that its results should be accepted without hesitation. The applications discussed in the previous sections illustrate that the  $k-\epsilon$  model can often provide useful engineering predictions, but may also fail to capture localized though possibly important flow details. There is some numerical evidence that the  $k-\omega$  and the RNG models can yield, in certain flows and in certain flow regions, performance superior to that of the standard  $k-\epsilon$  model, but a blanket recommendation in favor of one or the other cannot yet be made. Full Reynolds stress models have been rather disappointing (it should be admitted that a wide range of RS models have been and continue to be proposed, and lumping them together as has been done here is not altogether fair); the improvements in prediction performance have not always been dramatic. They are likely to remain research rather than practical engineering tools in the foreseeable future. The intermediate algebraic and the related nonlinear turbulence models may, however, be of more practical interest in the near future because of their less severe computational demands.

The value of validation data, either from the field or from laboratory experiments, can hardly be overemphasized. At the same time, it must be recognized that accurate measurements in sediment-transporting flows pose very difficult challenges, in the laboratory but particularly in the field. Certainly, one of the most significant obstacles to improvement in turbulence modeling and prediction of sediment transport lies in the inadequacy of experimental techniques for detailed reliable measurements of flow and, especially, sediment transport, particularly near the bed or boundary. Although turbulence modification has been discussed at some length, the limited experience so far obtained with simulations suggests that, insofar as a stratification model was invoked, the effect is weak, and as a first approximation might be neglected, except in special cases such as a turbidity current or other predominantly sediment-generated flows. The question remains open of whether the actual effects of turbulence modification might be stronger than those predicted by a stratification analogy, and might be manifested in near-bed boundary conditions.

The numerical aspects of flow simulation have received almost no mention in this chapter, though they may exert a

large influence on results as well as choice of models. These are discussed in greater detail in a number of specialized monographs (e.g., Gresho and Sani 2000; Ferziger and Peric 2001). Discretization schemes, particularly the treatment of advection in a high  $Re$  flow, may significantly influence the results of simulations because of numerical diffusion. It is now recognized (Speziale and Thangam 1992) that a large part of the discrepancy between measurements and early predictions of the classic turbulent backward-facing-step flow was due to numerical error rather than to the shortcomings of the  $k$ - $\epsilon$  model. The use of higher-order discretization schemes and of grid-dependence tests are both strongly recommended in any turbulent simulations. The greater computational effort for more sophisticated turbulence closures stems not only from the larger number of partial differential equations that must be solved, but also from convergence characteristics of their numerical solution being substantially worse than those of simpler models. Second-moment closure models tend to be numerically stiff, such that the additional computational effort may be much larger than might otherwise be thought. Similarly, inclusion of buoyancy effects may in a  $k$ - $\epsilon$  model entail difficulties in convergence of the numerical solution.

### 16.6.2 Other Types of Models

The chapter has focused on Reynolds-averaged Navier-Stokes (RANS) approaches to the problem of predicting turbulent sediment transport, since these are likely to remain dominant in practical computations. Two other general approaches may be mentioned very briefly. Large-eddy simulation (LES) attempts a solution of the unsteady three-dimensional Navier-Stokes equations. Unlike RANS models, time averaging is not applied, but spatial averaging or filtering over small scales is performed. This necessitates modeling on these small subgrid scales, which is thought to be easier because of the more universal characteristics of small-scale motion. Reviews of this approach may be found in the book edited by Galperin and Orszag (1993) and articles by Ferziger (1996) and Piomelli and Chasnov (1996). LES is extremely demanding of computational resources, much more so than even second-moment closure, because sufficient numerical spatial and temporal resolution is needed to ensure realization of a turbulent flow, and the computation must be conducted over a sufficiently long duration for meaningful flow statistics, even for a statistically steady problem. When the typical scale of hydraulic and sediment transport problems is considered, it is doubtful that LES will be applied to problems outside of the laboratory for the foreseeable future. Like the even more extreme direct numerical simulation, where the aim is to resolve all scales with no modeling assumptions being made, one of the main advantages of LES applied to homogeneous fluids is the minimal modeling involved. In its extension to the two-phase sediment-transport problem, however, the modeling involved is much more substantial, and so the attractiveness of LES is

correspondingly diminished. For example, Zedler and Street (2001) performed an LES study of sediment transport over a rippled bed (the size of the larger computational domain was  $20.3 \times 2.1 \times 7.7$  cm!), in which an advective-diffusion equation (similar to Eq. (16-7)) is used to model sediment transport. Already a continuum model assumption is made about which some question might be raised (in regions of high concentration, with  $c \sim 0.005$ , it is estimated that there might have been less than five particles within a numerical cell). Further, a molecular diffusion coefficient (equal to the fluid kinematic viscosity!) was imputed to the sediment for modeling reasons, but its physical origin is dubious. Even for a single-phase flow, LES encounters problems in the flow region near a wall (Ferziger 1996), such that, with the added difficulties posed by high particle concentrations and roughness, not to mention bed forms, the model component become much more substantial. Nevertheless, research results with LES applied to problems related to sediment transport are beginning to appear with greater regularity (Chang and Scotti 2003; Portela and Oliemans 2003).

The last general approach deserving of some mention is less specifically a distinct modeling approach than a conceptual framework for developing models that may ultimately be formally similar to classic models such as a mixing-length model. The central role of coherent structures, especially in wall-bounded turbulence, is emphasized in this framework (Nezu and Nakagawa 1993). Early contributions from researchers in sediment transport include Einstein and Li (1959), Grass (1971), and Jackson (1976), but recent experimental work has attempted to interpret sediment transport in terms of coherent structures (e.g., Müller and Gyr 1986; Wei and Willmarth 1991; Bennett and Best 1995; Nelson et al. 1995; Nino and Garcia 1996; Bennett and Best, 1998), and first attempts have been made to base quantitative predictive models (e.g., Cao 1996) on these concepts. Although these may eventually lead to models competitive with the standard RANS models, experience outside of the sediment transport field is not conducive to optimism (Bradshaw 1997).

## APPENDIX I. CARTESIAN TENSOR NOTATION

In this chapter, the governing equations involved scalars (concentration), characterized only by a magnitude, vectors (momentum), characterized by magnitude and direction, with three components, and second-order tensors (stresses), characterized by magnitude, direction, and a surface orientation, with nine components. The use of Cartesian tensor notation offers an economical means of expressing what would in conventional notation be rather lengthy equations.

### I.1 Index Notation for Vectors and Tensors

Rather than the conventional use of different symbols for different coordinate directions, the use of a subscripted index

notation is preferred. A position vector,  $(x, y, z)$ , is therefore denoted as  $(x_i, x_j, x_k)$ , which can be further reduced to  $x_i$ ,  $i = 1, 2, 3$ . Similarly, the velocity vector, often denoted by  $(u, v, w)$ , is written as  $(u_i, u_j, u_k)$  or simply  $u_i$ . The benefits are multiplied when the quantity of interest is a tensor quantity, such as stress, which has nine rather than the three components of a vector quantity. It is helpful to view a second-order tensor as a matrix quantity; e.g., the stress tensor,  $T_{ij}$ , can be written as

$$T_{ij} = \begin{bmatrix} \tau_{11} & \tau_{12} & \tau_{13} \\ \tau_{21} & \tau_{22} & \tau_{23} \\ \tau_{31} & \tau_{32} & \tau_{33} \end{bmatrix}. \quad (16-76)$$

The tensors discussed in the preceding are symmetric in that the matrix is symmetric; i.e.,  $\tau_{12} = \tau_{21}$ ,  $\tau_{13} = \tau_{31}$ , and  $\tau_{23} = \tau_{32}$ . For stresses, the first subscript indicate the surface on which the stress acts (the surface is perpendicular to the coordinate direction referred to by the first subscript), where as the second subscript indicate the direction of the stress.

The tensor product of two vectors yields a tensor, such as the Reynolds stress tensor, which is the product of fluctuating velocity vectors, averaged over time. Thus, it can be written as

$$-\overline{u'_i u'_j} = \begin{bmatrix} -\overline{u'_1 u'_1} & -\overline{u'_1 u'_2} & -\overline{u'_1 u'_3} \\ -\overline{u'_2 u'_1} & -\overline{u'_2 u'_2} & -\overline{u'_2 u'_3} \\ -\overline{u'_3 u'_1} & -\overline{u'_3 u'_2} & -\overline{u'_3 u'_3} \end{bmatrix}. \quad (16-77)$$

A useful tensor quantity is the Kronecker delta,  $\delta_{ij}$ , which can be interpreted as an identity matrix; i.e.,

$$\delta_{ij} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}. \quad (16-78)$$

The Boussinesq eddy-viscosity model can therefore be expressed alternatively as

$$\begin{aligned} & \begin{bmatrix} -\overline{u'_1 u'_1} & -\overline{u'_1 u'_2} & -\overline{u'_1 u'_3} \\ -\overline{u'_2 u'_1} & -\overline{u'_2 u'_2} & -\overline{u'_2 u'_3} \\ -\overline{u'_3 u'_1} & -\overline{u'_3 u'_2} & -\overline{u'_3 u'_3} \end{bmatrix} \\ &= \begin{bmatrix} \nu_t \left( \frac{\partial \bar{u}_1}{\partial x_1} + \frac{\partial \bar{u}_1}{\partial x_1} \right) - \frac{2}{3} k & \nu_t \left( \frac{\partial \bar{u}_1}{\partial x_2} + \frac{\partial \bar{u}_2}{\partial x_1} \right) \\ \nu_t \left( \frac{\partial \bar{u}_2}{\partial x_1} + \frac{\partial \bar{u}_1}{\partial x_2} \right) & \nu_t \left( \frac{\partial \bar{u}_2}{\partial x_2} + \frac{\partial \bar{u}_2}{\partial x_2} \right) - \frac{2}{3} k \\ \nu_t \left( \frac{\partial \bar{u}_3}{\partial x_1} + \frac{\partial \bar{u}_1}{\partial x_3} \right) & \nu_t \left( \frac{\partial \bar{u}_3}{\partial x_2} + \frac{\partial \bar{u}_2}{\partial x_3} \right) \end{bmatrix} \end{aligned}$$

$$\left[ \begin{array}{c} \nu_t \left( \frac{\partial \bar{u}_1}{\partial x_3} + \frac{\partial \bar{u}_3}{\partial x_1} \right) \\ \nu_t \left( \frac{\partial \bar{u}_2}{\partial x_3} + \frac{\partial \bar{u}_3}{\partial x_2} \right) \\ \nu_t \left( \frac{\partial \bar{u}_3}{\partial x_3} + \frac{\partial \bar{u}_3}{\partial x_3} \right) - \frac{2}{3} k \end{array} \right]. \quad (16-79)$$

Equation (16-79) may be compared with Eq. (16-14). It also illustrates more concretely how restrictive the Boussinesq eddy-viscosity assumption is regarding the relationship between the Reynolds stress tensor and the mean strain tensor.

## I.2 The Summation Convention

In multidimensional problems, the governing equations often involve sums of contributions from components associated with different coordinate directions. The summation convention provides a conveniently compact manner of expressing sums involving vectors and tensors. In Cartesian coordinates, whenever the same (roman) letter subscript is repeated, then that subscript takes on all possible values and the results are summed. Thus, the fluid continuity equation for an incompressible fluid can be written as

$$\frac{\partial u_j}{\partial x_j} = \frac{\partial u_1}{\partial x_1} + \frac{\partial u_2}{\partial x_2} + \frac{\partial u_3}{\partial x_3} = 0. \quad (16-80)$$

The repeated index,  $j$ , takes on all values,  $j = 1, 2, 3$ , and the respective quantities are summed. Another example is the advection term in the momentum equation, e.g.,

$$\frac{\partial (u_i u_j)}{\partial x_j} = \frac{\partial (u_i u_1)}{\partial x_1} + \frac{\partial (u_i u_2)}{\partial x_2} + \frac{\partial (u_i u_3)}{\partial x_3} \quad (16-81)$$

Here, although there are two indices,  $i$  and  $j$ , only  $j$  is repeated, so that  $u_i$  remained unchanged, but  $j$  again takes on all values and the results are summed. For  $i = 1$ , this would be the advection term for the momentum balance in the  $x_1$ -direction. A final example is given by the production term,  $P_k = -\overline{u'_i u'_j} S_{ij}$ , in the turbulent kinetic energy equation. Because the  $k$ -equation is a scalar equation,  $P_k$  is necessarily a scalar, but it is a product of two tensors, the Reynolds stress tensor,  $-\overline{u'_i u'_j}$ , and the mean strain rate tensor,  $S_{ij}$ . The procedure of arriving at a scalar from a (scalar) product of second-order tensors is sometimes termed a contraction, and is signaled by two repeated indices, both  $i$  and  $j$ . Because there are two repeated indices rather than one, a total of nine rather than three terms are included in the summation. If expanded, Eq. (16-35) would appear as

$$\begin{aligned}
P_k = & -\overline{u'_1 u'_1} \left[ \frac{1}{2} \left( \frac{\partial u_1}{\partial x_1} + \frac{\partial u_1}{\partial x_1} \right) \right] - \overline{u'_1 u'_2} \left[ \frac{1}{2} \left( \frac{\partial u_1}{\partial x_2} + \frac{\partial u_2}{\partial x_1} \right) \right] \\
& - \overline{u'_2 u'_1} \left[ \frac{1}{2} \left( \frac{\partial u_2}{\partial x_1} + \frac{\partial u_1}{\partial x_2} \right) \right] - \overline{u'_2 u'_2} \left[ \frac{1}{2} \left( \frac{\partial u_2}{\partial x_2} + \frac{\partial u_2}{\partial x_2} \right) \right] \\
& - \overline{u'_3 u'_1} \left[ \frac{1}{2} \left( \frac{\partial u_3}{\partial x_1} + \frac{\partial u_1}{\partial x_3} \right) \right] - \overline{u'_3 u'_2} \left[ \frac{1}{2} \left( \frac{\partial u_3}{\partial x_2} + \frac{\partial u_2}{\partial x_3} \right) \right] \\
& - \overline{u'_1 u'_3} \left[ \frac{1}{2} \left( \frac{\partial u_1}{\partial x_3} + \frac{\partial u_3}{\partial x_1} \right) \right] - \overline{u'_2 u'_3} \left[ \frac{1}{2} \left( \frac{\partial u_2}{\partial x_3} + \frac{\partial u_3}{\partial x_2} \right) \right] \\
& - \overline{u'_3 u'_3} \left[ \frac{1}{2} \left( \frac{\partial u_3}{\partial x_3} + \frac{\partial u_3}{\partial x_3} \right) \right].
\end{aligned} \tag{16-82}$$

The first three terms on the right hand side hold  $i = 1$ , while  $j$  takes on all three values; the next three terms hold  $i = 2$ , while  $j$  takes on all three values; and so on.  $P_k$  is sometimes written in an alternative manner, namely,  $P_k = -\overline{u'_i u'_j} (\partial \bar{u}_i / \partial x_j)$ , which can be shown to lead ultimately to the same expression for  $P_k$ .

Although tensor notation has been exploited here primarily for convenience, much of the current development of new turbulence models relies heavily on the language associated with tensors, such as invariance and material frame indifference, which arises in the development of constitutive equations in continuum mechanics. An introduction to such concepts is given in Malvern (1969).

## APPENDIX II. SPATIALLY AVERAGED MODELS

The problem of turbulence closure arose from a simplification of the Navier-Stokes equations in which temporal averages were taken. A similar though quite distinct problem arises when simplification by spatial averaging is sought. In traditional one-dimensional (sediment-free) hydraulics, cross-sectional averaging leads to momentum and kinetic energy correction coefficients that vary with the degree of spatial heterogeneity of bulk flow velocity at any specific cross section. Model equation(s) must be developed for these coefficients if these play any significant role. The classic problem of longitudinal shear dispersion in a pipe or channel provides another example of the effects of spatial averaging, which is more directly comparable to the turbulence problem. In this case, a cross-sectionally averaged model leads to apparently substantially increased (longitudinal) transport, which under certain conditions can be effectively modeled by a gradient-transport relationship with a constant *dispersion coefficient* (Fischer et al. 1979). Apart from cross-sectional averaging, the most common form of spatial averaging

is averaging over the depth, which can often be justified because vertical variations in flow quantities are much less important than variations in the plan or horizontal directions. Less frequently encountered, width averaging may have special appeal for sediment-transport problems because the vertical direction, central to the sedimentation process, retains an explicit role in the simulation. Other, more subtle forms of spatial averaging are often implicitly applied. Approaches where bed forms are present in a flow but are not explicitly modeled may be viewed as implicitly spatially averaging or filtering out bed details. The following is limited to depth-averaged models, but similar issues would arise in other spatially averaged models. Further discussion of spatially averaged and depth-averaged models may be found in Chapter. 15, as well as in the review by the ASCE Task Committee on Turbulence Models in Hydraulic Computations (1988).

Similarly to a time-averaged variable (recall Eq. (16-1)), the depth-averaged variable,  $\langle f \rangle$ , can be obtained by integration over the local depth,  $h(X, Y, t)$ ,

$$\langle f \rangle (X, Y, t) = \frac{1}{h(X, Y, t)} \int_{Z_{\text{bed}}(X, Y, t)}^{Z_{\text{bed}}(X, Y, t) + h(X, Y, t)} f(X, Y, Z, t) dZ \tag{16-83}$$

where  $X$  and  $Y$  denote the plan location in the streamwise and in the lateral direction, and  $Z_{\text{bed}}$  is the local elevation of the bed (see Fig.16-24). The deviation of  $f$  from  $\langle f \rangle$  along the vertical coordinate,  $Z$ , is denoted as  $f^*$ , so that  $f$  can be decomposed as  $f = \langle f \rangle + f^*$ . In much the same way as in Reynolds averaging, problems arise from the nonlinear advection terms when the momentum equations are integrated over the depth. Consider, for example, the depth-averaging of the advective flux of streamwise momentum over the depth,

$$\langle uu \rangle = \langle (\langle u \rangle + u^*) (\langle u \rangle + u^*) \rangle = \langle u \rangle^2 + \langle u^* u^* \rangle \tag{16-84}$$

Fig. 16-24. Definition sketch for depth-averaged model.

where

$$\langle u^* u^* \rangle = \frac{1}{h(X, Y, t)} \int_{z_{\text{bed}}}^{z_{\text{bed}} + h(X, Y, t)} (u - \langle u \rangle)^2 dZ. \quad (16-85)$$

The spatial correlation terms such as  $\langle u^* u^* \rangle$  are not necessarily zero, and when they are not negligible should be included in the transport equations.

Almost invariably, depth-averaged models invoke the shallow-water-wave approximation, i.e., neglect of vertical accelerations such that the vertical momentum equation reduces to the equation of hydrostatics, with the resulting governing equations

$$\frac{\partial h}{\partial t} + \frac{\partial(h\langle u \rangle)}{\partial X} + \frac{\partial(h\langle v \rangle)}{\partial Y} = 0 \quad (16-86a)$$

$$\begin{aligned} & \frac{\partial(h\langle u \rangle)}{\partial t} + \frac{\partial(h\langle u \rangle^2)}{\partial X} + \frac{\partial(h\langle u \rangle \langle v \rangle)}{\partial Y} \\ &= -gh \frac{\partial}{\partial X} (h + Z_{\text{bed}}) + \frac{(\tau_{sx} - \tau_{bx})}{\rho} \\ &+ \frac{1}{\rho} \left[ \frac{\partial}{\partial X} \left\{ h(\bar{\tau}_{xx} - \rho \langle u^* u^* \rangle) \right\} \right. \\ & \left. + \frac{\partial}{\partial Y} \left\{ h(\bar{\tau}_{xy} - \rho \langle u^* v^* \rangle) \right\} \right] \end{aligned} \quad (16-86b)$$

$$\begin{aligned} & \frac{\partial(h\langle v \rangle)}{\partial t} + \frac{\partial(h\langle u \rangle \langle v \rangle)}{\partial X} + \frac{\partial(h\langle v \rangle^2)}{\partial Y} \\ &= -gh \frac{\partial}{\partial Y} (h + Z_{\text{bed}}) + \frac{\tau_{sy} - \tau_{by}}{\rho} \\ &+ \frac{1}{\rho} \left[ \frac{\partial}{\partial X} \left\{ h(\bar{\tau}_{xy} - \rho \langle u^* v^* \rangle) \right\} \right. \\ & \left. + \frac{\partial}{\partial Y} \left\{ h(\bar{\tau}_{yy} - \rho \langle v^* v^* \rangle) \right\} \right]. \end{aligned} \quad (16-86c)$$

The shear stresses at the bed and at the water surface,  $\tau_{bx}$  and  $\tau_{sx}$ ,  $\tau_{by}$  and  $\tau_{sy}$ , follow from integration over the depth, and flow-resistance relationships specifying these in terms of the other variables, such as  $\langle u \rangle$  and  $\langle v \rangle$ , must be externally provided. In many practical cases where the flow may be considered well-mixed over the depth, the deviation or *dispersion* terms,  $\langle u^* u^* \rangle$ ,  $\langle u^* v^* \rangle$ , and  $\langle v^* v^* \rangle$ , are small and can be justifiably neglected. As suggested by the form of Eq. (16-86), these terms act like effective stresses, but, unlike Reynolds stresses, are *not* related to turbulence, but rather, as should be clear from Eq. (16-85), stem *entirely* from spatial averaging over nonuniformities in time-averaged quantities in the vertical direction. If these are important, then separate models, most likely problem-specific, must be provided for

them. As might be expected from Taylor dispersion (Fischer et al. 1979), a gradient-transport model, possibly with a constant dispersion coefficient, might under certain conditions be appropriate. For expedience, such a model assumption is frequently made in practice, even when a theoretical justification cannot be rigorously made, to account for the dispersion terms if these are not altogether ignored. More sophisticated models of dispersion make specific assumptions regarding the vertical distributions of mean velocity and concentration, and compute the dispersive transport by integration, similarly to Eq. (16-85). Lane (1998) discusses the modeling of dispersive transport in depth-averaged models. Evidently vertical motion features, e.g., due to buoyancy effects, are not captured in Eq. (16-86), except possibly indirectly in the dispersion terms, so that if these are of interest, a depth-averaged model is unlikely to be appropriate.

A depth-averaged turbulence model is concerned *solely* with determining the remaining stress terms,  $\bar{\tau}_{xx}$ ,  $\bar{\tau}_{xy}$ ,  $\bar{\tau}_{yy}$ . Turbulence models ranging from zero- to two-equation models may be considered for this purpose in a manner analogous to the non-depth-averaged models already discussed. Zero-equation constant-eddy-viscosity and mixing-length models have been applied. Depth-averaged two-equation models could conceivably be derived in the same way as the continuity and momentum equations by integrating the equations, say for  $k$  and  $\epsilon$ , over the depth. This would pose difficulties in the treatment of the important production and destruction source/sink terms, as well as in the definition of eddy viscosity, which must be related, preferably in a computationally simple manner, to depth-averaged quantities, such as  $\langle u \rangle$ . Thus, a more heuristic approach is taken in formulating turbulence two-equation model equations that are analogous to those applied in non-depth-averaged models. A  $k$ - $\epsilon$  model for depth-averaged simulations (Rastogi and Rodi 1978; Rodi 1993) may therefore be given as

$$\begin{aligned} & \frac{\partial(\langle k \rangle)}{\partial t} + \frac{\partial(\langle u \rangle \langle k \rangle)}{\partial X} + \frac{\partial(\langle v \rangle \langle k \rangle)}{\partial Y} \\ &= \frac{\partial}{\partial X} \left( \frac{\langle v_t \rangle}{\sigma_{\langle k \rangle}} \frac{\partial \langle k \rangle}{\partial X} \right) + \frac{\partial}{\partial Y} \left( \frac{\langle v_t \rangle}{\sigma_{\langle k \rangle}} \frac{\partial \langle k \rangle}{\partial Y} \right) \\ &+ \langle P_k \rangle + \langle P_k \rangle_b - \langle \epsilon \rangle \end{aligned} \quad (16-87a)$$

$$\begin{aligned} & \frac{\partial(\langle \epsilon \rangle)}{\partial t} + \frac{\partial(\langle u \rangle \langle \epsilon \rangle)}{\partial X} + \frac{\partial(\langle v \rangle \langle \epsilon \rangle)}{\partial Y} \\ &= \frac{\partial}{\partial X} \left( \frac{\langle v_t \rangle}{\sigma_{\langle \epsilon \rangle}} \frac{\partial \langle \epsilon \rangle}{\partial X} \right) + \frac{\partial}{\partial Y} \left( \frac{\langle v_t \rangle}{\sigma_{\langle \epsilon \rangle}} \frac{\partial \langle \epsilon \rangle}{\partial Y} \right) \\ &+ c_{1\langle \epsilon \rangle} \langle P_k \rangle + \langle P_k \rangle_b - c_{2\langle \epsilon \rangle} \frac{\langle \epsilon \rangle^2}{\langle k \rangle} \end{aligned} \quad (16-87b)$$

The term  $\langle P_k \rangle$ , modeling the production of the depth-averaged turbulent kinetic energy  $\langle k \rangle$  by gradients in  $\langle u \rangle$  and  $\langle v \rangle$ , is the two-dimensional version of Eq. (16-35) (or Eq. (16-82)); i.e.,

$$\langle P_k \rangle = \langle v_t \rangle \left[ 2 \left( \frac{\partial \langle u \rangle}{\partial X} \right)^2 + 2 \left( \frac{\partial \langle v \rangle}{\partial Y} \right)^2 + \left( \frac{\partial \langle u \rangle}{\partial Y} + \frac{\partial \langle v \rangle}{\partial X} \right)^2 \right]. \quad (16-88)$$

Equations (16-87) are *not* derived from integrating the corresponding three-dimensional equations over depth, but rather may be more precisely viewed as a plausible but ad hoc extension to a two-dimensional model. As such,  $\langle k \rangle$ ,  $\langle \epsilon \rangle$ , and  $\langle v \rangle$  should *not* be interpreted literally as depth-averaged analogues of the three-dimensional  $k$  and  $\epsilon$ . Equations (16-87) are therefore most appropriate in simulating flows where the turbulent flow features of greatest interest are those in the horizontal plane.

The constitutive relationship between stress and “rate of strain” is sometimes written in the same manner as Eq. (16-14), namely,

$$\begin{aligned} \frac{\bar{\tau}_{xx}}{\rho} &= 2 \langle v_t \rangle \left( \frac{\partial \langle u \rangle}{\partial X} \right) - \frac{2}{3} \langle k \rangle, \\ \frac{\bar{\tau}_{yy}}{\rho} &= 2 \langle v_t \rangle \left( \frac{\partial \langle v \rangle}{\partial Y} \right) - \frac{2}{3} \langle k \rangle, \\ \frac{\bar{\tau}_{xy}}{\rho} &= \langle v_t \rangle \left( \frac{\partial \langle u \rangle}{\partial Y} + \frac{\partial \langle v \rangle}{\partial X} \right). \end{aligned} \quad (16-89)$$

A difficulty is apparent in Eq. (16-89) in that the term  $-2\langle k \rangle/3$  no longer serves the purpose of ensuring consistency between the stress-rate-of-strain relationship and the definition of  $\langle k \rangle$  (note the difference in continuity equations, Eq. (16-2a) and Eq. (16-86a)). An alternative constitutive relationship, due to Chapman and Kuo (1985), and adopted by Biglari and Sturm (1998) in a study of flow around bridge abutments, expresses, e.g.,  $h\bar{\tau}_{xx}$  in terms of gradients of  $\partial(h\langle u \rangle)/\partial X$  and so on; it is consistent only for steady flows, and its basis in the physics of turbulent flows is somewhat tenuous. As seen before with buoyancy and vegetation effects, the presence of additional forcing terms in the momentum equations, i.e., the stresses at the bottom (and presumably at the water surface, though this is generally ignored) requires additional source terms,

$$(P_{\langle k \rangle})_b = (c_{\langle k \rangle})_b u_*^3 / h, \quad (P_{\langle \epsilon \rangle})_b = (c_{\langle \epsilon \rangle})_b u_*^4 / h^2 \quad (16-90)$$

where  $u_*$  is a bottom shear velocity obtained from the same friction relationship used to obtain  $\tau_{bx}$ .

The closure constants,  $c_{\langle k \rangle}$ ,  $c_{\langle \epsilon \rangle}$ ,  $\sigma_{\langle k \rangle}$ , and  $\sigma_{\langle \epsilon \rangle}$ , are rather boldly chosen to be the same as in the standard model (Table 16-2), whereas the remaining closure constants,  $(c_{\langle k \rangle})_b$  and  $(c_{\langle \epsilon \rangle})_b$ , are chosen for consistency with results for the simple case of unidirectional steady uniform channel flow. In the latter case, where  $\langle P_k \rangle \equiv 0$  and transport terms are either zero or negligible, with a local-equilibrium balance being established between production and dissipation, the usual relationships,  $\langle \epsilon \rangle \sim u_*^3$  and  $\langle k \rangle \sim u_*^2$ , are obtained:

$$u_* = \left[ c_f (\langle u \rangle^2 + \langle v \rangle^2) \right]^{1/2}, \quad (c_{\langle k \rangle})_b = c_f^{-1/2}, \quad (c_{\langle \epsilon \rangle})_b = E_* \frac{c_{2\epsilon} c_\mu^{1/2}}{c_f^{3/4}} \quad (16-91)$$

where  $c_f$  is a friction coefficient and  $E_*$  is a constant that may be used for calibration (Minh Duc et al. 1998; Rodi 1993 gave  $E_* = 3.6$ ). The eddy viscosity for the depth-averaged model is obtained exactly as before,  $\nu_t^* = c_\mu \langle k \rangle^2 / \langle \epsilon \rangle$ . Again, in the simple case of unidirectional steady uniform channel flow, this reduces to a constant-coefficient zero-equation model,  $\nu_t^* \sim u_* h$ .

The depth-averaged equation for suspended sediment transport can be similarly expressed as

$$\begin{aligned} \frac{\partial(h\langle c \rangle)}{\partial t} + \frac{\partial(h\langle u \rangle \langle c \rangle)}{\partial X} + \frac{\partial(h\langle v \rangle \langle c \rangle)}{\partial Y} \\ = \frac{\partial}{\partial X} \left[ h \left( \frac{\nu_t^*}{\sigma_c} \frac{\partial \langle c \rangle}{\partial X} - \langle u^* c^* \rangle \right) \right] \\ + \frac{\partial}{\partial Y} \left[ h \left( \frac{\nu_t^*}{\sigma_c} \frac{\partial \langle c \rangle}{\partial Y} - \langle v^* c^* \rangle \right) \right] + \mathcal{B} \end{aligned} \quad (16-92)$$

where  $\langle u^* c^* \rangle$  and  $\langle v^* c^* \rangle$  are the dispersion terms, and  $\mathcal{B}$  is a source/sink term analogous to the terms involving  $\tau_{bx}$  and  $\tau_{by}$  in Eq. (16-86) representing entrainment and deposition at the bed, essentially equivalent to  $(J_s)_b$  of Eq. (16-57). It is reiterated that the dispersion terms,  $\langle u^* c^* \rangle$  and  $\langle v^* c^* \rangle$ , may not necessarily be well described by a simple gradient-transport model. The difficulty of defining an appropriate bottom boundary condition for sediment remains in depth-averaged models, and is compounded by the need to express this in terms, not of local bottom concentration,  $c_b$ , as in Eq. (16-57), but of the modeled depth-averaged concentration,  $\langle c \rangle$ . Similarly to the more complete model, a bed-load model may also be needed.

The commonly used depth-averaged models described above are undoubtedly useful tools, but they constitute engineering compromises, the limitations of which should be recognized. If vertical nonuniformities and motion are important, then neglect of dispersion terms can really not

be justified. For sediment transport applications where suspended load is significant, the vertical distribution of suspended sediment is likely to be much more nonuniform than that of velocity. Even with dispersion terms included, the effects of vertical motion may only be quite imperfectly modeled, because flow is constrained to be in the  $X$ - $Y$  plane. Differences in the *direction* of the depth-averaged velocity vector and the point velocity (non-zero-velocity skewness angles) will be important in sediment transport, not only for the suspended load, but also for the bed load, since the direction of the bottom shear force may differ from the direction of the depth-averaged velocity. Additional model elements, typically involving specific models of vertical velocity distributions, can be introduced in order to sensitize the standard depth-averaged  $k$ - $\epsilon$  model to effects due to flow and nonuniformities in the vertical direction. The depth-averaged model clearly involves a greater number of modeling assumptions, based largely on the convenience and simplicity of the resulting model equations and empirical experience.

## CHAPTER 17

### *Watershed Sediment Yield*

*Deva K. Borah, Edward C. Krug, and Daniel Yoder*

#### 17.1 INTRODUCTION

##### 17.1.1 General

Watershed sediment yield is the total amount of sediment generated within a watershed and delivered at its outlet during any given time. It starts with soil erosion, which is defined as the removal (detachment) of soil particles from the earth's surface. A portion or all of the eroded soil is then transported by flowing water as sediment. Sediment yield is defined as the amount of sediment that is delivered to a point remote from its origin. In a watershed, sediment yield includes erosion from land surface slopes, gullies, streams, and mass wasting, minus sediment that is deposited after it is eroded but before it reaches the point of interest.

Estimation of watershed sediment yield is critical in planning soil conservation and sustainable development of natural resources. Erosion is an important and pervasive watershed process that sculpts all aspects of watershed topography and affects all terrestrial and aquatic ecosystems. It reflects the interactive factors of climate, geology, biology, time, and topography and the influence that these exert on watersheds. Planners of human watershed activities must be cognizant of current erosion from all pristine and human-impacted watershed elements, as well as how the planned watershed activities themselves may influence erosion. Erosion can also affect those planned activities and can cause major damage to the environment. Sediment generated from erosion can pollute streams, rivers, and estuaries, fill reservoirs and navigation channels, and cover valuable floodplain lands and properties.

Agricultural, mining, forestry, and construction activities often involve clearing of vegetation and massive movement of soil, exposing it directly to the erosive actions of rain and flowing water. As a result, enormous amounts of soil can be lost from these sites, degrading the environmental quality and soil fertility of such highly eroded land surfaces. Sediment is also generated from streambeds, stream banks,

and floodplains by the erosive actions of flowing water. As reported by Gianessi et al. (1986), the percentages of eroded soil in the United States attributable to various sources are as follows: cropland (37%), forests (16%), rangeland (11%), stream banks (11%), gullies (6%), pasture (4%), and other sources, including roads, construction sites, mines, and rural lands (15%).

In addition to its direct impact on waterways and aquatic ecosystems, sediment is a major contributor to non-point-source pollution. It can carry nutrients (particularly phosphates) to waterways, and it contributes to eutrophication of lakes and streams. This can severely affect aquatic habitat in streams, rivers, lakes, and wetlands. Adsorbed pesticides and toxic substances are also carried with sediment, and can adversely affect surface-water quality.

Proper land use and planning can greatly reduce the erosion potential during the periods of serious erosion hazard before the land is stabilized by vegetation growth or permanent structures. A good understanding of the complex processes of soil erosion, sediment transport, and sediment deposition (sedimentation or siltation) provides a sound basis for developing improved prediction and control methods. This chapter will discuss these processes and available methodologies for predicting the amount of sediment reaching a point collectively from different sources (sediment yield) and for evaluating the impacts of current or potential land-use changes and management practices. All of the erosion and sedimentation processes contributing to sediment yield take place within the boundary of a watershed. Therefore, watershed sediment yield from all watershed sources, managed and unmanaged, is the primary topic of interest.

This chapter deals only with sediment from rain and water erosion. In arid, semiarid, and some humid regions, wind causes considerable erosion of soil and damage to crops and infrastructure (fences, buildings, highways, etc.). The impact of wind erosion is generally not described or delimited by watershed boundaries, and although it does cause

significant soil degradation, whether it has any impact on aquatic systems depends on the specific situation. Wind erosion is therefore not covered here, though much information is available elsewhere in the literature (Schwab et al. 1993).

The remainder of this section discusses soil erosion, sedimentation processes, and physical factors affecting those processes. The remaining sections describe available methodologies, ranging from simple empirical equations to more comprehensive watershed models, for estimating soil erosion generated from different sources (upland slopes, gullies, and streambeds and banks) and finally computing sediment yield.

### 17.1.2 Soil Erosion and Sedimentation Processes

From a plan (bird's-eye) view, erosion begins on the relatively planar hillslopes that slope down from the watershed divides, and from ridges or other divides between subwatersheds. The runoff from these hillslopes concentrates in the lower portions of the local topography where the warped planar surfaces converge, defining the beginning of a concentrated-flow channel system. Though exceptions may exist—as when a steep channel empties onto a floodplain and forms an alluvial fan and poorly defined channel—most channels are ultimately linked together in a dendritic network. The smaller upland channels may be poorly defined broad swales, and generally have flow only when there is runoff from a storm event. Further down the watershed, larger drainage areas contribute flow, so channels generally become better defined and are more likely to have flow from subsurface baseflow even when there is no runoff. The channel system itself usually makes up a very small portion of the entire watershed area, with the planar hillslopes feeding runoff and any associated sediment into the channel system along most of its length.

Soil erosion and sedimentation by water include detachment from the soil mass, transport of some or all of the eroded soil as sediment downslope, and during its transit depositing some of the sediment or picking up more eroded soil. In following a droplet of runoff down the hillslope, three distinct forms of erosion are seen in the upland areas. These are sheet erosion, rill erosion, and gully erosion. Sheet erosion, also known as interrill erosion, takes place uniformly between rills or gullies and results primarily from raindrop impact. The erosive potential of this impact depends on raindrop size, fall velocity, and total mass at impact, but can be devastating. In the absence of vegetation, mulch, or other cover to absorb the impact, raindrops can detach tremendous quantities of soil. For that detachment to result in erosion, the detached particles must then be transported downslope. In sheet erosion areas, this is accomplished by the resulting shallow surface flow, which does not have enough power to detach particles but does have enough power to transport them.

In moving downslope, additional runoff water collects as the contributing area grows. The runoff soon (usually

within 1-3 m of slope length) reaches a depth at which it has sufficient energy to begin detaching soil particles. This in turn lowers the soil surface at that point, causing even more runoff to flow in that direction. This ultimately forms a rill, which is defined as a small concentrated flow channel in the generally planar hillslope. Rills may be very shallow or very deep, but generally form parallel channels running downslope on the planar surface. Their location is controlled somewhat randomly by small irregularities in the microtopography, so if they are destroyed by tillage they will reform in different places.

Rill erosion is much more noticeable than interrill erosion. These small channels carry runoff and sediment from interrill areas, the rain that falls directly on them, and any sediment produced from erosion within the rill. Rill erosion increases rapidly as the slope steepens or lengthens and as the runoff rate increases.

Gully erosion is massive removal of soil by large concentrations of runoff. These occur in the low portions of the macrotopography where the planar hillslopes converge, so they are best thought of as the uppermost portions of the watershed channel system. When the gullies are small the erosion in them occurs primarily through the erosive action of the concentrated flow acting on the bottom and to a lesser extent the sides of the channel. Such gullies are referred to as ephemeral gullies, and are usually small enough so that they can be crossed by vehicles and can be erased by normal tillage operations. If precautionary measures are not taken, gullies will grow, and soon the erosive action of the flow is augmented by headcutting and sidewall sloughing, at which point the channels are defined as classical gullies. These may yield tremendous volumes of sediment. Timeliness of implementation and maintenance of erosion-control practices is all-important to keep this from occurring.

These processes take place primarily in the upland areas and upper channels of a watershed. Once the flow has reached the watershed channel system, sediment may also be generated from streams or channels as a result of streambed and bank erosion, in which case the channel is said to be degrading. On the other hand, if more sediment is added from the upland areas than the channel flow can transport, significant deposition and storage of upland sediment may occur within the channel system, in which case the channel is said to be aggrading. In a stable channel, very little net erosion occurs because of equilibrium between the sediment transported out of the channel system and that added by the upland erosion processes. When instability is introduced within the channel by removing vegetation along the banks, increasing the channel slope, or changing other channel characteristics, those influences on the channel can result in the production of significant amounts of sediment from erosion of streambed and/or bank.

The quantity and size of sediment material transported by channel flow are functions of runoff (or flow) velocity and turbulence, both of which increase as the slope steepens and

the flow increases. The larger the eroding material, the greater the flow velocity and turbulence must be to transport it. When velocity or turbulence decreases, some of the sediment may deposit. The largest and densest particles settle first, whereas the finer particles are carried farther downslope or downstream. The overall result depends on the balance between the flow's transport capacity and current sediment load. If the transport capacity is higher than the current sediment load, the potential exists for additional erosion. If the converse is true (sediment load > transport capacity), deposition will result. Though this is conceptually simple, both factors are constantly changing temporally and spatially as water and sediment are added to or removed from the flow and as the channel and flow characteristics change the flow velocity and degree of turbulence and therefore the transport capacity.

### 17.1.3 Factors Affecting Erosion by Water

The major factors affecting soil erosion are climate, soil, vegetation, topography, and time. Of these, vegetation—and to a lesser extent soil and topography—may be controlled through normal management. For our purposes, climatic factors are assumed to be beyond human control. The important climatic factors are precipitation, temperature, wind, humidity, and solar radiation. Temperature and wind are most evident through their effects on evaporation and transpiration, but wind also changes raindrop velocity and angle of impact. Humidity and solar radiation are recognized as being somewhat less directly involved, in that they are associated with temperature and rate of soil-water depletion, although humidity affects raindrops in that very dry conditions may prevent precipitation from ever reaching the ground.

Physical properties of the soil affect infiltration, detachment of soil particles, and transport of the sediment. In general, soil detachability increases as the size of soil particles and/or aggregates increases, and soil transportability increases with decrease in particle and/or aggregate size. For example, clay particles are more difficult to detach than sand, but clay is more easily transported. Other general soil properties that influence erosion include soil structure, texture, organic matter, water content, clay mineralogy, and density (or compactness), as well as chemical and biological characteristics of the soil. No single soil characteristic or index has been identified as a satisfactory means of predicting erodibility, so it is usually measured directly through field studies. However, it can generally be said that human activities that loosen and pulverize soil often promote accelerated erosion.

Vegetation has the major impact on resisting or reducing soil erosion. Vegetation intercepts rainfall and absorbs the raindrop energy, thus reducing soil detachment. It retards erosion by decreasing surface-water velocity and by physically restraining sediment movement. Vegetation improves soil aggregation and porosity through the impact of its roots and plant residues. These increase biological activity in the

soil, and through transpiration decrease soil water, resulting in increased storage capacity and less runoff. Vegetation effects vary with season, crop, degree of maturity, and soil and climate interactions with the vegetation and with the nature of the vegetative material, i.e., roots, plant tops, and plant residues. Residues from vegetation protect the surface from raindrop impact and improve soil structure. Residue and tillage management practices used in growing the vegetation can have a dramatic effect on soil erosion.

Soil erosion is also controlled by topographic features, such as slope steepness, length, and shape, and the size and shape of the watershed. On steep slopes, runoff water is more erosive and can more easily transport detached soil downslope. On longer slopes, increased accumulation of overland flow tends to increase rill erosion and the potential for gully formation. Concave slopes, with lower slopes at the foot of the hill, are less erodible than are convex slopes.

## 17.2 UPLAND SOIL EROSION

Upland soil erosion consists mostly of sheet or interrill and rill erosion, the basic forms of erosion. Predictions of upland soil erosion and sediment yield are needed to guide the making of rational decisions in conservation planning. The prediction equations enable the planner to predict the average rate of soil erosion for alternative combinations of cropping systems, management techniques, and erosion-control practices on any particular site.

### 17.2.1 Soil Loss Tolerance

The term “soil loss tolerance” ( $T$ ) denotes the maximum rate of soil erosion that can occur and still permit crop productivity to be sustained economically. A deep, medium-textured, moderately permeable soil that has subsoil characteristics favorable for plant growth has a greater tolerable soil loss rate than do soils with shallow root zones or high percentages of shale at the surface. For the soils of the United States,  $T$  values of 1 to 5 tn/acre/year were derived by soil scientists and conservationists, agronomists, engineers, geologists, and federal and state researchers at regional workshops around the country. These recommended  $T$  values may be obtained from the United States Department of Agriculture (USDA) Natural Resources Conservation Service (NRCS).

As part of the conservation planning process, if the predicted soil erosion rate exceeds the  $T$  value, various combinations of management practices, as discussed below, can be tested through application of a soil loss prediction equation until the predicted soil loss erosion rate is at or below the  $T$  value.

### 17.2.2 Soil Loss Equation

As discussed above, the rate of upland soil erosion depends on rainfall erosivity, soil erodibility, the length, steepness,

and shape of the slope, cultural practices used, stage of vegetation growth, and supporting conservation practices applied to the area. Factors representing these erosion-influencing characteristics have been combined in the Universal Soil Loss Equation (USLE), developed originally by Wischmeier and Smith (1965; 1978). Thousands of plot-years of data from runoff plots and small watersheds were used to develop the relationships in the USLE. This equation predicts soil loss from sheet (or interrill) erosion and rill erosion from the roughly planar hillslope areas. It enables land management planners to estimate average annual soil erosion rates from upland slopes for a wide range of rainfall, soil, slope, cover, and management conditions. It also enables planners to select from alternative cropping as cover and management combinations that would limit erosion rates to acceptable (*T*-value) levels.

A revised version of the USLE, called the Revised Universal Soil Loss Equation (RUSLE), was developed and documented by Renard et al. (1997) for computer applications, allowing more detailed consideration of farming practices and topography for erosion prediction. Both USLE and RUSLE use the following equation to compute average annual soil erosion expected on upland (field) slopes:

$$A = R \cdot K \cdot L \cdot S \cdot C \cdot P \quad (17-1)$$

where

- A* = spatial and temporal average soil loss (erosion) per unit area, expressed in the units selected for *K* and for the period selected for *R*. In practice, these are usually selected so that *A* is annual soil erosion rate expressed in tn/acre/year or t/ha/year.
- R* = rainfall-runoff erosivity factor—the rainfall erosion index plus a factor for any significant runoff from snowmelt.
- K* = soil erodibility factor—the soil-loss rate per erosion index unit for a specific soil as measured on a standard plot, which is defined as a 72.6-ft (22.1-m) length of uniform 9% slope in continuous clean-tilled fallow.
- L* = slope length factor—the ratio of soil loss from the field slope length to soil loss from a 72.6-ft length under identical conditions.
- S* = slope steepness factor—the ratio of soil loss from the field slope gradient to soil loss from a 9% slope under otherwise identical conditions.
- C* = cover-management factor—the ratio of soil loss from an area with specified cover and management to soil loss from an identical area in tilled continuous fallow.
- P* = support practice factor—the ratio of soil loss with a support practice such as contouring, stripcropping, or terracing to soil loss with straight-row farming up and down the slope.

These factors and their representative values for different geographic locations in the United States, and for different soils, topography, covers, and practices, are given and extensively described for the USLE by Wischmeier and Smith (1965; 1978), and more recently for RUSLE by Renard et al. (1997). Brief descriptions and recently updated values from Renard et al. (1997) are given here. Since the release of Renard et al. (1997), additional work has been done on RUSLE. A version released in 1998 (RUSLE1.06) includes features that allow the RUSLE hillslope to be carried all the way down to a concentrated flow channel (Toy et al. 1999). A new version, RUSLE2, is currently under testing and implementation by USDA-NRCS, but is based primarily on the science found in RUSLE1.06, with several enhancements.

Other significant differences exist between the USLE and the most recent version of this technology as found in RUSLE2. Perhaps the greatest of these is that in the USLE the factors could be considered relatively independent. This meant that simple comparison of the *C* factors could usually be used to compare management systems. This is no longer the case in the later version of RUSLE1 or in RUSLE2, because these recognize that many of the factors are inter-related. In RUSLE2, therefore, comparisons of management alternatives must be made on the basis of overall erosion estimates rather than on the basis of individual factors.

### 17.2.3 Rainfall-Runoff Erosivity Factor (*R*)

The rainfall-runoff erosivity factor *R* quantifies the effects of raindrop impact and reflects the amount and rate of runoff likely to be associated with rain. Field data indicate that when factors other than rainfall are held constant, soil losses from cultivated fields are directly proportional to the total storm energy (*E*) times the maximum 30-min intensity (*I*<sub>30</sub>). The *R* factor used to estimate average annual soil loss *A* (Eq. (17-1)) must include the cumulative effects of the many moderate-sized storms as well as the effects of the occasional severe ones. The average annual total of the storm *EI*<sub>30</sub> values in a particular locality is the *R* for that locality. Local values of *R* in the United States are calculated from rainfall data around the country and are plotted in isoerodent maps (Renard et al. 1997) as shown in Figs. 17-1 to 17-5 for the eastern United States, western United States, California, Oregon and Washington, and Hawaii, respectively. Isoerodents are lines of equal *R* values. *R* values for locations between the lines can be obtained by linear interpolation.

Although the *R* factor is assumed to be independent of slope, splash erosion is less on flatter slopes, where raindrops tend to be more buffered by water ponded on the soil surface. A correction factor (Renard et al. 1997) as shown in Fig. 17-6 may be used to adjust *R* values for various flatter slopes and 10-year-frequency *EI*<sub>30</sub> values.

In the dry-farmed cropland areas of the northwestern U.S. wheat and range region (Washington, Oregon, and Idaho),

**Fig. 17-1.** Isoerodent map of eastern United States. Units are hundreds ft tnf in (ac h year)<sup>-1</sup>. After Renard et al. (1997).

melting snow, rain on snow, and/or rain on thawing soil accelerate soil erosion resulting from higher  $R$  values. Renard et al. (1997) present a procedure to compute " $R$  Equivalent ( $R_{eq}$ ) for Cropland in the Northwestern Wheat and Range Region" and the  $R_{eq}$  isoerodent maps for estimating soil loss under these conditions.

#### 17.2.4 Soil Erodibility Factor ( $K$ )

The soil erodibility factor ( $K$ ) is the rate of soil loss per rainfall erosion index unit for a specific soil as measured on a unit plot, which is defined as being 72.6 ft (22.1 m) long, with a minimum width of 6 ft (1.83 m), 9% slope, and in a continuously clean-tilled fallow condition with tillage performed up and down slope (Wischmeier and Smith 1978). These factors are best obtained from direct measurements on natural-runoff plots. Guidelines for preparation and maintenance of natural-runoff plots in the United States were issued in 1961 by D. D. Smith (Romkens 1985). Renard et al. (1997) lists the soils and the locations in the United States on which natural-runoff plots for  $K$ -factor determinations were established, along with the resulting  $K$ -factor values. Rainfall simulation studies may also be used to determine  $K$  factors, but these short-term results are generally less accurate.

Soil erodibility is related to the integrated effect of rainfall, runoff, and infiltration on soil loss. The  $K$  factor accounts

for the influence of soil properties on soil loss during storm events on upland areas. It is the average long-term soil and soil-profile response to the erosive powers of rainstorms and is a lumped parameter that represents an integrated average annual value of the total soil and soil profile reaction to a large number of erosion and hydrologic processes. These processes consist of soil detachment and transport by rain-drop impact and surface flow, localized deposition due to topography and tillage-induced roughness, and rainwater infiltration into the soil profile. There is some interdependency of the  $K$  factor with the other USLE or RUSLE factors, specifically the topographic ( $LS$ ), rainfall erosivity ( $R$ ), and cover-management ( $C$ ) factors.

The soil erodibility  $K$  can also be estimated by a variety of relationships. The most widely used relationship between the  $K$  factor and soil properties is the soil erodibility nomograph (Wischmeier et al. 1971; Wischmeier and Smith 1978; Renard et al. 1997). The nomograph comprises five soil and soil-profile parameters: percent modified silt (0.002–0.1 mm), percent modified sand (0.1–2.0 mm), percent organic matter (OM), and classes for structure ( $s$ ) and permeability ( $p$ ). The structure and permeability classes and groups of classes were taken from the *Soil Survey Manual* (USDA 1951). Structure ( $s$ ) values are 1 for very fine granular, 2 for fine granular, 3 for medium or coarse granular, and 4 for blocky, platy, or massive structure. Permeability ( $p$ ) values

**Fig. 17-2.** Isoerodent map of western United States. Units are hundreds ft tnf in (ac h year)<sup>-1</sup>. After Renard et al. (1997).

are 1 for rapid, 2 for moderate to rapid, 3 for moderate, 4 for slow to moderate, 5 for slow, and 6 for very slow. A useful algebraic approximation (Wischmeier and Smith 1978) of the nomograph for those cases where the silt fraction does not exceed 70% is

$$K = [2.1 \times 10^{-4} (12 - \text{OM}) M^{1.14} + 3.25(s - 2) + 2.5(p - 3)] / 100 \quad (17-2)$$

where  $M$  is the product of the primary particle size fractions (% modified silt or the 0.002–0.1 mm size fraction)  $\times$  (% silt + % sand) and  $K$  is expressed as tn/acre per erosion index unit. For example, a soil having 65% modified silt, 5% modified sand, 2.8% OM, fine granular structure ( $s = 2$ ), and

slow to moderate permeability ( $p = 4$ ) will have a computed  $K$  value of 0.31.

The nomograph relationship was derived from rainfall-simulation data from 55 U.S. Midwest surface soils, mostly (81%) medium-textured surface soils. It is well suited for the less aggregated and medium-textured surface soils of the Midwest. Renard et al. (1997) present more relationships based on other soil types and soils from other locations, including Hawaiian volcanic soils (El-Swaify and Dangler 1976), soils from the upper Midwest (Young and Mutchler 1977), and Midwest clay subsoils (Romkens et al. 1977).

The presence of rock fragments in the soil may significantly affect soil detachment by rainfall. When present in a coarse-textured-soil profile (sands and loamy sands), the

Fig. 17-3. Isoerodent map of California. Units are hundreds ft tnf in (ac h year)<sup>-1</sup>. After Renard et al. (1997).

fragments can appreciably reduce infiltration, whereas in a fine-textured soil the fragments may actually increase infiltration. The effect of rock fragments on the soil surface is included in the  $C$  factor. However, the effect of rock fragments within the soil profile is included with the  $K$  factor insofar as it affects infiltration and runoff. These effects are discussed and quantified in Renard et al. (1997).

Seasonal variation of  $K$  values is also discussed and quantified in Renard et al. (1997). Soil freezing and thawing are major causes of these variations, because such processes change the effective soil texture and soil-water content, thereby increasing the  $K$  factor. The greater the number of freeze-thaw cycles, the longer the erosion resistance of a soil is at a minimum, resulting in higher erosion and  $K$  factor. In locations where frozen soil is not a problem, the  $K$  factor gradually decreases over the course of the growing season until it reaches a minimum near

the end of growing season. Then it gradually increases until it reaches the maximum. For many locations this pattern follows rainfall patterns.

### 17.2.5 Slope Length and Steepness Factors ( $LS$ )

The slope length factor ( $L$ ) and the steepness factor ( $S$ ) account for the effects of topography on upland soil erosion. Erosion increases as slope length and/or steepness increases. Slope length for the USLE and early RUSLE versions was defined as the horizontal distance from the origin of overland flow to the point where either the slope gradient (steepness) decreases enough so that deposition begins or runoff becomes concentrated in a defined channel (Wischmeier and Smith 1978). In later versions, including RUSLE1.06 and all versions of RUSLE2, process-based deposition routines have been added, so the slope length extends down to a concentrated flow channel, which will normally be part of the watershed channel system. Surface runoff usually enters such a concentrated flow channel in less than 400 ft (122 m), which is a practical slope-length limit in many situations, although longer slope lengths of up to 1,000 ft (305 m) are occasionally found, most often when the surface has been carefully graded into ridges and furrows that maintain flow for long distances.

The factors  $L$  and  $S$  are usually evaluated together as the topographic factor  $LS$ , which represents the ratio of soil loss on a given slope length and steepness to soil loss from a slope that has a length of 72.6 ft (22.1 m) and steepness of 9%, where all other conditions are the same. The value of  $LS$  is 1.0 at the 72.6-ft slope length and 9% steepness. Values of  $LS$  for horizontal slope lengths from less than 3 ft (0.9 m) up to 1,000 ft (305 m), with steepness values ranging from 0.2% to 60%, and low, moderate, and high ratios of rill to interrill erosion are given in tabular form in Renard et al. (1997). These tables also present  $LS$  values for thawing soils where most of the erosion is caused by surface runoff. All of those values can also be computed using separate relations for  $L$  and  $S$  as given from Renard et al. (1997):

$$L = (\lambda / 72.6)^m \quad (17-3)$$

where

$\lambda$  = horizontal slope length (ft) and

$m$  = a variable slope-length exponent (Wischmeier and Smith 1978).

The slope-length exponent  $m$  is related to the ratio of rill erosion (caused by flow) to interrill erosion (principally caused by raindrop impact), and is expressed (Foster et al. 1977) as

$$m = \beta / (1 + \beta) \quad (17-4)$$

where

$\beta$  = ratio of rill to interrill erosion.

**Fig. 17-4.** Isoerodent map of Oregon and Washington. Units are hundreds ft tnf in (ac h year)<sup>-1</sup>. After Renard et al. (1997).

For conditions where the soil is moderately susceptible to both rill and interrill erosion,  $\beta$  is expressed (McCool et al. 1989) as

$$\beta = (\sin\theta / 0.0896) / [3.0(\sin\theta)^{0.8} + 0.56] \quad (17-5)$$

where

$\theta$  = slope angle.

Equation (17-5) gives  $\beta$  values for conditions that are typical of agricultural fields in seedbed condition, where the soil is moderately susceptible to both rill and interrill erosion.

When runoff, soil, cover, and management conditions indicate that the soil is highly susceptible to rill erosion, a condition most likely to occur on steep, freshly prepared construction slopes, the  $\beta$  value is doubled from that calculated by Eq. (17-5). Conversely, when the conditions favor less

rill erosion than interrill erosion, a condition common to rangelands,  $\beta$  values are taken as half of those calculated from Eq. (17-5).

For the erosion of thawing, cultivated soil by surface flow, a condition common in the Northwest U.S. Wheat and Range Region, a constant value of 0.5 is used for the slope length exponent  $m$  (McCool et al. 1989; 1993). When runoff on thawing soil is accompanied by rainfall sufficient to cause significant interrill erosion, the  $\beta$  value is taken as half of that calculated from Eq. (17-5). To ease these calculations, RUSLE2 automatically calculates the  $\beta$  value based on the presumed soil, management, and climatic conditions.

Soil loss increases more rapidly with slope steepness than it does with slope length. The slope steepness factor  $S$  is computed using the following relations (McCool et al. 1987):

$$S = 10.8 \sin\theta + 0.03 \quad s < 9\% \quad (17-6)$$

**Fig. 17-5.** Isoerodent map of Hawaii. Units are hundreds ft tnf in (ac h year)<sup>-1</sup>. After Renard et al. (1997).

### Adjustment to R to account for ponding Multiply initial R by multiplication factor

**Fig. 17-6.** Correction for  $R$  factor for flat slopes and large  $R$  values to reflect amount of rainfall on ponded water. After Renard et al. (1997).

$$S = 16.8 \sin \theta + 0.5 \quad s \geq 9\% \quad \lambda \geq 15 \text{ ft} \quad (17-7)$$

$$S = 3.0 (\sin \theta)^{0.8} + 0.56 \quad s \geq 9\% \quad \lambda < 15 \text{ ft} \quad (17-8)$$

where  $s$  = ground slope in percent. Equation (17-8) assumes that rill erosion is insignificant on slopes shorter than 15 ft (4.6 m), and therefore this equation should not be used on such slopes where rill erosion is expected to occur. Rill erosion usually begins with a slope length of 15 ft; however, it may take longer slope lengths on soils that are consolidated and resistant to detachment by flow.

For recently tilled soil under thawing, in a weakened state and subjected primarily to surface flow, Eq. (17-7) is rewritten as (McCool et al. 1993)

$$S = (\sin \theta / 0.0896)^{0.6} \quad s \geq 9\% \quad \lambda \geq 15 \text{ ft} \quad (17-9)$$

These relations are applicable to uniform slopes where steepness is the same over the entire length. Procedures of accounting for nonuniform or irregular concave, convex, or complex slopes in the erosion computations are outlined in Renard et al. (1997). They can also account for changing soil type along the slope. Within limits, they can be further extended to account for changes in the  $C$  and  $P$  values. These adjustments are all done automatically in RUSLE2. Renard et al. (1997) provides extensive guides for choosing slope lengths.

### 17.2.6 Cover-Management Factor ( $C$ )

The  $C$  factor is designed to reflect the effect of cropping and management practices on erosion rates, and is the factor used most often to compare the relative impacts of management options on conservation plans. The  $C$  factor is essentially a soil loss ratio (SLR), which is defined as the ratio of soil losses under actual conditions to losses

experienced under the clean-tilled continuous fallow reference conditions. The  $C$  factor depends on previous cropping and management, vegetative canopy, surface cover and roughness, and, in some cases, soil moisture, each of which is assigned a subfactor value. These subfactor values are multiplied together to yield an SLR (Lafren et al. 1985), expressed as

$$\text{SLR} = \text{PLU} \cdot \text{CC} \cdot \text{SC} \cdot \text{SR} \cdot \text{SM} \quad (17-10)$$

where

SLR = soil-loss ratio for the given conditions;  
 PLU = prior-land-use subfactor;  
 CC = canopy-cover subfactor;  
 SC = surface-cover subfactor;  
 SR = surface-roughness subfactor; and  
 SM = soil-moisture subfactor.

PLU incorporates the influence of subsurface residue effects from previous crops and the effects of previous tillage practices on soil consolidation. PLU values range from 0 to 1. Renard et al. (1997) provide an extensive discussion and procedure to estimate PLU.

The CC subfactor value ranges from 0 to 1 and incorporates the effectiveness of vegetative canopy in reducing the energy of rainfall striking the soil surface. It is expressed as

$$\text{CC} = 1 - F_c \cdot \exp(-0.1 \cdot H) \quad (17-11)$$

where

$F_c$  = fraction of land surface covered by canopy, and  
 $H$  = canopy height (ft), which is the distance that raindrops fall after striking the canopy.

The SC subfactor incorporates the effects of surface cover, including crop residues, rocks, cryptogams, and other nonerodible materials that are in direct contact with soil surface, on soil erosion. These affect erosion by reducing the transport capacity of runoff water, by causing deposition in ponded areas, and by decreasing the surface area susceptible to raindrop impact. It is perhaps the single most important factor in determining the SLR. The SC subfactor is expressed as

$$\text{SC} = \exp[-b \cdot S_p \cdot (0.24/R_u)^{0.08}] \quad (17-12)$$

where

$b$  = an empirical coefficient;  
 $S_p$  = percentage of land area covered by surface cover;  
 and  
 $R_u$  = surface roughness (in.).

The  $b$  value in Eq. (17-12) ranges from 0.030 to 0.070 for row crops, and from 0.024 to 0.032 for small grains. In the Northwest U.S. Wheat and Range Region,  $b$  values may be greater than 0.050. For rangeland conditions with the impact of subsurface biomass removed, a  $b$  value of 0.039 is recommended. The  $b$  value can be also chosen based on the dominant erosion process. When rill erosion is the primary mechanism of soil loss (such as for irrigation or snowmelt or for highly disturbed soils),  $b$  values should be about 0.050. Fields dominated by interrill erosion have a  $b$  value of around 0.025. For typical cropland erosion conditions, a  $b$  value of 0.035 is suggested. Calculation of the  $b$  value is done automatically in RUSLE2, based again on the estimated soil and management conditions.

In RUSLE2 and recent versions of RUSLE1, the SC and CC subfactors are linked, so that canopy cover with a very low canopy height essentially becomes surface cover. In other words, a 50% canopy cover with a height of 0 will give combined SC and CC subfactors providing the same erosion reduction as 50% surface cover, not the CC = 0 value indicated by Eq. (17-11).

An  $R_u$  value of 0.24 in. (0.61 cm) is typical of a field in seedbed condition. An  $R_u$  value of 4 in. indicates more roughness than from most primary tillage operations.  $R_u$  values for various tillage operations in croplands, ranging from 0.30 to 1.9 in., and various conditions in rangelands, ranging from 0.25 to 1.30 in., are given in Renard et al. (1997).

Surface roughness directly affects soil erosion by reducing flow velocity and by decreasing transport capacity and runoff detachment. It also indirectly affects soil erosion by causing ponded water and reducing raindrop impact, as incorporated into Eq. (17-12). The direct impact of surface roughness on erosion is incorporated into the SR subfactor. Its baseline condition ( $\text{SR} = 1$ ) is established in a unit plot of clean cultivated conditions smoothed by extended exposure to rainfall of moderate intensity. These conditions yield a random roughness of 0.24 in. The SR subfactor for random roughness greater than 0.24 in. is computed using the expression

$$\text{SR} = \exp[-0.66 (R_u - 0.24)] \quad (17-13)$$

The SM subfactor incorporates the influence of antecedent soil moisture on infiltration and runoff and hence on soil erosion. In general, antecedent moisture effects are an inherent component of continuously tilled fallow plots, which are reflected in variation in soil erodibility throughout the year, and are already taken into account in the derivation of soil erodibility factors. Therefore, the SM subfactor is kept at 1 without any adjustment for changes in soil moisture. However, it is recommended that SM subfactor in the Northwest U.S. Wheat and Range Region be adjusted between 1.0 on April 1, indicating response equivalent to that of a continuous fallow with soil moisture near field capacity,

and 0.0 from September 1 to October 1, indicating no runoff and erosion with soil moisture in soil profile near wilting point to a 6-ft (1.8-m) depth. SM values between these dates are linearly interpolated: 0.0 to 1.0 for October 1 to April 1, and 1.0 to 0.0 for April 1 to September 1.

For areas such as pasture or rangeland that have reached a relative equilibrium, the subfactors used in computing SLR values may change very slowly with time. In these cases, the PLU, CC, SC, and SR subfactor values are assumed to be annual averages, and are simply multiplied together to yield *C*-factor value ( $SM = 1.0$ ), as

$$C = PLU \cdot CC \cdot SC \cdot SR \quad (17-14)$$

In almost all cropland scenarios and in many cases where rangeland or pasture are being managed, the crop and soil characteristics change over time. This demands that the SLR values be calculated frequently enough over the course of a year or a crop rotation to provide an adequate measure of how they change. These values depend on tillage type, elapsed time since a tillage operation, canopy development, and date of harvest. An individual SLR value is calculated for each time period over which the subfactors can be assumed to remain constant. Each of the SLR values is then weighted by the fraction of rainfall and runoff erosivity (*EI*) associated with the corresponding time period, and these weighted values are combined into an overall *C*-factor value (Wischmeier and Smith 1978), expressed as:

$$C = (SLR_1 EI_1 + SLR_2 EI_2 + \dots SLR_n EI_n) / EI_t \quad (17-15)$$

where *C* = average annual or crop *C* factor value,  $SLR_i$  = soil-loss ratio for time period *i*,  $EI_i$  = percentage of the annual or crop *EI* occurring during that time period, *n* = number of periods used in the summation, and  $EI_t$  = sum of the *EI* percentages for the entire period. For RUSLE1 these calculations were performed for half-month periods; in RUSLE2 they are performed on a daily time-step.

### 17.2.7 Support Practice Factor (*P*)

The *P* factor represents support practice effects on soil erosion. These practices generally modify the amount, rate, flow pattern, or direction of surface runoff. For cultivated land, support practices include contouring (tillage and planting on or near the contour), stripcropping, terracing, and subsurface drainage. On dryland or rangeland areas, soil-disturbing practices oriented on or near the contour that result in storage of moisture and reduction of runoff are also used as support practices. For construction and mine reclamation areas, this includes such practices as contour plowing and diversions. Note, however, that improved tillage practices such as no-till and other conservation tillage systems, sod-based

crop rotation, fertility treatments, and crop-residue management are not included in support practices, but rather are included in the *C* factor. The *P*-factor value is a product of *P* subfactors for individual support practices, some of which are used in combination. For example, contouring generally accompanies stripcropping and terraces.

The *P*-factor value for farming upslope and downslope is 1.0. Other *P*-factor values given in Renard et al. (1997) were obtained from experimental data, supplemented by analytical experiments involving scientific observation of known cause-and-effect relationships in physically based models such as CREAMS (Knisel 1980). Such an extensive discussion and procedure development are beyond the scope of this chapter, but the *P*-factor values for three major support practices in cultivated lands, as given earlier by Wischmeier and Smith (1978), are shown in Table 17-1. Within a practice type, the *P* factor is most effective for the 3 to 8% slope range, and effectiveness decreases as the slope increases. As the slope decreases below 2%, the *P*-factor value increases, due to the reduced effectiveness of the practice when compared to up-and-down-hill cultivation. The *P* factor for terracing in Table 17-1 is for prediction of total off-the-field soil loss. If within-terrace interval soil loss is desired, the terrace interval distance should be used for the slope length factor (*L*) and the contouring *P* value for the practice factor.

## 17.3 GULLY EROSION

Gully erosion is defined as the erosion process whereby runoff water accumulates and often recurs in narrow channels and, over short periods, removes soil from these narrow areas to considerable depths (Poesen et al. 2002). Gullies are often defined for agricultural land in terms of channels that occur in the low areas of the macrotopography and that are too deep to ameliorate easily with ordinary farm tillage equipment, typically ranging from 0.5 m to as much as 25 to 30 m (Soil Science Society of America 2001). In the 1980s, the term “ephemeral gully erosion” was introduced to include

**Table 17-1 Support Practice Factor *P* for Cultivated Lands<sup>a</sup>**

Land slope, %	Contouring	Contour, strip cropping, and irrigated furrows	Terracing <sup>b</sup>
1–2	0.60	0.30	0.12
3–8	0.50	0.25	0.10
9–12	0.60	0.30	0.12
13–16	0.70	0.35	0.14
17–20	0.80	0.40	0.16
21–25	0.90	0.45	0.18

<sup>a</sup>From Wischmeier and Smith (1978).

<sup>b</sup>For prediction of contribution to off-field sediment yield.

concentrated flow erosion larger than rill erosion but smaller than classical gully erosion. According to the Soil Science Society of America (2001), ephemeral gullies are small channels eroded by concentrated overland flow that can easily be filled by normal tillage, only to be reformed in the same location by additional runoff events. In the United States, the sediment contribution from ephemeral gullies has been estimated to average about 80% of that contributed by sheet and rill erosion (Bennett et al. 2000b). A study in Kenya (Wijdenes and Bryan 1994) reported that 50% of the eroded sediment in their study watershed was produced from gullies, with the other half resulting from sheet and rill erosion.

Numerous field and modeling studies on gully erosion are reported in the literature (Woodburn 1949; Beer and Johnson 1963; Thompson 1964; Piest et al. 1975; Bocco 1991; Wijdenes and Bryan 1994; Bennett et al. 2000a; 2000b; Nachtergaele et al. 2002; Poesen et al. 2002; 2003; Torri and Borselli 2003). Sources and references for many other studies may be found in these publications. However, there is still a lack of understanding of the processes that form gullies, including headcut migration. Understanding and quantification of gullies lag behind those for other forms of water erosion. One reason is scale. Gully erosion tends to operate on a larger scale than the runoff plot scale, where the vast majority of water erosion research has been conducted. Gully development also operates over longer time periods than is common for water erosion research studies. Finally, because of these scale and temporal issues it is very difficult to replicate scientific field studies of gullies, because no two gullies are found in exactly the same place in the landscape and because gullies are dependent on everything that happens upslope over long periods. In spite of these difficulties, there are some commonly used relationships describing gullies. A few of the key empirical relations discussed in Thompson (1964), United States Soil Conservation Service (1966), and Nachtergaele et al. (2002) are presented here.

Leopold and Maddock (1953) and Wolman (1955) described the hydraulic geometry of river channels by a set of empirical relations (as presented in Nachtergaele et al. 2002):

$$W = a Q^b \quad (17-16)$$

$$d_m = c Q^f \quad (17-17)$$

$$u_m = k Q^l \quad (17-18)$$

where

$W$  = channel width (m);

$Q$  = flow discharge ( $\text{m}^3 \text{s}^{-1}$ );

$d_m$  = mean flow depth (m);

$u_m$  = mean flow velocity ( $\text{m s}^{-1}$ ); and

$a, b, c, f, k$ , and  $l$  = empirical constants.

The empirical constants are related as follows:

$$a \cdot c \cdot k = 1 \quad (17-19)$$

$$b + f + l = 1 \quad (17-20)$$

Wide variations of the empirical constants have been documented in the literature. From 20 investigators worldwide, the ranges of  $b, f$ , and  $l$  were found to be (Ming 1983)

$$0.39 < b < 0.60, 0.29 < f < 0.40, 0.09 < l < 0.28 \quad (17-21)$$

The coefficients  $a, c$ , and  $k$  depend on a number of variables, including the size of bed material and the type of channel bank. From an extensive study of rill development in seedbeds on 10 different soil types, Gilley et al. (1990) proposed  $a = 1.13$  and  $b = 0.303$  in the width-discharge relation (Eq. 17-16). From a limited number of data ( $n = 7$ ), Lane and Foster (1980) obtained  $a = 4.48$  and  $b = 0.482$ .

Sidorchuk (1996) analyzed extensive erosion data ( $n = 617$ ) from the Yamal peninsula in the permafrost area of northwestern Siberia, which resulted in width-discharge constants of  $a = 3.17$  and  $b = 0.368$  (Nachtergaele et al. 2002), and which was recommended by Nachtergaele et al. (2002) for modeling ephemeral gully erosion. Based on rill and gully erosion data from laboratory and field experimental plots and field measurements in simulated cultivated topsoil and on cropland around the world, Nachtergaele et al. (2002) proposed the width-discharge constants of  $a = 2.51$  and  $b = 0.412$ . Based on all these values, Nachtergaele et al. (2002) suggested different width-discharge exponent  $b$  values for the rill, gully, and river erosion domains of 0.3, 0.4, and 0.5, respectively.

An extensive equation for predicting ephemeral gully channel width has been used in the ephemeral gully erosion model (EGEM; Woodward 1999), and is expressed as (Watson et al. 1986)

$$W = 2.66 Q_p^{0.396} n^{0.387} s^{-0.16} \tau_{cr}^{-0.024} \quad (17-22)$$

where

$Q_p$  = peak flow discharge ( $\text{m}^3 \text{s}^{-1}$ );

$n$  = Manning's roughness coefficient;

$s$  = soil surface slope ( $\text{m m}^{-1}$ ); and

$\tau_{cr}$  = critical flow shear stress (Pa).

EGEM computes the critical flow shear stress as (Smerdon and Beasley 1961):

$$\tau_{cr} = 0.311 \cdot 10^{(0.0182 P_c)} \quad (17-23)$$

where

$P_c$  = percentage of clay content.

From an analysis of 409 data points obtained from slopes ranging from 0.035 to 0.45 m m<sup>-1</sup> and soil materials ranging from stony sands over silt loams to vertisols, Govers (1992) found the coefficient and exponent of  $k = 3.52$ ,  $l = 0.294$  in flow velocity-discharge relationships (Eq. 17-18) for developing rills on loose nonlayered materials (e.g., seedbed conditions). Once  $a$ ,  $b$ ,  $k$ , and  $l$  are determined, the mean depth-discharge relation constants  $c$  and  $f$  may be computed from solving Eqs. (17-19) and (17-20).

The next major difficult variable in predicting gully erosion is the gully advancement rate. Thompson (1964) studied gully head advancement at locations in Minnesota, Iowa, Alabama, Texas, Oklahoma, and Colorado and developed the empirical equation

$$R = (7.13 \times 10^{-5}) A^{0.49} S^{0.14} P^{0.74} E \quad (17-24)$$

where

$R$  = gully head advancement for the time period of interest (m);

$A$  = drainage area above the gully head (m<sup>2</sup>);

$S$  = slope of the approach channel above the gully head (%);

$P$  = summation of rainfall from 24-h rains equal to or greater than 12.7 mm for the time period of interest (mm); and

$E$  = clay content of the eroding soil profile (%).

The United States Soil Conservation Service (1966) recommended a simplified form of this equation:

$$R = (5.25 \times 10^{-3}) A^{0.46} P^{0.20} \quad (17-25)$$

## 17.4 STREAMBED AND BANK EROSION

Streambed erosion mechanics and quantification are extensively discussed in Chapters 2 to 4. Local bridge scour is another form of streambed erosion; its processes and quantification are discussed in Chapter 10. Quantification of streambed erosion and bed elevation changes using one-, two-, or three-dimensional numerical models is discussed in Chapters 14 and 15. Quantification of streambed erosion, along with upland soil erosion (sediment yield), using watershed simulation models is discussed later in this chapter.

Mechanics of streambank erosion and river width adjustment and their quantification are extensively discussed in Chapter 7 and by the ASCE Task Committee on Hydraulics, Bank Mechanics, and Modeling of River Width Adjustment (1998a; 1998b). Twelve quantitative time-dependent models

that may be used to quantify streambed and bank erosion were also reviewed and described there.

## 17.5 GROSS EROSION, DELIVERY RATIO, AND SEDIMENT YIELD

Gross erosion is the total soil eroded in a drainage area or watershed through interrill, rill, gully, and stream erosion processes. All the sediment generated from these processes (gross erosion) may not be delivered at the watershed outlet because some of it may be deposited at various locations in the watershed. Soil material eroded from a field slope may be deposited along field boundaries, in terrace channels, in depressional areas, or on flat or vegetated areas traversed by overland flow before it reaches a watercourse (stream). Sediment may be also deposited within the stream channel system itself, either in specific locations such as sand bars, or generally across the bottom of a long stream reach.

Sediment yield is the total sediment delivered past a point of interest or the watershed outlet during any given time. Sediment yield at a point may be computed simply by multiplying gross erosion in the watershed above that point by a delivery ratio. The sediment delivery ratio is the fraction of the gross erosion that is expected to be delivered to the point of the watershed under consideration.

The sediment delivery ratio is dependent upon drainage area size, watershed characteristics as described by relief and stream length, sediment source and its proximity to the stream, transport system, and texture of the eroded material. The United States Soil Conservation Service (1971) developed a general sediment delivery ratio versus drainage area relationship from data of earlier studies. The relationship shows that the sediment delivery ratio varies approximately inversely as the 0.2 power of the drainage area in acres (1 acre = 0.405 ha). The wide scatter of data used in the development of this relationship indicates that additional variables affect the relationship. Table 17-2 shows some estimates of the delivery ratios.

The use of the sediment delivery ratio estimates from Table 17-2 should be tempered by consideration of other factors that may affect the values at a particular location. A higher delivery ratio should be used when the eroding soil is fine-textured (high in silt or clay content) and a lower one if the eroding soil is coarse-textured (high in sand content). The conditions of the streams and the delivery system should also be evaluated to assess and alter, if need be, the general relationship of Table 17-2. Delivery ratio values from Table 17-2 should be used only if local or regional relationships are not established and time is not available to develop a sediment-yield relationship for the area of interest.

Note that the sediment delivery ratios listed in Table 17-2 all have values of less than 1.0. This implies that the channel system is aggrading, or accumulating deposited sediment. This will be the case in most watershed studies examining

**Table 17-2 General Sediment Delivery Ratios<sup>a</sup>**

Drainage area, km <sup>2</sup>	Sediment delivery ratio
0.05	0.580
0.10	0.520
0.50	0.390
1.00	0.350
5.00	0.250
10.00	0.220
50.00	0.153
100.00	0.127
500.00	0.079
1000.00	0.059

<sup>a</sup>Based on United States Soil Conservation Service (1971).

the impacts of increased human activities, because such activities generally increase upland erosion and the delivery of sediment to the channel system. If things go the other way, and a watershed undergoing severe erosion is put under conservation management so that upland erosion is greatly reduced, the sediment delivery ratio may in fact become greater than 1.0, as little new sediment is delivered to the channel system but the sediment within the system is flushed out or new sediment is generated from streambed and/or bank erosion by continuing stream flows.

The most reliable sediment yield estimates come from direct measurements of suspended sediment and bed load at the point of interest. Sediment-yield calculations for the Illinois River Basin (Demissie et al. 2003) are an example. Reservoirs of known age and sedimentation history determined by surveys are also excellent data sources for determining sediment yields. The sediment accumulation over a known time span can be used to obtain the average annual sediment yield. However, reservoir deposition and sediment yield may not be the same, because the reservoir trap efficiency may not be 100%. The trap efficiency of a reservoir is the portion of the total sediment delivered to the reservoir that is retained in the reservoir. These methods and the associated data were presented and discussed extensively in Vanoni (1975). Recent advancements are discussed here in Chapters 5 and 12 and Appendix D.

More discussions and methods of computing delivery ratio and sediment yield may be found in Agricultural Research Service—U.S. Department of Agriculture (1975), Walling (1983), and Williams (1977). The first publication is a comprehensive compilation of research prior to 1972 and provides excellent background, data, analysis, and conceptual materials.

## 17.6 WATERSHED MODELS

Watershed models simulating hydrologic processes, upland soil and stream erosion, and transport and deposition of sediment are comprehensive tools in computing and predicting sediment yields from watersheds. In addition to simulating hydrologic, erosion, and sedimentation processes, some of the watershed models simulate chemical mixing with water and sediment and transport of these through watersheds. These models are also called non-point-source pollution models because they simulate surface-water pollutants, including sediment, nutrients, pesticides, and other chemicals, originated from nonpoint or diffused sources. Such models are useful analysis tools to understand some of environmental problems (flooding, upland soil and streambed-bank erosion, sedimentation, contamination of water, etc.) and to find solutions through land-use changes and best management practices (BMPs).

The models assist in the development of total maximum daily load (TMDL) estimates required by the United States Clean Water Act and in evaluating alternative land-use and BMP scenarios, implementation of which can help in meeting water-quality standards and reducing the damaging effects of storm-water runoff on water bodies and the landscape. The TMDL is the maximum amount of a pollutant from point (e.g., wastewater treatment plant) and nonpoint sources that a water body can receive and still meet water-quality standards. According to the U.S. Environmental Protection Agency report (USEPA 1998), agriculture is the leading contributor of non-point-source pollutants (sediment and nutrients) to streams and rivers in the United States. Other contributors include golf courses, urban development, streambank erosion, and mining operations.

Some of the commonly used watershed-scale hydrologic and non-point-source pollution models include the Areal Nonpoint Source Watershed Environment Response Simulation or ANSWERS (Beasley et al. 1980), the Precipitation-Runoff Modeling System or PRMS (Leavesley et al. 1983), the Agricultural NonPoint Source pollution model or AGNPS (Young et al. 1987), the KINematic runoff and EROSion model or KINEROS (Woolhiser et al. 1990), the Hydrological Simulation Program—Fortran or HSPF (Bicknell et al. 1993), the European Hydrological System model or MIKE SHE (Refsgaard and Storm 1995), the Soil and Water Assessment Tool or SWAT (Arnold et al. 1998), the Annualized Agricultural NonPoint Source model or AnnAGNPS (Bingner and Theurer 2001), the Dynamic Watershed Simulation Model or DWSM (Borah et al. 2002b), ANSWERS-Continuous (Bouraoui et al. 2002), and CASCade of planes in 2-Dimensions or CASC2D (Ogden and Julien 2002). Sources and descriptions of more models, including field-scale models, are available in the literature (e.g., Singh 1995; Singh and Frevert 2002a; 2002b).

Some of the models are based on simple empirical relations having robust algorithms, and others use physically

based governing equations having computationally intensive numerical schemes. The simple models are sometimes incapable of giving desirable detailed results, and the detailed models are inefficient and could be computationally prohibitive for large watersheds. Therefore, finding an appropriate model for an application and for a certain watershed is quite a challenging task. Borah and Bera (2003) reviewed the 11 models mentioned and compiled a report on their mathematical bases, computational techniques, and important features or structures. This report is useful for selecting the most suitable model for a specific application depending upon the problem, watershed size, desired spatial and temporal scales, expected accuracy, user's skills, computer resources, etc. The review is also helpful in determining the strengths, weaknesses, and directions for enhancements of the models. The following nine subsections are based on that review.

In addition to these 11 watershed-scale models, two other field-scale models are worth mentioning: Chemicals, Runoff, and Erosion from Agricultural Management System or CREAMS (Knisel 1980) and Water Erosion Prediction Project or WEPP (Foster and Lane 1987; Lane and Nearing 1989). These two models have been widely used in estimating sediment yields from field-scale catchments and hill slopes. WEPP is a detailed soil-erosion and sediment-transport model and can be considered as state-of-the-art in hill-slope simulations. There are many other models available in the literature. The Department of Defense (Doe et al. 1999) evaluated 24 soil-erosion models for use on military installations. Among those, the Simulated Water Erosion (SIMWE) model (Mitas and Mitasova 1998) was found to be one of the "best" erosion models.

### 17.6.1 Review of Watershed Models

AnnAGNPS, ANSWERS-Continuous, HSPF, and SWAT are long-term continuous simulation models useful for analyzing long-term effects of hydrological changes and watershed management practices, especially agricultural practices. AGNPS, ANSWERS, DWSM, and KINEROS are single-storm-event models useful for analyzing severe actual or design single-event storms and evaluating watershed management practices, especially structural practices. CASC2D, MIKE SHE, and PRMS have both long-term and storm-event simulation capabilities. The mathematical bases of different components of these models, the most important elements of these mathematical models, were identified and compiled by Borah and Bera (2003). A summary compilation is presented in Table 17-3 for the long-term continuous models and Table 17-4 for the storm-event models. PRMS has both long-term and storm-event modes. The long-term mode of PRMS is only a hydrological model. The storm mode of PRMS has a sediment component as well. Therefore, only the PRMS storm mode is reviewed and presented in Table 17-4. MIKE SHE and CASC2D are listed separately; MIKE SHE is presented in Table 17-3 with

the continuous models, and CASC2D is listed in Table 17-4 with the storm-event models. In each of these tables, the summary includes model components or capabilities, temporal scale, watershed representation, procedures to compute rainfall excess or water balance on overland planes, overland runoff, subsurface flow, channel runoff, reservoir flow, overland sediment, channel sediment, reservoir sediment, chemicals, and BMP evaluations. Sources and brief backgrounds of the 11 models are given below.

AGNPS, the Agricultural NonPoint Source pollution model (Young et al. 1987; 1989), was developed at the USDA-ARS North Central Soil Conservation Research Laboratory in Morris, Minnesota. It is an event-based model simulating runoff, sediment, and transport of nitrogen (N), transport of phosphorus (P), and chemical oxygen demand (COD) resulting from single rainfall events. Version 4.03 of the model (Young et al. 1994) was widely distributed. The model is currently undergoing extensive revisions and upgrading at the USDA-ARS National Sedimentation Laboratory (NSL) in Oxford, Mississippi, and one of its upgrades is AnnAGNPS, the Annualized Agricultural NonPoint Source model (Bingner and Theurer 2001), for continuous simulations of hydrology, soil erosion, and transport of sediment, nutrients, and pesticides. It is designed to analyze the impact on the environment of non-point-source pollutants from predominantly agricultural watersheds.

ANSWERS, Areal Nonpoint Source Watershed Environment Response Simulation (Beasley et al. 1980), was developed at Purdue University in West Lafayette, Indiana, and uses a distributed parameter concept to model the spatially varying processes of runoff, infiltration, subsurface drainage, and erosion for single-event storms. The model has two major components: hydrology and upland erosion responses. The conceptual basis for the hydrologic model was taken from Huggins and Monke (1966) and for the erosion simulation from Foster and Meyer (1972). Similar to AnnAGNPS, ANSWERS-Continuous (Bouraoui and Dillaha 1996; Bouraoui et al. 2002) emerged from ANSWERS as a continuous model at the Virginia Polytechnic Institute and State University in Blacksburg, Virginia. The model was expanded with upland nutrient transport and losses based on GLEAMS (Leonard et al. 1987), EPIC (Williams et al. 1984), and others.

CASC2D, CASCade of planes in 2-Dimensions, initially developed at Colorado State University in Fort Collins, Colorado (Julien and Saghafian 1991; Julien et al. 1995), and further modified at the University of Connecticut in Storrs, Connecticut (Ogden 1998; Ogden and Julien 2002), is a physically based model. It simulates water and sediment in two-dimensional overland grids and one-dimensional channels and has both single-event and long-term continuous simulation capabilities. Similarly, MIKE SHE (Refsgaard and Storm 1995), based on SHE, the European Hydrological System (Abbott et al. 1986a; 1986b), is a comprehensive, distributed, and physically based model simulating water,

**Table 17-3 Summary of Watershed-Scale Long-Term Continuous Models<sup>a</sup>**

Description/ criteria	AnnAGNPS	ANSWERS- Continuous	HSPF	MIKE SHE	SWAT
Model components/ capabilities	Hydrology, transport of sediment, nutrients, and pesticides resulting from snowmelt, precipitation and irrigation, source accounting capability, and user interactive programs including TOPAGNPS (Bingner and Theurer 2001) generating cells and stream network from Digital Elevation Model.	Daily water balance, infiltration, runoff and surface-water routing, drainage, river routing, evapotranspiration, sediment detachment, sediment transport, nitrogen and phosphorus transformations, nutrient losses through uptake, runoff, and sediment.	Runoff and water-quality constituents on pervious and impervious land areas, movement of water and constituents in stream channels and mixed reservoirs, and part of the USEPA BASINS modeling system with user interface and ArcView Geographic Information System (GIS) platform.	Interception-ET, overland and channel flow, unsaturated zone, saturated zone, snowmelt, exchange between aquifer and rivers, advection and dispersion of solutes, geochemical processes, crop growth and nitrogen processes in the root zone, soil erosion, dual porosity, irrigation, and user interface with pre- and postprocessing, GIS, and UNIRAS (Refsgaard and Storm 1995) for graphical presentation.	Hydrology, weather, sedimentation, soil temperature, crop growth, nutrients, pesticides, agricultural management, channel and reservoir routing, water transfer, and part of the USEPA BASINS modeling system with user interface and ArcViewGIS platform.
Temporal scale	Long-term; daily or subdaily steps.	Long-term; dual time steps: daily for dry days and 30 s for days with precipitation.	Long-term; variable constant steps (hourly).	Long-term and storm event; variable steps depending on numerical stability.	Long-term; daily steps.
Watershed representation	Homogeneous land areas (cells), reaches, and impoundments.	Square grids with uniform hydrologic characteristics, some having companion channel elements; one-dimensional simulations.	Pervious and impervious land areas, stream channels, and mixed reservoirs; one-dimensional simulations.	Two-dimensional rectangular/square overland grids, one-dimensional channels, one-dimensional unsaturated and three-dimensional saturated flow layers.	Subbasins grouped based on climate, hydrologic response units (lumped areas with same cover, soil, and management), ponds, groundwater, and main channel.
Rainfall excess on overland/ water balance	Water balance for constant subdaily time steps and two soil layers (8-in. tillage depth and user-supplied second layer).	Daily water balance, rainfall excess using interception, Green-Ampt infiltration equation, and surface storage coefficients.	Water budget considering interception, ET, and infiltration with empirically based areal distribution.	Interception and ET loss and vertical flow solving Richards equation using implicit numerical method.	Daily water budget; precipitation, runoff, ET, percolation, and return flow from subsurface and groundwater flow.
Runoff on overland	Runoff curve number generating daily runoff following SWRRB and EPIC procedures and USSCS (1986) TR-55 method for peak flow.	Manning and continuity equations (temporally variable and spatially uniform) solved by explicit numerical scheme.	Empirical outflow depth to detention storage relation and flow using Chezy-Manning equation.	Two-dimensional diffusive wave equations solved by an implicit finite-difference scheme.	Runoff volume using curve number and flow peak using modified Rational formula or SCS TR-55 method.

**Table 17-3 Summary of Watershed-Scale Long-Term Continuous Models<sup>a</sup> (Continued)**

Description/ criteria	AnnAGNPS	ANSWERS- Continuous	HSPF	MIKE SHE	SWAT
Subsurface flow	Lateral subsurface flow using Darcy's (1856) equation or tile drain flow using Hooghoudt's (Smedema and Rycroft 1983) equation and parallel drain approximation.	Subsurface flow defined by tile drainage coefficient and groundwater or interflow release fraction; unsaturated zone drainage determined using Darcy's gravity flow.	Interflow outflow, percolation, and groundwater outflow using empirical relations.	Three-dimensional groundwater flow equations solved using a numerical finite-difference scheme and simulated river-groundwater exchange.	Lateral subsurface flow using kinematic storage model (Sloan et al. 1983), and groundwater flow using empirical relations.
Runoff in channel	Assuming trapezoidal and compound cross-sections, Manning's equation is numerically solved for hydraulic parameters and TR-55 for peak flow.	Manning and continuity equations (temporally variable and spatially uniform) solved by explicit numerical scheme.	All inflows assumed to enter one upstream point, and outflow is a function of reach volume or user-supplied demand.	One-dimensional diffusive wave equations solved by an implicit finite-difference scheme.	Routing based on variable storage coefficient method and flow using Manning's equation adjusted for transmission losses, evaporation, diversions, and return flow.
Flow in reservoir	Average outflow during runoff event is calculated based on permanent pool storage and stage, runoff volume, and coefficients derived from elevation-storage relation.	Not simulated.	Same as channel.	No information.	Water balance and user-provided outflow (measured or targeted).
Overland sediment	Uses RUSLE to generate sheet and rill erosion daily or user-defined runoff event, HUSLE (Theurer and Clarke 1991) for delivery ratio, and sediment deposition based on size distribution and particle fall velocity.	Raindrop detachment using rainfall intensity and USLE factors, flow erosion using unit-width flow and USLE factors, and transport and deposition of sediment sizes using modified Yalin equation.	Rainfall splash detachment and washing off of the detached sediment based on transport capacity as function of water storage and outflow plus scour from flow using power relation with water storage and flow.	No information.	Sediment yield based on Modified Universal Soil Loss Equation (MUSLE) (Williams and Berndt 1977) expressed in terms of runoff volume, peak flow, and USLE factors.
Channel sediment	Modified Einstein equation for sediment transport and Bagnold equation to determine transport capacity of flow (Theurer and Cronshey 1998).	Not simulated.	Noncohesive (sand) sediment transport using user-defined relation with flow velocity or Colby (1957) or Toffaleti (1969) method, and cohesive (silt, clay) sediment transport based on critical shear stress and settling velocity.	No information.	Bagnold's stream power concept for bed degradation and sediment transport, degradation adjusted with USLE soil erodibility and cover factors, and deposition based on particle fall velocity.

sediment, and water-quality parameters in two-dimensional overland grids, one-dimensional channels, and one-dimensional unsaturated and three-dimensional saturated flow layers. It also has both continuous long-term and single-event simulation capabilities. The model was developed by a consortium of the U.K. Institute of Hydrology, the French consulting firm SOGREAH, and the Danish Hydraulic Institute.

DWSM, the Dynamic Watershed Simulation Model (Borah et al. 2002b), was put together at the Illinois State Water Survey (ISWS) in Champaign, Illinois, based on research conducted over many years at several institutions

(Borah 1989a; 1989b; Ashraf and Borah 1992; Borah et al. 1980; 1981; 2002b; 2002c; 2004). DWSM simulates distributed surface and subsurface storm-water runoff, propagation of flood waves, upland soil and streambed erosion, sediment transport, and agrochemical transport in agricultural and rural watersheds during rainfall events. Similarly, KINEROS, the KINematic runoff and EROSion model (Woolhiser et al. 1990; Smith et al. 1995), which evolved from the 1960s to the 1980s at the USDA-ARS in Fort Collins, Colorado, is a distributed rainfall-runoff and soil erosion-sediment transport model for single rainfall events.

<sup>a</sup>After Borah and Bera (2003).

HSPF, the Hydrological Simulation Program—Fortran (Donigian et al. 1995), first publicly released in 1980, was put together by a group of consultants (Johanson et al. 1980) under contract with the USEPA. It is a continuous watershed simulation model that produces a time history of water quantity and quality at any point in a watershed. HSPF is an extension of several previously developed models: the Stanford Watershed Model (SWM) (Crawford and Linsley 1966); the Hydrologic Simulation Program (HSP) including HSP Quality (Hydrocomp 1977); the Agricultural Runoff Management (ARM) model (Donigian and Davis 1978); and the Nonpoint Source Runoff (NPS) model (A. S. Donigian, Jr., and N. H. Crawford, unpublished report, U.S. EPA Environmental Research Lab, 1979). HSPF uses many of the software tools developed by the U.S. Geological Survey (USGS) to providing interactive capabilities for model input, data storage, input-output analyses, and calibration. Several versions of the model have been released: Version 8 was released in 1984 (Johanson et al. 1984), and Version 10 was released in 1993 (Bicknell et al. 1993). HSPF has been promoted and marketed by these consultants worldwide. Its major application in the United States is the Chesapeake Bay basin model (Donigian et al. 1986). HSPF has been incorporated as a non-point-source model (NPSM) into the USEPA's Better Assessment Science Integrating Point and Nonpoint Sources (BASINS), which was developed by Tetra Tech, Inc. (Lahlou et al. 1998), under contract with the USEPA. The main purpose of BASINS is to analyze for and develop TMDLs nationwide.

PRMS, the Precipitation-Runoff Modeling System (Leavesley et al. 1983; Leavesley and Stannard 1995), developed at the USGS in Lakewood, Colorado, is a modular-design, distributed-parameter, physical-process watershed model that was developed to evaluate the effects of various combinations of precipitation, climate, and land use on watershed response. Watershed response to normal and extreme rainfall and snowmelt can be simulated to evaluate changes in water-balance relations, flow regimes, flood peaks and volumes, soil-water relations, sediment yields, and groundwater

recharge. PRMS has been coupled with USGS's data management program ANNIE (Lumb et al. 1990) and the U.S. Weather Service's Extended Streamflow Prediction (ESP) program (Day 1985) to produce a watershed-modeling and data-management system for hydrologic simulation and data analysis. PRMS has both long-term and single-storm modes. The long-term mode of PRMS is only a hydrological model. The storm mode of PRMS has a sediment component as well. Therefore, only the PRMS Storm Mode is considered and discussed here.

SWAT, the Soil and Water Assessment Tool (Arnold et al. 1998; Neitsch et al. 2002), was developed at the USDA-ARS Grassland, Soil, and Water Research Laboratory in Temple, Texas. It emerged mainly from SWRRB (Arnold et al. 1990) and has features from CREAMS (Knisel 1980); EPIC (Williams et al. 1984); GLEAMS (Leonard et al. 1987); and ROTO (Arnold et al. 1995). It was developed to assist water resources managers in predicting and assessing the impact of management on water, sediment, and agricultural chemical yields in large ungauged watersheds or river basins. The model is intended for long-term yield predictions and is not capable of detailed single-event flood routing. It is an operational or conceptual model that operates on a daily time step. The model has eight major components: hydrology, weather, sedimentation, soil temperature, crop growth, nutrients, pesticides, and agricultural management. Although most of the applications of SWAT have been on a daily time step, recent additions to the model are the Green and Ampt (1911) infiltration equation using rainfall input at any time increment and channel routing at an hourly time step (Neitsch et al. 2002). Similarly to HSPF, SWAT is also incorporated into the USEPA's BASINS for non-point-source simulations on agricultural watersheds.

### 17.6.2 Basic Flow-Governing Equations

Flow routing is governed by flow equations basic to all of the hydrologic, soil erosion-sediment transport (sediment yield) and non-point-source pollution models. Performance,

efficiency, and applicability of a model depend greatly on these basic equations and how they are solved.

The basic flow-governing equations are the dynamic wave equations, often referred to as the St. Venant equations or shallow-water wave equations. These consist of the equations of continuity and momentum, respectively, for gradually varied unsteady flow, expressed as (Singh 1996)

$$\frac{\partial h}{\partial t} + \frac{\partial Q}{\partial x} = 0 \quad (17-26)$$

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + g \frac{\partial h}{\partial x} = g (S_0 - S_f) \quad (17-27)$$

where

- $h$  = flow depth (m);
- $Q$  = flow per unit width ( $\text{m}^3 \text{s}^{-1} \text{m}^{-1}$ );
- $u$  = water velocity ( $\text{m s}^{-1}$ );
- $g$  = acceleration due to gravity ( $\text{m s}^{-2}$ );
- $S_0$  = bed slope ( $\text{m m}^{-1}$ );
- $S_f$  = energy gradient ( $\text{m m}^{-1}$ );
- $t$  = time (s);
- $x$  = longitudinal distance (m).

There is no analytical solution of Eqs. (17-26) and (17-27). Approximate numerical solutions of these two equations have been used in river flood routing models, such as the U.S. Army Corps of Engineers' Unsteady flow through a full NETwork of open channels (UNET) model (Barkau 1993); the National Weather Service's OPERational Dynamic Wave (DWOPER) model (Fread 1978); and models by Amein and Fang (1970), Strelkoff (1970), and Balloffet and Scheffler (1982), to name a few.

The dynamic wave equations have not been used in watershed models because of their computationally intensive numerical solutions. Only the CASC2D model uses these equations on a limited basis. Some of the models use approximations of these equations, ignoring certain terms in the momentum equation (Eq. (17-27)), as discussed below.

### 17.6.3 Diffusive Wave Equations Used by CASC2D and MIKE SHE

The diffusive wave equation consists of the continuity and simplified momentum equations, respectively expressed as (Singh 1996)

$$\frac{\partial h}{\partial t} + \frac{\partial Q}{\partial x} = q \quad (17-28)$$

$$\frac{\partial h}{\partial x} = S_0 - S_f \quad (17-29)$$

where

$$q = \text{lateral inflow per unit width and per unit length} \\ (\text{m}^3 \text{s}^{-1} \text{m}^{-1} \text{m}^{-1}).$$

These equations are also known as “noninertia wave” equations (Yen and Tsai 2001).

The continuity equation (Eq. (17-28)) includes lateral inflow. The simplified momentum equation (Eq. (17-29)) expresses the pressure gradient as the difference between the bed slope and energy gradient, and is derived from Eq. (17-27) after ignoring the first two terms, representing, respectively, the local and convective accelerations.

As with the dynamic wave equations, there is no analytical solution of the diffusive wave equations (Eqs. (17-28) and (17-29)). Watershed models CASC2D and MIKE SHE use approximate numerical solutions of these equations for routing surface runoff over overland planes and through channel segments. CASC2D uses two numerical methods to solve Eqs. (17-28) and (17-29) for overland flow and channel flow (Ogden and Julien 2002). In solving these equations, Manning's formula is used to compute flow, and is expressed as

$$Q = \frac{1}{n} A R^{2/3} S_f^{1/2} \quad (17-30)$$

where

- $n$  = Manning's roughness coefficient;
- $A$  = flow cross-sectional area per unit width ( $\text{m}^2 \text{m}^{-1}$ );
- $R$  = hydraulic radius (m).

### 17.6.4 Kinematic Wave Equations Used by DWSM, KINEROS, and PRMS

The kinematic wave equations are the simplest form of the dynamic wave equations. Lighthill and Whitham (1955) developed the kinematic wave theory and used it to describe the movement of flood waves in long rivers. Kinematic wave theory is now a well-accepted tool for modeling a variety of hydrological processes (Singh 1996). The governing equations consist of the continuity equation and the simplest form of the momentum equation, ignoring all the acceleration and pressure gradient terms of Eq. (17-27), respectively expressed as

$$\frac{\partial h}{\partial t} + \frac{\partial Q}{\partial x} = q \quad (17-31)$$

$$S_0 = S_f \quad (17-32)$$

The momentum equation (Eq. (17-32)) expresses simply that the energy gradient is equal to the bed slope. Any suitable law of flow resistance can be used to express this equation as a parametric function of the stream hydraulic parameters. A widely used expression is

$$Q = \alpha h^m \quad (17-33)$$

where

$\alpha$  = the kinematic wave parameter;

$m$  = the kinematic wave exponent;

and  $\alpha$  and  $m$  are related to channel (or plane) roughness and geometry. Manning's formula (Eq. (17-30)) may be used to define  $\alpha$  and  $m$  in terms of Manning's roughness coefficient ( $n$ ) and channel or plane geometry (Borah 1989a).

Equations (17-31) and (17-33) constitute the kinematic wave equations. The advantage of these equations is that they have an analytical solution by the method of characteristics (Borah et al. 1980). The equations generate only one system of characteristics, which means that they cannot represent waves traveling upstream, as in the case of backwater flow. Research suggests that for most cases of hydrological significance, the kinematic wave solution gives accurate results (V. P. Singh, unpublished paper, "Kinematic wave modeling in hydrology," ASCE-EWRI Task Committee on Evolution of Computer Methods in Hydrology, Reston, Va., 2002). In open-channel flow, dynamic waves always occur. The friction and slope terms modify the wave amplitudes to such a degree that the dynamic waves rapidly become negligible and the kinematic wave assumes the dominant role.

The analytical solution of Eqs. (17-31) and (17-33) does not apply when two characteristics intersect, forming a shock wave and physically representing a larger and faster wave superseding a smaller and slower wave. Approximate numerical solutions of Eqs. (17-31) and (17-33), such as the ones presented by Li et al. (1975) and Smith et al. (1995), do not recognize shocks. The numerical solutions can be used for any situation but the numerical solutions smooth out the waves and the hydrographs (Borah et al. 1980), thus undermining the fundamental reason that Lighthill and Whitham (1955) introduced this simple theory. With the analytical and an approximate shock-fitting (closed-form) solution, the kinematic wave theory represents salient features of a hydrograph, including the sharp rising part under shock-forming conditions (Borah et al. 1980).

The DWSM, KINEROS, and PRMS watershed models are based on the kinematic wave equations. KINEROS (Smith et al. 1995) and PRMS (Leavesley and Stannard 1995) use approximate numerical solutions of Eqs. (17-31) and (17-33), whereas DWSM uses the analytical and shock-fitting solution (Borah 1989a; Borah et al. 1980).

### 17.6.5 Storage-Based Equations Used by ANSWERS, ANSWERS-Continuous, and HSPF

Many of the models, such as ANSWERS, ANSWERS-Continuous, and HSPF, use the simple storage-based (non-linear reservoir) equations for flow routing. The equations consist of the spatially uniform and temporally variable

continuity equation and a flow equation expressed in terms of channel (or plane) roughness and geometry, such as the Manning equation (Eq. (17-30)). The continuity equation is expressed as

$$\frac{ds}{dt} = I - O \quad (17-34)$$

where

$s$  = storage volume of water ( $\text{m}^3$ );

$I$  = inflow rate ( $\text{m}^3 \text{s}^{-1}$ );

$O$  = outflow rate ( $\text{m}^3 \text{s}^{-1}$ ).

Equation (17-34) assumes a level water surface throughout the overland plane or channel segment and does not represent any waveforms. This equation is more suitable for flood routing in lakes and reservoirs.

### 17.6.6 Curve Number and Empirical Equations Used by AGNPS, AnnAGNPS, and SWAT

Many of the models, such as SWAT, AGNPS, and AnnAGNPS, do not route water using mass-conservation-based continuity equations as described above. SWAT and AnnAGNPS maintain water balance through daily or sub-daily water budgets. All three of them use the USDA Soil Conservation Service runoff curve number method (United States Soil Conservation Service 1972) to compute runoff volumes and other empirical relations similar to the rational formula (Kuichling 1889; Rosemiller 1982) to compute peak flows, which may be expressed as

$$Q_r = \frac{(P - 0.2S_r)^2}{P + 0.8S_r} \quad (17-35)$$

$$S_r = \frac{25400}{CN} - 254 \quad (17-36)$$

$$Q_p = 0.0028CiA \quad (17-37)$$

where

$Q_r$  = direct runoff (millimeters or mm);

$P$  = accumulated rainfall (mm);

$S_r$  = potential difference between rainfall and direct runoff (mm);

$CN$  = curve number representing runoff potential for a soil cover complex (values 2 to 100);

$Q_p$  = peak runoff rate ( $\text{m}^3 \text{s}^{-1}$ );

$C$  = runoff coefficient (values 0.02 to 0.95);

$i$  = rainfall intensity ( $\text{mm h}^{-1}$ );

$A$  = watershed area (ha).

In addition, SWAT uses an empirical procedure to route water through channels. The SCS runoff curve number

method (Eqs. (17-35) and (17-36)) is also used repeatedly by DWSM to compute rainfall excess rates at discrete time intervals in addition to an interception-infiltration alternative procedure (Table 17-4). Interception-infiltration routines are used by other models as well: ANSWERS, ANSWERS-Continuous, CASC2D, HSPF, KINEROS, MIKE SHE, and PRMS (Tables 17-3 and 17-4). The latest version of SWAT (Neitsch et al. 2002) has an option for using an infiltration equation for any time increment.

### 17.6.7 Model Algorithms and Efficiencies

CASC2D and MIKE SHE are both physically based models using multidimensional flow-governing equations with approximate numerical solution schemes, which make the models computationally intensive and subject to the numerical instabilities inherent in the numerical solutions. Both models use the diffusive (noninertia) wave equations (Eqs. (17-28) and (17-29)), and CASC2D uses the full dynamic wave equations (Eqs. (17-26) and (17-27)) on a limited basis, i.e., for stream channels less than 0.3% slope (Ogden and Julien 2002). Molnar and Julien (2000) examined the effects of grid size on the calculation of surface runoff using the CASC2D model. A sufficiently small time step is necessary to keep the model stable. The time step is on the order of 5 s for a 150-m grid size but decreases to about 1 s when standard 30-m GIS grid sizes are used. Calculation time can become prohibitive when the number of model grid cells exceeds 100,000 (Ogden and Julien 2002). MIKE SHE, using the same governing equations, has similar limitations. Although it uses a more stable numerical (implicit) scheme (Table 17-3), it is inefficient due to its iterative operation. Therefore, CASC2D and MIKE SHE would be suitable for small areas or watersheds for detailed studies of hydrology and non-point-source pollution under single rainfall events or for long-term periods in continuous mode.

Similar to CASC2D and MIKE SHE, the ANSWERS, KINEROS, and PRMS Storm Mode models (Table 17-4) are also physically based, using numerical solutions to solve the flow equations. ANSWERS uses the storage-based equations (Eqs. (17-34) and (17-30)), and KINEROS and PRMS use the kinematic wave equations (Eqs. (17-31) and (17-33)). These models were developed for single rainfall events using one-dimensional flow equations only, and therefore are less computationally intensive than CASC2D and MIKE SHE. However, potential problems inherent in the numerical solutions exist. Smith et al. (1995) suggested that KINEROS does a relatively good job of simulating runoff and sediment yield at watershed scales of up to approximately 1,000 ha. Therefore, applications of these models are limited to small watersheds and specific combinations of space and time increments for maintaining numerical solution stability. DWSM (Table 17-4), also a physically based model, uses analytical and approximate analytical solutions of the kinematic wave flow-governing equations (Eqs. (17-31) and

(17-33)). Due to its robust closed-form solutions and algorithms, DWSM is not limited to any combinations of space and time increment sizes, and could potentially be used for large watersheds.

### 17.6.8 Long-Term Continuous Models

AnnAGNPS, ANSWERS-Continuous, CASC2D, HSPF, MIKE SHE, and SWAT are continuous simulation models and are useful for analyzing long-term effects of hydrological changes and watershed management practices. HSPF is capable of simulating urban and suburban land uses as well. Due to its use of daily time steps, SWAT does not simulate single-event storms adequately. HSPF can use time steps smaller than a day and, therefore, can simulate individual storm events. However, due to its conceptualization of the overland (subbasin) areas as leveled detention storage and use of the storage-based or nonlinear flow equations in routings, HSPF is not adequate for simulating intense single-event storms, especially for large subbasins and long channels. Reviews of applications of the HSPF and SWAT models (Borah and Bera 2004) revealed that these two models are not suitable for analyzing severe storm events. AnnAGNPS and ANSWERS-Continuous are also not adequately formulated to simulate intense single-event storms. Borah and Bera's (2004) reviews also confirmed that SWAT is applicable to predominantly agricultural watersheds and HSPF mixed agricultural and urban watersheds.

The long-term continuous models AnnAGNPS, ANSWERS-Continuous, HSPF, MIKE SHE, and SWAT have all three major components: hydrology, sediment, and chemicals (Table 17-3). Both HSPF and SWAT models are parts of the USEPA's BASINS for developing TMDL. With BASINS, both models have graphical user interfaces for data analysis, data processing, and graphical presentation of model outputs, which are useful for model calibration, validation, and analysis of BMPs and dissemination of model results. AnnAGNPS is a recent upgrade of the single-event AGNPS model. Similarly, ANSWERS-Continuous is a recent upgrade of the single-event ANSWERS model with extensive upland process simulations. However, ANSWERS-Continuous does not have channel erosion and sediment transport routines (Table 17-3), and, therefore, the sediment and chemical components are not applicable to watersheds. Due to its computationally intensive numerical schemes, MIKE SHE may become prohibitive for long-term continuous simulations in medium-to-large watersheds.

### 17.6.9 Storm-Event Models

Intense single-event storms cause flooding. These storms are especially critical when most of the yearly sediment and pollutant loads are carried through and out of a watershed (David et al. 1997; Borah et al. 2003). Certain BMPs, such as structural BMPs, must be designed to withstand certain single-event

design storms. The storm-event models AGNPS, ANSWERS, CASC2D, DWSM, KINEROS, MIKE SHE, and PRMS-storm mode analyze severe actual or design single-event storms and evaluate watershed management practices, especially structural practices. The conceptual design and mathematical formulations of these models are different. AGNPS is a single-event, empirically based, lumped-parameter model using one time step (storm duration) and generating a single value for each of the output variables: runoff volume, peak flow, sediment yield, and average concentrations of nutrients. It is used to study the overall response from a single severe or design storm, but it is not suitable for analyzing a storm when the flow and constituent concentrations and loads vary with time. Time-varying water, sediment, and chemical discharges are critical in certain analyses. For example, peak flow, peak constituent concentrations, and their timings are crucial information in flood warning, floodwater management, watershed assessment, and BMP evaluations. Use of AGNPS in studying impacts of BMPs is qualitative (Borah et al. 2002a). ANSWERS, CASC2D, DWSM, KINEROS, MIKE SHE, and PRMS in storm mode can generate time-varying hydrograph and constituent graphs.

The storm-event models AGNPS, DWSM, and MIKE SHE all have the three major components hydrology, sediment, and chemical (Table 17-4). Among these three models, DWSM provides a balance between the simple AGNPS and complicated MIKE SHE models. It is suitable for simulations of agricultural and suburban watersheds (Borah and Bera 2004). CASC2D and KINEROS have complete hydrology and sediment components, but no chemical component (Table 17-4). ANSWERS and PRMS in storm mode have hydrology and overland sediment, but no chemical component, and no sediment simulation in stream channels (Table 17-4). AGNPS, CASC2D, KINEROS, and PRMS in storm mode have no subsurface flow simulations (Table 17-4).

#### 17.6.10 Sediment Yield Predictions Using Watershed Models

Watershed models can be used to predict sediment yields from a watershed through simulations of hydrologic, soil erosion, sediment transport, and sediment deposition processes (Tables 17-3 and 17-4). The models dynamically account for sediment delivery through their routing procedures, and therefore, delivery ratios are not required. As summarized in Tables 17-3 and 17-4, different models use different procedures and algorithms to simulate these processes. It is impossible to present here all those procedures beyond the summaries presented in Tables 17-3 and 17-4. However, the major steps taken in one of the models (DWSM) to simulate hydrology (the basic component), soil erosion, sediment transport, and sediment deposition and ultimately to compute sediment yield are outlined below to provide an understanding of a modeling approach.

To apply DWSM, the watershed is divided into one-dimensional overland planes, channel segments, and reservoir units (Borah et al. 2002b). These divisions take into account nonuniformities in topographic, soil, and land-use characteristics, which are treated as being uniform with representative characteristics within each of the divisions. An overland plane is represented as a rectangle, with width equal to the adjacent (receiving) channel length, and length equal to the overland plane area divided by the width. Representative slope, soil, land cover, and roughness are based on physical measurements and observations. A channel segment is represented with a straight channel having the same length as in the field and having a representative cross-sectional shape, slope, and roughness based on physical measurements and observations. A reservoir unit is represented with a stage-storage-discharge relation (table) developed based on topographic data and discharge calculations using outlet measurements and established relations.

The overland planes are the primary sources of runoff and sediment. Two overland planes contribute surface runoff, subsurface flow, and sediment to one channel segment laterally from each side. The excess rainfall and eroded soil are routed across an overland plane, resulting in variable flow and sediment discharge along its slope length. However, cross-slope flow and sediment discharge are assumed to be uniform. Thus flow and sediment routing are only necessary within a unit width of the plane. Tile drain flows are combined with lateral subsurface flow using an effective lateral saturated hydraulic conductivity concept (Borah et al. 2002b; 2004). As a result, each channel receives time-varying, but spatially uniform, lateral inflows of water and sediment from the adjacent overland planes.

The network of channel segments carries the receiving water and sediment from the overland planes toward the watershed outlet. Depending upon the sediment load and transport capacity of the flow, further erosion of soil materials from the channel bed or sediment deposition may take place. The model simulates erosion and deposition of the channel bed only, not the banks. Therefore, the model is applicable to fairly stable streambank channels only. Also, the model assumes that all the incoming sediment is settled (deposited) within a lake, reservoir, or detention pond. Therefore, the sediment component is applicable to large detention ponds, and perhaps most reservoirs and lakes, where sediment is largely trapped and sediment bypass is negligible. For routing water and sediment through the watershed, a computational sequence is determined starting from the uppermost overland plane and ending in a channel segment or reservoir unit at the watershed outlet.

Rainfall is the primary model input. Rainfall records either from single or multiple rain gauges may be used. With multiple rain gauges, rain gauges are assigned to the overland planes using the Thiessen polygon method (Thiessen 1911). Rainfall excess and infiltration rates on each overland plane are computed from the rainfall records using two alternative

procedures: the runoff curve number method (Eqs. (17-35) and (17-36)), as extended and described by Borah (1989a), and a detailed procedure involving computations of interception losses using a procedure of Simons et al. (1975) and infiltration rates using an algorithm developed by Smith and Parlange (1978), as described by Borah et al. (1981; 2002b). The first method computes rainfall excess rates, which are subtracted from rainfall rates (intensities) to compute infiltration rates assuming other losses, such as evapotranspiration are negligible during a storm event. The second method computes interception and infiltration rates, which are subtracted from rainfall intensities to compute rainfall excess rates. Losses in depression storage in the second method are indirectly accounted for in the interception as initial losses.

The excess rainfall over the overland planes and through the channel segments are routed using the kinematic wave equations (Eqs. (17-31) and (17-33)), as described in Borah (1989a). The routing scheme is based on analytical and approximate shock-fitting solutions (Borah et al. 1980) of Eqs. (17-31) and (17-33).

The sediment is divided into a number of particle size classes (groups). For agricultural watersheds, the sediment is divided into five size groups: sand, silt, clay, small aggregate, and large aggregate (Foster et al. 1985). Erosion, deposition, and transport of each size group are simulated individually, and total responses in the forms of sediment concentration and discharge and bed elevation change are obtained through integration of the responses from all the size groups.

The rate of soil detachment due to raindrop impact is computed using the relations (Meyer and Wischmeier 1969; Mutchler and Young 1975; Borah 1989b):

$$E_r = a_r I^2 (1 - D_c)(1 - D_g) \left(1 - \frac{h+e}{3d_{50}}\right), \text{ if } (h+e) < 3d_{50} \quad (17-38a)$$

$$E_r = 0, \text{ if } (h+e) \geq 3d_{50} \quad (17-38b)$$

where

$E_r$  = rate of soil detachment due to raindrop impact ( $\text{m s}^{-1}$ );

$a_r$  = raindrop detachment coefficient (RDC);

$I$  = rainfall intensity ( $\text{m s}^{-1}$ );

$D_c$  = canopy cover density ( $\text{m}^2 \text{m}^{-2}$ );

$D_g$  = ground cover density ( $\text{m}^2 \text{m}^{-2}$ );

$h$  = water depth (m);

$e$  = thickness of existing detached soil on the bed (m);

$d_{50}$  = median raindrop diameter (m).

Equation (17-38a) can also be expressed similarly to the USLE or RUSLE (Eq. (17-1)), as shown by Van Liew and Saxton (1984) and Van Liew (1998) for interrill soil detachment rate. In that form, only the  $K$  and  $C$  factors are kept in the equation, the  $R$  factor is replaced with some power of

rainfall intensity, and all multiplied by a coefficient (parameter). The  $L$  and  $S$  factors are dynamically accounted in the model algorithms, and the  $P$  factor is incorporated through changing all the model parameters affected by the support practice or appropriately subdividing the watershed to include the practice. These investigators use similar relationship for soil detachment rate by rill flow simply by replacing rainfall intensity with flow shear stress. In Eq. (17-38a), the  $K$  and  $C$  factors are lumped on the product  $a_r(1 - D_c)(1 - D_g)$  in computing rate of soil detachment due to raindrop impact. In computing flow-induced erosion, the  $K$  and  $C$  factors are lumped into the FDC parameter discussed below.

Equations (17-38a) and (17-38b) give the detachment rate for the entire size distribution used in the simulation. The rate for each size group is calculated by multiplying this rate by the fraction of the corresponding size group in the distribution. The eroded (detached) soil is added to an existing detached (loose) soil depth, from which entrainment to runoff takes place during erosion if the sediment-transport capacity of the runoff water is sufficient. The model maintains a loose soil depth on the bed to keep track of loose soil accumulated from bed materials detached by raindrop impact and from deposited sediment.

Flow-induced erosion and sediment deposition depend on transport capacity of the flow and the sediment load (amount of sediment already carried by the flow). Sediment-transport capacity is computed using established formulas. Based on Alonso et al. (1981), the bed-load formula of Yalin (1963) is used to compute sediment-transport capacities in overland planes under any flow condition and for all size groups. In computing capacities in the channels, the total load formula of Yang (1973) is used for sediment sizes  $\geq 0.1$  mm (fine to coarse sands) and the total load formula of Laursen (1958) is used for sediment sizes  $< 0.1$  mm (very fine sands and silts). If the capacity is higher than the sediment load, erosion takes place and the flow picks up more materials from the bed. If the loose soil volume at the bed is sufficient, sediment entrainment takes place from the detached soil depth. Otherwise, the flow erodes additional soil from the parent bed material of the overland plane or channel segment. The potential erosion is the remaining transport capacity after partial fulfillment with the existing sediment load and the loose soil volume, if any. The actual erosion is computed simply by multiplying the potential erosion by a flow detachment coefficient (FDC). The FDC is a distributed calibration parameter, which may have different values for different overland planes and channel segments, depending on resistance to erosion.

If the sediment-transport capacity is lower than the sediment load, the flow is in a deposition mode and the potential rate of deposition is equal to the difference of the two. The actual rate of deposition is computed by taking into account particle fall velocities. Deposited sediment is added to the loose soil volume. If the sediment-transport capacity and the sediment load are equal, an equilibrium condition is

assumed where there is neither erosion nor deposition. From the actual erosion and deposition, change in bed elevation during a computational time interval is computed.

All these processes are interrelated and must satisfy locally the conservation principle of sediment mass expressed by the sediment continuity equation (Borah 1989b),

$$\frac{\partial Q_s}{\partial x} + \frac{\partial CA}{\partial t} = q_s + g \quad (17-39)$$

where

- $Q_s$  = volumetric sediment discharge ( $\text{m}^3\text{s}^{-1}$ );
- $C$  = volumetric concentration of sediment ( $\text{m}^3\text{m}^{-3}$ );
- $A$  = cross-sectional area of flow ( $\text{m}^2$ );
- $q_s$  = volumetric rate of lateral sediment inflow per unit length of a channel segment ( $q_s = 0$  for overland plane) ( $\text{m}^3\text{s}^{-1}\text{m}^{-1}$ );
- $g$  = volumetric rate of material exchange with the bed per unit length ( $\text{m}^3\text{s}^{-1}\text{m}^{-1}$ );
- $x$  = downslope distance (m);
- $t$  = time (s).

Assuming sediment moves with the same velocity of water  $V$ , and water discharge  $Q$  remains constant within time and space intervals, Equation (17-39) may be written as

$$\frac{\partial A_s}{\partial t} + V \frac{\partial A_s}{\partial x} = q_s + g \quad (17-40)$$

where

- $A_s$  = sediment load, volume of sediment present in the flow per unit length ( $A_s = CA = Q_s/V$ ) ( $\text{m}^3\text{m}^{-1}$ );
- $V$  = average water velocity ( $\text{m s}^{-1}$ ).

Equation (17-40) is a quasi-linear hyperbolic equation governing the propagation of sediment load wave and is solved by the method of characteristics (Borah et al. 1981; Borah 1989b). Equation (17-40) and its solution are used to keep track of erosion, deposition, sediment discharge, and bed elevation change along the unit width of an overland plane or a channel segment as described in Borah (1989b) and Borah et al. (2002b).

Time integration of sediment discharges at outlet of any channel segment gives sediment yield from all the upstream areas (overland planes, channel segments, and reservoir units) contributing to the channel. Such a value at the watershed outlet gives the watershed sediment yield.

## CHAPTER 18

# *Engineering Geomorphology*

*S. A. Schumm and M. D. Harvey*

### 18.1 INTRODUCTION

Geomorphology is the study of earth-surface forms and processes. It is “The science that treats the general configuration of the earth’s surface; specifically the study of the classification, description, nature, origin and development of present landforms and their relationships to underlying structures, and of the history of geologic changes as recorded by these surface features” (Bates and Jackson 1987, p. 272). This rather involved definition stresses the origin and evolution of landforms, and such has been the traditional concern of geomorphologists. However, it is now acknowledged that a major contribution of geomorphology can be prediction, because an understanding of past landform changes can be a great aid in the recognition of problems and the future course of landform change. If, for example, we know how a river meander has changed through time, prediction of future change can be made with more confidence (Lagasse et al. 2004). Therefore, the historical perspective of most earth scientists is an aid in prediction for current and future conditions.

Engineering geology, a field in which geologists work closely with engineers to determine how earth materials will affect engineering structures, is a well-established field (Johnson and DeGraff 1988; Legget and Hatheway 1988; Kiersch 1991). However, the application of geomorphology to engineering and environmental problems has been a more recent phenomenon (Coates 1976; Fookes and Vaughn 1986). Coates (1976, p. 6) defines engineering geomorphology simply as the combining of the “talents of the geomorphology and engineering disciplines.” Sometimes this is difficult because of the disparity between engineering and geomorphic training and experience. However, Chow (1964) included a chapter on geomorphology by Strahler (1964) in his *Handbook of Applied Hydrology*, and Chang (1988) has drawn heavily on the geomorphic literature in his book on river engineering. Therefore, engineering geomorphology is the application of landform science (geomorphology) to

engineering problems (Schumm and Harvey 1993; Thorne et al. 1997; Anthony et al. 2001). The major objectives of this chapter are to bring to the attention of the engineering profession (1) the importance of landform history, (2) the need to view specific problems in a broad or system context, and (3) the importance of geologic and geomorphic controls and hazards to many engineering activities for which the nominal time scale is generally 50 to 100 yrs.

Landform history involves changes through time, which can lead to conditions that threaten engineering works. For example, the slow modification of landforms by erosion, deposition, and weathering can produce abrupt changes (gullying, channel avulsion, and slope failure) that can have significant effects on engineering activities. Hence, landform or geomorphic hazards need to be identified. In addition, it is important to realize that a specific engineering site or problem is part of an integrated geomorphic system. For example, a bridge site is a small part of a fluvial system, and the character of that system both up- and downstream can significantly affect future site stability and the stability of the structure itself (Mussetter et al. 1998). Therefore, a broader perspective on the situation is desirable, and one should back away from a specific site and view it in the context of the surrounding geomorphic setting. In addition, geologic and geomorphologic controls can be far more important than is generally supposed for an engineering time scale. For example, the world’s great alluvial rivers (Mississippi, Nile, Indus), although presumably dominated by hydrologic, sediment, and hydraulic controls, are, in fact, significantly influenced by geologic variables (Schumm and Winkley 1994; Schumm et al. 2000). It is important to recognize that geomorphology and engineering can be combined to provide a rational approach to many engineering and environmental problems.

In this chapter, the measurements that can be used to describe landforms quantitatively and methods that are used to date landforms will not be introduced. The reader

can obtain information on specific techniques in Strahler (1964), Goudie (1981), Catt (1988), Thorne et al. (1997), and Kondolf and Piégay (2003). In addition, a discussion of the landforms and processes involved in their modification can be found in any geomorphology textbook (Ritter 1986; Bloom 1991; Scheidegger 1991; Summerfield 1991). These texts cover a wide range of topics including coastal, glacial, wind, and weathering processes, and they provide references to these topics. Fluvial geomorphology will be stressed in this chapter. Nevertheless, because engineering problems and projects are global, it is important to recognize the significance of climate and climate changes upon geomorphic processes and landforms (Bull 1991; Molnar and Ramirez 2001). Wilson (1968) has identified six morphogenetic regions where geomorphic processes differ (Table 18-1). Therefore, experience gained in one part of the world may not be directly applicable elsewhere.

The *Encyclopedia of Geomorphology* (Fairbridge 1968) and the *Glossary of Geology* (Bates and Jackson 1987) provide a ready entry to geomorphic terminology and basic literature. Because of the interdisciplinary nature of geomorphology, its literature is scattered through a variety of geologic, hydrologic, hydraulic, environmental, and geographic journals. In most of the world, with the exception of the United States, geomorphology is taught as a subject within the field of physical geography. Three journals that publish on only geomorphic topics are *Earth Surface Processes and Landforms*, *Geomorphology*, and *Zeitschrift für Geomorphologie*. Of considerable value is the geomorphic abstract journal *Geomorphological Abstracts*, which provides short abstracts arranged by topic of papers from the international literature.

Geomorphologists have also provided descriptions and erosional and depositional histories of identifiable regions (Thornbury 1965; Graf 1987, 1988). These provide useful

background information. Goudie (1981) has provided a comprehensive review of techniques that have been used in the study of landforms and landscapes, and several volumes of collected “classic” papers deal with specific geomorphic topics (Schumm 1972; Schumm and Mosley 1973; Schumm 1977a).

Schuirman and Slosson (1992) provide examples of how geomorphic and geologic investigations can aid engineers and the courts in litigation resulting from landslides, flooding, and gravel mining. By citing examples, they indicate the type of information that is needed and the general approach that should be followed in such investigations. In a concluding chapter, they provide useful advice for engineers and geologists who become expert witnesses. It is essential to maintain objectivity and a high degree of professionalism. Similar advice to young scientists and consultants was proffered by Schumm (1988, 1991), who also stressed the need to maintain objectivity and to adhere to the standards of the profession if credibility is to be maintained and error is to be avoided.

Before the general field of engineering geomorphology is considered, especially as it pertains to the study of form, processes, and dynamics of rivers, it is necessary to consider the different types of rivers that exist and provide a brief discussion of river classification. Schumm (2005) has suggested that rivers and streams can be divided into two principal types, regime and nonregime (Table 18-2). The regime channels, defined as those that flow on and in sediments transported by the river during the present hydrologic regime, whose morphology is controlled primarily by the interactions of the flow regime and the sediment supply (Leopold et al. 1964; Schumm 1977b), can be further subdivided on the basis of patterns (straight, meandering, wandering, braided, anastomosing) and hydrology (ephemeral, intermittent, perennial, interrupted). Nonregime channels can be further subdivided into bedrock controlled or constrained, where the form of the channel is forced by nonalluvial factors such as bedrock, colluvium,

**Table 18-1 Morphogenetic Regions**

Region	Dominant geomorphic processes	Landscape characteristics
Glacial	Glaciation, nivation	Glacial scour and deposition, alpine topography
Periglacial	Frost action, solifluction, running water	Patterned ground, solifluction, lobes, terraces, outwash plains
Arid	Desiccation, wind action, running water	Dunes, salt pans (playas), deflation basins, angular slopes, arroyos
Semiarid (subhumid)	Running water, weathering (especially mechanical)	Pediment, fans, angular slopes with coarse debris, badlands
Humid temperate	Running water, weathering (especially chemical), creep (and other movements)	Smooth slopes, soil covered, stream deposits extensive
Selva	Chemical weathering, mass movements, running water	Steep slopes, knife-edge ridges, deep soils (laterites included)

After Wilson (1968).

glacial deposits, or extreme flood deposits (Montgomery and Buffington 1997; Tinker and Wohl 1998; O'Connor and Grant 2003) and unstable, which can include degrading (Schumm et al. 1984; Darby and Simon 1999), aggrading (Schumm 1977b), and avulsing (Schumm et al. 2000) channels.

There have been numerous attempts to classify rivers (Leopold and Wolman 1957; Schumm 1963, 1968; Mollard 1973; Kellerhals et al. 1976; Brice 1981; Mosley 1987; Rosgen 1994, 1996; Montgomery and Buffington 1997; Thorne 1997; Vandenberghe 2001), but no single classification has been developed that meets the needs of all investigators, and in fact Goodwin (1999) has even questioned the need for classification. Several factors have prevented the achievement of an ideal geomorphic stream classification, and foremost among these have been the variability and complexity of rivers and streams (Mosley 1987; Juracek and Fitzpatrick 2003). Extensive problems associated with the use of existing morphology as a basis for extrapolation (Schumm 1991) further complicate the development of a robust classification (Juracek and Fitzpatrick 2003).

However, notwithstanding the problems associated with classification in general, stream classification is widely used in the United States, with the Rosgen (1996) classification being the most commonly used. Numerous federal, state, and local agencies utilize the Rosgen (1996) classification for description of stream reaches and for guiding stream restoration or rehabilitation. Provided that the classification is used for descriptive or communicative purposes, it provides a useful tool. Unfortunately, given the widespread use of

the classification, it is not appropriate in its present form for assessing stream stability, inferring geomorphic processes, predicting future geomorphic responses, or guiding stream restoration or rehabilitation activities (Miller and Ritter 1996; Wilcock 1997; Juracek and Fitzpatrick 2003). From a practical perspective, the geomorphologist's measurements of sinuosity, width-depth ratio, gradient, dimensions (width and depth), and sediment type (bed and banks), when combined with the engineer's measurements of discharge, flow velocity, shear stress, and stream power, provide the information necessary for understanding of a river and the knowledge required for prediction of future change (Schumm 2005). When quantitative information about a river is available, classifications are of less value in the design of stable stream channels and prediction of channel change.

## 18.2 HISTORY

The first objective of this chapter is to convince the reader that a combination of an understanding of present conditions (model of the present) with historical information (model of the past) is of great value for prediction of landform (drainage network, slope, river, alluvial fan, etc.) change, as a result of natural or human influences (model of the future). For the study of present conditions the collection of available topographic maps, aerial photographs, soil maps, and land-use maps, as well as hydrological and meteorological data and information on the geotechnical properties of bed and bank materials, bank vegetation, and the hydraulic character of flow, is necessary. These types of information permit description of the present situation, and this can be considered a *direct approach*, where existing information is assembled and utilized to provide present and recent historical information. However, such a short record often does not provide an adequate basis for prediction of future landform stability or change. This requires an *indirect approach*, which involves geomorphic evaluation of groups of landforms.

### 18.2.1 Direct Approach

A simple example of the need for recent historical information and of the direct approach is provided by a court case involving the Snake River in Jackson Hole, Wyoming (Schumm 1994). It was claimed that because the present banks of the river do not correspond with the banks as surveyed by the General Land Office (GLO) surveyors in the late 19th century, the surveys were either fraudulent or in gross error. This conclusion was supported by expert testimony that the river had not changed position for centuries. However, when the GLO surveys were compared with more recent maps and a series of aerial photographs, it became obvious that the Snake River was and is a very active river that continually erodes its banks, and therefore, the position of the banks changes through time. The historical evidence,

**Table 18-2 Channel Types**

<i>Regime channels</i>	
Patterns	straight meandering (passive/active) wandering braided anastomosing (can be any of above patterns)
Hydrology	ephemeral intermittent perennial interrupted
<i>Nonregime channels</i>	
Bedrock	confined constrained
Unstable	aggrading (transport-limited) degrading (supply-limited) avulsing

After Schumm (2005).

as well as dendrochronological and pedological data, convinced a federal judge that the GLO surveys were accurate.

The direct approach uses readily available historical information. For example, information that can be used to determine the stability of a bridge crossing can be obtained in at least five ways, as follows (Shen and Schumm, 1981):

1. The history of nearby bridges should be determined. If the new bridge is to replace an older one, considerable information should be available on the past morphology and behavior of the river at that site. For example, channel width and the distance from the crown of the highway to the streambed will be available. Any change can be readily determined by comparison of the present cross-sectional characteristics with those at the time of the construction of the old bridge.
2. Conversations with long-time residents of the valley can be useful in establishing the relative stability of the river channel. Recollections are sometimes suspect, but old photographs of the river obtained from private collections, family albums, and local historical societies can be invaluable. State archives and historical societies frequently contain photographs of old bridges and fords, and hence they are a source of valuable information.
3. In the midwestern and western United States, General Land Office surveys made in the nineteenth century frequently provide information on former river widths and patterns. The earliest maps can be compared with more recent topographic maps and aerial photographs. For example, there is a series of maps, the earliest being 1765, that can be used to document Mississippi River channel pattern changes. Aerial photographs may be available from the late 1930s.
4. Records such as newspaper reports, railroad company files, church records, court transcripts, and accounts of early travelers are all possible sources for identifying channel changes.
5. Gauging station records (specific stage analysis) can be used to assess channel stability and to detect long-term hydrologic trends or the occurrence of large morphologically significant floods.

According to Brice (1974), meander shift is one of the major problems at bridge crossings. Needless to say, this hazard should be one of the easiest to recognize if maps and aerial photographs for a period of years are available to provide historical background. An example of this problem and the procedure applied to the problems at the U.S. Highway 177 crossing of the Cimarron River near Perkins, Oklahoma is abstracted from Keeley (1971).

In 1953 a new bridge was constructed over the Cimarron River downstream from an old bridge, which in 1949 was judged to be in poor condition, with erosion concentrated on the south bank about 1,500 ft (457 m) above the bridge abutment (Fig. 18-1). In 1957, there was continued erosion of

the south bank immediately upstream of the south abutment during a period of large floods. Following floods, 650 ft (198 m) of riprap was emplaced on the south bank between the piles and the bridge abutment.

The second highest flood of record occurred in 1959 and all five pile-dike diversions were damaged. There was some bank erosion on the northwest bank 1,500 ft (457 m) upstream of the north abutment. During a period of high discharges between 1959 and 1962, the point of attack shifted from the south bank to the north bank. There was up to 325 ft (99 m) of erosion of the north bank between the north abutment and 2,600 ft (793 m) upstream. Five pile-dike diversion structures were constructed on the north bank, and riprap was extended upstream from the north abutment. In 1965, there was further scour of the north bank.

The continuing problem at this crossing, especially the shift of erosion from the south to the north bank, could have been anticipated if an evaluation of the stability of the channel had been made prior to or after construction. For example, the 1938 aerial photographs show that the channel was straight and braided at the site at the time of bridge construction, but there was a large bend about one mile upstream (Fig. 18-1).

Relatively little effort would have been required to conclude that the Cimarron River was a relatively unstable channel at this site and that a major problem would be downstream bend shift. Examination of the 1938 aerial photographs with rapid field examination of the channel would have revealed the potential problem of bend shift. Hence, a minimum of historical information (the aerial photographs), combined with the perspective that a site is only a small part of a complex system, would have led to investigations of channel conditions both upstream and downstream of the bridge crossing. The major hazard was bend shift, but the accompanying shifting pattern of bank erosion and scour attracted the most attention. From the point of view of the engineer, the bridge site selected in 1958 was a reasonable one, because the channel was straight and it was near bedrock on the south side of the

**Fig. 18-1.** Cimarron River meander shift as shown by 1938, 1956, and 1968 aerial photographs (from Keeley 1971).

channel. Only if the upstream changes in the channel position were recognized and the hazard identified could the engineer have anticipated the problems that developed at this site.

This example illustrates the utility of obtaining historical information as well as the need to consider a longer reach of a river rather than focusing entirely on the site of the bridge crossing. In this case, very little historical information was needed to identify the problem.

### 18.2.2 Indirect Approach

The indirect approach involves utilizing geomorphic information to develop a model of landform changes that in turn can be used to identify hazards and to predict change. A longer historical record can be developed using the *location for time substitution* (LTS) technique (Fig. 18-2). This has been used with great success to determine future changes of rapidly evolving landforms such as gullies, arroyos, and channelized streams, and it can be used to determine long-term evolutionary changes of landscapes (Schumm et al. 1984; Paine 1985; Schumm 1991).

If a series of cross-sections are surveyed along a channel (Fig. 18-2) that is incising as a result of natural or human-induced changes (e.g., channelization), an evolutionary model of channel adjustment can be developed (Fig. 18-3). In this way, location is substituted for time (LTS). The model presented in Fig. 18-3 was developed for incised channels in northern Mississippi using LTS, and it has both academic and practical value because it permits estimation of sediment production and agricultural land loss (Schumm et al. 1984;

**Fig. 18-2.** Sketch shows method used to obtain data for location for time substitution (LTS) along an incised channel. Incision commences at mouth of channel and progresses upstream. Therefore cross sections a to e show channel evolution from original (a) to oldest (e); see Fig. 18-3.

Darby and Simon 1999). The location-for-time substitution technique can be an effective means of developing a model of evolving landforms, which can aid the engineer in predicting change and developing a strategy for mitigation of or promotion of the change, depending upon his goals.

In using LTS it is important to compare features produced by the same processes operating under the same physical conditions. For example, the evolution of an incised channel in alluvium can be determined by surveying cross-sections at several locations where the channel is in alluvium (Fig. 18-2), but one cannot combine data or compare channels in weak alluvium with channels in resistant alluvium or bedrock and expect to find meaningful results. LTS can be used to determine not only channel evolution, but also hillslope and drainage network change.

Time is an important variable in the development of an incised channel and therefore it should be an important variable in any scheme to curtail gully erosion and to reduce sediment loads. Fig. 18-4 is a conceptual diagram that shows the change in sediment yield and incised channel (gully) drainage density (length of gullies per unit area) with time. In a drainage basin that has been rejuvenated and in which gullies are developing, sediment production will increase as the length of incising channels increases (Fig. 18-4, times 1 to 4). However, at time 4 maximum headward growth of the channels has occurred, and they begin to stabilize between times 4 and 7, when there is an increase in the length of relatively stable reaches, and the length of active reaches decreases. By understanding this cycle of channel incision and gullying from initial stability (time 1) to renewed stability (time 8), it is possible to select spans of time in the cycle when land management and incised channel control practices will be most effective. For example, gullies just being initiated (time 1 or 2) and gullies almost stabilized (time 6, 7, or 8) will be the most easily controlled by structural means. Although the efforts at times 7 and 8 will have little effect, because the channels are stabilizing naturally. At time 4 control will be difficult and expensive. Obviously, consideration of such a complex evolving system for only short periods of record and short time spans can yield erroneous conclusions.

The sequence of events shown in Figs. 18-3 and 18-4 can also have wider applications. In the nineteenth century, throughout the arid and semiarid regions of the southwestern United States, channels incised to form the arroyos that were notorious suppliers of sediment to the Colorado, Green, Rio Grande, and San Juan rivers. Their incision also lowered water tables, and as a result, former grazing and farmlands were abandoned, as well as some small agricultural communities. Projections of the life of reservoirs on these rivers were based on the assumption that the high sedimentation rates generated by arroyo incision and widening (Fig. 18-3) would continue. However, if the sequence of incised-channel evolution as shown in Fig. 18-4 is generally applicable, then the arroyos will begin to stabilize, erosion will be less, and sediment will be stored in newly

**Fig. 18-3.** Evolution of incised channel from original channel (I) to initial incision (II), widening (III), aggradation (IV), and eventual stability (V) (from Schumm et al. 1984).

forming floodplains. Indeed, sediment moving through the Grand Canyon of the Colorado River has decreased significantly since the later 1930s (Gellis et al. 1991), although discharge has not.

For example, based upon the average sediment delivery to Lake Powell from 1914 to 1957, it was estimated that 85,400 acre-feet (105,340,050 m<sup>3</sup>) of sediment would be deposited in the reservoir each year. In 1963, the dam was closed, and 409 ranges were surveyed across the reservoir, which provided a means of measuring sediment accumulation in the reservoir. In 1986, the ranges were resurveyed and it was determined that only 36,946 acre-feet (45,554,420 m<sup>3</sup>) of sediment was being deposited each year (Ferrari 1988), which is 43% of the previous calculation. During this time, flow into the reservoir was 91% of the 1914–1957 average. Hence, an understanding of the incised-channel cycle would have permitted a significant increase in the estimated reservoir life from 700 to 1,600 yrs. The same principle can be applied to other, smaller reservoirs and to sediment delivery to lakes and bays.

Location-for-time substitution is a valuable indirect tool that can be used to develop a qualitative incised channel evolution model (ICEM) that aids in understanding and prediction of landform change in both humid and semiarid regions of the United States. Harvey and Watson (1986),

Watson et al. (1988, 1988b), Mussetter et al. (1994), Simon (1994), Bledsoe et al. (2002), and Watson et al. (2002) have taken this approach, and they have quantified and integrated four important facets of the ICEM process: (1) bank stability, (2) magnitude and frequency of the range of dominant

**Fig. 18-4.** Hypothetical change of sediment production and incised channel (gully) drainage density (ratio of channel length to drainage area) with time. Dashed lines indicate effect of gully-control structures at various times during channel evolution (from Schumm 1991).

discharges, (3) hydraulic energy of those discharges, and (4) morphological adjustments of the channel. These factors in the evolution of the incised channel can be further reduced to two dimensionless stability numbers,  $N_g$ , the geotechnical stability number, and  $N_h$ , the hydraulic stability number.

The geotechnical stability number  $N_g$  is defined as the ratio of the actual bank height ( $h$ ) at a given bank angle to the critical bank height ( $h_c$ ) (defined computationally or observationally):

$$N_g = \frac{h}{h_c}$$

When  $N_g$  is less than 1, the bank is geotechnically stable; when  $N_g$  is greater than 1, the bank is unstable and bank failure and channel widening are likely.

The hydraulic stability factor ( $N_h$ ) is defined as the ratio of the sediment supply to the sediment transport capacity.  $N_h$  can be interpreted as a ratio of energy parameters. An example would be the ratio of shear stress or shear intensity at the effective or dominant discharge to the same parameter under conditions of equilibrium between sediment transport capacity and sediment supply. It is important to note that  $N_h$  includes sediment transport and supply. This is in contrast to most channel design procedures, which are generally based on fixed boundary approximations (Harvey and Watson 1986).  $N_h$  provides a rational basis for determining the equilibrium sediment transport–sediment supply relationship that will be required to achieve a state of dynamic equilibrium. Hydraulic stability in the channel is attained when  $N_h = 1$ . If  $N_h > 1$ , the channel will degrade, and if  $N_h < 1$ , the channel will aggrade.

When  $N_g$  and  $N_h$  are combined, they provide a set of design criteria that define both geotechnical and hydraulic stability in the channel. Channel stability is attained when  $N_g < 1$  and  $N_h = 1$ . Because sediment supply to a channel fluctuates through time, it is prudent to aim for a hydraulic condition that is marginally aggradational; therefore, a more conservative approach is to allow for  $N_h > 1$ .

The relationship between the ICEM and the stability numbers can be seen in Fig. 18-5. The points labeled A through F can be viewed as individual locations along an incised channel (Fig. 18-3), or as a sequence of locations that are linked spatially or temporally, with point A being upstream and point F being downstream, or moving from point A counterclockwise to point F through time at a given location. These points generally correspond with the stages illustrated in Fig. 18-5. For example, if the geotechnical and hydraulic calculations place a reach of channel at point A on the diagram, the strategy should be to prevent the channel depth from increasing to the point where the critical bank height is exceeded. In contrast, if the reach is located at point E, there will be no need to treat the channel because it is in a condition of quasiequilibrium. If no action is taken when a reach is in a condition represented by point A, the sequence

**Fig. 18-5.** Stability number ( $N_g/N_h$ ) diagram showing the thresholds of bank stability and hydraulic stability for an incised channel. Also shown are the ICEM stages (Fig. 18-4). Note that the ICEM reach types form a continuum and the type boundaries are gradational (from Water Engineering & Technology 1989).

of channel incision and widening will move from point A to point F through time as the channel evolves.

As the channel evolves from a state of disequilibrium (A) to a state of dynamic equilibrium (E), the reach types move from the lower right to the lower left quadrant via the upper right and upper left quadrants (Fig. 18-5). Management of the channel should be aimed at keeping the channel in the lower right quadrant, or forcing it to move directly to the lower left quadrant, thereby eliminating the evolution cycle that is an inevitable consequence of bed degradation causing exceedence of the critical bank height. Forcing the channel to move directly into the lower left quadrant generally requires the use of grade-control structures and bank protection.

Utilization of ICEM and the dimensionless stability numbers  $N_g$  and  $N_h$  not only enables equilibrium reaches to be identified (i.e.,  $N_g < 1$ ;  $N_h < 1$ ), but also permits reaches that are at risk to be identified, and provides a process-based rationale for selecting appropriate treatments. Further, this approach enables the effects of changed land use (runoff and sediment supply) to be evaluated in the context of a systems approach to watershed evaluation that is equally applicable in humid or arid regions as well as in rural or urbanizing situations (Musssetter et al. 1994; Watson et al. 2002).

### 18.3 SYSTEMS APPROACH

A systems approach simply means that one should not be fixated on site conditions. Rather, the site should be considered in the context of adjacent areas or landforms. Again, a court case provides a good example. Twenty-two landowners claimed that the erosion of their property along the Ohio River was caused by the raising of water levels behind navigation locks and dams. To maintain navigation on the

Ohio River during low water, a series of low dams with locks maintain a minimum navigation depth of 9 ft (2.7 m). The pool level behind the dam, therefore, never falls to the old low-water levels. It was alleged that the maintenance of the pools at a constant level caused bank erosion by wave action. Preliminary studies showed that, indeed, erosion was occurring on the litigants' lands, and their claims seemed valid. However, when the river as a whole was considered, rather than just 22 limited portions of the bank, it became clear that the river has eroding, stable, and healing banks, and the type and extent of erosion could be predicted (Schumm 1994). In fact, much of the erosion was due to the landowners' activities behind the bankline, which added water to the banks and caused slumping well above the pool level. In this case, the ability to consider a long reach of the river rather than a few specific locations permitted the development of a strong argument that the bank erosion was natural and that, in some cases, it was induced by the landowners themselves. The landowners lost the case because the judge found that the geomorphic arguments were convincing, but the landowners probably were not convinced because of their limited perspective.

### 18.3.1 Direct Approach

The direct approach here involves simply an evaluation of present conditions and recognition of anomalous conditions.

A major problem for the engineer is to anticipate changes of floodplain utilization and channel alterations. An excellent example is provided by the Salt River at Phoenix, Arizona, where the river and its floodplain are a convenient and abundant supply of sand and gravel. Human changes have significantly altered the Salt River in Phoenix, thereby causing changes of flow alignment, constriction of the channel, and degradation (Arizona Department of Transportation 1979).

The Interstate 10 bridge over the Salt River was constructed in 1962 (Fig. 18-6). The bridge was designed

**Fig. 18-6.** Map showing 1-10 Bridge, Phoenix, Arizona, and downstream gravel pits (from Arizona Department of Transportation 1979).

to accommodate a 50-yr flood with a peak discharge of 175,000 cfs (4,956 m<sup>3</sup>/s). Discharges were relatively low or nonexistent for a number of years, but a large flood (67,000 cfs [1897 m<sup>3</sup>/s]) occurred in January 1966, and a 22,000-cfs (632 m<sup>3</sup>/s) flood in April 1973. The river was essentially dry until in March 1978 there was a 115,000-cfs (3,257-m<sup>3</sup>/s) flood, and it was followed by a 120,000-cfs (3,398-m<sup>3</sup>/s) flood in December 1978. In January 1979 there was an 80,000-cfs (2267-m<sup>3</sup>/s) flood, and finally in March 1979 there was a 48,000-cfs (1,359 m<sup>3</sup>/s) flood. During the latter flood, scour undermined the footing of Pier No. 11 (Fig. 18-7), which caused subsidence and tilting of one of the bridge spans. The footing was 20 ft (6 m) below the channel in 1962, and a low-water channel was dredged artificially to the north between Piers 5 and 10 (Fig. 18-7). The footings of these piers were 10 ft (3 m) deeper than for Piers 11 through 19.

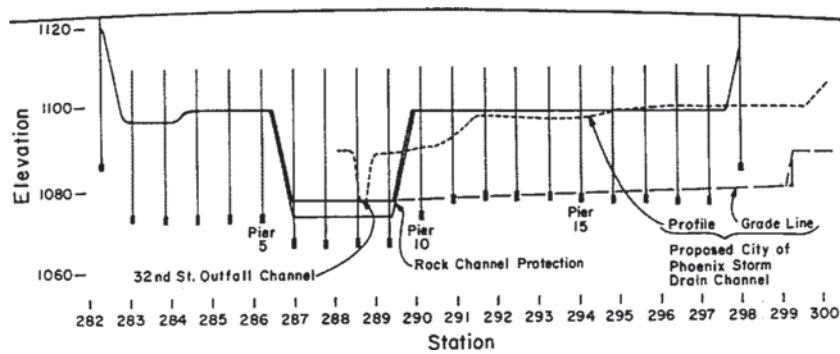

When the bridge was designed, it was assumed that the low-water thalweg would remain fixed in position 5 ft (1.5 m) above the deepest pier. However, as the city of Phoenix grew during the period following bridge construction, gravel mining increased and gravel pits were opened near the bridge. For example, a 30-ft-(9.1-m-) deep gravel pit was dredged on the south side of the river about 2,000 ft (609 m) downstream and 750 ft (229 m) south of the low-water channel (Fig. 18-6).

Study of aerial photographs shows that during the large 1968 flood, another thalweg developed as the existing low-water channel was filled with sediment. Floodwaters flowed into the gravel pit (Fig. 18-6), and erosion of the head wall caused development of a new channel, which was centered on Pier 11 (Fig. 18-7). Scour and undermining of Pier 11 resulted, with serious damage to that span of the bridge. The rapidly developing Phoenix area ensured that this would be the case, as gravel was excavated for construction purposes. However, a cursory look downstream would have forewarned the engineer that a grade-control structure was needed to protect the bridge, because local base level had been lowered as a result of gravel mining.

Along a 5-mile-(8-km-) long reach of the San Benito River near Hollister, California, sand and gravel mining-induced channel degradation between 1952 and 1995 has resulted in the loss of one bridge and severe damage to two others, as well as loss and damage to utility crossings (Harvey and Smith 1998). Compilation and review of historical surveys of the channel and bridges showed the progression of the channel degradation through time, and could have been used to anticipate the occurrence of the infrastructure problems. Instead, each site of damage was considered singularly and repairs were conducted without consideration of further system changes. Ongoing channel adjustments caused many of the repairs to fail and ultimately led to failure and abandonment of the structures.

Another example of a systems approach is provided by the Nile River in Egypt (Schumm and Galay 1994). It was

**Fig. 18-7.** Cross section at I-10 Bridge, Phoenix, Arizona, showing channel cross-section and location of low-water channel and bridge piers and footings (from Arizona Department of Transportation 1979).

assumed by many that following construction of the High Aswan Dam the sand-bed Nile River would be subjected to major degradation between Aswan and Cairo. However, degradation was minimal, although the bed material was mobile. Subsequent inspection of tributaries revealed that they contained coarse gravel and cobbles, which during infrequent floods and during past more humid periods were transported into the Nile valley. Available data from bores into the bed of the river reveal that gravel is encountered at shallow depths. A reasonable explanation for the lack of significant degradation is that below the sand bed of the river there is sufficient gravel to prevent degradation. Inspection of tributaries as well as of the main Nile channel would have provided information that might have led to a more complete sampling program and better estimates of potential degradation.

### 18.3.2 Indirect Approach

The indirect approach is similar to the location-for-time substitution, as described above, except that it is present conditions that need to be evaluated. The *location-for-condition* approach, which involves collecting data for a number of similar landforms in an area, is a means of determining the condition or relative sensitivity of a single landform or a site. A location-for-condition evaluation (LCE) has been used to identify sensitive valley floors (Fig. 18-8) that are likely to gully in Colorado and New Mexico (Patton and Schumm 1975; Begin and Schumm 1979; Wells et al. 1983a, 1983b); river reaches that are susceptible to a pattern change (Fig. 18-9) from meandering to braided (Schumm and Khan 1972; Schumm and Beathard 1976; Schumm et al. 1987); alluvial fans that are susceptible to fan-head incision (Schumm et al. 1987); and thresholds of hillslope stability (Carson 1975). Therefore, it is a means of identifying threshold conditions and the relative sensitivity of landforms (Schumm 1988).

In each of these cases data were collected at a number of locations, and a quantitative relation was developed, that could lead to the identification of threshold conditions of sensitive

landforms. For example, the slope of the line in Fig. 18-8 identifies a valley floor slope in a given drainage area (a surrogate for discharge) at which erosion is likely to occur and gullies to form. The curve of Fig. 18-9, when developed for a specific river, can be used to identify river reaches that are susceptible to change from meandering to braided and vice versa. When a quantitative relation is developed between alluvial-fan slope and fan stability, alluvial fans that are susceptible to fanhead trenching can be identified (Fig. 18-10).

Both the location-for-time substitutions and the location-for-condition evaluation involve the collection of data at a number of locations and the utilization of the data

**Fig. 18-8.** Relation between valley slope and drainage area, Piceance Creek Basin, Colorado. The line defines the threshold slope that generally separates gullied from ungullied valley floor (from Patton and Schumm 1975).

**Fig. 18-9.** Diagram showing how sinuosity (channel length divided by valley length) varies with stream power (tractive force times velocity of flow). With an increase of stream power or velocity, sinuosity remains constant at low values (a to b), increases with meandering (b to c), decreases through a transition from meandering to braided (c to d), and then remains braided (d to e) (from Schumm and Khan 1972).

to develop an evolutionary model (LTS) or to determine the sensitivity of a site (LCE). Both are valuable techniques that have been used primarily by geomorphologists for practical purposes of prediction, as well as for explanation of past events. Of even greater value is the fact that both techniques require that the investigator back away from a single site

and look at many sites, which provides the big picture and a basis for identification of sensitive landforms.

A good example of how the system approach can put a local problem into perspective is that of Mississippi River variability. The lower river between Cairo, Illinois and Old River, Louisiana can be divided into 25 reaches based upon changes of valley slope, sinuosity, and sinuosity variability (Schumm et al. 1994). It becomes apparent immediately that this great alluvial river has significant variability, and it is not uniform for long distances. Clearly, any plan for river improvement should take these reach differences into consideration.

The number of severely eroded channelized streams in the Yazoo Basin of Mississippi precludes intensive study of all of them. Therefore, a lower-order reconnaissance-level approach to determining the status of the channel is required for planning purposes (Schumm et al. 1984; Harvey and Watson 1986). Historical and institutional data were obtained prior to the field investigation and aerial photographs and topographic maps were utilized for base maps. Aerial overflight of the watershed permitted the watershed problems to be identified in a general manner as watershed erosion, channel erosion, or flooding and sedimentation. Fieldwork involved walking (3 to 5 mi/day [5 to 8 km/day]) as much of the channel as was possible within the constraints of available time. Field mapping of ICEM reach types (Fig. 18-3) was done during the fieldwork. Thalweg slope measurements in relatively stable type reaches (Fig. 18-3) provide a minimal measurement for determining

**Fig. 18-10.** Relation between gradient at a fanhead and alluvial fan apex instability through time. Line 1 portrays the gradually increasing slope of the fanhead. When the ascending line of fanhead slope intersects line 2, which represents the maximum slope at which the apex is stable, trenching will occur, at time B. Superimposed on line 1 are vertical lines representing changes in fanhead instability that are related to high-magnitude runoff events or longer-term climatic fluctuations. Normally, the operation of these processes has little significant morphological effect on the alluvial fan. However, when the fan slope and apex instability are high, trenching will occur sooner than expected (at time A) when a large-magnitude event exceeds the stability threshold (line 2). In reality, the event merely precipitated the eventual incision at time A rather than at time B (from Schumm and Hadley 1957).

hydraulic stability ( $N_h$ ) for the channel. These values then can be compared with a regional relationship of equilibrium thalweg slope and drainage area (Fig. 18-11) that was developed from more intensive studies of other Yazoo Basin streams with similar characteristics (LCE) (Water Engineering & Technology 1989; Watson et al. 2002). For these Yazoo Basin streams, the amount of channel degradation that may occur can be estimated by plotting the hypothetical equilibrium stream slope profile of Fig. 18-11. Comparison of the existing channel profile with the hypothetical equilibrium slope profile provides information to determine possible grade control structure locations and reaches that may become geotechnically unstable ( $N_g > 1$ ) or hydraulically unstable ( $N_h > 1$ ). Within the range of drainage basin areas between about 5 and 250 square miles, equilibrium slopes range from 0.0025 to 0.0005. Bed-material samples should be obtained during the fieldwork because coarser sediments will result in higher equilibrium slopes. Most of the locations represented in Fig. 18-11 have bed material of approximately 0.15 to 0.3 mm sand.

The extent of channel erosion can also be mapped during the fieldwork. This mapping will include both bed and bank erosion, and a preliminary determination of the causes of the erosion can be made. The use of either generalized or channel-specific bank stability relations will provide an estimate of  $N_g$ .

Field mapping will provide an estimate of the number of small tributaries, field drains, and top-bank gullies that may have to be treated to prevent further erosion of these features. Further, the extent of threatened infrastructure features (bridges, culverts, and pipeline crossings) can be identified during the fieldwork. Measures previously installed to prevent erosion of the channel also can be mapped and an evaluation of their success or failure can be made. The

information derived from the reconnaissance geomorphic study can be used to provide a preliminary estimate of the requirements for watershed and channel rehabilitation.

In summary, the geomorphic investigation will permit the watershed problems to be quantified on a preliminary basis. The ability to define the ICEM types permits the equilibrium reaches to be identified. The equilibrium thalweg slope values (Fig. 18-11) provide a target slope for rehabilitation of reaches that are in a state of disequilibrium. A critical bank height can be estimated from a generalized relationship, or from a relationship that is specific to the channel under investigation. These data can then be used to develop a preliminary integrated watershed rehabilitation plan.

An example of how purely geomorphic observations can be of value to engineers concerned with highway and pipeline crossings of landforms and the identification of hazardous sites on landforms is provided by detailed geomorphic mapping of alluvial fans.

An alluvial fan is “a sedimentary deposit located at a topographic break, such as the base of a mountain front, escarpment, or valley side, that is composed of fluvial and/or debris flow sediments and which has the shape of a fan either fully or partly extended” (National Research Council 1996). Because fans can grow both vertically and longitudinally, highways and bridges on fans can be buried and culverts blocked either by vertical deposition on the fan or by fan enlargement (Fig. 18-12a). In addition, lateral channel shifting, avulsion, and bifurcation can direct flood flows against unprotected areas. Channel incision can lead to breaching of highways and bridge failure, and the instability of channels on fans can lead to abandonment of bridges as new channels form and as old channels fill. In addition, highways can redirect flow paths, causing property damage and even loss of life. Therefore, “an alluvial fan is an environment where the combination of sediment availability, slope and topography creates hazardous conditions . . .” (National Research Council 1996). In addition, urban development on fans requires a careful evaluation of alluvial fan topography to avoid construction in flood-prone areas.

Flood paths and the morphology of alluvial fans can differ greatly in space and time. For example, the sketches of Fig. 18-12 show examples from a continuum of alluvial fan types. Figure 18-12a shows a fan that has been trenched, and flow that is confined to a single deep channel from the topographic apex (T) to the hydrographic apex (H), where the flow expands. On this type of fan, a highway crossing the toe of the fan is subject to alluvial-fan flooding, whereas a highway crossing the middle or upper part of the fan is affected only by changes of the incised channel. The greater part of this fan lies above the effects of flooding. Figure 18-12b shows a fan with a fanhead trench. The hydrographic apex is closer to the topographic apex at the fanhead. Most of this fan below the hydrographic apex is subject to flooding. Figure 18-12c shows a fan that does not have a well-defined incised channel. The topographic and

**Fig. 18-11.** Equilibrium channel slope plotted against drainage area for Hickahala, Batupan Bogue, and Hotopha Creeks, Mississippi (from Water Engineering & Technology 1989).

**Fig. 18-12.** Three examples of alluvial-fan morphology. The letter T identifies the topographic apex, which is the location where sediment and water from the upstream drainage basin enter the fan. The letter H identifies the location of the hydrographic apex, where channel flow becomes unconfined and produces alluvial-fan flooding. The shaded portions of the main channels of fans a and b are incised (from Schumm 2005).

hydrographic apex occupies the same location, and most of the fan surface is subject to flooding.

This range of fan types has been described by Hunt and Mabey (1966) in Death Valley and observed through time in experimental studies (Schumm et al. 1987). Therefore, within one area a range of fan types can occur, and during floods, fan morphology can change significantly.

A report prepared by the Committee of Alluvial Fan Flooding and published by the National Research Council (NRC) (1996) may provide engineers with useful information about these dynamic landforms. The purpose of the committee was to aid floodplain managers in determining the potential extent of flooding on alluvial fans.

Flooding on alluvial fans differs greatly from riverine flooding because it is characterized by (a) flow path uncertainty below the hydrographic apex, (b) abrupt deposition of sediment as a stream or debris flow loses its competence to carry material eroded from a steeper, upstream source area, and (c) channel incision, which reworks previously deposited sediment and shifts it down-fan (Fig. 18-12a). The potential for avulsion, deposition, and channel blockage and incision is important and some aspects of a three-stage procedure developed by the NRC committee can be of value to any engineer involved with alluvial fans.

The committee's procedure consisted of (1) identifying the fan and its extent, (2) identifying active areas on the fan, and (3) identifying areas subject to 100-yr flooding. Stages 1 and 2 involve the identification of active portions of a fan, where there is a probability of channel change, channel abandonment,

and channel incision. For example, debris flows are effective in blocking existing channels. A drainage basin may produce stream flows for a very long time as sediment is stored in the valleys of the drainage basin above the topographic apex, but during major storms, flushing of the stored sediments may block channels on the fan and convert fan (a) of Fig. 18-12 to fan (b) or (c).

Surprisingly, identification of relatively recent debris flow deposits, which suggests very high sediment delivery from the drainage basin, may, in fact, be an indication of future stability. That is, stored sediment has been flushed from the drainage basin, and it may be a very long time before sufficient sediment accumulates again to produce debris flows, even under extreme rainfall.

Local aggradation in a channel can lead to avulsion because avulsion is likely to occur in places where deposition has raised the floor of the channel to a level that is nearly as high as the surrounding fan surface. This condition can be identified in the field by observation or by surveying cross-fan profiles.

To evaluate the relative stability of an alluvial fan or an alluvial-fan complex, the investigations should consist of three parts. The first part is an office study of aerial photographs and maps, which should identify the active zones of the fan that are subject to alluvial-fan flooding (Fig. 18-12) and the sites of potential channel change. If it is determined that the fan is deeply incised (Fig. 18-12a), then the hazards are restricted to incised-channel change (Fig. 18-3). Initial office procedures include the review of topographic maps and aerial photographs to determine the location and the morphology of the fan and its channels. Other data that can be gathered include historical maps and old photographs to document previous channel changes, changes in channel morphology, and the areas of the fan that may be classified as either active or inactive. Soil and geologic maps can be examined to confirm the relative geologic age of fan deposits. Climatologic data and appropriate hydrologic analyses will be needed to determine the magnitude and frequency of flooding to be expected.

The second part of the investigation consists of a field evaluation of sediment storage in the drainage basin above the topographic apex and the specific morphologic characteristics of the fan. Field investigations by a trained observer should include gathering information on elevation differences across the fan, if detailed topographic maps are not available. Vegetation types, soil characteristics, and other evidence of age (desert varnish, desert pavement) should be noted to confirm the location of active or inactive portions of the fan. Observations and measurements of channel conditions must be made. The results of the office and field investigations should provide sufficient information for the identification of potential problems. This is the third part of the investigation, which utilizes the results of Parts 1 and 2 of the investigation to provide sufficient information for an evaluation of the potential for debris flows and to

identify locations of potential channel deposition, incision, and avulsion on the fan. For example, on a fan like that of Fig. 18-12b, if two of the three unincised channels below the hydrographic index were to join, any bridge that was designed for present conditions would be inadequate, and it would probably fail. However, the field investigation should have determined if one of the channels would become dominant and capture the flow of other channels. If this would threaten the stability of the highway crossing, appropriate countermeasures could be undertaken.

The ideal result of any study of an alluvial fan is a geomorphic map delineating active and inactive portions of the fan and the identification of problem sites within the active portions of the fan. Figure 18-13 shows a hypothetical alluvial fan that has a variety of features of different ages. Careful investigation of the characteristics of the fan reveals areas that have not changed in perhaps thousands of years, whereas others are hazardous sites for construction. For example, the area designated as A is an old fan surface that has been entrenched and does not receive runoff or debris flows from the mountain source area. B is a surface that is entrenched (but stands at an elevation below that of A) and will not be flooded or eroded by the channel, but it can become subject

to these hazards if the current channel becomes blocked by a debris-flow deposit. C and D are, respectively, bouldery lobes and levees indicating former deposition by debris flows within and along the channel. E denotes distributary channels that show no evidence of major scour, fill, migration, or avulsion during recent large floods and can convey all or most of a 1% (100-yr) flood. Areas indicated with F are subject to sheet flooding. G is a channel with signs of recent migration and for which future behavior is highly uncertain. H is a surface that is subject to overbank flooding, channel shifting, or invasion from a distributary channel that might avulse from G, and hence it is subject to alluvial fan flooding. A map such as Fig. 18-13 will be of great value to anyone concerned with the safety of structures on alluvial fans (highways, bridges, and urban development).

There are numerous ways that the landscape and individual landforms can change. An important issue in this regard is landform sensitivity. This involves the development of a condition at which a major change can be precipitated by a relatively minor perturbation. Examples are gullying in alluvial valleys or at the heads of alluvial fans as deposition progressively steepens these surfaces until incision occurs (Figs. 18-8, 18-9, 18-10). A further example is the growth of meander amplitude until a cutoff is inevitable as the gradient around a bend progressively decreases.

Point-bar development and concave bank erosion have been a principal concern of those studying the dynamics of meandering rivers. Figure 18-14 is a schematic diagram of a reach of a meandering river that defines the terms that are used in this discussion of the dynamics of the Sacramento River. Erosion along the concave bank occurs because of convective acceleration in downstream flow (Henderson 1966) and because of intensification of cross-stream flow. Both are caused by flow convergence, which implies that the shape of a meander bend significantly affects bank erosion (Nanson and Hickin 1986). As the radius of curvature of the bend decreases, the channel cross-section in the pool zone is constricted laterally because of vertical growth of the

**Fig. 18-13.** Example of idealized geomorphic map of an alluvial fan. The areas with solid shading are recognizable channels; the darker ones have stable forms and positions; and the lighter ones have the capacity to change form or position. See text for discussion (from National Research Council 1996).

**Fig. 18-14.** Schematic diagram showing in planform the geomorphic surfaces and features that are associated with meander bends (from Harvey 1989).

point bar (Carson 1986). Therefore, lateral migration of the channel and concave bank erosion are dependent on the flow characteristics and the shape of the bend.

The rate of bank retreat is dependent on the resistance to erosion of the concave bank materials (Nanson and Hickin 1986), the duration and magnitude of the flows (Odgaard 1987), the radius of curvature of the bend (Nanson and Hickin 1986; Odgaard 1987), and the capacity of the flows to transport bed-material sediment (Neill 1984; Nanson and Hickin 1986). Channel migration is a discontinuous process because it is dependent on the occurrence of flood flows (Brice 1977). Initially bends migrate in a cross-valley direction (extension), but eventually bends advance in the down-valley direction (translation) (Leeder and Bridge 1975; Brice 1977; Nanson and Hickin 1986).

Meander bends eventually cut off when the radius of curvature decreases below a certain value, which is specific to each stream. Reduction of the radius of curvature of a bend causes backwater upstream of the bend, and this is expressed physically as a reduction in the slope of the water surface. Because the sediment transport capacity of the flows is proportional to the slope of the water surface squared, a reduction in slope reduces the sediment transport capacity of the flows. This causes deposition of sediment in the upstream limb of the bend between the pool and riffle (Fig. 18-14). Deposition of sediment reduces the flow capacity of the channel and this causes flows to be diverted over the point bar. These flows erode the point bar surface and form chutes (Carson 1986; Lisle 1986). However, cutoffs can occur as a result of either chute development (Brice 1977; Lewis and Lewin 1983) or neck closure (Fisk 1947).

Bagnold (1960), Leeder and Bridge (1975), and Nanson and Hickin (1986) have demonstrated that lateral migration rates of meandering rivers can be correlated with the radius of curvature ( $R_c$ ) of bends. Migration rates are highest when the ratio of radius of curvature to channel width ( $W$ ),  $R_c/W$ , is about 2.5. Radii of curvature and 1981–1986 migration rates (MR) for 11 Sacramento River bends were measured to obtain short-term data on river behavior (Harvey 1989). Radii of curvature ranged from 381 to 838 m and migration rates varied from 37 to 10 m/yr. A least-squares regression of the data is

$$MR = 53.57 - 0.049R_c \quad (R^2 = 0.69) \quad (18-1)$$

To determine long-term behavior of the river, radii of curvature and migration rates of the Sacramento River for the period of record (1896–1986) were utilized. The radii of curvature were assigned to nine class intervals that varied by 76-m increments from 229 to 838 m. The average channel width in each bend was determined, and both the migration rate and radius of curvature were divided by the channel width. The average width of the river in the study reach was 150 m. The relationship between the ratio of radius of curvature to width ( $R_c/W$ ) and the ratio of migration rate to width (MR/W) is shown in Fig. 18-15.

**Fig. 18-15.** The ratio of migration rate (MR) to channel width ( $W$ ) plotted against the ratio of radius of curvature ( $R_c$ ) to width. The asterisks and bars represent the means and standard errors, respectively. The curves are from Nanson and Hickin (1986) (from Harvey 1989).

For radii of curvature greater than 381 m ( $R_c/W > 2.5$ ) the least-squares regression is

$$MR = 6.98 \times 10^{-4} R_c^{1.333} \quad (R^2 = 0.83) \quad (18-2)$$

and for radii of curvature less than 381 m ( $R_c/W \leq 2.5$ ) the least-squares regression is

$$MR = 2.2 \times 10^{-6} R_c^{2.875} \quad (R^2 = 0.94) \quad (18-3)$$

The reason for subdividing the data is provided by Fig. 18-15. Nanson and Hickin's (1986) curves show that for  $R_c/W$  values between 1 and 2.5 there is a direct relationship between MR/W and  $R_c/W$ . Conversely, for  $R_c/W$  values greater than 2.5 there is an inverse relationship between MR/W and  $R_c/W$ .

Brice (1977) assumed that most bends on the Sacramento River would cut off by the time the radius of curvature had decreased to 381 m. However, a number of low-radius-of-curvature bends (less than 381 m) are located in the lower part of the study reach near Colusa. This may be due to the fact that the sediments are finer, more cohesive, and therefore more resistant to erosion. The median radius of curvature for a cutoff is 380 m, but the range is from 305 to 610 m. Ninety percent of all cutoffs occur when the radius of curvature is less than 533 m. The radii of curvature of bends that had cut off since 1908 (10) and pre-1908 meander scars on the floodplain (22) were measured. The radii of curvature of four bends that had cut off following revetment were also measured.

A dimensionless cutoff index, defined as the ratio of the radius of curvature to the migration distance ( $R_c/MD$ ), was developed to predict cutoff occurrence (Harvey 1989).

Equation (18.1) was used to determine the MD values for the cutoff index for both the recent (10) and floodplain (22) cutoffs. With the exception of two floodplain cutoffs, the  $R_c/MD$  values were less than 4. The mean and standard deviation for the recent cutoffs were 2.7 and 1.0, respectively, and the values for the floodplain cutoffs were 2.6 and 0.9, respectively. Therefore, cutoffs can be expected to occur when the value of the cutoff index ( $R_c/MD$ ) lies between 1.7 and 3.7.

The cutoff indices for 14 bends between Glenn and Chico Landing were calculated using measured values of MD between 1981 and 1986. The data indicate that seven of the bends have  $R_c/MD$  values that lie within the range of values that were identified for cutoffs ( $1.7 < R_c/MD < 3.7$ ). Associated with these  $R_c/MD$  values for these seven bends are two other characteristics that were identified on 1986 aerial photographs: (1) the presence of a midchannel bar in the upstream limb of the bend, and (2) the presence of chutes across the point bar. Therefore, it appears that cutoffs can be predicted on the basis of the value of the cutoff index and the presence of the two ancillary features. This was tested on the bend at river distance 278.4 km, which had cut off in 1986. This bend was revetted prior to 1981 and, therefore, no migration of the bend took place between 1981 and 1986. However, the radius of curvature of the bend decreased from 572 m in 1981 to 343 m in 1986. The MD value for a radius of curvature of 343 m (Eq. (18.1)) is 181 m and, therefore, the cutoff index ( $R_c/MD$ ) is 1.9. The aerial photographs confirm the presence of both a midchannel bar in the upstream limb of the bend and chutes on the point bar.

The ability to predict changes in river planform is important for managing rivers for erosion and flood control. Prediction of future changes is dependent on understanding the past behavior of the river, but uncertainty in prediction is introduced because of the stochastic nature of flood events, which cause the change, and variability of floodplain sediments, which can either accelerate or retard erosion.

## 18.4 GEOMORPHIC HAZARDS

Objective 3 of this chapter is to consider the geomorphologic factors that influence landforms (engineering sites) and the hazards associated with them. This should aid the engineer in anticipating problems and avoiding hazardous situations, or at least, being aware of potential hazards.

Landform change can be considered to be a geomorphic hazard if it impacts on engineering plans or works. The word *hazard* refers to a potential danger or risk. The hazard may pose a relatively minor risk that will have a minimal impact, or it may be a potential catastrophe or disaster that involves great damage and loss of life. Most books on natural hazards concentrate on the spectacular events such as coastal erosion during hurricanes, volcanic eruptions, earthquakes, avalanches, landslides, and subsidence (White 1974; Bolt et al. 1975; Hewitt and Burton 1975; Asimov 1979; Blong and Johnson 1986).

There are at least three types of geomorphic hazards that involve different spans of time, different degrees of damage, and different energy expenditures: (1) an abrupt change that is a catastrophic event, e.g., a landslide that occurs rapidly as a result of an equally catastrophic meteorological event, earthquake, or human activity (removal of toe support); (2) a progressive change that leads to an abrupt change, e.g., weathering that leads to slope failure, gullyng of a steepening alluvial fan, meander growth to cutoff, and channel avulsion; and (3) a progressive change that has slow but progressive results, e.g., bank erosion, hillslope erosion, channel incision, and channel enlargement. The difference between geomorphic hazards and others is that geomorphic hazards may involve a slow progressive change that, although in no sense catastrophic, can eventually involve costly preventive and corrective measures. Therefore, geomorphic hazards can be defined as any landform change, natural or otherwise, that adversely affects the geomorphic stability of a place.

As noted earlier (Figs. 18-8, 18-9, and 18-10), a major concern of the geomorphologist, which will be of value to the engineer, is the identification of sensitive landforms and the threshold conditions under which either failure or stability occurs. A failure threshold can be a meander cutoff, channel avulsion, channel incision, gullyng, or slope failure. A stability threshold is the condition under which an unstable landform achieves a new condition of relative stability. Both conditions are important because the engineer would like to anticipate and plan for the first, and recognition of the second could result in less drastic reclamation or stabilization efforts (Fig. 18-4).

### 18.4.1 Hazard Identification

For purposes of discussion, the fluvial system can be divided into four landform types: (1) drainage networks, which consist of the stream channels and valleys that compose the sediment source area; (2) hillslopes, which fill the area between the channels of the drainage network; (3) main channels, which convey water and sediment from the drainage networks; and (4) piedmont and plain areas that include alluvial fans and deltas, the areas of sediment accumulation.

A list of 28 geomorphic hazards and the four major variables that influence them is summarized in Table 18-3, which can serve as a check list during site selection or evaluation, particularly if it is anticipated that human activity will alter hydrologic conditions or base level. Base level here is defined as the level to which a stream is graded, and a change, as a result of reservoir or lake draining or filling or any activity that causes a lowering of a stream channel such as channelization or gravel mining, will affect the stream. Time is included with the variables discharge (increase or decrease,) sediment load (increase or decrease), and base-level change (up or down), because landforms change naturally through time, and time is an index of energy expended or work done. The hazards are grouped according to the landforms affected

**Table 18-3 Variables Affecting Geomorphic Hazards**

After Schumm (1988).

(drainage networks, slopes, channels, piedmont, and plains) and the results of the hazard (erosion, deposition, pattern change, metamorphosis). In Table 18-2, the hazards that will be affected by the passage of time or by a change of discharge, sediment load, or base level are indicated by an X. This provides a ready means of identifying potential geomorphic hazards that should be of concern at any site, and they are described in sequence below.

#### 18.4.2 Drainage Network Hazards

*Rejuvenation* (Aa1) involves the deepening or incision of a drainage network. The deepening will also cause headward growth of tributaries and perhaps the addition of tributaries in formerly undissected areas. The depth of incision may only be minor if discharge is increased slightly or if sediment loads are decreased, but it can be major and deep with a major lowering of base level. In the latter situation any site may be in jeopardy, but in the former, only sites on floodplains or terraces will be affected. Rejuvenation of a drainage system and its headward extension can be halted by emplacement of grade-control structures (Schumm et al. 1984). If left unchecked, the impact can be very great over large areas, especially on fragile lands of the semiarid western United States (Cooke and Reeves 1976).

*Extension* (Aa2) is the headward growth of tributaries, and it involves the addition of tributaries in formerly undissected areas. It causes erosion closer to drainage divides, and surface sites can be significantly affected by gullying and the headward growth of channels (Schumm et al. 1984).

*Valley filling* (Ab1) involves major sediment deposition in channels and on floodplains. This is caused by a great influx of sediment or by base-level rise. Deposition may bury a site, or it may be inundated by floods, as flood levels increase. This type of major deposition can follow channel incision

and rejuvenation (Aa) when large quantities of sediment are set in motion and eventually deposited on flatter slopes and wider reaches of valleys. Deforestation, urbanization, and agricultural and mining activities can have the same impact (Toy and Hadley 1987).

*Capture* (Ac1) is the change of a stream course by the natural diversion of water into a stream at a lower elevation. The diversion causes steepening of the stream gradient and rejuvenation and probably extension (Aa1, Aa2) of the captured drainage network. The progress can be induced by base-level lowering, which increases the energy of the lowland stream, or by base-level rise, which as a cause of deposition may induce a channel to shift to a steeper straighter route. It can occur naturally through time, and the process can be accelerated by an increase of discharge and sediment load. Capture is a type of channel avulsion (Cc4), but although evidence for it is common in the landscape, it will be a slow process and an unlikely event unless promoted by human activities that cause major flow diversions.

#### 18.4.3 Slope Hazards

*Denudation and retreat* (Ba1) of both hillslopes and escarpments in a watershed can be accelerated by increased water flow over the slope, by reduced vegetation cover, and by increased flow in adjacent streams or decreased sediment loads that lead to channel degradation and undercutting of slopes (Ca1) or to drainage network rejuvenation (Aa1) by base-level lowering. However, slope erosion will occur inevitably, during the passage of time, which will threaten a site near the top, or near the edge of a slope (Carson and Kirkby 1972; Selby 1982; Brunnsden and Prior 1984; Toy and Hadley 1987; Parsons and Abrahams 1992).

*Slope dissection* (Ba2) by channels will occur if there is network extension (Aa2) as a result of adjacent channel

incision or headward growth caused by discharge, sediment load, or base-level change.

*Mass failure* (Ba3) may occur (slumping, debris flow) owing to increased water content of the slope material or by an increase of slope height by channel incision or undercutting of the slope by fluvial or human action (Schuster and Krizek 1978).

#### 18.4.4 River Hazards

Stream channels, wherever they are located in the fluvial system, change morphology and behavior with time, they respond to discharge, sediment load, and base-level changes, and they potentially pose a great hazard to the works of humans (Gregory 1977; Richards 1987; Brookes 1988; Petts et al. 1989).

*Degradation* (Ca1) is the lowering of a streambed by erosion. Degradation is a major adjustment of a river to external controls. The adjustment takes place over long reaches of channel. The deepening of the channel may also cause the undermining of banks and widening of the channel (Ca3).

*Knickpoint migration* (Ca2) is the upstream shift of an inflection in the longitudinal profile of the stream. This break in the smooth curve of the stream gradient results from rejuvenation of the stream or from the outcropping of more resistant materials in the bed. It is the former that is of concern here. A knickpoint in alluvium moves upstream, especially during floods. Above the profile break the river is stable; below the break there is erosion. As the knickpoint migrates past a point, a dramatic change in channel morphology and stability occurs (Schumm et al. 1987). Knickpoints are of two types: first is a sharp break in profile that forms an in-channel scarp called a headcut (Fig. 18-16a), and second is a steeper reach of the channel or knickzone over which

elevation change is distributed (Fig. 18-16b). It is important to recognize that through time a stable reach of river may suddenly become very unstable as a result of passage of a knickpoint.

*Bank erosion* (Ca3) is the removal of bank materials either grain by grain or by mass failure. Erosion can occur by river action that undercuts a bank or by simple erosion of the bank sediments. In addition, bank erosion can occur by mass failure, as a result of surcharging the bank by construction or dumping, or by seepage forces and pore-water pressures that are related to increased water movement through bank sediment. In the latter case, the river is the transporting agent that removes the slumped bank materials rather than the primary erosive agent. The effect of bank erosion is a shift in the bankline of the river and the introduction of additional sediment into the channel. Erosion of both banks widens the channel, and may lead to aggradation (Cb1). Bank erosion is a major component of other hazards such as degradation and scour, meander shift, cutoffs, and various types of river metamorphosis.

Bank erosion is a natural consequence of normal river behavior through time, but it can be accelerated by changes of discharge, sediment load, and base level. Either an increase or decrease of sediment load or a rise or fall of base level can cause bank erosion. Channel incision increases bank height and the likelihood of bank failure.

*Aggradation* (Cb1) is defined simply as the raising of a streambed by deposition. Aggradation is not local; it is rather a major adjustment of a river to external controls. The main effect of aggradation is to raise the streambed. However, aggradation may continue to the extent that new hazards are generated. For example, it may cause avulsion, cut off meanders, and change channel pattern. In addition, aggradation may lead to bank erosion (Ca3) as flow paths are changed by bar formation, and decreased channel capacity will increase flooding.

*Backfilling and downfilling* (Cb2) are deposition or channel filling from downstream to upstream or vice versa. With backfilling, the channel is partly or entirely blocked and deposition begins at this point and then proceeds upstream (Schumm 1977, p. 150). Backfilling differs from aggradation as defined earlier because it starts at one location in the channel and then is propagated upstream. In contrast, downfilling (Cb2) occurs when deposition progresses in a downstream direction, and it is the reverse of backfilling. Both backfilling and downfilling are types of aggradation that influence long reaches of a channel, and they can affect a reach of river from either the upstream or downstream direction after it has been stable for a long time. Consequences of backfilling and downfilling are similar to those of aggradation (Cb1). The channel bed will rise as the wave of sediment passes. Increased flooding will result as the channel fills.

*Berming* (Cb3) refers to the deposition of primarily fine-grained sediments on the sides of the channel, and it is the opposite of bank erosion. Berming will reduce the area of the channel and cause increased flood stages. Berming reduces channel capacity, but the narrowing of the channel

Fig. 18-16. Types of knickpoints. Dashed lines show former and future position of channel floor and knickpoint.

may cause degradation and scour. This hazard is less serious than the other depositional hazards.

*Pattern change (Cc)* refers to the change of channel pattern and position that occurs naturally through time. The four types of pattern-change hazards occur in different ways. Meander growth and shift (Cc1) and bar and island formation and shift (Cc2) usually occur relatively slowly and at variable rates, but the change can be viewed as progressive, whereas cutoffs (Cc3) and avulsion (Cc4) occur relatively rapidly and episodically. Nevertheless, the conditions leading to cutoffs and avulsion can be observed, and these hazards should be predictable.

*Meander growth and shift (Cc1)* involve a change in the dimensions and position of a meander. Meander amplitude and width increase as a meander enlarges (Fig. 18-17). Meander shift involves the displacement of the meander in a downstream direction (Fig. 18-17). Usually the meander both grows and shifts downstream, although some parts of the bend can actually shift upstream. There is probably more information available on this hazard than on any other, with the exception of cutoffs. Meander growth and shift not only cause bank erosion at the crest and on the downstream side of the limbs of a meander, but also change the flow alignment. Further, increased meander amplitude results in local reduction of gradient, with possible aggradation in the bend. Meander growth and shift will be of greatest significance where discharge is great, bank sediments are weak, and bank vegetation is negligible due to aridity or to agricultural practices.

*Island and bar formation and shift (Cc2)* are within-channel phenomena. Unlike meander shift or meander cutoffs, which involve the entire channel pattern, bars and islands can evolve within the channel, and the bankline pattern itself may remain unchanged. Therefore, this hazard involves the development and migration of sediment accumulations (bars and islands) in alluvial channels, which can lead to increased bank erosion, local flooding, and threats to structures.

Popov (1964) has classified the types of island changes that he observed occurring in the River Ob in the Soviet Union. He found that there were five ways islands changed

**Fig. 18-17.** Patterns of meander growth and shift: (a) extension, (b) translation, (c) rotation, (d) conversion to a compound meander, (e) neck cutoff, (f, g) chute cutoffs (from Brice 1974).

(Fig. 18-18). A sixth and seventh could be added, the formation of an island and the complete destruction of an island, but Fig. 18-18 does convey the important concept that bars and islands may be ephemeral as well as dynamic features of a channel (Osterkamp 1998; Osterkamp et al. 2001; Harvey et al. 2003). The result of bar and island formation in a channel is to deflect the flow and perhaps to increase erosion of the banks of the channel. This erosion will enlarge the channel and islands may form as a result of reduced water stage and increased channel width.

*Cutoff (Cc3)* produces a new and relatively short channel across the neck of a meander bend. This drastically reduces the length of the stream in that reach and significantly steepens its gradient. The neck cutoff has the greatest effect (Fig. 18-17e) on the channel. Another type of cutoff is the chute cutoff (Figs. 18-17f and 18-17g), which forms by cutting across a portion of the point bar. The chute cutoff generally forms in recently deposited alluvium, whereas the neck cutoff forms in recent alluvium as well as in older consolidated alluvium or even in weak bedrock.

The consequence of cutoffs of both types is that the river is steepened abruptly at the point of the cutoff. This can lead to scour at that location and propagation of the scour in an upstream direction. The results are similar to those described for degradation and knickpoint migration (hazards Ca1, Ca2).

**Fig. 18-18.** Island change according to Popov (1964). Arrows show direction of flow. Solid lines are original locations of islands; dashed lines show changes. (a) Island shifts up or downstream. (b) Island shifts laterally. (c) Island divided by channel. (d) Small islands coalesce and island joins floodplain. (e) Islands increase or diminish in size.

In the downstream direction, the gradient of the channel is not changed below the site of the cutoff, and therefore, the increased sediment load caused by upstream scour will usually be deposited below the cutoff, forming a large bar, or it may trigger additional downstream cutoffs.

*Avulsion* (Cc4) is the abrupt change of the course of a river. A channel is abandoned and a new one formed as the water and sediment take a new course across the floodplain, alluvial fan, or alluvial plain (Figs. 18-12 and 18-13). A meander cutoff (Cc3) is a type of avulsion because it is a relatively rapid change in the course of the river during a short period of time, but avulsion, as defined here, involves a major change of channel position below the point of avulsion. If, through avulsion, the river takes a shorter course to the sea, it will have a steeper gradient, and erosion above the point of avulsion is likely unless a bedrock control prevents upstream degradation.

*River metamorphosis* (Cd) is a complete change of river morphology (Schumm 1977, p. 159). As the word indicates, this consists of significant changes not only in the dimensions of the river, but in its pattern and shape. Considering the types of channels identified, it is possible to consider six types of river metamorphosis as follows: a straight channel changes to (1) meandering or (2) braided, a braided channel changes to (3) meandering or (4) straight, and a meandering channel changes to (5) straight or (6) braided. It is not necessary to define each type of metamorphosis, because the change is obvious based on pattern alone. There is some similarity in the hazards posed by some types of metamorphosis, and they can be discussed as three pairs.

*Straight and braided to meandering (Cd1 and Cd3).* A straight channel may develop alternate bars and a sinuous thalweg if there is an increase of discharge and sediment load. If the straight channel begins to meander, meander growth, shift, cutoff, and avulsion (Hazards Cc1, Cc3, and Cc4) will also occur when the metamorphosis takes place.

In the case of a metamorphosis from braided to meandering, the change may actually result from a decrease of sediment load that produces increased channel stability. The decreased gradient will reduce the erosional forces acting on the channel, and although the development of meanders is a hazard itself (Hazard Cc1), they will probably form in the space occupied by the old braided channel. In both cases, the channel may degrade.

*Meandering and braided to straight (Cd5 and Cd4).* A bar-braided channel can become island-braided when the bars are colonized by vegetation, and then these islands are incorporated into a new floodplain to form a straight channel. The narrowed straight channel should degrade, but not appreciably. The narrower channel will probably represent a more stable condition, although the increased presence of vegetation may raise the stage of large floods.

The conversion of a meandering channel to a straight channel will be the result of a series of natural cutoffs. The steepened gradient will cause bank erosion and perhaps

degradation. Unless there have been hydraulic changes, the channel will attempt to meander, and the channel will be very unstable. This is especially true when the channel has been straightened artificially.

*Straight and meandering to braided (Cd2 and Cd6).* A straight channel can braid if significant bank erosion occurs with aggradation (Cb1), a result of a major increase of sediment load. A meandering channel will braid for the same reasons. The result will be bank erosion and channel widening (Ca3) with bar and island formation (Cc2). Obviously the change from meandering to braided will be very dramatic.

#### 18.4.5 Piedmont and Coastal Plain Hazards

On a coastal plain, piedmont plain, alluvial fan (Rachocki and Church 1990), or delta, the major hazards are associated with the channel changes discussed above. For example, an increase of discharge, a decrease of sediment load, or a fall of base level will cause channels to incise, dissecting (Da1) the alluvial or bedrock surface. Similar change may cause rejuvenation and extension of drainage networks (Aa1, Aa2) or the *development of a new drainage network* (Dc1). General *aggradation* (Db1) will eventually bury a site, but before the burial is complete, it will be subjected to increased flooding and potential erosion.

*Progradation* (Db2) is the growth of a delta or fan. It is characteristic of a dynamic landform that will be subjected to periods of erosion as it grows. *Avulsion* (4c2) will be common on an unconfined surface such as an alluvial plain, delta, or alluvial fan, especially if progradation or aggradation is occurring. This channel shifting will render any surface site hazardous. The avulsion can also occur on piedmont or alluvial plains by capture (1c1).

The identification of 28 geomorphic hazards provides a check list (Table 18-2) that can be used to review the potential geomorphic hazards that may exist at a site. For most sites, only a few hazards will be of concern. Although Table 18-2 provides a means of determining what hazards may occur in a landscape through time or with a change of discharge, sediment load, or base level, the most important aspect of hazard research is to determine where and when the hazard will occur.

### 18.5 THE ENGINEERING GEOMORPHIC APPROACH

An understanding of landform history, taking a broader view of the problem, and a recognition that geologic and geomorphic controls can exert a dominant influence on a river reach or construction site should provide the engineer with a valuable basis upon which to develop plans and to select sites that will not be exposed to geomorphic hazards, or at least to plan for the occurrence of particular hazards (Table 18-2).

Numerous problems must be considered in dealing with the complex surface of the planet. In particular, one should not extrapolate beyond the limits of available data. In fact, well-established relations developed in other areas may not always pertain, and therefore, field investigations are usually necessary. A good example of the need to understand the geomorphic setting is provided by litigation between the U.S. Forest Service and the State of Colorado regarding the need for channel maintenance flows. The Forest Service claimed that any diversion of streams in the National Forests would cause the streams to decrease in size, which was considered to be an unfavorable condition. This assumption was based upon hydraulic geometry relations that show close positive relations between channel width, depth, and discharge, which were developed for low-gradient alluvial streams (Leopold and Maddock 1953). However, these relations were not valid for mountain streams draining areas of less than 15 square miles with slopes greater than about 4% because other factors such as log jams, beaver dams, glacial deposits, colluvium, and bedrock become the dominant controls on channel morphology and adjustability (Montgomery and Buffington 1993, 1997; Schmidt and Potyondy 2004). Obviously, careful field study was necessary to determine the major influences on these streams. Additionally, even in locations where the form of the channel is not forced by nonfluvial factors, caution must be used with generalized hydraulic geometry relationships for design purposes (Rinaldi and Johnson 1997; Doll et al. 2002).

Examples have been provided of how a combined geomorphic engineering approach can result in better and cost-effective planning. The incised-channel model for channelized streams (Fig. 18-3), the evaluation of bridge sites (Figs. 18-1 and 18-6), and meander growth and shift (Fig. 18-17) are all examples of how consideration of change through time, taking a broader perspective, and recognition of geologic and geomorphic controls can aid the engineer. Thorne and Baghirathan (1994) have developed a scheme for morphological studies of large rivers using this approach.

The geomorphic-engineering approach to a problem or site evaluation should ideally consist of three phases or levels of sophistication, as follows: reconnaissance level, survey level, and design level. At the preliminary stage of a project the reconnaissance level would involve a system approach that brings together geologic and geomorphic data and observations, as well as available climatic and hydrologic data as needed. The survey level involves surveying, mapping, and perhaps geomorphic mapping (Fig. 18-13), to quantify the qualitative relations developed during the reconnaissance-level study. Both of these levels involve both geomorphologists and engineers. The final design-level work is carried out by the engineer, relying on the relations and data obtained during the previous two levels of study. This approach is described in some detail, with examples, in Schumm et al. (1984).

A final example reveals the problem of ignoring the cooperative approach (Keaton et al. 1988; Keaton 1995). In May and June 1983, significant damage occurred along the Wasatch Front, Utah, due to snowmelt-induced debris flows. The worst damage occurred in Farmington due to a debris slide, which mobilized into a debris flow, incorporating over 90% of its mass from the channel of Rudd Creek.

The 1983 debris flows were triggered by landslides caused by a heavy snow pack, an abnormally late rapid snowmelt, and an undrained bedrock aquifer. Geologic studies of the structural fabric and hydrogeology of the landslide source areas indicate that these landslide-induced debris flows were a rare geologic event, perhaps the first such event during the last few thousand years. Most of the earlier historical debris flows were generated by erosion during cloudburst storms that fell on watersheds depleted of vegetative cover by overgrazing and burning. Geologic studies of alluvial fans at the mouths of central Davis County canyons indicate that (1) the majority of alluvial-fan building occurred during the early Holocene (about 10,000 yrs ago) when much ice-age sediment was available for transport, (2) few if any debris flows occurred between the early Holocene and the 1920s, and (3) if historical debris-flow events were representative of the long-term rate of sediment deposition on alluvial fans, the fans would be major landforms instead of the minor features they actually are. The majority of sediment incorporated into debris flows triggered by either landslides or cloudburst storms was derived from the stream channel. Geologic studies of central Davis County stream channels indicate that (1) debris production and accumulation in channels is a slow, intermittent process, (2) stream channels that have produced debris-flow events during historical time have not yet been recharged with sediment, (3) future debris flows from drainages cleaned of sediment will likely be of less volume than initial historical events, until the drainages have been recharged with sediment, and (4) the most likely channels to produce large debris flows in the near future are those that have not produced historical debris flows.

Approximately \$12 million was spent in Davis County to build or refurbish debris basins following the 1983 debris-flow events; less than \$30,000 was spent on geologic research to understand the debris-flow processes. Had geologic studies been conducted prior to construction of the debris basins, more emphasis could have been placed on building debris basins at the mouths of canyons that have not produced historical debris flows, instead of canyons that had produced debris flows during historical time.

The results of the geologic investigation appear to be contrary to common sense, but the evidence is clear. The changing situation through time along the Wasatch Mountains front is expectable from a geomorphic point of view, and it is analogous to the declining sediment loads in the Colorado River as a result of decreased erosion in the incised arroyos of the Southwest (Fig. 18-4).

## 18.6 CONCLUSIONS

Geomorphology is the study of landforms, which involves their classification, description, origin, and evolutionary development. The traditional concern of geomorphologists has been the origin and evolution of landforms, but a more recent development is the prediction, based upon understanding of system dynamics, of landform response to natural and human influences.

The major objectives of this chapter were to bring to the attention of the engineering profession (1) the importance of system history, (2) the need to view a specific problem in a system context, and (3) the importance of geologic and geomorphic variables in engineering activities. For example, if a river meander has changed through time, prediction of future change can be made with more confidence. Therefore, the historical perspective can be a valuable aid in prediction. In addition, it is important to realize that a specific engineering project site is part of a larger geomorphic system. For example, a bridge site is a small part of a fluvial system and the character of that system both up- and downstream can significantly affect future site stability. Finally, geology and geomorphology can be far more important than is generally supposed within an engineering time scale. For example, the world's great alluvial rivers (Mississippi, Nile, Indus), although presumably dominated by hydrological, sediment, and hydraulic controls, are, in fact, significantly influenced by geologic variables. These principles were illustrated in the chapter by examples that were selected to demonstrate how geomorphology and engineering can be combined to provide a rational approach to engineering and environmental problems.

## CHAPTER 19

### *Sedimentation Hazards*

*Marcelo H. García, Robert C. MacArthur, Richard French, Julianne Miller  
with Appendix by Jeffrey Bradley, Tom Grindeland and Hans Hadley*

#### 19.1 INTRODUCTION

In May 1980 Mount St. Helens erupted, removing the upper 404 m (1,324 ft) of the mountain and depositing approximately 2.8B m<sup>3</sup> (3.7B cubic yd) of material over an area of 596 km<sup>2</sup> (230 square mi). The resultant debris avalanche buried the upper 27.2 km (17 mi) of the North Fork Toutle River to an average depth of 46 m (150 ft). Mudflows carried a significant amount of this material downstream into the Toutle, Cowlitz, and Columbia Rivers. It became clear at the time that knowledge about mass sediment movement was extremely limited. This geologic event of catastrophic proportions generated a substantial amount of interest on debris-flows and mudflows. Mount St. Helens is presented as a case study in an appendix to this chapter.

Hyperconcentrated flows had not received much attention in *ASCE Manual 54*, “Sedimentation Engineering”, (Vanoni, 1975; 2006), which was originally published five years before the eruption of Mount St. Helens. In fact, one of the few references to hyperconcentrated flows was about the seminal work by Beverage and Culbertson (1964).

Since 1975, when *Manual 54* was first published, there have been several publications on the subjects of debris-flow (Takahashi, 1991; Lorenzini and Mazza 2004); hyperconcentrated flows (Wan and Wang 1994); mud flows (United Nations 1996; Coussot 1997); alluvial fans (French 1987; NRC 1996a); and landslides (NRC, 1996b). There have also been several international meetings devoted to debris-flows hazards and their mitigation (Walling et al. 1992; Chen, 1997a; Wieczorek and Naeser 2000; Rickenmann and Chen 2003). However, this is clearly an area where much interdisciplinary research is still needed, because there is quite a gap between theoretical analysis, numerical modeling, laboratory experiments and what is observed in the field.

In the past decade, a plethora of models for debris-flows and mud flows have appeared in the literature. Some of them

are coupled to hydrologic models with GIS frameworks for hazard mapping. A recent international conference on debris-flows provides a good source of information on debris-flow modeling, laboratory experiments and field observations (Rickenmann and Chen 2003). Although computational modeling capabilities have increased substantially, it is also important to realize that physical experiments and field observations need to continue at a steady pace so that theoretical and numerical models can be tested and further improved. In this regard, many studies have been conducted at the USGS debris-flow facility located at H. J. Andrews Experimental Forest in Oregon (Iverson et al. 1992; Major and Iverson, 1999; Denlinger and Iverson 2001). Prototype-scale experiments such as these yield high-resolution data that help refine the interpretation of field observations as well the predictions of theoretical and numerical models.

The fact that current knowledge about sedimentation hazards is still rather limited, in particular for hazard assessment and mitigation, was made evident recently in Latin America. The torrential flows that took place in the north coastal range of Venezuela (state of Vargas) in December, 1999 were a unique event in Latin American history, and perhaps in the world. On that day simultaneous extreme debris-flows occurred in about 20 streams (Fig. 19-1) along 50 km of a narrow coastal strip (Lopez et al. 2003). The disaster caused losses of more than \$2 billion and killed an estimated 20,000 people. In terms of human losses this was the worst natural disaster in Venezuelan history and one of the worst in South America (Wieczorek et al. 2001).

As shown in Fig. 19-2, most of the cities along the Venezuelan coastline that were devastated by sedimentation are located in alluvial fans (Lopez and Garcia, 2000). Obviously the people living at these locations were not aware of the potential dangers and the authorities were not aware of the need to have any evacuation or emergency plans. There is a clear need to create public awareness of mudflows and

**Fig. 19-1.** Image of Venezuela northern coastline a few days after catastrophic sedimentation events of December 1999. (Source: SPOT Satellite)

**Fig. 19-2.** Town of Tanaguarena located in the alluvial fan of the Cerro Grande River in the aftermath of catastrophic sedimentation events, December 1999, Venezuela. (From López and García 2000 with permission).

sediment hazards in general. In a paper published in *Natural Disaster Science*, Takahashi (1981b) pioneered the estimation of potential debris-flow hazards, including the hydrologic and soil conditions leading to them, in Japan. His approach has great potential for the estimation of hazardous areas as well as countermeasures to prevent disasters in other

debris-flow prone areas around the world. More recently, Rickenmann (1999) has advanced a series of useful empirical relationships that can be used by practicing engineers to assess debris flow hazard potential. Obviously the need to conduct field reconnaissance and to search for historic events wherever possible cannot be overemphasized.

In order to mitigate the damage caused by landslides, debris-flows and mudflows, it is necessary to introduce various structural and non-structural measures (United Nations 1996). For this purpose, policy makers, community leaders, and teachers in mudflow-prone regions have important roles to play. At the same time, most universities do not cover in their courses the mechanics of sediment transport during extreme hydrologic or geologic events, when the most destructive sedimentation events take place. Thus there is a need to summarize what is known about the subject of sedimentation hazards in this second volume *Manual 110* "Sedimentation Engineering."

This chapter attempts to summarize what is known about hyperconcentrated flows such as mud-floods, mudflows, and debris-flows, so that hydraulic and sedimentation engineers involved in the planning and design of mitigation measures as well as risk assessment have the best tools available for their use. However, the importance of public information and education to improve sediment hazard awareness and avoidance cannot be emphasized enough.

## 19.2 SEDIMENTATION HAZARDS—HISTORY AND MAGNITUDE

Throughout recorded history natural disasters have claimed lives and resulted in significant losses of property, income and social stability. Today there is far greater potential for worldwide catastrophic events, and there are far greater impacts from such events, because of a growing population in high-hazard areas, mounting investment and value of structures, dependency upon lines of communication, and the growing economic interdependence of businesses, communities and nations (NRC 1989). People's propensity to occupy areas subject to natural hazards, to alter natural watercourses, to alter land forms, and to engage in other activities that impact natural hydrologic and sedimentation processes creates a need to understand and forecast where and when such hazards may occur and to be able to avoid and mitigate for hazards. The first step for reducing natural sedimentation hazards is to become aware of their likely occurrence and their consequences. This awareness is necessary to motivate financial and scientific resources to prepare means for reducing and mitigating natural hazards.

Worldwide, nearly 3 million people died and approximately 820 million more were injured, displaced, or otherwise affected by natural disasters during the period from 1969 to 1989 (NRC 1989). Nearly 670,000 people were killed and approximately 211 million were adversely affected by natural disasters from 1991 to 2000 (IFRCRCS 2001). During the period from 1965 to 1985, floods and flood-related sedimentation processes were the greatest cause of deaths and property damage by natural disasters in the United States (Rubin, et al. 1986). Global flood disasters accounted for more than two-thirds of the people

adversely affected by natural disasters from 1991 to 2000. Singh (1996) summarizes the historical occurrence of many of the largest worldwide natural and man-induced disasters since the turn of the century.

Singh (1996) also reports that flood damages, which exceeded \$50 million per event in the United States from 1947 to 1964 (22 yrs.), accounted for approximately \$5 billion in 1966 dollar equivalents. In 1968, the U.S. Water Resources Council (WRC) projected annual flood-related damages in the United States from the mid-1950's to 2020. The WRC forecast that during the period from 1966 to 2000, annual flood damages in the United States would double and by the year 2020, the annual damages would triple [from Singh (1996)]. According to the 1987 National Research Council, that forecast was low and the occurrence of significant flood-related damages in the United States and worldwide is growing because of increasing population, dramatic land use changes, and the propensity for people and valuable developments and infrastructure to locate in flood-prone zones.

Deaths and property losses from floods and fluvial processes exceeded those caused by other natural disasters such as earthquakes, hurricanes, tornadoes, tsunamis, landslides and volcanoes. These facts surprise many because floods are not usually thought to be significant causes of destruction and loss of life. This lack of public awareness of the increasing potential danger of floods and other fluvial processes, especially in the vicinity of rivers, channels, alluvial fans and coastal areas, is itself a problem. Rapidly urbanizing communities worldwide are especially susceptible to flooding problems because of the rate at which urbanization and land use are occurring. There is insufficient time to plan developments properly and they are commonly designed and constructed with a severe lack of long-term continuous rainfall and runoff records to document past flood occurrences and the capability of severe storm events to produce high-intensity, large-volume rainfall events in relatively isolated catchments. In regions where special sedimentation hazards occur (e.g., hyperconcentrated flows, flow bulking, and mud and debris-flows), traditional clear-water hydraulic design procedures for flood control works can lead to under sizing of debris retention facilities by 10 to 100 times and flood conveyance channels by 3 to 10 times depending on event sequencing, the severity of the storm event and geomorphic characteristics of the basin (MacArthur et al. 1992).

Landslide and debris-flow hazards often result from earthquakes, volcanic eruptions, and excessively wet rainy seasons, particularly those that immediately follow summer wildfires. Schuster and Flemming 1986 provide a historical review of large landslide and debris-flow events that have occurred in the western hemisphere, including the economic costs and loss of life associated with each event. The largest landslide in recorded history occurred during the May 1980 eruption of Mount St. Helens, a volcano in the state of Washington. The rock slide-debris avalanche contained

approximately 2.8 km<sup>3</sup> of material, which traveled as far as 22 km downslope along the North Fork Toutle River. The 1964 earthquake in Anchorage Alaska was one of the largest in recorded history (M9.2) and produced the most economically costly landslides of the 20th century, amounting to nearly \$180 million (\$1 billion in today's dollars) in damage to property and infrastructure in a series of landslides that moved an estimated 260,000 km<sup>3</sup> of material (Youd 1978). Earthquake-triggered landslides occurred in Whittier, California, causing property damages exceeding \$350 million when a magnitude 5.9 earthquake struck the area for less than 5 s. In South America, the once prosperous Armero region of Colombia was devastated by mudflows spawned by the November 1985 eruption of Nevado del Ruiz, South America's northernmost active volcano. Though not a great eruption, a pyroclastic flow melted part of the mountain's snow and ice cap, generating mudflows called *lahars* that swept down the valleys flanking the summit (NRC 1989). "Two of the largest flows, augmented by scoured slope and valley debris and moving at more than 30 kph, swept from the mouth of Rio Lagunillas Canyon into the valley cradling the town of Armero. Successive waves of mud surged through the town, tearing homes from their foundations and burying sleeping residents to a depth of up to 3 meters. The peak discharge of the mudflow, estimated from the super-elevation left by the flood mark on a river bend immediately upstream from Armero, was 30,000 m<sup>3</sup>/s (Takahashi, 1991). At least 22,000 perished, though the eruption had been predicted weeks in advance" (NRC, 1989). Similar eruption-induced mud and debris-flows, lahars and surge release debris torrents occurred at Mount St. Helens, Washington in 1980 and at Mount Pinatubo in the Philippines in 1991, killing many people and dramatically changing the landscape and rivers draining those mountains and floodplains (MacArthur et al. 1993).

Massive landslides occurred in many California coastal communities during the heavy rainfall El Nino years of 1983, 1986 and 1995. Copious winter rains raise the local water level and pore pressures within hillslope soil materials, which increase the weight of hillslope materials while reducing the binding forces between layers of soil and bedrock. This often results in large slabs of weathered rock and earthen materials breaking free and sliding as a massive soil slip or rotational landslide or running out as a mud or debris-flow. Mechanisms for these types of rainfall-induced hazard are discussed by Varnes (1958), Campbell (1975), Krohn and Slosson (1976), Cannon and Ellen (1985), and Wilson and Wiczorek (1995). In 1987, California and Oregon experienced summer wildfires that lead to rainy-season fire-flood sequence-associated mud and debris-flows that damaged hundreds of homes and thousands of acres of urbanized area and dramatically affected the economies of many communities for years to come. Additional occurrences of fire-flood-associated landslides and mud and debris-flows have had dramatic effects in the states of Idaho, Wyoming, Montana,

California, Arizona, New Mexico, Oregon, and Washington during the past decade (Bigio and Cannon 2001).

Death tolls and the collapse of homes or buildings often grab headlines after an earthquake or landslide. However, the effects of the quake and slides do not end there. Chassie and Goughnour (1976) of the Federal Highway Administration estimated that more than \$100 million is a conservative total annual cost for landslide damage to highways and roads in the United States as of 1976. Water supply and sewer lines, reservoirs, pipelines, irrigation canals, flood-control channels, energy distribution and communication systems, and other transportation facilities—often referred to as *socio-economic lifelines*—are often directly impacted by landslide events as well.

Developments on alluvial fans may be at risk of severe periodic sedimentation and flooding hazards. During the spring of 1983, widespread flooding and mudflows caused an estimated \$250 million in damages to Davis County communities located on numerous alluvial fans along the base of the Wasatch Mountains in Utah. The destruction was so extensive that 22 of Utah's 28 counties were declared national disaster areas (MacArthur and Hamilton 1988). Flash flooding and mudflows resulted from a rapidly melting snow pack that triggered over 1,000 landslides in the steep canyons above Farmington, Centerville, Bountiful and Salt Lake City. Detailed flood insurance studies had been completed for the communities in Davis County, Utah just prior to the events. Traditional steady-state, clear-water flood insurance study methods were used to delineate potential flood hazard zones. However, these studies did not account for the severe sedimentation processes (hyperconcentrated sediment loading and mud and debris-flows) associated with the events, so they grossly underestimated the magnitude and aerial extent of damage such an event could cause. The City of Rancho Mirage, located in Coachella Valley, California, experienced similar sedimentation hazards and debris-flow flood events on the Magnesia Spring Creek alluvial fan in 1976 and 1979. The occurrences of these destructive, high-velocity sedimentation-associated flood events led to the design and construction of a flood-control project by the U. S. Army Corps of Engineers. Unique to that project, however, was the recognition of the need to develop new methods for estimating severe-event hydrology (peak flows and event volumes) and for the design of mud—and debris-control facilities subject to such episodic, high-energy flood hazards.

Alluvial fan flooding and mud and debris-flow-hazards are often thought to occur in arid ephemeral locations of the world; however, similar hazards occur in warm tropical as well as cold polar regions of the world (Lecce, 1990; HEC, 1993). On New Year's Eve, 1987, severe flash floods and debris-flows occurred in Hawaii. The disaster happened unexpectedly, resulting in significant property loss, injuries, and economic impacts. The event was triggered by intense rainfall occurring in steep saturated basins above residential communities, resulting in several hillslope failures and

initiating significant mud and debris-flows that ran down valley for many miles, slamming into bedroom communities in the middle of the night (see MacArthur et al., 1992). As mentioned earlier, in December 1999 heavy rains in the mountains near Caraballeda, Venezuela caused landslides, debris-flows, and flash flooding on alluvial fans located along the densely populated coast. The community of Caraballeda, constructed on an alluvial fan, was partially buried by over 1.8 million tn of debris. Total damage caused by the storm was estimated at \$1.9 billion with a loss of life exceeding 19,000 (Larsen et al., 2001; Wieczorek et al. 2001). Flash floods, debris-flows, and debris and boulder torrents are also common in steep cold-region catchments of Alaska and British Columbia. Neill, in *Hydrology of Floods in Canada* (Neill 1989), discusses special flood and sedimentation hazards associated with debris torrents and debris jam floods, phenomena typical of steep terrain. Neill (1989) also describes other unique sedimentation conditions associated with glacial outburst floods and ice jam flooding, typically found in cold regions of the world.

Other common types of sedimentation-related flood hazards include the following:

- Coastal flood and erosion hazards, including tsunamis, hurricane surges, coastal bluff erosion and retreat, seasonal littoral sand transport, accelerated shoaling, sand dune and barrier island dynamics, and underwater debris-flows and turbidity currents resulting from seismic activity;
- Failure of natural debris dams formed by landslides in mountain areas;
- Collapse of mine-tailings dams. *In Tesero, Italy, a tailings dam collapsed in 1985 and the stored tailings together with the dam body material flowed down the Stava River as a mudflow, claiming the lives of 268 people and washing away 47 houses (Takahashi, 1991).*
- Gullyng and hillslope instability due to deforestation, land use modification, road building, and urbanization;
- River and flood control channel instability due to local scour processes;
- Bridge pile, footing, and abutment instability due to local scour processes;
- Excessive accumulation of sediment and debris resulting in channel blockage and avulsion;
- Dam-break or glacial outburst-flood-induced debris-flows.

Even though much is yet to be learned about physical processes and consequences of sedimentation-related flood hazards, much has been learned on these esoteric topics since the first publication of *Manual 54* in 1975. During the past 30 yr, local, state, and federal researchers have advanced our abilities to identify hazard-prone zones and to estimate risks associated with sedimentation-related hazards. Since the passage of the Flood Control Act of 1936, the U. S. Corps of Engineers has been the leading federal agency responsible

for regulating flood flows and building projects to reduce flooding damage. Beginning in the late 1970's and early 1980's, the U.S. Army Corps of Engineers, in cooperation with the Federal Emergency Management Agency (FEMA) and many private and state researchers, began to develop new study and design procedures to better account for sedimentation processes that affect fluvial systems during severe floods (MacArthur and Hamilton 1988; HEC 1993). Beginning in 1987, the United Nations General Assembly initiated the International Decade for Natural Disaster Reduction (IDNDR) to run from 1990 to 2000. Its aim was to reduce the loss of life, property damage, and social and economic disruption caused by natural disasters, including those attributed to sedimentation processes. The Decade concluded that floods cause about one-third of all deaths, one-third of all injuries and one third of all damage from natural disasters worldwide (Askew 1997). The IDNDR called for action by governments and international organizations to put greater emphasis and financial commitments to disaster prevention. Today, therefore, we see more awareness and understanding of flooding and special sedimentation hazards and improved study methods for forecasting their risk of occurrence and for designing mitigation measures are becoming available.

## 19.3 MECHANICS OF MUDFLOWS, DEBRIS-FLOWS, AND MUD-FLOODS

### 19.3.1 Definition of Hyperconcentrated Flow

Hyperconcentrated sediment flows can be initiated by numerous causes including intense rainfall, rapid snowmelt, and volcanic and man-made activities (Wan and Wang, 1994). The sediment load may also be increased by hill-slope failure and bank collapse during flood events. The volume and properties of the fluid matrix, which is composed of the fluid and the sediment particles, govern flow hydraulics, flow cessation, and runout distances of hyperconcentrated sediment flows. The fluid matrix properties are usually dependent on sediment concentration, size fraction and clay content. A hyperconcentrated flow can be defined as a fluid in movement in which a high percentage of solid material is transported. The mean solid concentration by volume is defined as the ratio between the volume occupied by the solid fraction and the total mixture volume:

$$C_V = \frac{V_{\text{solid}}}{V_{\text{solid}} + V_{\text{liquid}}}, \text{ in which } V_{\text{solid}} \text{ and } V_{\text{liquid}} \text{ are the}$$

volume of the solid fraction and that of the liquid fraction of the mixture, respectively.

To avoid misinterpretation, the term *concentration* requires clarification, particularly for the case of hyperconcentrations. The units used in the measurement of sediment concentration vary with the range of concentrations and the standard measurement techniques utilized in different countries. The most common unit for sediment concentration is milligrams

per liter, which describes the ratio of the mass of sediment particles to the volume of the water-sediment mixture. Other units include kilograms per cubic meter ( $1 \text{ mg/l} = 1 \text{ g/m}^3$ ), the volumetric sediment concentration  $C_v$ , the concentration in parts per million  $C_{\text{ppm}}$ , and the concentration by weight  $C_w$ , which are defined as follows:

$$C_v = \frac{\text{sediment volume}}{\text{total volume}} \quad (19-1a)$$

$$C_w = \frac{\text{sediment weight}}{\text{total weight}} = \frac{C_v G}{1 + (G - 1)C_v} \quad (19-1b)$$

in which  $G = \gamma_s/\gamma$  is the specific gravity of the sediment and

$$C_{\text{ppm}} = 10^6 C_w \quad (19-1c)$$

Note that the percentage by weight  $C_{\text{ppm}}$  is given by 1,000,000 times the weight of sediment over the weight of the water-sediment mixture. The corresponding concentration in milligrams per liter is then calculated by the following formula:

$$C_{\text{mg/l}} = \frac{1 \text{ mg/l } GC_{\text{ppm}}}{G + (1 - G)10^{-6} C_{\text{ppm}}} = 10^6 \text{ mg/l } GC_v \quad (19-1d)$$

The conversion factors in going from  $C_{\text{ppm}}$  to  $C_{\text{mg/l}}$  are given in Table 19-1. Note that there is less than 10% difference between  $C_{\text{ppm}}$  and  $C_{\text{mg/l}}$ , at concentrations  $C_{\text{ppm}} < 145,000$ .

**Table 19-1 Equivalent Concentrations for  $C_v$ ,  $C_w$ ,  $C_{\text{ppm}}$ , and  $C_{\text{mg/l}}$**

$C_v$	$C_w$	$C_{\text{ppm}}$	$C_{\text{mg/l}}$
Suspension			
0.001	0.00264	2,645	2,650
0.0025	0.00660	6,598	6,625
0.005	0.01314	13,141	13,250

0.25	0.46903	469,027	662,500
0.5	0.72603	726,027	1,325,000
0.75	0.88827	888,268	1,987,500

*Note:* Calculations are based on mean density of water of 1g/ml and specific gravity of sediment  $G = 2.65$ .

*Source:* from Julien (1995) with permission.

In the laboratory, the sediment concentration  $C_{\text{mg/l}}$  is measured as 1,000,000 times the ratio of the dry mass of sediment in grams to the volume of the water-sediment mixture in cubic centimeters ( $1 \text{ cm}^3 = 1 \text{ ml}$ ). Two methods are commonly used: evaporation and filtration. The evaporation method is employed when the sediment concentration of samples exceeds 2,000 to 10,000 mg/l; the filtration method is preferred at lower concentrations. The lower limit applies when the sample consists mostly of fine material (silt and clay), and the upper limit when the sample is mostly sand. For samples having low sediment concentration, the evaporation method requires a correction if the dissolved solids content is high (Julien 1995).

*Mud-floods* are typically hyper concentrations of non-cohesive particles (e.g., sand). They display very fluid behavior for a range of sediment concentrations by volume  $C_v$  as high as 40%. *Mud-floods* are turbulent and flow resistance depends on boundary roughness, as for turbulent flows with clear water. At volumetric sediment concentrations  $C_v > 0.05$  the sediment concentration of small particles tends to become more uniform than described by the Rousean vertical concentration profiles for dilute suspensions presented in Chapter 2. Increased buoyancy and fluid viscosity reduce the settling velocity of sediment particles. A detailed analysis of hyperconcentrations of sands was presented by Woo et al. (1988). Turbulent diffusion and settling fluxes are dominant despite an increase in specific weight and viscosity of the mixture. An example of a *mud-flood* is shown in Fig. 19-3. Notice the instabilities in the free surface of the flow as predicted by Engelund and Wan (1984).

*Mudflows* are characterized by a sufficiently high concentration of silts and clays (sediment size  $< 0.0625 \text{ mm}$ ) to change the properties of the fluid matrix and help support large clastic material. *Mudflows* behave as a highly viscous fluid mass, which at high concentrations is capable of rafting boulders near the flow surface. Based on laboratory results, the volumetric sediment concentration of a mud-flow fluid matrix is in the approximate range  $45\% < C_v < 55\%$  (O'Brien, 1986). *Mudflows* exhibit high viscosity and yield stress, can travel long distances on mild slopes at slow velocities, and leave lobate deposits on alluvial fans. A detailed analysis of *mud-flow* properties has been presented by O'Brien and Julien (1988); Major and Pierson (1992); and Coussot (1997). An example of a *mud-flow* deposit is shown in Fig. 19-4.

*Debris-flows* are mixtures of clastic material, including boulders and woody debris, where lubricated interparticle collision is the dominant mechanism for energy dissipation. Knowledge of debris-flows is based largely on the contributions of Bagnold (1954) and Takahashi (1978). A recent review of debris-flows is given by Hutter et al. (1996). Granular flows (non-cohesive) flows without a lubricating fluid) constitute a sub class of debris-flows in which the exchange of momentum between the flow core and the boundary occurs exclusively through particle collision and friction.

**Fig. 19-3.** Example of mud flood (From Julien and Leon, 2000, with permission).

**Fig. 19-4.** Example of mudflow frontal deposit (from O'Brien et al, 1993, with permission).

Debris-flows involve the motion of large clastic material and debris characterized by destructive frontal impact surging and flow cessation on steep slopes (Fig. 19-5). Dispersive stresses arising from the collision of clastic particles control the exchange of flow momentum and energy dissipation.

Debris-flows are much less fluid than mud-floods. The fluid matrix viscosity is comparatively small corresponding to the small concentration of fine sediments. The fluid matrix is essentially non-cohesive. The interstitial fluid does not significantly inhibit particle contact, permitting frequent collisions and impact between the solid clasts. Using a linear stability analysis, Lanzoni and Seminara (1993) have explored the conditions for the development of *debris waves* similar to the commonly observed *roll waves* in steep channels conveying clear water (Chow 1959).

### 19.3.2 Main Classification Criteria

In the past, the main classifications of hyperconcentrated flows were based on criteria obtained from direct observations, experimental process evaluations, and morphological analysis of deposits, physical models, and theoretical studies. Some investigators have focused on the classification of hyperconcentrated flows based on sediment concentration. Another group have categorized hyperconcentrated flows based on the triggering mechanism responsible for generation of these flows, and the third group of researchers have classified these flows according to the rheological and kinematic behavior. Classifications based on sediment concentration date back to the seminal study of Beverage and Culberson (1964). Motivated by the wide spectrum of sediment-laden flows observed in the aftermath of Mount St. Helens eruption, Bradley and McCutcheon (1987) were among the first to provide a comprehensive review on the classifications of hyperconcentrated flows. Their summary of commonly used classifications is shown in Table 19-2.

The first mass-wasting classifications concentrated in particular on landslides, a phenomenon that is of great interest to any new urban settlement (NRC 1996b). Sharpe (1938) considered two main parameters, relative velocity and sediment concentration and despite the fact that he did not specify transition boundaries, this classification has been widely used and refers to the following process categories: *debris avalanches*, *mudflows*, *earthflows*, *solifluction*, *soil creep* and *streamflows*.

Two decades after the Sharpe (1938) classification scheme first appeared in the literature, Varnes (1958) presented a classification that became a main reference point for the terminology of these processes. Varnes' classification is based on two main characteristics, the type of material and the type of movement involved, whereas velocity and mixture composition are used for subclassification purposes. Therefore, for coarser materials it identifies the phenomena as block streams, debris avalanches, debris-flows (mudflows if the coarser material content is lower than 50%), solifluction, and creep, and for finer materials: blends of dry sands and silt, blends of wet sands or silt, and *earthflows*. In the Chinese literature (Wan and Wang 1994), the term "hyperconcentrated" is generally used to indicate a material having measurable yield strength and therefore debris-flows

**Fig. 19-5.** Video images of debris flows passing by town of Iruya, Salta, Argentina, February 7, 1999 (courtesy of Daniel Brea and Pablo Spalletti).

are considered as hyperconcentrated flows. However, more recent classifications have attempted to systemize established terminology by introducing quantitative criteria.

Takahashi (1991) defines mass wasting as the fall, slide, or flow of a conglomerate or dispersed mixture of sediment in which gravity moves all the particles and the interstitial fluid, so that the relative velocity between the solid and fluid phases in the main direction of motion plays a minor role, whereas in a fluid flow the forces of lift and resistance caused by relative velocity are essential for the transport of each single particle. In this approach, the following four phenomena can be distinguished on the basis of the mechanism that supports the clasts, the properties of the interstitial liquid, velocity, and distance reached: *falls*, in which the single particles move separately with relatively small internal deformation; *sturzstroms*, particularly rapid and destructive events; *pyroclastic flows*, which are rapid and explosive events originated by volcanic eruptions, in which the suspension mechanism is linked to the expansion of the gas trapped within the flow; and,

finally, *debris-flows*, in which the grains are dispersed in a water-clay interstitial fluid. These last three processes can be termed collectively *gravitational sediment flows* (Takahashi 1991) and constitute continuous processes that require a certain force for grain suspension.

In the case of debris-flows, the approach of Bagnold (1954) and Takahashi (1978) considers the dispersive pressure that results from the exchange of momentum between grains as predominant; if the interstitial fluid is particularly dense, large clasts can be suspended with relatively low dispersive pressures by floating in the fluid phase. Another approach, first advanced by Johnson (1970), considers that the viscous stress of the interstitial fluid is predominant and neglects interactions between grains.

Following a number of laboratory experiments with samples from Colorado, O'Brien and Julien (1985) classified hyperconcentrated flows according to the properties controlled by sediment concentrations, as *water floods*, *mud-floods*, *mudflows*, and *landslides* (Fig. 19-6). The characteristic

stresses of such processes are yield stress, viscous stress, turbulent stress in the fluid, and dispersive stress caused by the inertial impact of the coarser sediments. Which of these stresses dominates depends on the volumetric concentration of sediment and the percentage of the fine fraction. Despite

the fact that the transition between the types of flow is difficult to determine, according to this approach they can be divided into three categories, which lie between conventional stream flooding on the one hand and landslides on the other end.

*Mud-floods* are hyperconcentrated flows of cohesionless particles (mainly sand) with limited quantities of cohesive particles, which show characteristics that are typical of fluids, with sediment concentrations by volume of 20 to 45% (Winterwerp et al. 1990). From a hydrodynamic point of view, *mud-floods* have characteristics that are typical of a conventional turbulent flow and resistance to motion depends on the roughness of the channel in which the flow occurs. Moreover, they are not able to support stress without deforming and show no yield stress. Sediment concentration tends to be uniformly distributed throughout the flow depth, because the viscosity of the interstitial fluid reduces the velocity of particle sedimentation.

*Mudflows* are hyperconcentrated flows composed, to a large extent, of cohesive silt and clay particles (smaller than 0.0625 mm), in which sediment concentration by volume varies between 45 and 55%. This composition alters the properties of the interstitial fluid, making it extremely viscous and giving it considerable yield strength. Consequentially, in the free surface area, *mudflows* can hold clasts of considerable size in suspension for long distances even on slight slopes, resulting in the formation of lobe-shaped deposits. Typical resistance to motion is a characteristic of pseudoplastic fluids that appears with high viscosity (Huang and Garcia 1998).

*Debris-flows* are mixtures of clastic material with high coarse particle contents, in which collisions between particles and therefore dispersive stresses are the dominant mechanisms in energy dissipation. Cohesionless granular debris-flows are a subcategory of debris-flows, in which momentum exchange takes place due to friction and collisions. These phenomena occur depending on the simultaneous occurrence of the following conditions:

- high volumetric concentration of sediments ( $>0.5$ );
- high shear rates ( $>100 \text{ s}^{-1}$ );
- large particle dimensions ( $>5\%$  compared to stream-flow depth).

Cousot (1992) considers two types of debris-flow: *granular* ones, which have a fine particle fraction quantity (dimension smaller than  $40 \mu\text{m}$ ) 10% lower than the entire solid mass, and *muddy* ones in which the fine fraction exceeds 10%. Cousot's classification is given in terms of dimensional grain distribution, as shown in Fig. 19-7.

When the rheological behavior of granular mixtures is used for classification purposes, two further studies must be considered. Savage (1984) identified three flow regimes for granular mixtures, each one characterized by a value of the solid fraction, interstitial viscosity, and deformation rate: the *macroviscous* regime, in which the viscous effects of the interstitial fluid and solid particle interactions cause the stresses; the *quasistatic* regime, in which dry friction and prolonged contacts between particles are important, whilst inertial effects are negligible; and last, the *inertial-granular* regime, in which the inertia associated to the individual particles prevails. Iverson (1985) developed a constitutive equation for the idealized behavior of mass wasting, based on linear and nonlinear rheological models, which range from the purely plastic case to the purely viscous one; this equation represents an important analytical relationship for differentiating between various types of flow.

**Fig. 19-7.** Cousot's (1992) conceptual classification of hyper-concentrated streamflows.

A rheological classification of the various types of flow using a two-dimensional matrix (Fig. 19-8) that considers the mean flow velocity and sediment concentration was proposed by Pierson and Costa (1987). This classification makes it possible to distinguish each process from the others, if mean flow velocity is known or can be estimated and additional information is available on the existence of yield strength and stream capacity to suspend large clasts, characteristics that can be determined by an analysis of sediment deposits. This approach distinguishes between a dilute, ordinary streamflow and a hyperconcentrated streamflow according to whether the flow is Newtonian or non-Newtonian, and between a slurry and a granular flow, the limit being a function of sediment size and particle gradation. In the graph shown in Fig. 19-8, vertical rheological divisions A, B, and C depend on grain size and concentration. From left to right, boundary A represents the appearance of yield strength; boundary B marks sudden increase in yield strength rapid increase that enables the static suspension of granules and the onset of liquid behavior; boundary C marks the cessation of liquid behavior. The horizontal velocity limits, which are also functions of

**Fig. 19-8.** Classification of water-sediment mixtures proposed by Pierson and Costa (1987).

grain-size distribution and sediment concentration as well as particle density, are determined by how shear stress is transmitted between particles during the flow. In the case of cohesive materials or those that contain a high proportion of fine materials, the vertical lines on the graph, that divide the various rheological behavior types, must be shifted to the left; the opposite is true if the mixture contains mainly well-sorted, coarse clasts. It is therefore possible to identify two large-flow categories: one that includes *ordinary streamflows* and *hyperconcentrated streamflows* and a second one that includes *slurry flows* and *granular flows*.

According to Davies (1986; 1988), who reviewed numerous debris-flow descriptions, basically three different debris-flow types can be distinguished:

*Type 1:* low-density, steadily moving turbulent flows, carrying coarse particles as bed load only and with the fluid made up of a slurry.

*Type 2:* high-density, laminar flows, carrying fine and coarse particles uniformly distributed over the depth, of unsteady nature with pulse-like motion.

*Type 3:* the same as Type 2 but consists of a single pulse or wave.

The latter two types have a higher viscosity than the first one, and selective deposition of the coarser particles does not seem possible. Due to their larger flow depths and velocities their destructive power is considerable. In order to distinguish between steady- and unsteady-type debris-flows, Davies (1997) proposed a density of 1.6 to 1.8 tn/m<sup>3</sup>, corresponding to sediment concentrations of about 36 to 49% by volume. He pointed out that the transition seems to be rather abrupt if a particular flow changes from one type to another. This transition is also reflected in the sediment deposits of either a “water flood” or a debris-flow (Costa 1984).

One of the main problems in the development of a unifying classification scheme relates to the fact that the physical properties of debris-flows, and hyperconcentrated flows in general, vary over a wide range in the field (Iverson, 2003). A summary of physical properties of debris-flows prepared by Costa (1984) is reproduced in Table 19-3. It can be observed that the dynamic viscosity as well as the density of these flows can be much larger than in the case of dilute suspensions. Except for the fast-moving *mudflows* and *debris flows* observed in China, it is interesting to observe that most flows are laminar as pointed out by very low values of the estimated Reynolds number (Coussot, 1994).

An interesting graph showing a continuous spectrum of sediment concentrations from sediment-laden rivers to debris-flows first proposed by Hutchinson (1988) is shown in Fig. 19-9. What makes this graph particularly useful is that it includes information on conditions observed in the field (some of which are mentioned in Table 19-3), ranging from *streamflows* carrying modest amounts of sediment

all the way to *landslides* having very low water content and very large solids concentrations (Bagnold 1956). This graph includes also the water content in the sediment-water mixture, a parameter that is relatively easy to measure in the field. This is important because soil saturation with water is an important factor in the triggering of *landslides* that might evolve into *debris* and *mud flows*. As shown therein, debris-flows are often of very high density, over 80% solids by weight, and may exceed the density of freshly-mixed concrete. They can therefore move boulders that are meters in diameter as shown in Fig. 19-10. The equation shown in Fig. 19-9 is given by the following expression,

$$\gamma_{\text{sat}} = G \gamma_w \left[ \frac{1+W}{1+WG} \right]$$

where  $\gamma_{\text{sat}}$  is the specific or unit weight of a saturated soil (sediment plus water) sample,  $G = \gamma_s/\gamma_w$  is the specific gravity of the sediment defined earlier as the ratio between the specific weight of the sediment and the specific weight of water. This parameter can have values between 2.6 and 2.75. The water content  $W = M_w/M_s$  in the sample is defined as the ratio between the water mass  $M_w$  and the sediment mass  $M_s$  in the soil sample. It is clear that when the water content  $W$  is very large  $\gamma_{\text{sat}} \rightarrow \gamma_w$  corresponding to a dilute open-channel suspension; and when the water content decreases and the sediment concentration increases  $\gamma_{\text{sat}} \rightarrow \gamma_s$  corresponding to *hyperconcentrated flows* such as *mudflows* and *debris flows*.

As observed in Fig. 19-10, the impact of large boulders can cause substantial destruction of buildings so it can be useful to estimate potential impact loads resulting from *debris flows*. Impact loads result from objects entrained in the flow striking a structure surface with a velocity component perpendicular to the flow direction (Julien and O'Brien 1997). To compute the impact load, consideration should be given to the evidence of debris and boulders transported on the fan by recent flood events. To be conservative, the largest boulder transported by a flow should be used to determine the impact load. The impact loading  $P_I$  is given by:

$$P_I = \frac{wV}{(Ag \Delta t)}$$

where  $w$  is the weight of the object (largest boulder),  $g$  is the gravitational acceleration,  $V$  is the flow velocity,  $A$  is the area of impact assumed to be a percentage of the cross sectional area of the object and  $\Delta t$  is the duration of impact. It has been observed that the largest boulders in a given flow have a tendency to accumulate on the frontal area of debris flows (Suwa 1987), where they can be expected to have the largest effect when impacting a structure. Recently, the effect of particle segregation and its implications for debris flows have been studied experimentally by Zanutigh and Di Paolo

(2006). There is also a FEMA Manual (1994) that provides equations for the computation of the hydrostatic and hydrodynamic loads on structures.

### 19.3.3 Rheology of Hyperconcentrated Sediment Flows

The general flow behavior of hyperconcentrated sediment flows can be inferred from an examination of the physical processes triggering hyperconcentrations in a watershed, an assessment of sediment availability and sediment source, an investigation of historical flood events on the same or neighboring watershed, and a rheological and particle size analysis of deposits. Deposits from historical or recent events can be brought to the laboratory for a rheological investigation at various sediment concentrations. As discussed above, hyperconcentrated sediment flows can be classified, in general, as mud-floods, mudflows, and debris-flows. Distinct physical processes differentiate these types of hyperconcentrations based on the rheology of the water-sediment mixture.

Various researchers have developed and applied models of mud and debris-flow rheology. These models can be classified as Newtonian models (Johnson 1970; Hunt 1994; Aguirre-Pe et al. 1995); linear and nonlinear viscoplastic models (Johnson 1970; O'Brien and Julien 1988; Liu and Mei 1989; Huang and Garcia 1997a; 1997b; 1998; Imran et al. 2001); dilatant fluid models (Bagnold 1954; Takahashi

1978; Mainali and Rajaratnam 1994); dispersive or turbulent stress models (O'Brien et al. 1993); and frictional models (Iverson 1997).

Rheology is the science of describing the deformation and flow of matter. More specifically, the graphical measure of the shear stress applied at a given rate of deformation of a fluid defines a rheogram. In clear water flows, the shear stress increases linearly with the rate of deformation (i.e., velocity gradient) in the laminar flow regime and the fluid is said to be Newtonian (i.e.,  $\tau = \mu du/dz$ ). The dynamic viscosity of a sediment-water mixture  $\mu$  is then defined as the slope of the rheogram.

There is substantial evidence indicating that mud at high enough concentrations shows non-Newtonian rheological behavior (e.g., Coussot 1994). Videos taken by Davies (1988) during his laboratory experiments show that there are both a thin shear layer near the bed and an upper plug-like layer in which the particles are nearly locked together. This upper plug-like layer is a property of non-Newtonian fluids, and is clearly associated with some yield stress. Rheological studies by Krone (1963), Migniot (1968), and Wan (1982) indicate that mud from different sources behaves approximately as a Bingham plastic fluid whose yield stress,  $\tau_y$ , and viscosity,  $\mu$ , increase monotonically with clay concentration. The ranges of values commonly observed for such parameters values are  $10^{-6} \text{ m}^2/\text{s} < \mu/\rho < 1.2 \times 10^{-3} \text{ m}^2/\text{s}$  and  $10^{-3} \text{ N/m}^2 < \tau_y < 10^2 \text{ N/m}^2$ , whereas sediment concentration varies in the

Fig. 19-9. Continuous spectrum of sediment concentrations and water content from sediment-laden rivers through ephemeral streams to mudflows and debris flows (Hutchinson 1988).

range from 2 to 700 kg/m<sup>3</sup>. Such a fluid at rest is capable of resisting any shear stress less than the yield stress. When the yield stress is exceeded, the fluid structure changes and the material behaves like a Newtonian fluid driven by the excess of the shear stress beyond the yield stress. When the shear stress falls below the yield stress, the fluid structure changes again, and there is no fluid flow. There is also evidence that fine-grained debris-flows (Mainali and Rajaratnam 1991; 1994; Dominique and Coussot, 1997), liquefied mine tailings materials (Jeyapalan et al. 1983), molten lava (Johnson 1970), and snow avalanches (Dent and Lang, 1983) can be modeled as Bingham plastic fluid flows (Huang and García 1997b).

The Bingham rheological model is to some extent a limiting or idealized rheological model. Beyond a finite shear stress (i.e. *yield stress*  $\tau_y$ ) the rate of deformation,  $du/dz$ , is linearly proportional to the excess shear stress. The constitutive equation is

$$\tau = \tau_y + \mu \frac{du}{dz} \quad (19-2)$$

The Bingham plastic model is well suited to homogeneous suspensions of fine particles, particularly at low rates of deformation. Experimental laboratory results of Qian and Wan (1986) and others confirm that under rates of deformation observed in the field, fluids with large concentrations of fine particles behave like Bingham plastic fluids. Huang and Garcia (1997b) extended the perturbation-technique approach first proposed by Hunt (1994) for Newtonian flows and proposed a Bingham model to estimate the run-out distance of mudflows. However, it should be clear that rheological models can only provide a first-order approximation for the purpose of modeling hyperconcentrated flows in the field. A number of non-Newtonian rheological models have been proposed for debris-flows and mudflows, including Herschel-Bulkley's viscoplastic model (Chen 1988; Liu and Mei 1989; Huang and García 1998; Imran et al. 2001). It is difficult to say which constitutive equation best represents the behavior of a mud flow.

The analysis of coarse sediment mixtures as observed in debris-flows is somewhat more complex and involves an additional shear stress due to particle-particle interaction (MacTigue 1982; Shen and Ackermann 1982; Mih 1999).

**Fig. 19-10.** Boulders deposited by debris flows in the alluvial fan of the San Julian River, Venezuela, December 1999 (from López and García 2000 with permission).

Bagnold (1954) pioneered laboratory investigations on the impact of sediment particles. He defined the dispersive shear stress  $\tau_d$  induced by the collision between sediment particles as

$$\tau_d = c_B \rho_s \left[ \left( \frac{0.615}{C_v} \right)^{1/3} - 1 \right]^{-2} D_s^2 \left( \frac{du}{dz} \right)^2 \quad (19-3)$$

where

- $C_v$  = volumetric sediment concentration;
- $D_s$  and  $\rho_s$  = sediment particle diameter and density, respectively; and
- $c_B$  = an empirical impact coefficient defined by Bagnold ( $c_B \approx 0.01$ ).

Takahashi (1980) has found experimentally that the impact coefficient ranges between 0.35 and 0.5; an order

of magnitude larger than the value suggested by Bagnold (1954).

The dispersive shear stress is shown to increase with three parameters: the second power of the particle size, the volumetric sediment concentration, and the second power of the rate of deformation. It is important to recognize that the dispersive stress is proportional to the product of these three parameters; therefore, high values of all parameters are required to induce a significant dispersive shear stress. An excellent analysis of constitutive equations for debris-flows and their applicability can be found in Egashira et al. (1997).

The non-Newtonian nature of hyperconcentrated sediment flows results from several physical processes and sediment-water mixture properties (Julien and O'Brien 1997): the cohesive yield strength  $\tau_c$ , which accounts for the cohesive nature of fine sediment particles; the Mohr-Coulomb shear  $\tau_{mc}$ , which accounts for the internal friction between grains; the viscous shear stress  $\tau_v$ , which accounts for the fluid-particle viscosity; the turbulent shear stress  $\tau_t$ ; and finally,

the dispersive stress  $\tau_d$ , which accounts for the collision of the largest particles or clasts. Then the total fluid shear stress  $\tau$  in a hyperconcentrated sediment flow results from the sum (assuming that all the shear stresses can be linearly added) of the five shear stress components:

$$\tau = \tau_{mc} + \tau_c + \tau_v + \tau_t + \tau_d \quad (19-4)$$

A quadratic rheological model has been proposed by O'Brien and Julien (1985) and Julien and Lan (1991), which describes the flow continuum through the range of sediment concentrations for these shear stresses. When written in term of shear rates, or velocity gradient  $du/dz$ ,  $\tau_{mc}$  and  $\tau_c$  are independent of velocity gradient,  $\tau_v$  varies linearly with velocity gradient, and both  $\tau_t$  and  $\tau_d$  vary with the second power of the velocity gradient. The resulting quadratic constitutive equation is given by

$$\tau = \tau_y + \mu_m \frac{du}{dz} + \zeta \left( \frac{du}{dz} \right)^2 \quad (19-5)$$

where

$\tau_y = \tau_{mc} + \tau_c$  = yield stress;  
 $\mu_m$  = dynamic viscosity of the sediment-water mixture;  
 and  $\zeta$  = the turbulent-dispersive parameter. The last term of the quadratic model combines the effects of turbulence with the dispersive stress induced by the inertial impact of sediment particles. Combining the conventional expression for the turbulent stress in sediment-laden flows with Bagnold's dispersive stress gives

$$\zeta = \rho_m l_m^2 + c_B \rho_s \lambda_B^2 D_s^2 \quad (19-6)$$

where

$\rho_m$  and  $l_m$  = the mass density and mixing length of the mixture, respectively;  $D_s$  and  $\rho_s$  = sediment particle diameter and density, respectively;  
 $\lambda_B$  = Bagnold's linear sediment concentration (defined below);

and

$c_B$  = Bagnold's empirical impact coefficient ( $c_B \approx 0.01$ ). The mass density of the mixture,  $\rho_m$ , is calculated from  $\rho_m = \rho + (\rho_m - \rho)C_v$ , where  $C_v$  is the volumetric sediment concentration and  $\rho$  is the density of water. Bagnold's (1954) linear sediment concentration is estimated as

$$\lambda_B = \frac{1}{\left( \frac{0.615}{C_v} \right)^{1/3} - 1} \quad (19-7)$$

Viscosity  $\mu_m$  and yield stress  $\tau_y$  have generally been explained through increasing exponential functions of the volumetric

sediment concentration (Julien 1995; Lorenzini and Mazza 2004). O'Brien and Julien (1988) measured the rheological properties of natural silt and clay mudflow deposits from the Colorado Rocky Mountains. The yield stress and the viscosity increase by three orders of magnitude as the volumetric concentration increases from 0.10 to 0.40.

It is important to consider that the occurrence of granular debris-flows as prescribed by a dispersive stress relationship alone requires that the following three conditions be simultaneously satisfied: the flow has (1) very large sediment concentrations, typically  $C_v > 0.5$ ; (2) large velocity gradients, typically exceeding  $100 \text{ s}^{-1}$ ; and (3) very large sediment particles, typically coarser than 5% of the flow depth.

Yield stress is a factor that not only influences debris-flow mobilization, but also is indirectly connected to the resistance that causes stoppage in the final stages of movement. During experiments one can observe that yield stress is always higher for initiation of motion than the corresponding values in stoppage conditions. Thus the yield stress presents a certain form of hysteresis, which must be considered in forecasting the overall distance covered by a debris-flow (*runout*) for a given topography (Contreras and Davies 2000). In fact, by using the yield stress associated with initiation of motion in a runout-distance forecasting model, one is likely to seriously underestimate it.

### 19.3.4 Dimensionless Rheological Model

To establish a rheological classification for hyperconcentrated flows, Julien and Lan (1991) and Julien and O'Brien (1997) proposed a dimensionless formulation of the quadratic rheological model presented above (Eq. 19-5) in the form

$$\tau^* = 1 + (1 + T_d^*) c_B D_v^* \quad (19-8a)$$

in which the three dimensionless parameters  $\tau^*$ ,  $D_v^*$  and  $T_d^*$  are defined as follows:

1. Dimensionless excess shear stress

$$\tau^* = \frac{\tau - \tau_y}{\mu_m \frac{du}{dz}} \quad (19-8b)$$

When  $\tau^* = 1$ , the mixture behaves as a Bingham fluid.

2. Dimensionless dispersive—viscous ratio

$$D_v^* = \frac{\rho_s \lambda_B^2 D_s^2}{\mu_m} \left( \frac{du}{dz} \right) \quad (19-8c)$$

This is essentially the Bagnold number (Hanes and Bowen 1985). When  $D_v^*$  is large, the flow is dispersive; when  $D_v^*$  is small, it is viscous.

## 3. Dimensionless turbulent-dispersive ratio

$$T_d^* = \frac{\rho_m l_m^2}{c_B \rho_s \lambda_B^2 D_s^2} \quad (19-8d)$$

When  $T_d^*$  is large, the flow is turbulent; when  $T_d^*$  is small, it is dispersive.

Julien and Lan (1991) tested the dimensionless model and the results are in agreement with the data sets from Bagnold (1954), Govier et al. (1957), and Savage and McKeown (1983), as shown in Fig. 19-11. The quadratic model is valid for all values of the parameter  $D_v^*$  and reduces to the Bingham model when  $D_v^* < 30$  and to turbulent-dispersive formulations when  $D_v^* > 400$ .

The transition between grain-flow and fluid-mud is not easy to characterize, even in the realm of laboratory experiments (Parsons et al., 2001). Thus the limiting conditions should be used with caution in trying to distinguish between *mudflows* and *debris-flows*.

To relate the parametric delineation to the classification of hyperconcentrated sediment flows, the following guidelines are suggested (Julien and O'Brien 1997):

1. *Mud-flows* occur when the turbulent shear stress is dominant, as given by  $D_v^* > 400$  and  $T_d^* > 1$ ;
2. *Mudflows* occur when yield and viscous stresses are dominant, as given by  $D_v^* < 30$ ;
3. *Debris-flows* or *granular flows* are expected when the dispersive stress is dominant, as given by  $D_v^* > 400$  and  $T_d^* < 1$ .

A transition regime exists in the parameter range  $30 < D_v^* < 400$ , for which all the terms of the quadratic equation are not negligible. A series of examples showing the relative magnitudes of these terms can be found in Julien (1995).

Coussot et al. (1998) have proposed a laboratory test to obtain the rheological characteristics of a debris-flow that occurred on Moscardo Torrent, Italy. They added successively coarser particles obtained from the debris-flow deposits to clear water. At each addition different suspensions were obtained and tested with different rheometric

Fig. 19-11. Comparison of dimensionless model with Experimental Data (from Julien and Lan, 1991 with permission).

techniques, such as a laboratory rheometer, inclined plane test, a large-scale rheometer, and field tests. The behavior was found to be viscoplastic and well represented by a Herschel-Bulkley model (Huang and Garcia, 1998). Schatzmann et al. (2003) have presented a new rheometer, the ball measuring system, to determine the behavior of fluids with large particles. In the absence of direct rheological measurements, Locat (1997) has shown that the liquidity index can provide a good first approximation for both mixture viscosity and yield stress of fine-grained mud flows. Bin and Huilin (2000) have advanced a methodology to determine the rheological properties of debris flows in the field which is similar to the one proposed earlier by Phillips and Davies (1991).

## 19.4 ALLUVIAL FAN FLOODING AND SEDIMENTATION

### 19.4.1 Introduction

It is generally acknowledged that the delineation of flood hazards and the design of flood mitigation structures in the semi-arid and arid western United States, and in similar environments throughout the world, is more difficult than in the humid areas of the country. The primary reason is that the southwestern United States remains sparsely settled, and most of the population and economic growth is concentrated in a few widely separated urban areas. Further, most of the development in the Southwest has taken place over the last five decades. Given this pattern of economic and population development and the episodic nature of precipitation and runoff events, few precipitation or flow gauges have records that could be characterized as either long-term or reliable; see, for example, French (1989). Also, flooding in the arid environment is less dependent on the magnitude of the event and more dependent on the ferocity, quickness, and sheer volume of materials moved. Compounding these challenges is that much of the development in arid environments has taken place on alluvial fans, which are complex landforms where ephemeral channels may be neither well-defined nor stable.

The classic definition of an alluvial fan (Doehring 1970) is

“An alluvial fan is a relatively thick deposit of coarse, poorly sorted, unconsolidated, clastics found as a semi-conical mass whose apex is adjacent to a mountain front. It has a relatively smooth subaerial surface which declines away from the mountain front.”

From the viewpoint of hydraulic engineering, a more descriptive definition by the U.S. Federal Emergency Management Agency (FEMA) of an alluvial fan (Federal Register 1989) is

Alluvial fans are geomorphic features characterized by cone- or fan-shaped deposits of boulders, gravel, sand,

and fine sediments that have been eroded from mountain watersheds, and then deposited on the adjacent valley floor. Flooding that occurs on an active alluvial fan is characterized by fast-moving debris and sediment laden shallow flows. The paths followed by these flows are prone to lateral migration and sudden relocation to other portions of the fan. In addition, these fast moving flows present hazards associated with erosion, debris-flow, and sediment transport.

The FEMA definition itemizes the hydraulic processes expected to occur on a generic alluvial fan from an engineering viewpoint, and this definition makes it clear that flood hazards on alluvial fans are due to a wide range of hydraulic processes that involve sediment movement and transport. Many of these processes are not yet well-quantified. Finally, Schumm et al. (1996), in a study of alluvial fan flooding for the National Research Council (NRC 1996a), proposed the following definition:

“Alluvial fan flooding is a type of flood hazard that occurs only on alluvial fans. It is characterized by flow path uncertainty so great that this uncertainty cannot be set aside in realistic assessments of flood risk or in the reliable mitigation of the hazard. An alluvial fan flooding hazard is indicated by three related criteria: (a) flow path uncertainty below the hydrographic apex, (b) abrupt deposition and ensuing erosion of sediment as a stream or debris-flow loses its competence to carry material eroded from a steeper, upstream source area, and (c) an environment where the combination of sediment availability, slope, and topography creates an ultra hazardous conditions for which elevation on fill will not reliably mitigate the risk.”

An alluvial fan is a surface attempting to reach equilibrium with the long-term spectrum of precipitation and runoff events and will attempt to reach a new equilibrium in response to deviations from the existing surface. Engineers, primarily trained in temperate environments, often attempt a comprehensive control of the drainage—sediment transport problem without developing an appreciation of the geomorphologic viewpoint of the situation (Schick 1974; French and Keaton 1992; Keaton et al., 1990).

#### 19.4.2 Background

Although the data on flow and precipitation in arid environments are generally sparse, the anecdotal record is replete with examples of the clear-water and sedimentation hazards associated with development on alluvial fans (McPhee 1989b). For example, in 1983, there was landslide-induced flooding at Ophir Creek, Nevada (Glancy and Bell 2000). Ophir Creek is a small, elongated watershed with an area of approximately 11.7 km<sup>2</sup> (4.5 mi<sup>2</sup>) terminating in an alluvial fan. The total sediment deposited during this event was approximately

555,000 m<sup>3</sup> (450 ac-ft), and the flood surge was estimated to have a peak flow of approximately 1,400 m<sup>3</sup>/s (50,000 ft<sup>3</sup>/s). A wall of boulders, mud, trees, and water, 9 m (30 ft) high by 30 m (100 ft) wide destroyed structures outside of the estimated 100-yr regulatory floodplain; one life was lost.

Common sense, given the magnitude of these estimates, suggests that this was an extreme event; however, the historical record suggests a different answer. From the historical record, Glancy and Bell (2000) discovered that significant flooding had taken place on the Ophir Creek alluvial fan in 1874, 1875, 1890, 1907, 1937, 1943, 1950, and 1963. It would appear that this single event in 1983 confirms the old adages that those who fail to learn from history are destined to repeat it. This 1983 event was recorded because it took place along a major transportation alignment in the proximity of two major urban areas. It is unknown how many similar or larger events took place in the arid and semiarid areas of the world in 1983 and were not recorded or even noticed.

From the definitions of an alluvial fan presented previously, it is important to note that alluvial fans are not features unique to the arid environment. Rather, alluvial fans are ubiquitous to all climatic environments (see Fig. 19-12 of alluvial fans in Venezuela), which leads to the following observations:

1. The interest of engineers and geologists in alluvial fans in arid and semiarid environments may be due to their prominence in these environments given the lack of vegetation and state of preservation due to the episodic nature of precipitation and runoff. For example, Anstey (1965) estimated that alluvial fans constitute approximately 30% of the land area in the southwestern United States.
2. The current and anticipated rates of development on these landforms throughout the world demand that adequate and cost-effective flood mitigation be provided to residents and property owners.
3. There are significant differences between the FEMA and geological definitions of alluvial fans. As noted by French et al. (1993), the regulatory definition itemizes the hydraulic processes that may occur on an *engineering time scale*, whereas the geological definition focuses on the process that led to the shape and location of the landform on a *geological time scale*. This contradiction of definitions is appropriate given that the engineer is concerned with an analysis of structures on an engineering time scale, whereas the geologist is concerned with the geomorphic processes that resulted in the landform regardless of time scales.

The foregoing observation leads to the conclusion that when an analysis of flood flows on an alluvial fan is undertaken, the engineer must be sensitive to the processes that are active on the landform under current, engineering time scales, but also should be very aware of the geomorphic processes that continually form and reform the alluvial fan.

**Fig. 19-12.** SPOT Satellite images taken before and after the events of December 1999 of the alluvial fans in San Julián (above) and Carmen de Uria (below), Venezuela.

As Parker (1999) noted, the disparity between the engineering and geological time scales on alluvial fans can lead to significant misunderstandings regarding risk. For example, the fan-delta system on the Mississippi River south of Baton Rouge has avulsed several times to form multiple deltaic lobes over the past 5,000 years. However, over the lifetime of one engineer there was likely no change, which gives the illusion of stability (Parker 1999). It is pertinent to note that a lay discussion of this particular issue is provided in McPhee (1989a).

#### 19.4.3 Early Developments

Attention to and focus on alluvial fan flooding and sedimentation issues in the engineering literature began with the publication of a probabilistic approach to identify regulatory flood hazard on alluvial fans (Dawdy 1979). The work by Dawdy was partially based on earlier results regarding channels formed by rare flood events on the surfaces of alluvial fans in the Albuquerque, New Mexico area, which were subsequently published (Magura and Wood 1980). These initial approaches to identifying flood hazard on alluvial fans were followed by others (*e.g.*, Edwards and Thielman 1984), and the establishment, by the regulators (*e.g.*, FEMA 1985), of guidance specifically for the evaluation of flood hazard on alluvial fans. These early papers dealt exclusively with the clear-water hazard on alluvial fans and did not incorporate the work and knowledge that the geoscience community had gained from decades of studying sediment processes on these landforms. Also, they

did not acknowledge that not all alluvial fans are active alluvial fans and that sound engineering judgment and new technical approaches were required to properly evaluate the clear-water and sediment hazard issues on these landforms.

The original FEMA (1985) approach to delineating flood hazard on alluvial fans contained the following key assumptions: (1) alluvial fan flooding is conveyed at critical depth in flow-formed channels governed by regime equations of depth, velocity, and discharge at the apex; (2) the location of the flood channel is unpredictable; (3) topographic relief and urbanization on the fan are minimal; and (4) the hazard is due only to clear-water flows. These and other implied assumptions were discussed by French (1987). In the view of many competent professionals, this generic approach to alluvial fan flood hazard incorporated assumptions that were not valid on all alluvial fans and, in some cases, had been misapplied (*e.g.*, Fuller 1990; Pearthree 1991; and Pearthree et al. 1991). This controversy over the use of a generic model to identify alluvial fan flood hazards led the Flood Control District of Maricopa County, Arizona (FCDMC), to undertake a study of alluvial fans (FCDMC 1992). The results of this study were published in French et al. (1993). The measurable characteristics and expected hydraulic processes during flood events on the types of alluvial fans identified during the FCDMC study are shown in Tables 19-4 and 19-5.

The early studies neglected the need to address not only clear water but also water transporting a wide range of sediment loads. Dependent on the concentration of sediment relative to the water, flood flows on an alluvial fan can be

**Table 19-4 Measurable Alluvial Fan Characteristics**

Active alluvial fan	Distributary flow system	FEMA alluvial fan	Inactive alluvial fan
Abandoned discontinuous channels	Discontinuous channels	Continuous channels	Continuous channels
Channel capacity decreases downstream	No definite trend in channel capacity	Cummulative capacity constant downfan	Channel capacity increases downstream
Channel flow changes to sheetflow	Channel and sheetflow	Channelized flow (no overbank or sheetflow)	Channelized flow (overbank flow possible)
Debris-flow possible	Minor (or no) debris-flow	Debris-flow important	No debris-flow
Frequent channel movement	Rare channel movement	Unpredictable channel location	Stable channels
Low channel capacity	Variable channel capacity	Channel capacity equals flow rate	High channel capacity
No calcrete	Calcrete horizons possible	No calcrete	Calcrete horizons
No (or buried) desert varnish	Varnished surfaces possible	No (or buried) desert varnish	Varnished surfaces possible
No surface reddening of soils	Minor reddening of soils	No surface reddening of soils	Surface reddening of soils
Overall deposition	Local erosion and deposition	Overall deposition	Overall erosion
Radiating channel pattern changes to sheetflow area	Radiating channel pattern changes to tributary	Single or multiple channels	Tributary drainage pattern
Slope decrease downstream	Slope increase at apex	Slope not a factor above bifurcation point	Slope variable
Stream capture or avulsions?	Channel movement by stream capture	Channel movement by avulsions	No channel movement
Uniform topography (low crenulation index)	Medium to low topographic relief (medium to low crenulation index)	Uniform topography (low crenulation index)	Topographic relief (high crenulation index)
Uniform vegetation in floodplain	Diverse vegetative community	Uniform vegetation in floodplain	Diverse vegetative community
Variable channel geometry	Variable channel geometry	Regular channel geometry	Regular channel geometry
Weak soil development	Variable soil development	Weak soil development	Strong soil development

*Note:* In a specific application not all of the characteristics noted may be present.

a fluvial flow, a hyper-concentrated flow, a mudflow, or a debris-flow; and in each of these situations a different modeling approach is required.

#### 19.4.4 Current Developments

In response to the controversies raised over the use and misuse of the probabilistic method of identifying flood hazards promulgated in FEMA (1991), the National Research Council undertook a study of alluvial fan flooding (NRC 1996a). Although the report provides valuable data and insights, there are many issues that may be unresolved. In particular, the report relied mainly on the experience of the geosciences community but did not take full advantage of the valuable experience available in the engineering community. It is clear that cooperative input from both the geosciences and engineering fields is necessary to effectively study and analyze alluvial fan flooding. The NRC report did not consider also

the alluvial fan development situation in what was then, and remains, one of the fastest growing, and most arid states in the United States—Nevada. It is in this state where alluvial fans are currently both primary engineering research and legal issues. The U.S. Department of Energy, Nevada Operations Office, has likely dedicated more resources to identifying and evaluating flood hazards on alluvial fans and arid region hydrology than most other Federal Agencies combined.

In addition, there are now two-dimensional models available for modeling flows on alluvial fans. FLO-2D (O'Brien 1999) is a two-dimensional hydrodynamic model designed for both clear water and sediment-laden flood flows on alluvial fans. An application of FLO-2D by Bello et al. (2003) is presented later in *section 19.6.3.6* of this chapter. Important new experimental-field scale advances regarding alluvial fans have also been recently published; for example by Parker et al. (1998a and 1998b) and Whipple et al. (1998). Progress has also been made with the linking of channel process with

**Table 19-5 Expected Hydraulic Processes during Flood Events**

Active alluvial fan	Distributary flow system	FEMA alluvial fan	Inactive alluvial fan
Channel movement possible	Channel movement rare	Unpredictable channel location	Channel location stable
Channel, overbank, and sheetflow	Channel, overbank, and sheetflow	All flow channelized	Channel, overbank, and sheetflow
Debris-flows important	Debris-flows not important	Debris-flows not considered	Debris-flows not important
Flows along existing and new channels	Flows along existing channels	Flow cuts new channel	Flow along existing channel
Flow attenuation	Flow attenuation	No flow attenuation	Flow attenuation likely
Net deposition on surface	Local deposition and erosion	Deposition not considered	Net erosion on surface
On-fan watershed flooding	On-fan watershed flooding	On-fan watersheds not considered	On-fan watershed flooding
Probable sediment bulking	Probable sediment bulking	No sediment bulking	Probable sediment bulking
Stream capture or avulsions?	Rare stream capture or avulsions	Channel movement by avulsions	No avulsions
Topography influences flow	Topography influences flow	Flow not affected by topography	Topography controls flow

*Note:* In a specific application not all of the characteristics noted may be present.

large-scale morphodynamic changes in fluvial fan-deltas such as the Mississippi delta (Sun et al., 2002) as well as in the use of physical models to assess flooding risks in alluvial fans (Cazanacli et al., 2002) and the limitations of such physical models (French and Miller, 2003). Physical modeling of sedimentation processes is addressed in *Appendix C-Sediment Transport Scaling for Physical Models* of this manual.

#### 19.4.5 Conclusions

Although much has been done regarding the accurate and reliable definition of flood hazard on alluvial fans on an engineering time scale, still much remains to be accomplished. For example, even the basic definition of an engineering time scale remains to be defined. French et al. (1993) arbitrarily defined an engineering time scale to be 1,000 yr or less and a geologic time scale to be 10,000 yr or more. Although this definition provides a 9,000 yr difference, it is pertinent to observe that in the arid environment, engineers may be required to predict, given Federal requirements, the performance of flood mitigation structures for up to 10,000 yr. From the engineering viewpoint, predicting the performance of facilities 10,000 yr into the future involves pure speculation; however, under regulatory guidance specific to some types of waste management sites, this period is considered an engineering time scale. For example, by definition, an alluvial fan is an aggradational landscape feature on a geologic time scale; however, there are no guarantees that a channel could not be incised through a facility in response to a major event that occurs within an engineering time period,

given that the facility design period (or likelihood of a rare event that has the same probability of occurring) may be up to 10,000 yr. That is, the Dawdy (1979) or random channel movement across an alluvial fan surface is correct on a geologic time scale, which accounts for the symmetrical depositional shape of the fan.

The challenge facing the research community is that of producing results that are useful to the regulators, the practitioners, and the public. Modern researchers in engineering and science have to understand the need to show how their results relate and pertain to a larger world. At the same time, regulators ought to become more flexible and use good engineering judgment rather than rigidly adhering to a single approach to defining flood hazard on alluvial fans. The need to move away from rigidity was one of the recommendations of Schumm et al. (1996) that struck a common cord in the professional community.

The engineering community has to remember that alluvial fan flooding is a cutting-edge technology. Hazard evaluations in this field require field investigations by engineers together with colleagues who have expertise in geosciences and risk analysis. As shown above, it is also very important to search for historical records that might help in conducting flood hazard risk analysis. The accurate identification of flood hazard and mitigation of flood hazard on alluvial fans must be a shared experience between the engineers, geologist and geomorphologists to ensure that the public will be afforded the best technologically feasible level of protection and to avoid potential litigation issues. Readers can find more material on alluvial fans in Chapter 18, *Engineering Geomorphology*, while legal issues associated with flood

and sedimentation hazards are addressed in Chapter 20—*Sedimentation Law*.

## 19.5 METHODS TO MITIGATE THE CONSEQUENCES OF SEDIMENTATION HAZARDS

### 19.5.1 Background

Reliable assessment and mitigation of hydraulic and sedimentation hazards depend on the engineers' ability to understand and describe in written and mathematical forms the physical processes that govern the fluvial system they are dealing with. As presented under 19.2, *Sedimentation Hazards—History and Magnitude*, significant hazardous conditions and natural disasters associated with sedimentation processes have occurred throughout recorded history. Today, however, engineers and scientists have greater access to data, information, and knowledge regarding where, when and how such events may occur. New procedures and mathematical modeling tools have evolved as aids to better assess present conditions and forecast future conditions. However, it must be recognized that the present state-of-the-science and our understanding of mobile boundary hydraulic processes related to different types of sedimentation hazards and mud and debris-flow processes are still limited. Exacerbated by our having few or no measured field data, these complex processes often evade theoretical attempts to characterize flow depth, location, orientation, velocity, sediment- and debris carrying capacity, and event predictability with a high degree of accuracy.

Methods for assessing and mitigating the consequences of severe sedimentation hazards, including mud and debris-flows, fall into three general approaches and levels of effort:

- *Hazard mapping and avoidance*—e.g., perform a hazard mapping study and have people not live there if it is mapped as a likely hazard zone; or if people already live there, help them to understand the risk and require that they buy hazard insurance. This approach focuses on avoidance of hazards, not mitigation.
- *Apply currently accepted hazard assessment and mitigation design procedures*; e.g., if you wish to develop in a hazard zone, apply currently accepted assessment procedures to define hazards and their levels of risk, and then apply appropriate design procedures to develop structural or nonstructural methods for mitigating the hazards.
- *Apply new state-of-the-science procedures*; e.g., if you wish to evaluate the risk of hazards or wish to develop in a hazard zone, you may elect to apply innovative methods including hazard forecasting, risk assessment, and process-simulation modeling and apply new design concepts to mitigate the hazards. New mitigation methods may include structural, nonstructural,

or bio-technical procedures or a combination of these methods.

### 19.5.2 Hazard Mapping

Prior to the mid-1990's, there was very little guidance available for evaluating site-specific conditions or the mapping of flood hazards on alluvial fans or of hazards directly related to ultrahazardous sedimentation processes. As of the year 2000, however, hazard-mapping procedures predominantly follow those supported and documented by the Federal Emergency Management Agency (FEMA 1990; 1995; 2000), Federal Register (1989) guidelines and the National Research Council (NRC 1996a). FEMA prepares Flood Insurance Rate Maps (FIRMS) of flood hazard areas based on the results of Flood Insurance Studies (FIS). Those studies determine the areas with a 1% annual chance of being inundated (by water). The flood is called the *base* (100-year) *flood* by FEMA. The FIS must evaluate the existing flood conveyance system, including installed flood-control measures. Determination of the inundated area may depend on whether flood-control measures protect part of the floodplain. With increased development in the United States and other countries of the world, more people are being exposed to extreme flood hazards associated with flash floods, mud and debris-flows, high flow velocity, channel avulsion, severe erosion, and channel migration and episodic alluvial fan processes. FEMA (2000) recently expanded their guidance regarding the identification and mapping of traditional flood hazards to include procedures for flood hazards occurring on alluvial fans, *irrespective of the level of fan-forming activity* (see Section 19.4).

### 19.5.3 Currently Accepted Hazard Assessment and Mitigation Design Procedures

Most *accepted* assessment and design procedures depend on empiricism, experience, field observation, and the application of traditional clear-water assessment methods that have been modified to account for flow bulking, sediment dynamics, and the unpredictable and often episodic nature of sedimentation processes leading to hazardous flow conditions. These accepted practices have come into general usage because of their simplicity and relative accuracy. Accepted practices used primarily for the design of flood control channels are emphasized in this chapter. The most accepted and best documented sediment hazard assessment and design procedures are documented by the following federal agencies: the U.S. Army Corps of Engineers (USACE 1989; 1991; 1993; 1994), the HEC (1993), the Federal Highway Administration (FHWA, 2001), and the U.S. Department of Agriculture (1992; 1996). In the relatively new area of evaluating significant sedimentation hazards, and mud and debris-flows, sufficient time and proven testing has not yet occurred for accepted design practices to emerge.

### 19.5.4 State of the Science Procedures

New state-of-the-science procedures are often related to new computer simulation models or untested design concepts that may implement hybrid techniques, bio-technical flow diversion or stream stabilization measures. In such cases, the latest research has not yet been fully tested or documented sufficiently to become general practice. State-of-the-science procedures can be applied, but they, as well as the accepted practices, need to be thoroughly checked against real data and a reasonable range of possible hazard scenarios to cover all likely sedimentation and flow conditions the project area may experience during its lifetime. New procedures are most often presented in technical and trade journals or conference proceedings. For the most part these newly developed procedures are relatively untested and have not yet become general practice.

The following discussions are aimed at providing guidance to engineers and flood-hazard managers for planning and assessing the adequacy of flood-control measures exposed to significant sedimentation hazards and mud and debris-flows. This section is not intended to be a design manual for mitigation of sedimentation problems. It is intended to summarize general procedures for assessing flood hazards and for developing reasonable mitigation alternatives. A following section will list several accepted methods for hazard mitigation. Readers should also read Chapter 20—*Sedimentation Law*, for recent interpretations of pertinent court decisions regarding standards of practice and prudent levels of assessment and design.

### 19.5.5 General Approach

The following general approach is suggested to assess and develop sedimentation hazard mitigation alternatives. The approach consists of three phases of work:

#### Phase 1: Problem identification, preliminary assessment and design

- Perform site assessment and geomorphic analysis of project area
- Define hydrologic, hydraulic and sedimentation processes and hazards
- Perform surveys and hazard mapping if required
- Develop preliminary alternatives for hazard mitigation
- Perform preliminary engineering and environmental evaluation of alternatives for hazard mitigation
- Initiate the regulatory and environmental process
- Perform screening of preliminary alternatives to select a preferred alternative(s)
- Perform feasibility level design of preferred alternative(s)
- Prepare draft environmental documents (EIR and/or EIS)
- Seek public involvement and consensus

#### Phase 2: Prepare plans, specifications, and estimates (PS&E) along with CEQA/NEPA documentation and permitting

- Perform detailed design and environmental analyses
- Prepare final plans and specifications
- Prepare cost estimates
- Prepare final CEQA and NEPA documentation
- Respond to public comments
- Define project-related mitigation requirements
- Obtain regulatory permits
- Finalize project authorization and funding

#### Phase 3: Project construction, project mitigation, and monitoring

- Construct project
- Perform project-related mitigation
- Initiate project monitoring program

Phase 1 is perhaps the most important phase because it must identify the underlying physical processes affecting the site and properly define existing and potential hazards as well as other project constraints related to regulatory or environmental concerns if mitigation activities were to occur. It is essential that hazard mitigation alternatives not only reduce or eliminate identified hazards, but also not result in the initiation of other problems or impacts for areas upstream or downstream of the proposed project site (channel stability, scour, and significant changes in the hydrologic regime, environmental impacts, or significant project maintenance requirements). It is, therefore essential to perform a thorough regional assessment of the area's geomorphology, hydrology, hydraulics and sedimentation characteristics and compare those *existing* (baseline) *characteristics* to proposed *with-project conditions* to avoid project-induced impacts. MacArthur, et al., (1993) recommend that "reliance and single all-purpose model or computer program should be avoided," and they outline 14 elements of a multi-phased modeling and assessment approach for evaluating special sediment hazards. Environmental regulations require equal detail regarding the evaluation of potential impacts on the environment or endangered species.

### 19.5.6 Guidance

Detailed guidance on how to conduct planning and design studies for mitigation of flood hazards is found in many state and federal guidelines. Section 1–6 in the USACE (1991), manual *Hydraulic Design of Flood Control Channels (Engineering Manual 1110-2-1601)* outlines steps for conducting preliminary investigations for selection of type of improvement for mitigation of flooding hazards. The Corps emphasizes the need for careful consideration of the physical characteristics of the site, its history of flooding, and the nature of aggradation and degradation, debris transportation,

bank erosion, cutoffs, and bar formation. Other hydrologic, hydraulic, and economic aspects of the project are also important.

*Engineering Manual 1110-2-1416, River Hydraulics* (USACE 1993), states that “effective analysis of river problems requires recognition and understanding of the governing processes in the river system. There are two basic items that must always be considered in river hydraulics analyses: the characteristics of the flow in the river, and the geomorphic behavior of the river channel.” These two components are sometimes treated separately, however, in alluvial channels and floodplains (zones with movable boundaries) the flow and the shape of the boundary are interrelated. This is especially true during severe events occurring on movable boundaries such as alluvial fans.

*Engineering Manual 1110-2-4000, Sedimentation Investigations of Rivers and Reservoirs* (USACE 1989) outlines procedures for conducting staged sedimentation studies, including (1) sediment impact assessments, (2) detailed sedimentation studies, and (3) feature design sedimentation studies for the final design and location of project features. *EM 1110-2-4000* discusses the approach, data requirements, analyses, validation requirements, and design procedures for conducting thorough sedimentation investigations and designs. The manual discusses the importance of and procedures for identifying potential river sedimentation problems, and associating those problems with project purposes and presents methods for analyzing them at various levels of detail.

*Engineering Manual 1110-2-1418, Channel Stability Assessment for Flood Control Projects*, provides guidance for determining potential channel instability and sedimentation effects (potential problems) in flood control projects. “It is intended to facilitate consideration of the type and severity of stability and sedimentation problems, the need for and scope of further hydraulic studies to address those problems, and design features to promote channel stability. The concept of channel stability implies that the plan, cross-section, and longitudinal profile of the channel are economically maintainable within tolerable limits over the life of the project” (USACE 1994). Principles of stability and the causes and forms of instability and sedimentation problems are discussed.

The HEC (1993) prepared a report for the Federal Emergency Management Agency on *Assessment of Structural Flood-Control Measures on Alluvial Fans*. The report summarizes key geomorphic aspects of alluvial fans and discusses their unique hydrologic and hydraulic characteristics. It also discusses the effects of channel avulsion, occurrence of mud and debris-flows, channel incision or entrenchment, and an alluvial fan’s capacity to carry and deposit sediments during various flood events. The Flood Insurance Administration requires an assessment of the effectiveness of various structural approaches to flood control in alluvial fan special flood hazard areas (SFHAs),

(HEC, 1993). This report documents how installed flood-control measures have performed during major floods and presents current methods for assessing the performance and adequacy of the measures. HEC did not investigate nonstructural measures or procedures for mapping of alluvial fans as part of their study. The report is not intended to be a design manual. It is aimed at providing guidance to floodplain managers and engineers in assessing the adequacy of structural flood-control measures on alluvial fans (primarily improved channels, flow diversions, bypasses, and detention storage facilities) to protect against the Base Flood (HEC, 1993).

### 19.5.7 Examples of Structural Flow, Sediment and Debris Management Measures

HEC (1993) presents several case studies of flooding problems and in some cases, failures of flood-control project features that were exposed to high flow, sedimentation, and/or mud- and debris-flow conditions. Types of bank protection, flow diversion, and debris and sediment management measures include the following:

#### Bank Protection Works:

- Works designed to stabilize erodible channel banks and protect them from high-energy flows
- Pipe-and-wire fences
- Riprap (dumped rock)
- Rock paving (hand-placed)
- Wire and rock mattresses
- Gunite slope paving
- Reinforced concrete open channels
- Reinforced concrete closed conduits
- Bio-technical bank stabilization and erosion control measures (see USDA 1996)

#### Debris Barriers:

- Structures, usually located in the watershed, that stop or reduce the movement of debris down the channel system
- Debris fences (typically vertical beams or rails anchored in a foundation, sometimes with wire or cable reinforcement, oriented perpendicular to expected debris-flows)
- Debris barrier walls, typically referred to as fire barriers in southern California and built across canyon mouths following fires to retard debris-flow induced by heavy rains on the burned watershed (LACFCD, 1979).

#### Crib Barriers:

- Series of check dams across a channel constructed from concrete, rock, or logs, which retard flows, capture sediment and debris, and may provide seasonal wetland areas, and help stabilize the toe of canyon side slopes (see LACFCD 1959 for sketches and designs).

**Debris Basins:**

- Facilities designed to capture, store and settle out coarse material and trash resulting from a major storm event
- Guidance for Debris Basin design may be found in (LACFD 1979)

**Sediment Traps and Sediment Retention Structures:**

- Sediment traps are constructed depressions in a channel, stream bed or floodway that encourage rapid accumulation of bed load sediments during high flows. The Corps of Engineers occasionally installs sediment traps in high bed load river systems in locations where sediment removal can be managed more effectively and with the least amount of impacts to the environment.
- Sediment retention structures (similar to debris barriers and basins) are designed to capture, store, and settle out sediment materials from major storm events. Perhaps the most documented large-scale sediment retention structure was designed and constructed by the Portland District Corps of Engineers on the Toutle River downstream of Mount St. Helens following its eruption in 1980 (HEC 1985). The structure was designed to retain annual sediment loads, as well as significant mud and debris-flows that could move down-valley from areas affected by the eruption of Mount St. Helens.

**Other Sediment Control Structures:**

- Constructed wetlands
- Vegetative filter strips and strategic planting of riparian vegetation
- Porous structures: small check dams, filter fences and straw bales

**Retention Basins:**

- Storage structures (usually uncontrolled) designed to reduce the peak flood flow from a drainage basin. Such structures can also (often by default) capture sediment and debris, which may affect their original design performance. A well-documented debris basin project with a spillway and concrete-lined flood control channel and energy dissipater is discussed by the Los Angeles District Corps of Engineers; see (USACE 1983; 1988).

**Operation of Small Dams:**

- Existing small dams also work as retention basins during large storm events unless they are operated to remain full for water supply, hydropower, or other reasons
- Outlet and storage capacity are typically reduced by sediment and debris accumulation

**Flood Control Channels:**

- Engineered works designed to pass flood flows more efficiently than natural, unimproved channels, thereby reducing flood stages.
- Unlined channels
- Lined channels
- Maintained and stabilized natural channels

**Diversions and Bypasses:**

- Constructed channels designed to provide additional flow capacity during floods, or designed to direct flows away from developed areas

**Floodwalls:**

- Vertical walls, usually constructed with reinforced concrete and typically oriented parallel to a stream or channel to prevent overtopping flows from leaving the channel and entering developed areas.

**Levees:**

- Usually constructed of earthen and rock materials, oriented parallel to the stream or channel; designed to prevent overflows into developed areas
- Single-levee projects (one side of channel only)
- Double-levee projects (both sides of channel)
- Set-back levees (levees set back on the floodplain a measurable distance from the main channel to allow controlled flows on the confined floodplain, although preventing overflows into developed areas)

**Floodwalls and Dikes:**

- Often used in conjunction with other flow or debris diversion structures
- May be placed across a channel, floodplain or alluvial fan to direct flow away from developed areas or direct flow into bypass or retention facilities

HEC (1993) discusses special problems related to sediment transport issues, including sediment accumulation, scour and debris. Evaluation and design procedures for these processes are documented in (USACE 1989; 1994). HEC (1993) also states:

“Every factor affecting the nature of flood and debris problems, plus the development and its susceptibility to flooding, affect the feasibility of flood-reduction options. There is no cookbook approach to developing an effective flood reduction project. Planning and design of flood-control (*and sediment and debris control*) structures . . . must always consider **the effect of all possible flows on the structure as well as the effects the structure may have on the flow locally and downstream.** While FIA criteria are based on the 1-percent chance flood, the proper design of any flood-control project must consider project

performance for the entire range of floods, including floods larger than the Base Flood.”

## 19.6 MATHEMATICAL MODELING OF MUDFLOWS AND DEBRIS-FLOWS

### 19.6.1 Introduction

Modeling mud flows and debris-flows has long been an interest of hydraulic and sedimentation engineers. Because of the complicated rheological structure of these flows, solving the fully dynamic equations for unsteady, non-uniform, non-Newtonian flows is still a complicated endeavor. Consequently, basic concepts of open-channel hydraulics are often applied to the simulation of mud flows. Parameters such as momentum and energy coefficients, Manning’s  $n$ , and Darcy-Weisbach resistance coefficients are usually defined with the help of velocity profiles defined by different rheological models. Such approach includes the work of MacArthur and Schamber (1986), Wright and Krone (1987), O’Brien et al. (1993), Hungr (1995), and Brufau et al. (2000), Lenzi et al (2004) and Zanutigh and Lambert (2004) among others. Literature reviews by Mainali and Rajaratnam (1991), Hutter et al. (1996), and Iverson (1997) show a great deal of work on modeling debris-flows and mud flows. However, due to the complicated composition and rheological constitutive relation of mud flows and debris-flows, a quantitative understanding of the fluid mechanics and the associated mathematics of these flows is still incomplete (Hunt, 1994; Huang and Garcia, 1997b).

From a sedimentation engineering point of view, two problems that are of particular interest: the routing of mud and debris-flows in steep mountain areas and the flooding of an alluvial fan with mud and debris (e.g. Parsons et al. 2001). These two problems are addressed here with (1) a one-dimensional kinematic-wave model (Choi and Garcia, 1993) and (2) a two-dimensional water flood and mudflow model (Bello et al. 2003).

### 19.6.2 Kinematic-Wave Approach to Debris-Flow Routing (Choi and Garcia, 1993)

**19.6.2.1 Introduction** A simple kinematic-wave model for debris-flow routing is presented. This model requires only a limited number of boundary conditions, making it suitable for the simulation of mudflows and debris-flows, for which direct observations are only rarely available. Observations of debris-flow surges at Kamikamihori Valley, Japan, are used to test the model. In spite of the crude approximations involved in the selection of values for the model parameters, reasonable agreement between observed and computed values is found. The following material is based on the analysis presented by Choi and Garcia (1993).

A similar approach was proposed also by Arattano and Savage (1992) as well as Takahashi (1991).

**19.6.2.2 Depth-Averaged Equations of Motion** The dynamic equations describing a one-dimensional, unsteady debris-flow in a wide channel, where no sediment erosion or deposition occurs are (Chen 1986)

$$\frac{\partial h}{\partial t} + \frac{\partial(h\bar{u})}{\partial x} = 0 \quad (19-9)$$

$$\frac{\partial(h\bar{u})}{\partial t} + \frac{\partial(\beta_* h \bar{u}^2)}{\partial x} = gh \sin \theta - gh \frac{\partial h}{\partial x} \cos \theta - \frac{\tau_0}{\rho} \quad (19-10)$$

Where

- $t$  = time;
- $x$  = space coordinate along downstream direction;
- $h$  = flow depth;
- $\bar{u}$  = depth-averaged velocity;
- $\theta$  = bed-slope angle;
- $\tau_0$  = bed shear stress;
- $g$  = acceleration of gravity;
- $\rho$  = density of the water-sediment mixture; and
- $\beta_*$  = momentum correction coefficient.

In principle, for a given set of boundary conditions, if the momentum correction factor could be estimated and the bed shear stress could be related to flow variables through an appropriate resistance coefficient (e.g. Darcy-Weisbach, Manning’s  $n$ ), the one-dimensional dynamic equations for unsteady water flow shown above could be applied to debris-flow routing (Schamber and MacArthur 1985; Iverson and Denlinger 2001). However, the kind of computational work involved in solving such equations requires a level of expertise that is not always at hand. Thus, simple routing schemes such as the one presented here, in spite of their limitations, can provide a useful tool (Takahashi 1991; Arattano and Savage 1992).

**19.6.2.3 Rheological Equations** To model debris-flows, a rheological model or constitutive equation for sediment-water mixture is needed. Here, the approach suggested by Chen (1988) is followed. Water-sediment mixture can be treated as a material that satisfies Coulomb’s yield criterion

$$\tau = \tau_y + \sigma \tan \phi \quad (19-11)$$

where

- $\tau$  = shear stress;
- $\sigma$  = normal stress;

$\tau_y$  = yield stress; and

$\phi$  = angle of internal friction of the mixture.

A simple rheological relation between the normal stress and shear rate is given by the semiempirical relation  $\sigma = \lambda_c (du/dz)^\eta$ , where  $\lambda_c$  is a constant of proportionality;

$u$  = longitudinal velocity component;

$z$  = direction upward normal to the bed; and

$\eta$  = exponent.

Substitution of the expression for  $\sigma$  into Eq. (19-11) gives

$$\tau = \tau_y + \mu (du/dz)^\eta \quad (19-12)$$

where

$$\mu = \lambda_c \tan \theta.$$

The parameters  $\mu$  and  $\eta$  are normally referred to as the consistency index and the flow behavior index, respectively (Chen 1988). Then, if  $\tau$  and  $\tau_y$  are expressed as  $\tau = \rho g S_0 (h - z)$  and  $\tau_y = \rho g S_0 (h - z_0)$ , respectively,

where

$z_0$  = depth corresponding to the yield stress, and

$S_0$  = bed slope,

we obtain from Eq. (19-12) the following expressions for the velocity gradient

$$du/dz = \left[ \frac{\rho g S_0 (z_0 - z)}{\mu} \right]^{1/\eta} \quad \text{for } 0 \leq z \leq z_0 \quad (19-13a)$$

$$du/dz = 0 \quad \text{for } z_0 \leq z \leq h \quad (19-13b)$$

Integrating the above equation in the  $z$ -direction normal to the bed, we have

$$u(z) = \frac{\eta}{\eta+1} \left( \frac{\rho g S_0}{\mu} \right)^{1/\eta} \frac{\eta+1}{z_0^\eta} \left[ 1 - \left( 1 - z/z_0 \right)^{\frac{\eta+1}{\eta}} \right] \quad (19-14a)$$

for  $0 \leq z \leq z_0$

$$u(z) = \frac{\eta}{\eta+1} \left( \frac{\rho g S_0}{\mu} \right)^{1/\eta} \frac{\eta+1}{z_0^\eta} \quad \text{for } z_0 \leq z \leq h \quad (19-14b)$$

Using the expression for  $u$  in the two regions, an equation for the depth-averaged velocity is obtained, as follows:

$$\bar{u} = \frac{1}{h} \int_0^h u(z) dz = \frac{\eta}{\eta+1} \left( \frac{\rho g S_0}{\mu} \right)^{1/\eta} (i)^\frac{\eta+1}{\eta} \left[ 1 - \frac{\eta}{2\eta+1} i \right] h^\frac{\eta+1}{\eta} \quad (19-15)$$

In this equation, the parameter  $i = z_0/h$ , indicates the relative strength of the yield stress  $\tau_y$  against the bed shear stress  $\tau_0$ .

A data base on experimental observations of non-Newtonian, open-channel flow can be found in Haldenwang and Slatter (2006). It could be used to estimate the parameters of the model presented above as well as the assumptions made in its derivation.

**19.6.2.4 Kinematic Wave Approximation** The kinematic wave approximation is frequently used in open-channel flow routing when the inertial and pressure terms in the momentum equation can be neglected with respect to others. In steep mountain streams, where mud and debris-flows take place, backwater effects are negligible, so this approximation is quite reasonable. The main advantages of using a kinematic wave model are not only the simplicity of the equation itself but also the number of boundary conditions needed. The hyperbolic nature of the dynamic equations requires upstream and downstream boundary conditions, which in the case of catastrophic events such as debris-flows are only rarely available. Because the mean flow velocity  $\bar{u}$  has been expressed as a function of the flow depth  $h$  in Eq. (19-15), it is possible to introduce the kinematic wave approximation for debris-flow routing by expressing the specific flow discharge  $q = \bar{u}h$  as

$$q = \alpha h^\beta \quad (19-16)$$

where

$$\alpha = \frac{\eta}{\eta+1} \left( \frac{\rho g S_0}{\mu} \right)^{1/\eta} (i)^\frac{\eta+1}{\eta} \left[ 1 - \frac{\eta}{2\eta+1} i \right] \quad (19-17a)$$

and

$$\beta = \frac{2\eta+1}{\eta} \quad (19-17b)$$

Substitution of Eq. (19-16) into Eq. (19-9) yields

$$\frac{\partial h}{\partial t} + \alpha \beta h^{\beta-1} \frac{\partial h}{\partial x} = 0 \quad (19-18)$$

For the numerical solution of Eq. (19-18), the algorithm proposed by Li et al. (1975), which consists of a second-order nonlinear scheme combined with a linear scheme, can be used. The nonlinear scheme ensures convergence, whereas the linear portion of the scheme speeds up the computations. This numerical scheme is unconditionally stable and conserves mass. Time and space derivatives are approximated by using a forward time and centered space (FTCS) scheme, and  $h = (h_{j+1}^n + h_j^{n+1})/2$  is used in Eq. (19-18). Then, a finite-difference equation for a linear kinematic wave is obtained as follows:

$$\frac{h_{j+1}^{n+1} - h_{j+1}^n}{\Delta t} + \alpha \beta \left( \frac{h_{j+1}^n + h_j^{n+1}}{2} \right)^{\beta-1} \left( \frac{h_{j+1}^{n+1} - h_j^{n+1}}{\Delta x} \right) = 0 \quad (19-19)$$

By solving Eq. (19-19), values of  $h_{j+1}^{n+1}$  can be obtained explicitly, which, in turn, can be used as initial estimates in the application of the nonlinear portion of the algorithm. For the nonlinear algorithm, one can use  $h_{j+1}^{n+1}$  directly. Then the finite-difference form of Eq. (19-18) becomes

$$\frac{\Delta x}{\Delta t} h_{j+1}^{n+1} + \alpha (h_{j+1}^{n+1})^\beta = \left( \frac{h_{j+1}^{n+1} - h_j^{n+1}}{\Delta x} \right) = \frac{\Delta x}{\Delta t} h_{j+1}^{n+1} + \alpha (h_j^{n+1})^\beta \quad (19-20)$$

where all the values on the right-hand side of Eq. (19-20) are known. This is a nonlinear equation in  $h_{j+1}^{n+1}$ ; therefore a numerical technique such as the Newton-Raphson algorithm can be used to solve it. This numerical solution was verified by Choi and García (1993) with the help of an analytical expression for a simple kinematic wave given by Whitham (1974).

In mountain areas, where slopes are pronounced, back-water effects are negligible and the kinematic wave approximation can be expected to work quite well for the routing of mudflows and debris flows. Rickenmann (1991) has proposed an experimentally-derived equation to estimate sediment transport by hyperconcentrated flows (fine-material slurry) on steep slopes (larger than 10%) than can be readily adapted for use with the approach presented above to estimate the propagation of sediment waves.

**19.6.2.5 Model Application** Data collected by Japanese scientists in the mountainous area of the Yakedake volcano were used to apply the kinematic wave model. Among the data collected, the first surge of debris-flows on July 21, 1985 at Kamikamihori Valley was used (Suwa 1989). A longitudinal view of Kamikamihori valley is shown in Fig. 19-13. To measure hydrologic and hydraulic parameters, on-line

systems were installed. Flow rate, maximum flow depth, and surface velocity were recorded at dam #6. According to the observed data, the frontal velocity ranged between 10 and 20 m/s in the upper reaches of the valley, where the slope angle is 20 to 30°. At the downstream end, the frontal velocity had a smaller value of 1 to 10 m/s. The bulk density of the debris mixture was between 1.5 and 2.0 tn/m<sup>3</sup>, corresponding to volume concentrations of solid particles between 40 and 80%.

For the upstream boundary condition, a simple step function was assumed, as shown in Fig. 19-14. The duration time was determined by trial and error after the calculated discharge was compared with the observed one. The longitudinal domain was discretized into 13 intervals according to the main surveying points, which are shown as dots in Fig. 19-13, and a time increment  $\Delta t = 4$  s was used. A debris mixture density of  $\rho = 1,750$  kg/m<sup>3</sup>, and a dynamic viscosity or consistency index of  $\mu = 2,000$  poise were used as input data. The value of  $\mu$  was chosen after an inspection of the data on sampled debris-flows provided by Costa (1984). A constant value of the flow behavior index  $\eta = 1$  (i.e., Bingham plastic) was used in the computation. In Fig. 19-15, the computational results (solid line) are compared with the observed values (dashed line) at the site of dam #6. The agreement is fairly reasonable, taking into account the uncertainty about the model parameters, as well as the lack of more detailed field observations. The computational results at the downstream end (point 14), where the time taken for the debris-flow surge to arrive is about 100 s, are shown in Fig. 19-16. The computed hydrograph shows that the rising stage has a fairly steep slope, and the hydrograph tail after the peak value is long. Similar behavior is observed in the analytical solutions obtained by Takahashi (1991, p. 97) using kinematic wave theory. There, the slope of the rising stage in both the depth and discharge hydrographs is approximately 90°, and the depth hydrograph also has a very long tail.

Fig. 19-13. Longitudinal profile of Kamikamihori Valley (Choi and Garcia 1993).

Fig. 19-14. Input Hydrograph at Upstream End (Choi and García 1993).

**19.6.2.6 Conclusion** The kinematic wave approximation has been applied to debris-flow routing. A nonlinear algorithm was used to compute the numerical solution. Comparison of model predictions against field observations gives encouraging results. It should be clear that the proposed model can provide only an approximate, yet useful, tool to compute the propagation of debris-flows. As new knowledge is gained about the rheological properties of debris and mud flows, it should be possible to incorporate it readily into the simple structure of the kinematic wave model (e.g. Whipple 1997).

There are more sophisticated models to predict the propagation of debris-flow surges, which include the dynamics of the pore-pressure evolution inside the flow (e.g., Savage and Iverson 2003). Although these models provide substantial insight into the mechanics of debris-flows (Savage and Hutter, 1989; 1991), their practical use is still limited to idealized conditions (Tubino and Lanzoni, 1993).

Fig. 19-16. Downstream Flow Hydrograph at Pt. #14 (Choi and Garcia 1993).

### 19.6.3 Simulation of Flooding and Debris-Flows in the Cerro Grande River, Venezuela (Bello et al. 2003)

**19.6.3.1 Introduction** During the first two weeks of December 1999, intermittent rainfall during a particularly wet rainy season saturated the steep watersheds of the north coast of Venezuela (Wieczorek et al. 2001). Then torrential rainfalls over a 3-day period (December 14–16) spawned landslides throughout the upper watersheds of the Cerro Grande River. Landslides were also observed on the steeper hill slopes of the lower watersheds. Mud-floods, debris-flows and flood surges destroyed much of the town of Tanaguarena. Tanaguarena was only one of about twenty coastal tourist communities developed on alluvial fans that were devastated by the flooding and debris-flows. Over 15,000 people perished during this 3-day period. Floods swept through these communities with frontal debris waves, a series of hour-long flood waves, and surges of flood waters and debris. The Cerro Grande River is located in the north coastal range of Venezuela and flows in a south-north direction into the Caribbean Sea. The highest elevation in the watershed is 2,750 m and the river course descends steeply to sea level in a horizontal distance of 10.5 km. The average slope of the Cerro Grande River is 20.2% and the area of the watershed is 23 km<sup>2</sup>. The Cerro Grande River is ephemeral, with flows usually occurring in response to short-duration high-intensity rainfalls. Prior to December 1999, aerial photos showed a vegetated watershed. Much of the middle of the basin is a rainforest ecosystem. The following material is based on the work presented at the “International Seminar on the Debris-flow Disaster of December 1999,” Institute of Fluid Mechanics, Universidad Central de Venezuela, Caracas, Venezuela, in 2000 (López and García 2000). More detailed information can be found in Bello et al. (2003).

**19.6.3.2 Description of the Flood** Tanaguarena is a residential coastal community with two- and three-story houses, buildings and a private resort (Club Tanaguarena). Many of the buildings were constructed within the confined river canyon or on the short alluvial fan leading to the ocean. The alluvial fan extends approximately 400 m out into the ocean from the foot of the mountain slope (Fig. 19-17). According to local reports, flows were approaching bank-full on December 14. On December 15, the river started to inundate the houses along the left bank, and in the early hours of December 16, right overbank flooding ensued and flooded many of the houses in canyon. People climbed to the rooftops to escape the mud-floods and debris that were coming in surges down the river channel. Cars and urban debris were swept up by the flood waves and deposited in the ocean or along the coastal streets. The flood receded in the final hours of December 16. Average sediment deposition in the river canyon was about 2 to 3 m and essentially buried most of the standing houses to the rafters. Water level marks as high as 7 m were observed in some of the buildings. The debris surges destroyed approximately 60% of the structures

in town of Tanaguarena and resulted in approximately 100 fatalities. The mining operation (Cantera Cerro Grande) reported damages in excess of \$3 million in lost structures and equipment.

Damages were incurred through a combination of river flood inundation and alluvial fan unconfined flooding. Upstream of the mining operation, the canyon-confined flooding functioned as a sediment transport zone, delivering source area sediment from the upper watershed. Downstream of the mining operation in the canyon and onto the alluvial fan, a geomorphic sediment deposition zone was apparent. Structures in the canyon sustained impact damage from debris and boulders in surges. Some structures were completely destroyed by impact, scour, and exposure to high-velocity flows. Foundations were undermined by scour and collapsed. High-velocity surges with boulders and debris were experienced across the entire canyon bottom as the channel conveyance capacity was lost. The structures that remained standing were buried in a coarse grain mixture of boulders, cobbles, sand, and debris (Bello et al. 2003).

On the alluvial fan, structures were inundated with water and buried by sand deposition. Boulders, debris and cars were piled against buildings and some buildings sustained impact and scour damage. Video footage of flood events along the coast indicated a long duration (hours) of high flows punctuated by surges of sediment and debris related to upstream hillslope and debris dam failure. Streets became important flood conveyance channels that isolated portions of the community and cut off emergency access (Bello et al. 2003).

**19.6.3.3 Rainfall Data and Frequency Analysis** Only two rainfall gauging stations were operating in the State of Vargas in December 1999: Maiquetia (43 m above sea level), located about 15 km west of Cerro Grande, and Mamo (81 m above sea level,) located 20 km west of Cerro Grande. Precipitation data indicate that a low-intensity but continuous rainfall occurred between December 1 and December 13, totaling 293 mm at Maiquetia. Rainfall intensity increased during December 14 to 16. Maiquetia station reported 911 mm during these three days, with a total precipitation of 1,207 mm for the first 17 days of December. At Mamo, however, the cumulative value for the same 17-day period was 438 mm.

Over a period of record of 51 yr, Maiquetia station recorded the following rainfall data (excluding 1999): annual average rainfall of 523 mm; annual maximum rainfall of 961 mm (1951); and annual minimum rainfall of 205 mm. The log Pearson III frequency distribution indicates that the return period of the 1999 storm, without including the 1999 data, is greater than 1,000 yr. When the 1999 storm total rainfall (410 mm) is included in the analysis, the return period is approximately 270 yr.

**19.6.3.4 Estimated 1999 Flood Hydrograph** Using estimates of the peak stage from high water marks upstream of the Cerro Grande water intake weir, Zhang et al. (2000)

**Fig. 19-17.** Comparison of Cerro Grande alluvial fan before and after the Dec. 1999 flood disaster-SPOT Satellite images (Bello et al. 2003).

estimated the debris-flow peak of the December 16, 1999 event to be equal to  $1,250 \text{ m}^3/\text{s}$  (Bello et al., 2003). Based on observations of the water damage and sediment deposition in the canyon and on the alluvial fan, it is assumed that the 1999 flood had an average sediment concentration of 35 to 40% by volume. Using this sediment bulking factor, the estimated water peak discharge was  $800 \text{ m}^3/\text{s}$ . Personal observations indicate that the peak discharge probably ranged from 800 to  $1,200 \text{ m}^3/\text{s}$ .

To obtain a flow hydrograph for the 1999 storm, an HEC-1 hydrologic model was prepared. The HEC-1 simulation was based on the 3-day period of maximum precipitation (December 14–16). Soils were considered to be partially saturated due to the 293 mm of rainfall reported in the previous days of December. HEC-1 loss parameters were calibrated to generate a peak water clear water discharge of  $800 \text{ m}^3/\text{s}$ . The effects of flow bulking are considered next.

Fig. 19-18 displays the HEC-1 simulated flood hydrograph for the Cerro Grande basin. The 3-day flood consisted of a series of approximately five major flood waves. These flood waves reflect the flood description reported by the local citizens. The rainfall intensity that created the flood waves were so high that the peak discharge was insensitive

to loss rate. It is unlikely that the peak rainfall intensities measured at the Maiquetia Station gauge (at sea level) were experienced in the upper Cerro Grande Basin. Although the distance from the rain gauge to the basin is only about 15 km, the elevation effects on the rainfall distribution over the entire watershed were not considered (2,000 m elevation variation). The rainfall peak intensities used in this analysis may be conservatively high. Assuming a sediment concentration that varied with discharge during the storm, the debris-flow hydrograph for the 1999 storm was predicted as shown in Fig. 19-19.

The steeply rising flood waves shown in Fig. 19-18 and 19-19 were also punctuated by debris and sediment surges related to failure of naturally forming debris dams, periodic landslides, hillslope sloughing into the channel, bank failures and roll waves phenomena. Each flood wave and debris surge had a fluid matrix with highly non-uniform sediment concentration ranging from perhaps 15 to 40% by volume.

Although tremendous quantities of sediment were delivered from the upper and middle watershed to the depositional zones in the canyon and on the alluvial fan, mudflows as characterized by viscous concrete-like consistency (see Fig. 19-9) did not occur on the fan. There was so much excess

**Fig. 19-18.** Cerro Grande HEC-1 simulated flood hydrograph, December 15–16, 1999 (Bello et al. 2003).

**Fig. 19-19.** Cerro Grande simulated debris-flow hydrograph, December 15–16, 1999 (Bello et al. 2003).

rainfall during this three-day storm that the flood waves, debris frontal waves and roll waves behaved essentially as water flood phenomena in the deposition zone. The depositional zone was essentially devoid of fine sediment (silts and clays), and there was little evidence of mudflow features such as levees, bouldery mud snouts, and undulating mud surfaces, which usually characterize mudflow alluvial fans.

Evidence indicates that near the source where the landslides and hillslope failures coalesced into moving fluid phenomena as they entered the water courses, mudflows were common. Generally, on western United States alluvial fans, mudflows occur in response to relatively frequent rainfall events with 5- to 50-yr return periods. Less frequent floods such as the 100-yr have too much water, compared to the available sediment supply, to generate long-duration mudflows. Once the watershed has a chance to recover from this catastrophic event, a process that could take several years, the Cerro Grande upper basin may be capable of producing mudflows for frequent return-period storms.

**19.6.3.5 Channel Morphological Response** A comparison between longitudinal profiles in the 2000 m Cerro Grande canyon reach before and after the 1999 storm is shown in Fig. 19-20. The slope of the channel bed did not significantly change; it varies from between 3 and 4% in the canyon to 2.5% on the fan. The alluvial fan extended into the sea about 140 m from the original mouth of the river. The sediment deposition along the river profile was 4 m to 5 m in the valley and 2 to 3 m on the alluvial fan.

Observation of the aerial photo of December 1999 (Fig. 19-17) indicates that in the lower canyon, where buildings were located, the river channel was obliterated and flows extended across the canyon floor. There was so much sediment moving as bed load and in flood waves that the flows became braided. During rising and recessional limbs of the five major flood waves, the flows followed multiple channel paths through the urbanized area. The area of sediment deposition extended about 1500 m east and west along the coast. Based on field observations and aerial photos, the amount of sediment accumulation was estimated to be on the order of 1.5 million cubic meters. This sediment deposition volume compares with 7.6 million cubic meters of water in the storm runoff hydrograph. Obviously most of the sediment conveyed by the flood washed into the ocean and is unaccounted for in deposition estimates.

**19.6.3.6 Mud and Debris-Flow Modeling** The FLO-2D model (O'Brien, 1999) was applied to simulate flooding in Cerro Grande canyon on the alluvial fan (Bello et al., 2003). FLO-2D is a two-dimensional flood-routing model that can simulate flows over complex topographies and roughness on urbanized alluvial fans and river floodplains and has a component to compute the channel-floodplain flow exchange. Hyperconcentrated sediment flows such as mudflows and the transition from water flows to fully developed mud and debris-flows can be simulated. Data requirements include a digital terrain model, channel geometry, estimates of channel and floodplain roughness, inflow flood hydrographs or rainfall, and rheological properties of the sediment-water mixture. The model is based on a finite difference solution of the two-dimensional Saint-Venant equations for non-Newtonian fluids.

A total of 1322 grid elements (50 m square) constituted the model flow domain covering the Cerro Grande canyon and urbanized alluvial fan area. This area is essentially the entire depositional area for the watershed, and the inflow node may be considered the fan apex even though the point is well upstream of the canyon mouth. The grid system coordinates and elevations were based on 1984 5-m contour mapping (Bello et al., 2003).

Other FLO-2D input data included the inflow hydrograph, channel geometry, estimates of sediment parameters and concentration and urban components (streets and buildings). In the absence of flow matrix samples, a number of simulations with temporal variations in the sediment concentration were attempted. It is apparent from the deposits that the fluid

**Fig. 19-20.** Longitudinal profiles of bottom elevation along the canyon and the alluvial fan before and after the flooding. Up to 5 meters of sediment accumulated at some locations (Bello et al. 2003).

matrix sediment concentration was highly variable especially during the flood waves perhaps reaching concentrations as high as 40 to 45% by volume. During the low-flow periods between the flood waves, the sediment concentrations may have been less than 20% by volume. The average sediment concentration was probably on the order of 30 to 35% by volume. Sediment parameters related to flow viscosity and yield stress were estimated from analysis of actual debris-flows in the United States (O'Brien et al. 1993). A rigid-bed analysis with potential deposition on the fan was simulated. The fluid matrix was assumed to be a continuum and conventional bed-load and suspended-load sediment transport were not simulated.

The volume of flood was so large in 3 days that the effect of the streets and building obstructions on the predicted area of inundation was relatively minimal. These model features are important to local hydraulic conditions such as maximum flow depth and velocity, but were not analyzed in the existing-conditions simulation. Floodplain roughness  $n$ -values of 0.05 to 0.06 and channel  $n$ -values ranging from 0.032 near the ocean to 0.062 near the fan apex were assumed.

**19.6.3.7 Simulation Results** Predicted maximum flows depth ranged from 3.0 to 6.0 m on the canyon floodplain and 1.5 m to 4.0 m on the alluvial fan (Bello et al. 2003). Flow depths were greater in the channel, although during the actual flood the channel ceased to function. Alluvial fan velocities were predicted in the general range from 1 to 2 m s<sup>-1</sup> with velocities as high as 5 m s<sup>-1</sup> in the canyon area. Again channel velocities were slightly greater. The predicted

channel discharge constituted only about 16% of the actual maximum discharge. In other words, most of the flood volume was distributed over the alluvial fan surface.

The key to the accuracy of the Cerro Grande flood simulation is the area of inundation and predicted flow depth as a function of the estimated bulk volume. The total volume of the inflow hydrograph was approximately 23.35 million m<sup>3</sup> (34.91 million m<sup>3</sup> bulked with sediment). The predicted area of inundation on the alluvial fan was 8,093,000 m<sup>2</sup> (Fig. 19-21).

**19.6.3.8 Conclusions** The December 1999 rainstorm was a severe flood event that none of the coastal communities were prepared for. Inadequate or nonexistent zoning and planning resulted in the construction of buildings along the Cerro Grande channel within the 100-yr floodplain. Although the flood event exceeded the 100-yr flood estimate, there was only limited flood protection from channel conveyance against more frequent floods. Once the channel capacity was lost to sediment deposition early in the three days of flooding, structures on the alluvial fan were subjected to the full flood event.

The frequency analysis of two rain gauges with relatively long records of 50 yr or more indicated that the December 1999 flood was on the order of a 250-yr flood event or higher for a 3 day storm. Simulating the rainfall with the HEC-1 hydrologic model revealed that the flooding occurred in a series of at least five major flood waves over the 3-day period, as was reported by local citizens. By applying the HEC-1 model and the rainfall distribution recorded at the Macuto

**Fig. 19-21.** General area of inundation of the Cerro Grande Canyon and Alluvial Fan estimated by Bello et al. (2003).

Station, which is closer than the Maquetia Station to the Cerro Grande basin, a hydrograph for the 1999 flood event was estimated at the fan apex. This hydrograph was used in the FLO-2D model to route the 1999 flood as both channel and unconfined flows. The bulked sediment hydrograph was estimated from properties of the limited sediment data and estimates of sediment concentration (Bello et al. 2003).

Flood damages were incurred by flood scour, debris impact and flood inundation in the Cerro Grande canyon. Sediment deposition and flood inundation were the primary hazards on the alluvial fan. There was so much sediment moving as bed load and in mud-flood surges that the channel was obliterated and the flows braided across the canyon floor.

FLO-2D results indicated that the model was able to replicate the general area of inundation and to reproduce the flow depth pattern of the 1999 flood and debris-flow event in Cerro Grande. Predicted flow velocities were also in the general range of anticipated maximum velocities.

The importance of replicating the 1999 flood relates to the possibility of expanding the simulation for mitigation design (Bello et al. 2003). Although the 1999 event was an infrequent flood, simulating the flood event still has practical applications. In mitigation design, flood timing, duration, magnitude, and flood wave attenuation are important.

As a result of this study, a methodology was developed to delineate hazards maps due to mud and debris-flow events,

based on the application of the FLO-2D model (García et al. 2003). The methodology was tested in 23 sites in the Caracas and Vargas state region in Venezuela. The model results compared very well to the maximum flow depths and areas of inundation observed during the December 1999 Vargas mud and debris-flow disaster. The hazard maps are being used by planners of the Venezuelan Ministry of the Environment and Natural Resources to design emergency plans and new land use policies.

Many more applications of debris flow simulations models, including several case studies and potential mitigation measures, can be found in Rickenmann and Chen (2003). Predictive models that have been used for engineering purposes, besides those presented above include those advanced by MacArthur and Schamber (1986), Han and Wang (1997) and Laigle and Coussot (1996). Modeling of hyperconcentrated flows and hazard mitigation measures will continue to be extremely challenging problems for the engineering and geosciences community (García and Zech 2007).

Because of the impact that this catastrophic event had on human lives as well as on infrastructure and water resources, the appendix to this chapter is devoted to the case of Mount St. Helens.

## APPENDIX CHAPTER 19

### *Case Study Mount St. Helens—20 Years Later*

#### INTRODUCTION AND CHRONOLOGY

On 18 May 1980, just before a magmatic blast signaled the onset of the Mount St. Helens eruption (Fig. 1 shows eruption and after effects), an earthquake triggered a major slope failure on the north flank of the mountain. Sliding off the cone, some 2.8 billion cu m (3.7 billion cu yd) of rock, ice and other material avalanched into the upper North Fork Toutle River Valley removing the upper 404 m (1,324 ft) of the mountain and depositing material over an area of 596 sq km (230 sq mi) (USACE, 1999). The resultant debris avalanche buried the upper 27 km (17 mi) of the North Fork Toutle River to an average depth of 46 m (150 ft). Melting snow and glacial ice combined with water from North Fork Toutle River and possibly Spirit Lake to produce mudflows. These swept down the valley, incorporating logs and debris, raising valley floors and diverting streams. Moving downstream into the Toutle and Cowlitz rivers, the mudflows destroyed bridges, inundated buildings, caused widespread flooding along the river banks and blocked the main navigation channel in the Columbia River (see Fig. 2).

Within 24 hours, the mudflows deposited some 38 million cu m (50 million cu yd) of sediment in the lower 37 km (23 mi) of the Cowlitz River including overbank areas, and an additional 38 million cu m (50 million cu yd) into the Columbia River upstream and downstream from Longview, WA. Infilling in the lower Cowlitz as much as 4.6 m (15 ft) in some places reduced the river channel hydraulic capacity by nearly 80% the discharge at bank-full capacity decreased from a pre-eruption level of 1,982 cms (70,000 cfs) to less than 368 cms (13,000 cfs). Downstream at the mouth of the Cowlitz, the Columbia River channel, normally maintained at a 12.2-m (40-ft) depth, shrank to less than 4.6 m (15 ft). Thirty-one deep draft vessels were trapped in upstream harbors; some fifty ships enroute to the area had to be diverted to other ports.

In the aftermath of the eruption, the U.S. Army Corps of Engineers coordinated efforts with other federal, state and local agencies to provide flood protection for the urban

areas and to remove sediment deposited in the river channels. Work was started to strengthen or construct levees at Castle Rock, Lexington, Longview and Kelso, Washington. Pipeline and hopper dredges began to remove sediment from the Columbia almost immediately; by July pipeline dredges and other equipment were at work on the lower Cowlitz and Toutle to restore flood carrying capacity. By the end of November some 10.7 million cu m (14 million cu yd) of sediment had been removed from the Columbia, and nearly 26 million cu m (34 million cu yd) from the Cowlitz and Toutle Rivers.

But while these initial recovery efforts were underway, the long-term effects of the emplacement of the debris avalanche were being assessed. Preliminary estimates ranged widely as to the amount of sediment the avalanche would deliver annually, but it was believed that it would be years before the basin would reach a state of dynamic equilibrium. For one thing, the eruption had left the upper valley devoid of stabilizing vegetation. As channels slowly evolved to carry off impounded water or storm runoff, they would also deliver blast deposits, ash and sediment downstream for an indeterminate time.

During the fall of 1980, two debris retention structures were built on the North and South Forks of the Toutle to trap sediment so that it could be removed from the river system. The larger structure, DRS N-1, was built just downstream of the debris avalanche on the North Fork of the Toutle. At nearly 2.4 km (1.5 miles) wide, it was designed to retain 4.6 million cu m (6 million cu yd) of sediment. The other structure, located on the South Fork, was 152 m (500 ft) wide with a capacity of 457,700 cu m (600,000 cu yd). To supplement the two structures, a dozen sediment stabilization basins, or sumps, were to be excavated in the North Fork, South Fork and Lower Toutle Rivers.

By the end of November 1980, when the winter storm season began in earnest, it became clear that the potential for continued sedimentation problems had not been overestimated. Erosion of the abutment at the Interstate 5 bridge over the Toutle River necessitated emergency repairs to

**Fig. 1.** Mount St. Helens eruption and after effects.

avoid extended closure of the main north-south highway. The south impoundment area of the N-1 debris retaining structure, completed in October, was already two-thirds full with an estimated 1.1 million cu m (1.5 million cu yd) of sediment. The smaller S-1 structure was completely filled and passing excess sediment over its spillway.

On 25 December 1980 a heavy but not uncommon winter storm occurred, with rainfall estimated in excess of 3.5 in. (8.9 cm) in the upper basin. The peak stage on the Cowlitz at Castle Rock produced by the storm was 5.73 m (18.8 ft), at a discharge of 1359 cms (48,000 cfs). Due to the storm a substantial amount of sediment moved into the Cowlitz from the Toutle, reducing hydraulic capacity: a shift of more than 0.6 m (2 ft) in the rating curve gave the first indication of the quantity of sediment that could be delivered by a single

storm. With approximately 1.5 million cu m (2 million cu yd) of sediment impounded behind N-1—despite operation and maintenance dredging of some 11,500 cu m (15,000 cu yd) a day—the south spillway of the debris retaining structure washed out, opening a breach 76 m (250 ft) long and 7.6 m (25 ft) deep.

Repairs on N-1 were initiated, and during the winter months other measures were taken to mitigate the sedimentation problems in the Toutle-Cowlitz-Columbia System. Contractors continued to dredge the sediment stabilization basins, but because of limited funding, many of the other basins could not be maintained. These filled quickly; moreover, lateral shifting of the river eroded the dredged material storage piles. Further downstream bank erosion during periods of high water necessitated revetment work

**Fig. 2.** Area Map—Mount St. Helens eruption impacts.

Source: U.S. Army Corps of Engineers (USACE), Portland District, *Mt. St. Helens Cowlitz and Toutle Rivers Sedimentation Study*, September 1984.

at Cowlitz River Kilometer 20.6 and 21.7 (Mile 12.8 and 13.5). At the mouth of the Cowlitz, a sump was excavated in January to trap sediment being delivered to the Columbia.

By mid-May 1981, a year after the eruption, 9.8 million cu m (12.9 million cu yd) of sediment had been dredged from the Toutle River, 42.7 million cu m (55.8 million cu yd) from the Cowlitz, and 15.4 million cu m (20.1 million cu yd) from the Columbia. At the debris retaining structures upstream, operation and maintenance dredging had removed 1.1 million cu m (1.4 million cu yd) from S-1, and 3.7 million cu m (4.8 million cu yd) from N-1. A roller-compacted concrete spillway replaced the gabion spillway that had

breached in December, and an estimated 2.3 million cu m (3 million cu yd) of sediment was trapped in the N-1 north and south impoundment areas. Above the debris retaining structures, several small lakes blocked by the debris avalanche had overtopped, and concern grew about the potential flood threat posed by other impounded bodies of water. During the summer, a 670-m-long (2,200-ft) channel was dug to provide outlets for a lake in Coldwater Canyon, and another channel was begun at a lake, which had formed on South Castle Creek.

At the end of water year 1981, aggradation was continuing in the Toutle and Cowlitz rivers. River channels tended to widen and shift in response to the sudden change in sediment

load and size, and channel depth and slope. Aggradation was exacerbated by erosion of river banks and dredged material disposal piles in some areas, and changes in channel alignment were an ongoing cause for concern at bridge locations, particularly at the I-5 Bridge. However, except for work at the mouth of the Cowlitz, mechanical removal of sediment from the Toutle-Cowlitz system had virtually ceased. Excavating at sediment stabilization sites had been completed by the end of May. All 13 of the original contractors dredging on the Cowlitz from kilometer 14.5 to 34.6 (mile 9.0 to 21.5) and the mouth of the Toutle had completed their work. Maintenance dredging of sediment impounded areas at N-1 and S-1 stopped at the end of September.

Water year 1982 was an extremely "wet" year. High sediment delivery to the Cowlitz River continued and, without channel dredging, aggradation of the channel was significant. Changes of the thalweg elevations from the original eruption through 1982 are shown in Fig. 3. Large amounts of deposition were noted, particularly in the January and February 1982 storm events. Very high concentrations were measured in February. Small mudflows were also noted in the debris avalanche during this period. The N-1 spillway failed in February and the structure was overtopped, as it was full prior to the event.

A major mudflow occurred on 19 March 1982. At that time, an explosive eruption was vented out of the south-east portion of the dome. A fraction of this blast melted ice and snow on the crater walls and ponded water behind the dome. This pond filled rapidly and breached. Subsequently, the floodwaters eroded sediment from the debris avalanche, becoming transformed into a mudflow. Two pulses of this flow entered the N-1 debris retaining structure, which trapped an estimated two-thirds of the flow volume. Fig. 4 shows the magnitudes of the 1982 water year bed material yields for mudflows, hyperconcentrated flows and "normal flows",

**Fig. 3.** Cowlitz River thalweg changes (in English Units).  
Source: U.S. Army Corps of Engineers (USACE), Portland District, *Mt. St. Helens Cowlitz and Toutle Rivers Sedimentation Study*, September 1984.

those not related to the March 1982 mudflow. Pierson and Scott (1985) have documented additional information on this event.

From 1983 until the mid-1990s nature was kinder. None of these seasons were wet; in fact they were quite dry. The U.S. Army Corps of Engineers again dredged portions of the Cowlitz and operated sumps at the mouth of both the Toutle and Cowlitz Rivers during this period. Significant floods occurred during the mid-1990s; their impacts will be discussed later in this Appendix.

The Mount St. Helens Project was formulated to control the projected movement of sediment from the debris avalanche along the North Fork Toutle River and to maintain an optimized level of flood protection downstream along the lower Cowlitz River. A major element of the Mount

**Fig. 4.** Comparison of measured bed material transport rates of the Toutle River Highway 99 Gauging Station (in English Units).

St. Helens Project is the Sediment Retention Structure (SRS) located at river kilometer 21.2 (RM 13.2) of the North Fork of the Toutle River. The SRS dam is 54.8 m (180 ft) high and has an estimated capacity of 197 million cu m (258 million cu yd). Construction was completed in 1987. The debris avalanche along the North Fork Toutle River has been evolving since 1980 and differs significantly from when the original SRS design was completed. Sediment deposits upstream of the SRS reached the elevation of the SRS spillway crest between November 1997 and March 1998 (see Fig. 5). The uppermost row of outlet pipes on the SRS was closed in April 1998.

## WATERSHED RECOVERY

Since the 1980 eruption, the Toutle River basin has adjusted itself in various ways. These adjustments include recovery of the watershed, vegetation, and development of the channel system. These ecological and morphological changes alter the hydrologic, hydraulic and sediment transport characteristics of the basin. Available data and information were evaluated to assess the extent and rate of watershed recovery. The objective of the analysis was to estimate the long-term trend of sediment supply from the debris avalanche to the North Fork Toutle River. Elements of the analysis included evaluation of historic cross-section data, channel profile comparisons, historic aerial photography comparisons, and computer-based evaluations of digital elevation models of the North Fork Toutle River basin for different time periods.

Historic cross-section survey information was evaluated to identify trends in channel cross-section development, such as channel widening and channel degradation. The rate at which channel cross-section development has occurred

**Fig. 5.** Sediment deposits behind the SRS.  
*Source:* WEST Consultants, Inc.

and whether or not the channel has stabilized was assessed. Surveyed cross-sections (USGS, 2000) along the North Fork Toutle, South Fork Toutle, and Toutle Rivers were utilized in the analysis. Cross-sections have been repeatedly surveyed at more than 100 locations along these three rivers. Cross-section surveys began as early as 1980, and have been resurveyed periodically up through 1999. Typical results are shown in Fig. 6. Cross-sections on the North Fork Toutle, South Fork Toutle, and Toutle Rivers show a general trend of increased cross-sectional area since the eruption. A majority of the cross-sections have had a significant amount of stream bank erosion and channel degradation. As a result, many locations show an increase in channel width and lowering of the thalweg elevation.

A profile analysis was performed for the North Fork Toutle River, Castle Creek, and Coldwater Creek in order to identify changes in the channel slope and thalweg elevation. Digital Terrain Models (DTMs) (CENWP 2000) of the North Fork Toutle River above the SRS for the years 1987 and 1999 were used in the analysis. Profiles were extracted from the two DTMs along the path of the 1999 channel starting at the upstream end of Loowit Creek, near the crater, down to the SRS along the North Fork Toutle River.

The profile analysis shows that the North Fork Toutle River, Coldwater Creek, and Castle Creek have all degraded between 1987 and 1999, except between the N-1 debris dam and the SRS. The most degradation on the North Fork Toutle River occurred near the Coldwater/Castle Creek confluence, and was as much as 12.2 m (40 ft). Up to 12.2 m (40 ft) of degradation was also observed on Coldwater Creek, and up to 18.3 m (60 ft) of degradation was observed on Castle Creek. More than 30 m (100 ft) of aggradation was observed upstream of the SRS. Even though the channels degraded significantly, the overall slope of the channels changed very little between 1987 and 1999, except near the SRS. Fig. 7 and Fig. 8 show changes in the North Fork Toutle River, Coldwater Creek and Castle Creek profiles, respectively.

A plan form analysis was made to observe the condition of sediment erosion and deposition upstream of the SRS. The analysis was made to observe and document geomorphic changes in the river valley over time and evaluate how the occurrence and severity of these channel changes has progressed since the eruption. To perform the analysis, historic aerial photography for the years 1980, 1982, 1983, 1984, 1985, 1987, and 1999 were compared. Analysis of the historical aerial photography indicates that the basin is beginning to recover. The majority of the channels were historically braided since the eruption; however, in many places the density of braided channels has declined, and at a few locations a single thread channel has formed. This would indicate that these channels have become more stable. The emergence of vegetation seen in the 1999 aerial photography adjacent to many of the channels provides additional evidence that watershed recovery is beginning to occur. However, the floodplains remain virtually unvegetated, indicating a continued lack of channel stability. The density and aerial extent of vegetation generally increases in the downstream direction.

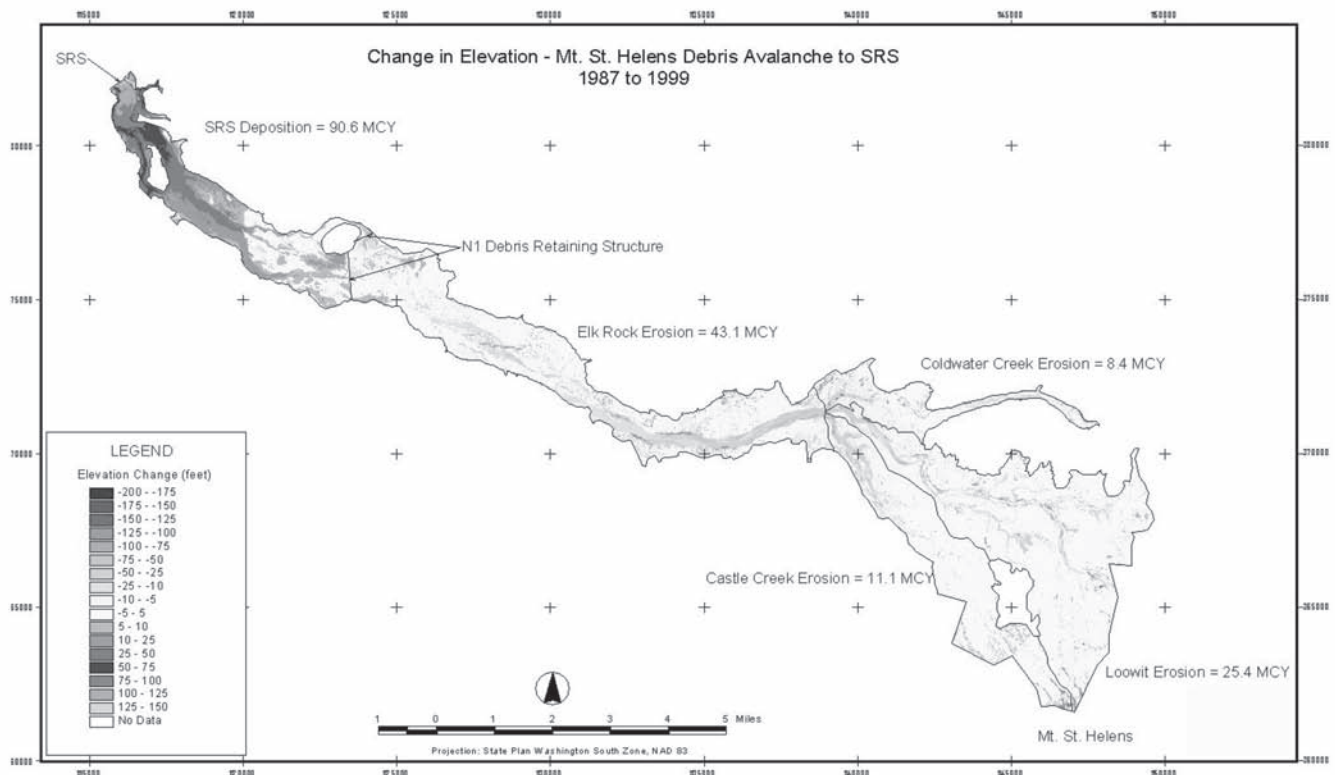

The majority of the debris avalanche lacks any significant vegetation while nearer to the SRS there are trees growing on the hillslopes, the floodplain fringe, and even portions of the floodplain. This is likely due to several factors, including

lack of sufficient soil nutrients, and soil moisture to promote vegetative growth on the debris avalanche, reduced impacts from the eruptive blast in the downstream direction, and replanting of private forest land outside of the volcanic monument. Additional evidence of watershed recovery can be seen by the stability and extensive vegetation of the delta formation in Coldwater Lake. This would indicate that South Coldwater Creek has started to stabilize.

While there are some indications of hydro-geomorphic recovery, the aerial photograph analysis also provides clear evidence that recovery is very slow. Watershed recovery to pre-eruption conditions has not occurred. The channels continue to shift and widen, and large-scale degradation and bank erosion is still occurring in many areas, as evidenced by the changes in channel plan form and the massive volume of sediment trapped behind the SRS since its completion in 1987.

## SEDIMENT SOURCES

Digital Terrain Models (DTMs) developed from aerial photography for the years 1987 (pre-SRS) and 1999 in the form of Triangulated Irregular Networks (TINs) were analyzed to estimate the total erosion on the debris avalanche upstream of the SRS as well as the total deposition behind the SRS over

**Fig. 9.** Elevation difference grid showing locations of erosion and deposition (in English Units).  
Source: WEST Consultants, Inc.

the involved time period. Erosion estimates were defined for each of the primary sediment sources (sub-areas) on the debris avalanche. These sub-areas were categorized as Elk Rock, Coldwater Creek, Castle Creek and Loowit Creek. Deposition estimates were developed for the North Fork Toutle River between the SRS and N-1 Debris Retention Structure.

The two TINs were converted to overlapping grids with 10 ft by 10 ft cells. The grids were clipped to contain only the data pertinent to the analysis (only the locations of deposition or erosion as seen in the 1999 aerial photography). An elevation difference grid was developed by subtracting the 1987 grid surface from the 1999 grid surface showing the location and magnitude of the changes in elevation that occurred between 1987 and 1999 (see Fig. 9). An extensive amount of deposition has occurred between the SRS and N-1 Debris Retaining Structure. In locations nearest the SRS deposition depths exceed 30m (100 ft). The majority of the debris avalanche erosion is associated with the North Fork Toutle River channel upstream of Elk Rock. The most extensive erosion typically occurs along the outside of channel

bends, where bank erosion has caused elevation changes of up to 55 m (180 ft). This suggests that bank erosion has played a major role in the contribution of sediment to the North Fork Toutle River. Site visit observations confirm this conclusion. Fig. 10 and Fig. 11 are 3-dimensional views of portions of the DTMs showing erosion from the debris avalanche and deposition behind the SRS.

The total erosion from the sediment source sub-areas were compared to the sediment deposition volume measured between the SRS and N-1 Debris Retaining Structure and the volume of sediment passing the Kid Valley gauge (assumed to be the same as the sediment passing the SRS) to evaluate data consistency. The total amount of erosion was measured to be 67.3 million cu m (88 million cu yd). When bulked by 16% to account for the reduction in density associated with deposition, the total erosion is estimated to be 78.1 million cu m (102.1 million cu yd). Total deposition measured between the SRS and N-1 is 69.3 million cu m (90.6 million cu yd). Suspended sediment passing the Kid Valley gauge was estimated to be 8.4 million cu m. (11 million cu yd). It is noted that the Green River enters the North Fork Toutle River above the Kid Valley gauge and would account for a small portion of the 8.4 million cu m (11 million cu yd) measured at the gauge. Between 1988 and 1998 the Green River was estimated to contribute approximately 0.5 million cu m (0.6 million cu yd) to the North Fork Toutle above Kid Valley. This estimate was based on suspended sediment discharge measurements made from 1988 and 1994 and correlation with the Tower Road suspended sediment record. Fig.12 shows historical channel evolution at selected areas in the debris avalanche.

The total North Fork Toutle River suspended sediment load that passed the SRS (above the Green River) for water years 1988 through 1998 was estimated to be 7.95 million cu m (10.4 million cu yd). The deposition behind the SRS plus the estimate of suspended sediment that passed through the SRS totals 77.2 million cu m (101 million cu yd). This volume is approximately 1% less than the total erosion volume estimated for the sediment source sub-areas. The most significant source of sediment has been the Elk Rock and Loowit sub-areas, which have a combined total of approximately 78% of the total debris avalanche erosion since 1987. Castle Creek sub-area and Coldwater Creek sub-area make up approximately 12.6 and 9.5% of the total debris avalanche erosion, respectively.

## SEDIMENT YIELD

The average annual sediment yield of the debris avalanche will be influenced by the hydrologic and geomorphic recovery

of the watershed and its stream channels. The trend and rate of recovery could be expected to significantly affect the accuracy of the average annual sediment yield estimate. Measured sediment yields at the Toutle River at Tower Road Gage and deposition behind the SRS were used to evaluate existing trends in sediment yield.

As seen in Fig. 13, annual sediment yields measured at Tower Road were significantly larger during the early 1980s, but then reduced fairly rapidly throughout the late 1980s and early 1990s. This would indicate that recovery in the watershed was causing a reduction in sediment supply to downstream areas. However, this time period was also a period of below average runoff. Total annual runoff was approximately 15% below normal for the period 1985 to 1995. A significant increase in sediment yield occurred during the 1996 and 1997 water years, as total annual runoff was approximately 45% above normal. This would indicate that sediment yield from the watershed is highly dependent upon the hydrology. Variability in the hydrologic cycle would tend to mask trends in the reduction of sediment yield. However, the fact that

the sediment yields measured for 1996 and 1997, the largest water years of record, were less than those measured in 1982 and 1983 would indicate that some recovery has taken place. However, the sediment yield in 1996 was nearly the same as that which occurred in 1984, which further indicates the dependence of sediment yield on the involved hydrology. To account for the dependence between sediment yield and hydrology, the annual sediment yield was divided by the annual runoff to determine the yield of sediment per unit volume of runoff or average sediment concentration. As seen in Fig. 14, the yield of sediment in 1996 was approximately 8.6 kg per cu m (11.7 tn per acre-ft) of runoff while the yield in 1984 was approximately 11.3 kg per cu m (15.3 tn per acre-ft) of runoff, a reduction of approximately 24%, providing further evidence of watershed recovery.

The average annual sediment concentrations were accumulated on an annual basis to determine if a trend of decreasing average sediment concentration over time is occurring in the system (see Fig. 15). A trend line was fit to the cumulative concentration data to develop a sediment concentration decay

curve. By extrapolation, a future sediment yield curve can be developed and is shown in Fig. 16 (WEST Consultants 2002). Total sediment yield from the debris avalanche is estimated to be 344 million cu m (450 million cu yd) by the year 2035. This is approximately 55 and 31% less than estimates of 765 million cu m (1 billion) and 497 million cu m (650 million cu yd) made previously (USACE 1984).

## CONCLUSIONS

A chronology of events has been presented at Mount St. Helens since the May 18, 1980 eruption to present. A further discussion of watershed recovery, sediment sources and sediment yields has also been presented to the reader. While there are some indications that watershed recovery has begun to occur, analyses of available data suggests that recovery has been very slow. Watershed recovery to pre-eruption conditions has not occurred. The channels continue to shift and widen, and large-scale degradation and

**Fig. 12.** Historical aerial photographs of the N.F. Toutle River upstream of the Castle Creek/Coldwater Creek Confluence.

 (Continued)

bank erosion is still occurring in many areas, as evidenced by the changes in channel plan form and the massive volume of sediment trapped behind the SRS since its completion in 1987. Additionally, the time period between the two most recent years of aerial photography (1987–1999) of 12 years combined with the occurrence of very high flows in 1996, makes it difficult to assess more recent hydrologic recovery. However, it is noted that the volume of sediment deposited behind the SRS during the 1996 water year was approximately two times larger than in any previous year since 1987. This would indicate that significant hydrologic recovery of the basin has not occurred in recent years as large flow events such as that which occurred in 1996 still have the ability to mobilize large volumes of sediment. However, it is expected that as watershed recovery progresses, sediment yields will decrease over time for similar flood events.

The SRS is currently filled with sediment to the spillway crest, though it is still a relatively horizontal deposit. There is still significant sediment storage behind the SRS for the sand and coarser fraction of the sediment load. Fine sediments that had been previously trapped by the SRS since its

1987 closure will now be passed downstream to the Toutle, Cowlitz and Columbia Rivers. It is expected that as the sediment deposits build behind the SRS, more and more of the coarse fraction of the sediment load will be passed over the spillway and be transported downstream by the Toutle and Cowlitz Rivers. Extremely high sediment transport rates should still be expected in the future.

## CHAPTER 20

# *American Sedimentation Law and Physical Processes*

*James E. Slosson, Douglas Hamilton, and Gerry Shuirman*

### 20.1 INTRODUCTION

#### 20.1.1 Recent Trends in American Sedimentation Law

This chapter, more than any other in the first edition of Manual 54, deserves to be updated and expanded. As the population of the United States grows, there is more demand for government to provide infrastructure, and to balance the pressure of urban expansion with regulatory objectives such as hazard mitigation and the environment. New theories of legal liability such as inverse condemnation have changed the way that government carries out this mission. In essence, the power we delegate to government and the decisions it makes on our behalf and with our participation add up to priorities that change society. This driving force is at least as great as the pursuit of science when it comes to breakthroughs in the application of sedimentation engineering concepts.

### 20.2 MANUAL 54: SEDIMENTATION ENGINEERING (VANONI 1975)

#### 20.2.1 General Summary

After devising the problem, author C. E. Busby, when writing Chapter VII of Manual 54 entitled “American Sedimentation Law and Physical Processes” (1975), mapped out these physical processes of sedimentation, how they relate to supreme court case-law, and how engineering practice responded. He used the following concise yet well informed outline.

#### 20.2.2 Legal Concepts Applied to Water, Air and Land

Erosion damage is part of the sedimentation process and possession or right to possession is the basis for rights in land and water. “In American jurisprudence, one cannot own the water as it runs in a stream or moves in the air, for one cannot legally possess it in these natural states. This has given rise to legal concepts as old as Roman Law; that these moving

waters are the property of no one (*res nullius*) or of all people (*res communes*).”

#### 20.2.3 Erosion and Sedimentation Processes Vary Geographically

The difference between natural rate and artificial rate produced by man is seen as significant in determining legal liability, and the concept of what is a public stream is changing as the needs of the public change.

#### 20.2.4 Land Pattern Affects Process and Legal Consequences

As in common law, jurisdictions that shape land ownership tracts per settlements of the original states by metes and bounds or by sections and townships virtually ignore drainage lines for younger settlements. There are also public geographic boundaries such as counties, municipalities, states, and the nation, which include national forests, public parks, and wildlife refuges that may have ownership boundaries wherein governmental powers may be exercised over natural resources and people. This deals mainly with sovereign control of development and use.

#### 20.2.5 Water Pattern Affects Process and Legal Consequences

Bearing in mind that the facts make the case, natural water patterns depend largely on slope, soil, bedrock, gullies, and stream channels and are superimposed by the invisible cultural pattern of water supply and rights of use, as defined and classified in law. Diffused surface waters, vagrant floodwaters, and watercourses defined as either navigable or non-navigable were originally based, per common law, on the ebb and flow of the tide. There is a need to bring law and science closer together in terms of reality and process.

## 20.2.6 Sources of Law

Water laws have been subject to local customs down through the ages, which has had a marked influence on such laws as they evolve. The old “*cujus est solum*” theory affects all water supplies because it affects every land ownership tract. Geographically, riparian laws are adapted according to the character of the land. Precipitation runoff plays a main part in common law, a partially unsound theory based on ownership per title to soil rights in turn expanding to ownership of all waters on and under titled soil, as well as the space above and the minerals below. Scientific fact brings into play other moving resources such as water, oil and gas, air and wildlife. Constitutional provisions within the broad scope of the law are veering away from older unscientific concepts and judicial administration toward more scientific concepts and executive administration. Due to this trend, the engineering and legal professions are increasing in importance due to development and application of basic scientific data within the broad framework of legal administrative processes and standards in the field of social engineering.

## 20.2.7 Rights in Land and Diffused Surface Waters

Busby’s chapter includes a section on this topic.

**20.2.7.1 Definitions of Supplies and Interests** Applicable engineering principles are at the core of water cycles related to diffused and defined surface waters. “Engineers know that water is usually conveyed in some sort of ‘channel’ as soon as it starts to move over the land.” Due to the law of streams, sediment deposits may be in one’s “possession” during one year and in transit and out of possession during another.

**20.2.7.2 Common Enemy Rule** The so-called absolute property right in land is qualified by exceptions in several states in the interest of the rights or needs of neighbors. The rule of reasonableness incorporates more science into law due to sound reasoning with consideration of relevant scientific fact, method and technique when supported by local custom and practice.

**20.2.7.3 Civil Law Rule** Problems arising out of land improvement have led to the adoption of the reasonable use rule which states “that the upper landowner may not unduly collect, concentrate, and discharge diffused surface waters on the lower land in increased velocity and volume, so as to do substantial injury to the lower lands.” This rule of reason law tends to balance the relative interests of upper, lower, and adjacent landowners as to damage resulting from harmful runoff. The task at hand for engineers is to define (for the courts) these rights and the interests thereof per scientific measure, evaluation and prediction of runoff and damage.

**20.2.7.4 Reasonable Use Rule** In effect, the reasonable use rule says that a landowner may use his own land as he pleases provided he does not unreasonably interfere with the like rights of others. Reasonableness and unreasonableness are questions of fact.

**20.2.7.5 Rules Governing Pollution Damage by Sediments to Lower Lands and Diffused Surface Waters** It has been upheld that the upper landowner is not liable for damage to lower lands caused by diffused surface waters carrying soil and rock when they constitute part of the “natural formation of the land.” He is liable for resulting damage if he places other soil and rock where the natural drainage of such water will carry it to lower tracts of land or where it interferes with normal drainage, though there are exception.

**20.2.7.6 Rules Governing Pollution Damage by Sediments to Navigable Waters and Adjacent Lands** Works of improvement must adhere to the non-obstruction of navigable waters. It is of special interest to lawyers and engineers to interpret Section 10 of the Rivers and Harbors Act of 1899 that states, “That the creation of any obstruction not affirmatively authorized by Congress, to the navigable capacity of any of the waters of the United States is hereby prohibited” further to include industrial solids in suspension but not in solution. This applies to organic waste that reacts chemically on discharge into a stream, so as not to remain permanently as an obstruction in the form of a shoal deposit.

## 20.2.8 Rights in Land and Defined Surface Waters

The following excerpts outline Busby’s findings on these subjects.

**20.2.8.1 Definitions of Supplies and Interests** Conditions under which riparian rights are acquired and lost are important to engineers and their clients due to the fact that engineers are called on to render services in measuring and appraising land and water resources and evaluating property damage from control and use.

**20.2.8.2 Rights to Riparian Land as Deposited Sediment** Sediments affect the position of a channel in the flood plain by changing channel capacity as well as the topography of the surrounding flood plain. Rights to deposited sediments in flood plains or stream channels may be gained or lost by changes in the position of the channel itself, due to the action caused by both water and sediment.

**20.2.8.3 Riparian Rights Gained or Lost by Accretion** This riparian right refers to permanent changes made to the land when a stream or river recedes below the watermark, exposing deposits recognized as accretions. For instance, an island “rising” in a river unconnected to the riverbank belongs to the owner of the bed at that particular place. In general the rule is that the State owns the bed of a navigable watercourse unless that State permits the adjacent riparian owner to own the bed subject to the navigation servitude.

**20.2.8.4 Riparian Rights Gained or Lost by Avulsion** Although the rule varies from state to state, generally speaking, when the tract of land is severed by sudden change in the channel of a given stream that does not indicate that the right to that tract has been lost. Basic riparian rights may be lost when the thread of the stream is no longer the natural boundary. The original owner may opt to ditch the stream back to its former

channel if done so within a reasonable amount of time and without trespassing on the land of another and without causing undue harm to another's land.

**20.2.8.5 Rights to Be Free from Undue Damage Caused by Obstructions; Major Works of Improvement, Sediment Wedges, and Similar Causes; Definition of Influences Causing Undue Damages** Environmental influences causing undue damage to lands, waters, and other resources are multiple in nature:

1. Construction of major works of improvement
2. Fluctuations in reservoir and other surface water levels
3. Severe erosion and high sediment yields of upstream watershed lands
4. Unwise use and treatment of upstream watershed lands
5. Backwater effects of dams, reservoirs, and sediment wedges
6. Combinations of environmental influences and their consequences

**20.2.8.6 Rules Governing Recovery of Damages Caused by Obstructions and Sediment Wedges** Discussion of sedimentation and other forms of related damage recognized in law due to court decisions related to taking of property by overflow, erosion, sediment deposition, and rise in groundwater table, with sediment depositions mapped out by date.

**20.2.8.7 Other Rights** Rights to be free from undue damage caused by obstructions such as major works of improvement, sediment wedges, and similar cases are outlined, with definitions of influences that cause undue damages; rules governing the recovery of damages caused by obstructions and sediment wedges.

## 20.2.9 Key Questions

The key questions the original Chapter VII addresses are:

1. Rights in and to sediments, as land (property), recognized in law as arising out of natural and artificial changes in the movement of water
2. Rights to legal damages recognized in law as arising out of artificial changes in the movement or effects of water and wind, with special reference to sedimentation; and
3. Powers of government recognized in law necessary to regulate land and water use to prevent undue change by sedimentation to resources and to the health, safety, and welfare of the community?<sup>1</sup>

## 20.2.10 Further Topics

In addition, the original chapter reiterates historical documentation that involves trends in sedimentation law due to legal consequences, as it relates to land development

and land use, dating back to original settlements, colonies, Indian boundaries, water boundaries and their authorities at that time. Legal concepts are reviewed as they apply to the possession of water, air, and land, and how changes in erosion and the sedimentation process vary geographically. Busby concludes that resource management hinges on natural boundaries and cultural ownership. His well-referenced chapter deals with theories of property ownership and the use of legal boundaries, which ultimately leads to a definition of today's changing law as it pertains to water supplies, sedimentation, and saline processes.

## 20.3 RECENT TRENDS IN AMERICAN SEDIMENTATION LAW

Within the law pertaining to sediment engineering, recent trends involve riparian matters pertaining to the environment and conservation. Water law has evolved from water consumption to quality control, covering a wide spectrum of engineering—from dairy operations on creeks to mining techniques to building dams. As a result of these ecological concerns, unresolved legal issues materialize as they pertain to changes in physical boundaries due to consequences of natural hazards such as unexpected floods, unprecedented weather, and subsequent sediment transport.

Conservation systems and programs that are designed to reduce soil losses from erosion to acceptable levels are on the rise. Stringent guidelines, amending old laws, provide a mechanism for encouraging landowners to reduce erosion and siltation. For example, federal policy discourages conversion of wetlands to farmland, because the remaining wetlands have important ecological and hydrologic value (USEPA, 1998).

On 7 January, 1998, the U.S. Environmental Protection Agency released its first national report on the quality of sediments in the nation's rivers and streams. Although the report discovered that the majority of watersheds do not pose adverse risks, it cited that 7% of the surveyed watersheds have contaminated sediments. Every state in the union has some level of sediment contamination affecting its streams, lakes and harbors. This fact goes hand in hand with the trend toward laws supporting a watershed-wide consideration of environmental elements. Bearing in mind that impervious areas affect how water runs off the land, the development and maintenance of properly engineered drainage basins continues to play an important part in the future of water science.

## 20.4 KEY TREND-SETTING COURT DECISIONS

One of the most difficult problems in the field of sedimentation law is how to arrive at a final accounting of legal damage in the face of a physical process that changes over a span

<sup>1</sup> "Sedimentation Law" (Vanoni 1975).

of years, during which natural processes of control become established (Busby, 1975). In fact, sedimentation law evolves around the concept that legal components of a stream change as the needs of the public change. In the 1970s, public interest was already shifting to smaller watersheds. As a result, sedimentation law is connected to key trend-setting court decisions as they relate to individual cases.

## **20.5 PUBLIC LIABILITY AND NATURAL HAZARDS: COMMON LAW AND REGULATORY "TAKINGS"—FUTURE DIRECTIONS**

Bearing in mind that the original chapter on this subject was written by an attorney, the authors of this revision, in order to maintain that same caliber of legal expertise, dedicate this portion of this chapter to the work of an expert in the field of law. In 1992, Jon A. Kusler, Executive Director for the Association of State Wetland Managers, Inc., in Berne, New York, an association dedicated to the protection and management of the nation's wetlands, prepared a book for the scientific community on the subject of natural hazards law. The draft entitled "Public Liability in Natural Hazards" was prepared for the National Science Foundation pursuant to Grant CES-8612277 and submitted to the foundation in 1992. The authors of Chapter 20 obtained permission from Kusler to quote portions of the draft for the purpose of documenting recent trends in sedimentation law.

Therefore, this portion of the revised chapter quotes extensively from the work of Kusler (1992). Kusler examined more than 1,000 flood and drainage-related cases. More generally, he addressed public liability, responsibility and defense. These hazard-related cases (both regulatory and nonregulatory) reveal that new legal issues, such as inverse condemnation, have come into existence.

Through Kusler's exhaustive research, it became apparent that tort-related hazard law has a rapidly changing nature. "Many state and federal statutory modifications in tort liability have been and are now being legislatively adopted. To some extent, the issue then becomes not simply the present status of law but: what should government liability be?"

Kusler's book is primarily a legal treatise designed to help public and private lawyers and agency employees understand when and where governments (federal, state, local) may be liable for actions or inactions with regard to natural hazard losses and avoidance of future losses. It was also designed for natural hazard policy-makers and managers, legislators, scientists, and others interested in the scope of government liability and possible techniques for limiting liability while, at the same time, reducing natural hazard losses.

To summarize his findings, we begin with an overview of public liability due to natural hazards including court cases addressing specific hazards. Although loss of life caused by natural hazards has been reduced in the United States from natural disasters, property losses continue to take heavy

tolls, in the United States and abroad, due to both private and public developments in hazardous areas subject to floods, erosion, earthquakes, landslides and mudslides, hurricanes, tornadoes, wild-fires, and other natural disasters.

According to Kusler's findings

when private individuals are damaged by natural hazards, they increasingly file liability suits against governments claiming that governments have caused the damages, contributed to the damages, or (in some instances) failed to prevent or provide adequate warnings of natural hazards. In determining the liability of governmental units for damages due to governmental activities which increase natural hazards or for damages due to mitigation measures, courts apply general common law and constitutional rules of liability. However, there are several aspects of these cases which are somewhat unique to natural hazards: an emphasis upon the "duties" of landowners rather than simply "rights"; the highly technical nature of suits; strong public health and safety and nuisance issues; and the existence of a variety of government programs to economically or otherwise compensate those injured by natural hazards.

Kusler also pointed out that landowners may opt to sue governments for regulating their property through zoning, building codes, special codes, and so forth. However, the success rate of this type of lawsuit is very low. It is well to note that allegations against the government concerning cause or increased damages to property or individuals form the basis for both types of suits. However, natural hazard losses versus reduced property values and options in the use of private land vary.

There has been an increase in the last part of the 20th Century of successful lawsuits against governments for government activities that increased natural hazard losses, such as the increase of erosion and flood flows, resulting in damages to private individuals. However, there were few successful cases that dealt with nonstructural hazard mitigation measures such as mapping, warning systems, evacuation measures, government regulations and insurance programs.

It is important to point out that most successful suits involving liability have revolved around situations in which governments have been responsible for directly increased flood or drainage problems to private properties located adjacent to public lands or public works projects, such as bridges, and roads, or through hazard reduction measures. Again, a modest number of suits have addressed situations in which governments were responsible for increased damages from mudslides and landslides and sometimes from snow, weather prediction, modification, and erosion. Very few suits have addressed other natural hazards such as earthquakes and volcanoes.

In most tort-related cases, the courts have held private individuals and governments increasingly liable for

natural-hazard and nonnatural-hazard-related injuries caused by “unreasonable” conduct which causes injury to individuals or to private property. “This trend toward increased successful liability suits for unreasonable conduct (usually based upon a theory of negligence) is particularly pronounced for governmental units not because governmental units are now being treated more harshly than private individuals but because the defense of government sovereign immunity has been eroded during this period, and increasingly, courts hold governmental units to the same standard of reasonable care as private individuals. See *Shipp v. City of Alexandria*, 392 So. 2d 1078, 1079 (La., 1980) Court agreed with “the modern trend . . . for public bodies to be treated in the same manner as private individuals unless policy considerations suggest otherwise.”

This trend is due to legislative policy rather than a willingness of courts to entertain suits against governments. Some expansion has been due to changes in standing which allow damaged individuals to bring suits under preexisting theories of action, which were formerly unable to be utilized. The Civil Rights Act of 1871 has been a standard for individuals claiming violation of their “civil rights” under Section 1983 of this original act. This is the result of U.S. Supreme Court decisions interpreting the Civil Rights Act of 1871 as applying to local government actions.

Liability litigation is a dynamic, evolving area of law. In its broader context, lawsuits against governments by private individuals based on natural hazard losses or based on government actions to reduce such hazards are broken into two principal forms.

First are suits by private individuals who suffer from natural hazard losses they claim were caused by governments. These suits are generally for damages and are based mostly upon common law tort or to a lesser extent on contract theories. Some suits are also based upon statutory or constitutional grounds.

Second are the less common cases by private individuals who are prevented by governments through the adoption of regulations from engaging in filling, construction of dams, houses roads or otherwise using, subdividing or selling hazard-prone lands. These cases are based on the 5th Amendment or the 14th Amendment of the U.S. Constitution, or similar provision in state constitutions. These cases are mostly to compel issuance of permits or they are filed for damages due to the partial or complete taking of private property without payment of just compensation.

There have been almost no successful lawsuits based upon regulatory takings in hazard area contexts despite a widespread perception among governmental units that regulatory “takings” are a significant problem.

Both case types require the proof of specific damages and they both require proof of causation. In addition, both types of cases have, at their core, the basic duties as well as rights of private landowners and individuals (both private and public) to other landowners and individuals.

Due to a lack of hard and fast rules for negligent or nonnegligent conduct, the site-specific nature of negligent actions encourages a large number of suits. However, negligence depends, to a considerable degree, upon the circumstances and negligence is also, to a considerable degree, what a judge or jury says it is in a specific circumstance.

Of course, advancements both in knowledge concerning hazards and in modelling techniques make it more difficult for landowners to prove that a particular activity on adjacent land substantially increases flooding, subsidence, erosion or other hazards on his or her land. “This was particularly true when the increase was due to multiple activities on many lands such as increased flooding due to development throughout a watershed. Today, sophisticated modelling techniques greatly facilitate proof of causation and allocation of fault.” See, e.g., *Lea Company v. North Carolina Board of Transportation*, 304 S.E. 2d 164 (N.C., 1983).

The contexts in which government liability for hazard-related actions may arise can be summarized into four categories:

- Natural hazard injuries that occur on public lands or in public buildings.
- Offsite impacts of various government activities on public lands.
- Government actions not related to public ownership or management of lands which increase natural hazard losses.
- Tightly regulating private activities within hazard areas to prevent hazard area occupants from increasing hazards on adjacent lands or regulating to reduce onsite losses.

The federal government, states, and local governments can all be sued for negligence, nuisance, breach of contract, or the “taking” of private property without payment of just compensation.

1. Local governments are the most vulnerable to such liability suits based upon natural hazards due to the fact that they are the very units of government undertaking most activities resulting in increased natural hazards or “takings of private property” and are “least protected by defenses such as sovereign immunity and statutory exemptions from tort actions.” It is at the local level that most hazardous lands are managed and occur (road construction and maintenance for example).
2. States may be sued for negligence, trespass, takings and contract theories. Limited land use controls limits cases against state governments.
3. Federal liability is much broader with regard to federal land use. Congress has specifically exempted federal agencies for liability for negligence with regard to flood control measures by the Flood Control Act of 1936. However, federal agencies may be sued for

uncompensated taking of private property under the 5th Amendment. For example, agencies may be held liable for permanently flooding private land or other activities of both a nonregulatory or regulatory nature that are a taking.

There are three phases of a natural disaster: predisaster, during-disaster, and postdisaster:

1. Prior to a disaster, inadequately designed, constructed, operated and maintained warning systems, emergency evacuation plans, and hazard reduction structures (such as groins, dams, and dikes), may result in damage and as a result cause public liability. A lawsuit might occur at this point if issuance of regulatory permits over a period of years without adequate consideration of natural hazards might in some jurisdictions result in liability.
2. During the time of an actual disaster, if government activities are undertaken without "reasonable care" a public liability may arise. Both loss of life and property loss during a disaster can impose huge demands upon government resources in a relatively short period of time. Actions with potential for liability include issuance of warnings, rescue, construction of emergency levees, emergency releases from dams, evacuation, fire-fighting, and destruction of buildings or other structures to prevent further damage.
3. Such post disaster activities such as clean-up, debris removal, repair of structures can put governments in a negligent position.

Rules of liability which apply to private landowners in their use of hazard areas is also relevant to the validity of government regulations which very tightly controls private actions in hazard areas (Kusler 1992). For example, the U.S. Supreme Court decision, *Lucas v. South Carolina Coastal Council* held that when a regulation denies all "economically viable use of land" such a regulation is not a taking only. In this case, constitutional and common law merge because the state background principles of nuisance and property law would not allow such uses.

Further proceedings on this case remanded a decision of the South Carolina Supreme Court holding that a Beachfront Management Act, designed to address flooding and erosion problems, prevented a landowner from erecting any permanently habitable structure on the barrier island parcels. This case was, therefore, not a taking of private property without first payment of just compensation.

Kusler's findings that pertain to flood hazard court cases are varied but all cases illustrate the fact that much of the landscape is subject to one natural hazard or another.

As a result of the broad incidence of flood and drainage problems and the foreseeability of the problems, most natural hazard-related liability suits against governments have been the result of flood or drainage damages. Cases illustrating various types of situations in which governments

have been sued for flooding or drainage damages include the following:

- *Pumpelly v. Green Bay Co.*, 80 U.S. (13 Wall) 166 (S. Ct., 1971). State is liable for taking of private property due to flooding private lands by state reservoir.
- *Rodriques v. State*, 472 P. 2d 509 (Haw., 1970). State is liable for damage due to inadequate maintenance of drainage culverts which were blocked by sandbars and tidal action.
- *United States v. Kansas City Life Insurance Co.*, 70 S. Ct. 885 (S. Ct., 1950). Federal government is liable for maintaining the Mississippi River at an artificially high level that raised the low water table blocking drainage of properties and destroying the agricultural value of lands.
- *Ducey v. United States*, (713 F. 2d 504 9th Cir., 1983). Federal government is potentially liable for failure to provide warnings for flash flood areas for an area subject to severe flooding in Lake Mead National Recreation Area.
- *Coates v. United States*, 612 F. Supp. 592 (D.C. Ill., 1985). Federal government is liable for failure to give adequate flash flood warning to campers in Rocky Mountain National Park and to develop adequate emergency management plan.
- *Barr v. Game, Fish and Parks Commission*, 497 P. 2d 340 (Col., 1972). State agency is liable for negligent design of dam and spillway inadequate to convey maximum probable flood; "act of God" defense inapplicable because of the foreseeability of the hazard event.
- *Masley v. City of Lorain*, 358 N.E. 2d 596 (Oh., 1976). City is not liable for increased flooding due to urbanization including lots and streets but may be liable for inverse condemnation for damages due to storm sewer system.

It is well to note that a relatively large number of challenges have been made to floodplain regulations that restrict private development in flood hazard areas. For reference, see Kusler (1971, 1984).

- *Linquist v. Omaha Realty, Inc.* 247 N.W. 2d 684 (S.D., 1976). Court held that resolution of Rapid City city council of June 1972, prohibiting issuance of building permits for one block on each side of Rapid Creek after the devastating flood until a study was completed by the planning commission, was a valid exercise of police powers and not a taking.
- *Cappture Realty corp. v. Board of Adjustment*, 313 A. 2d 624 (N.J., 1973). Court upheld interim zoning ordinance declaring a 1-year moratorium (with a 1-year extension) on construction in flood-prone area unless special exception permit was obtained.
- *Foreman v. State Department of Natural Resources*, 387 N.E. 2d 455 (Ind., 1979). Court sustained an injunction

prohibiting defendants from making deposits on a floodway and requiring removal of deposits previously made as not a taking of property.

Although hurricanes are generally foreseeable they are difficult to predict in specific terms. Two examples of lawsuits filed against governments based upon claims that they have increased various types of hurricane damage are listed below:

- *Alain-Lebreton, Co., v. Dept. of Army, etc.*, 670 F. 2d 43 (1982). No taking occurred in decision by local levee district and by Corps of Engineers not to locate hurricane protection levees on certain lands although levees were provided on other lands.
- *Annicelli v. Town of South Kingstown*, 463 A. 2d 133 (R.I., 1983). Court held that prohibition of construction on a heavily developed barrier island subject to hurricane damage was a taking of property where environmental values rather than hazards were heavily emphasized in regulation.

A modest number of lawsuits have been filed against governments for actions that increased erosion damages. The following court cases map out entitlements, limitations, and inverse condemnation decisions:

- *Owen v. U.S.*, 851 F. 2d 1404 (Fed. Cir., 1988). Erosion allegedly caused by government dredging in river which caused collapse of house could constitute a compensable taking.
- *Ballam v. U.S.*, 552 F. Supp. 390 (D. S.C., 1982). Erosion caused by wave wash along coastal water was a "continuous taking." Plaintiff was entitled to damages for valued land lost through erosion and for cost of protecting property from future erosion. However, recovery was limited to changes within 6-year statute of limitation period.
- *Souza v. Silver Dev. Co.*, 164 Cal. App. 3d 165, 210 Cal. Rptr. 146 (Cal., 1985). City held not liable under a theory of inverse condemnation for city's use of creek as part of storm drainage system which caused stream bank erosion due to inadequate proof of causation.
- *Baskett v. U.S.*, 8 Cl.Ct. 201 (Cl. Ct., 1985). Government potentially liable for flooding and erosion but no liability due to lack of proof of causation.

Challenges made to erosion-related regulations sometimes prohibit removal of sand and gravel or prohibiting or setting minimum standards for development in erosion-prone areas, such as the following case:

- *Rolleston v. State*, 266 S.E. 2d 189 (Ga., 1980). Court held that Georgia's beach was constitutional and that denial of permit for landowner to construct a bulkhead while permitting others to build bulkheads, was not a taking.

In some instances there are special issues with regard to hazard-related litigation. We will discuss what this means in relation to flooding and subsequent sedimentation liability.

Unprecedented weather beyond scientific foreseeability can bring expensive lawsuits into play, imposing hefty liabilities upon the government. This makes reasonableness of actions difficult at best. Courts and juries must decide whether events are foreseeable, bearing in mind reasonable and unreasonable actions due to possibility of occurrence and hazard mitigation options available.

The issue in determining the reasonableness of government actions is not simply whether hazards are foreseeable (because they are becoming increasingly foreseeable) but under what degrees of risk individuals and governments must take actions to protect others. For example, there is always a mathematical possibility that a dam will be overtopped and destroyed by a truly extraordinary rainfall or an earthquake (e.g., once in 500 years, 1000 years) killing many. See, for example, *Barr v. Game, Fish and Parks Commission*, 497 p. 2d 340 (Col., 1972) in which the court held an agency responsible for a "maximum probable" flood.

Insofar as the "Good Samaritan" doctrine applies to governments in hazard contexts, courts and juries alike face difficult decisions even according to classic negligence theory, which is that governments are liable for lack of due care when they act as good Samaritans and undertake actions that they are not required to undertake such as, e.g., *Indian Towing v. United States* 765 S. Ct. 122 (S. Ct., 1955). Because issues of overall equity and public policy are considered by the courts, complication arises in the application of strict legal doctrines. For instance, if a landowner living in a floodplain sues the government over a faulty warning system, the landowner may collect twice from the government: once for the faulty warning system and a second time for alleged losses.

The almost total lack of successful landowner actions against the government due to inadequate maps, warning systems, flood insurance, disaster assistance and other non-structural mitigation measures suggest that courts are reluctant to find governmental units liable in such contexts.

The trend in recent years at all levels is to shift government costs of occupancy of flood hazard areas to the landowner. In 1965, the Federal Task Force on Flood Control recommended "those who occupy the floodplain should be responsible for the results of their own actions." (A Unified National Program for Managing Flood Losses, H.R. Doc. No. 465, p. 3, 89th Congress 2d sess. 1966) (U.S. House of Representatives 1966). To date, cost-sharing requirements for federal flood loss reduction and reduced federal spending on flood damage issues support this philosophy. The interdependencies of liability suits with various hazard mitigation and disaster assistance programs such as FEMA's Project Impact suggest improved approaches for better coordination of liability and hazard mitigation and disaster assistance efforts across a broad spectrum (FEMA 2000b).

According to Kusler's findings, the relationship of court decisions to public policy support major hazard-related government programs that consist of laws and administrative guidelines that include the following key elements:

- A land planning and regulatory element preventing or controlling private and/or public development in high risk areas and establishment of a performance standard for development in low risk areas. Areas consistent with federal standards are given incentives on state and community levels of federally subsidized flood insurance. Federal agencies directly plan and control public/private activities on federal lands. Also, a limited measure of federal control is provided in some hazard areas such as flooding, subsidence and erosion through the Army Corps of Engineers Section 10 and Section 404 permit programs as well as by a variety of licensing statutes and federal permits. "The principal goal of these planning and regulatory efforts at all levels of government is to prevent private and public landowners from using their lands in a manner that will increase natural hazards on other lands, threaten public safety, or increase government natural hazard costs in other ways. Please note that these efforts are designed to prevent future problems while the common law tends to operate after-the-fact.
- Hazard prediction, mapping, warning and evacuation planning elements, not regulatory in nature tend to help inform the public and private sectors and other decision-makers just where hazards fall and the severity of risk per location. "Tort law and cases to date are, overall, consistent with government programs to encourage private and public actions to reduce potential losses since the overall trend in tort law is toward a reasonable use standard." Reasonable use standards require landowners to reasonably foresee hazards and take actions according and consistent to the foreseeable risk. "Tort law and contract-based actions such as the implied warranty of suitability for new residence help give teeth to and implement these non-regulatory efforts."
- Hazard reduction elements that include the construction of dikes, levees, reservoirs, beach nourishment, erosion control works, etc. Although smaller structures and projects have been accomplished at the state and local levels, most major hazard reduction measures in the case of flooding and erosion has been the responsibility of the federal government. "Tort law tends to discourage or add to the costs of such hazard reduction elements. As has been discussed, most successful tort cases to date have arisen with the design, operation, and maintenance of such structural measures. Most of the successful inverse condemnation cases have also arisen with these structures." In order to reduce potential liability suits, the government has been motivated to construct hazard reduction measures.
- A disaster-assistance element that includes assistance and rescue at the actual time of disasters such as emergency foods, medical care, temporary shelter, and post-disaster loans and grants also includes federally subsidized flood and erosion insurance. "Most of the funding for such disaster assistance efforts comes from the federal government while relief efforts are carried out on the state and local levels.

As a result of a Federal Task Force on Flood Control Policy in 1965 (Task Force on Federal Flood Control Policy, A unified National Program for Managing Flood Losses, H.R. Doc. No. 465, p. 3, 89th cong., 2d sess. 1966), a key policy for flood plain areas is, "Those who occupy the flood plain should be responsible for the results of their own actions." The upshot of this task force report serves as a blueprint for floodplain management at the national level over the past three decades. During the 1970s and 1980s, progress was made by reducing federal spending on hazard reduction measures by requiring that landowners in hazardous areas conduct their activities in a manner that keeps losses to a minimum:

- Flood loss reduction measures such as dams, dikes, and levees require a local cost share 25%.
- Emphasis upon nonstructural loss reduction measures such as flood plain regulations and warning systems funded privately.
- Cost-bearing by those in hazard areas directly related to potential losses.

But, rules evolve as the nation shifts from large national debts and growing budget deficits to a stronger economy. The rules, over a period of centuries, compensate one landowner for damages his or her actions may impose on other landowners (nuisance) or other individuals (negligence). As society continues to demand a high level of public and individual safety, the protection of this demand grows legislatively. Not only is the moral ethic ingrained in our national fiber to help those plighted by floods but America's high standard of protection for public health and safety is supported by tort and contract-related liability cases.

**The nuisance suit** in conjunction with broader regulations for land use when it comes to protection of the environment allows landowners to prevent industrial uses in a residential area. **Common law** practice enables private citizens who own land to prevent some types of potential water polluters through suits based upon riparian rights. However, due to limited abilities, common law suits are not able to allow governments or private sectors a broad planning objective.

Goals for the *reasonable* use of both private and public hazardous areas are both explicit and implicit in most government natural hazard programs. All hazard prevention and use measures tend to encourage or support "reasonable" use. "In general, both public and private landowners are responsible for 'unreasonable' conduct in light

of the conduct of others.” Courts consistently uphold that landowners have no property right to use their land in situations where actions would not be permitted under *common law*.

In general, disaster assistance and subsidized insurance are limited and, therefore, larger damage awards for specific damages and losses are available through *liability suits*, which are for the most part inefficient. In the situation where disaster insurance is not offered, governments may be sued for confirmed damages. But liability suits take an average of 4 to 10 yr to settle and most landowners are too poor to pursue this costly, hard-to-prove-fault type of legal action. Liability suits also may result in double-dipping, whereby lawyers and landowners get paid from policies and suits. In addition, this type of case adds to the cost of hazard measures themselves. The most successful liability suits have been the result of negligent design or badly operated hazard reduction measures such as a faulty dam or erosion control gone awry. Overall, the government views liability cases as a threat to its budget and hazard-reducing programs.

- For example, a community at risk might reduce that risk with the construction of a dike reducing flood elevations below natural levels, where the community has raised natural flood heights substantially over a period of years through bridge construction.
- Flood warning systems, evacuation plans, and other loss-reduction techniques can reduce liability potential if properly designed, operated, and maintained.
- Government insurance and disaster assistance programs can reduce the number of suits filed if customers are quickly compensated for their losses.
- Direct-pay compensation programs are relevant in some courts as a cause of action under the facts. See North Carolina Supreme Court, in *Responsible Citizens v. City of Asheville*, 302 S.E. 2d 204 (N.C., 1983), which upheld floodplain regulations against constitutional due process and taking challenges and which noted that plaintiffs were “benefitted” by enactment of the regulations because they qualified the community and the plaintiff for federal flood insurance.
- Regulation may somewhat reduce lawsuits by provision of a general standard of care for governments, private architects, and the like rather than a nebulous unquantified standard of “reasonableness” in a given circumstance.

Loss reduction and mitigation programs enhance the potential for successful lawsuits in some contexts:

- Government subsidy policies for disaster victims in high-risk areas can increase liability awards.
- Regulations can increase potential liability for public and private individuals who fail to comply with government regulations.

- Various mapping and hazard prediction techniques as part of insurance parcels and zoning, warning, or other loss-reduction programs can increase foreseeability of hazards.
- New techniques improperly applied or failure of application when affordable and available and when not applied before a disaster, foreseen or not, thus causing high death rates, may be considered “unreasonable” and result in adverse liability decisions.

Disaster assistance and loss reduction measures such as flood control, avalanche control, and storm drains, when applied in a professional, timely, and expert fashion, tremendously reduce potential government losses in liability suits. This involves decision making for structural hazard reduction measures because of the high incidence of successful suits related to such measures; administrative measures; education on the local level; prevention of double-dipping; beefed-up government lawsuits against negligent private landowners who cause public liability; and recovery of government losses per legal rules to discourage hazard-related losses. See *United States v. St. Bernard Parish*, 756 F. 2d 1116 (5th Cir. 1985).

Subrogation, a familiar insurance concept is defined in Black’s Law Dictionary as follows:

A legal fiction through which a person who, not as a volunteer or in his own wrong, pays the debt of another, is substituted to all rights and remedies of the other, and the debt is treated as still existing for his benefit.

The Standard Flood Insurance policy that is issued by the Federal Government specifically states that:

In the event of any payment under this policy, the Insurer shall be subrogated to all the Insured’s rights of recovery therefore against any party, and the Insurer may require from the Insured an assignment of all rights of recovery against any party for loss to the extent that payment therefore is made by the Insurer.

Government agencies that compensate landowners with disaster assistance, flood insurance and the like can potentially become the subrogees of rights of actions for flood, erosion, and other types of damage caused to the recipients of the disaster assistance, insurance, or payments by private individuals or any other public entities. See, e.g., *United States v. Dold*, 462 F. Supp. 801 (D.C., S.D., 1978).

See also *United States v. St. Bernard Parish*, 756 F. 2d 1116 (5th Cir., 1985) in which the U.S. government sought over \$100 million from various Louisiana public and private defendants for flood damages which the federal government alleged were caused by failure to adopt and administer floodplain regulations that met the minimum standards of the N.F.I.P. “In this case, the U.S. Court of Appeals held that no ‘contract’ right existed between the federal government and the parishes which could serve as the basis for a subrogation

suit.” It also held that the government could pursue damages under common law subrogation theories permitted by Louisiana law. Ultimately the federal government and the parishes settled this case.

Although by the 1990s there were few federal subrogation suits, the suits that were initiated in the 1980s attracted a great deal of attention across the nation and had an educational and enforcement value much greater than the actual recovery monies. They set a precedent for future suits, particularly if legislative changes provided an express contract basis for such suits.

The goal (in liability suits) should be not only to reduce government liability but also to promote responsible government and decision-making with natural hazards factored into the process. More specifically, administrative, legislative, and judicial approaches to achievement of these goals are paramount.

## 20.6 VARIOUS DEFENSES

Defenses based upon rules of law are decided by the courts, by judges. Defenses built on fact are decided either by juries or by judges in a trial without a jury. The general rule of thumb for cases based on the former defense (rules of law) is to raise questions/challenges during the preliminary pleadings stage through a process known as “demurrer’s” or requests for “summary judgment” because at this stage, if successful results materialize, the case can be dismissed before trial. “From a government perspective, an early victory in a natural hazards liability-related case is especially desirable due to the high costs of expert witnesses and attorney’s fees if the case goes to trial.” The latter case based on questions of fact, such as “act of God” cases, must be proved during trial.

In any case, plaintiffs suing governments under all theories of action (common law, statutory, constitutional) must prove that:

- the government owed them a duty;
- the government breached said duty;
- the plaintiff suffered damages; and
- the breach of duty was the cause of the damages.

The burden of proof is on the plaintiff to “prove all of the essential facts that form the basis for his or her liability claim. This is true for all theories of action.”

The most common successful challenges to a plaintiff’s proof of essential facts in tort-based cases include the failure to establish “unreasonableness” when it comes to defendants actions in relation to negligence or to establish causation. On the other hand, the most common successful challenge to a plaintiff’s proof of facts in a hazard-related regulatory takings case is the failure to show that regulations, as applied, deny all economic use of land.

The government cannot take private property in a hazard-prone area without just compensation. The hitch is that governments can reduce private land values through regulations adopted for proper goals when those regulations are adequately

related to those goals. Courts are agreed that such land reductions labeled as “damages,” often more severe than those serving as the basis for tort actions, are noncompensable as long as there is no physical interference with respect to the use of private land. So long as due process and equal protection have been a provision, and there is no taking of private property, courts are increasingly applying a “denial of all economic use test” in these cases. That being said, differences in allowable impacts as well as in the nature of these impacts; such as physical interference versus permissible uses, explain, in part, the great number of successful liability suits against governments operating as landowners, and on the other spectrum, the very small number of successful takings cases against governments acting as regulators of private property.

Governments claim that there is no breach of duty in tort-related, contract-related, or fact-driven cases. “Since most hazard-related cases are based upon claims of negligence, governments can rebut an allegation and attempted proof of breach of duty by establishing the reasonableness of government conduct in the circumstances taking into account the nature of the activity, the foreseeability of the hazard, the severity of the hazard, the possible impacts of government actions on landowners, and other factors.” Constitutionally based suits in general are a judicial question, breach or no breach. See *Belair v. Riverside County Flood Control District*, 253 Cal. Rptr. 693 (Cal., 1988), in which a determination of “negligence” in construction and maintenance of levees was necessary to establish an inverse condemnation claim.

Causation is straightforward in constitutionally based regulatory takings cases, as reductions in property values are caused by regulations but causation is hard to prove when the validity of basic regulations and impacts upon private lands is the issue.

Bearing in mind that no property will be taken if there is no damage, a plaintiff must prove damages in an inverse condemnation case. Exceptions exist when property is taken through public entry onto private land when no damages can be shown for such entry. See *City of Austin v. Teague*, 570 S.W. 2d 389 (Tex., 1978) whereby the court held that regulations took property with no awards because plaintiff failed to prove specific damages.

## 20.7 SOVEREIGN IMMUNITY

There is no taking without proof that regulations deny all economic uses. Courts have quite often held that landowners cannot show a taking until they have exhausted all administrative remedies proving once and for all that they are “deprived” of all economic uses. This lies under the category of “Sovereign Immunity” which continues to be the most essential defense to tort suits against governments. See *Little v. City of Myrtle Beach*, 279 S.E. 2d 131 (S.C., 1981), whereby the city was not liable for alleged defects or negligent management of drainage facilities that caused flooding, due to sovereign immunity.

Sovereign immunity is a doctrine adopted by American courts from English common law after the American Revolution was won. It is based upon the concept that the “king can do no wrong,” or at the very least, that the king is not responsible for his wrong. This concept has of course been broadly criticized as inappropriate for a nation without a king and particularly, a nation with strong egalitarian principles and strong restraints upon government action vis-à-vis the Constitution. Nonetheless, in the 19th century, the doctrine was applied to all levels of government and in 1834, the Supreme Court held that sovereign immunity applied to the federal government. See *United States v. Clarke*, 33 U.S. (8 Pet.) 436 (S. Ct., 1834). At the state level, courts have held that states have nearly complete sovereign immunity and municipalities and counties less. See, e.g., *Heffner v. Montgomery County*, 545 A.2d 67 (Md., 1968).

It is interesting to note that over time, the courts have provided a variety of explanations for adherence to this doctrine (Huffman, 1988, p. 449). For example, in 1868, the U.S. Supreme Court in the *Siren*, 74 U.S. (7 Wall.) 152, 154 (1868) observed that it was “obvious that the public service would be hindered and the public safety endangered” if the state could be sued and “consequently controlled” by its citizens. The Court also argued in another case that without sovereign immunity “government would be unable to perform the varied duties for which it was created.” See *Nichols v. U.S.*, 74 U.S. (7 Wall.) 122, 126 (1896).

During the last three decades of the 20th century, exceptions to the general rule involving sovereign immunity even at common law, have been rapidly expanded by judicial or legislative action or a combination of both. See *Kind v. Johnson City*, 478 S.W.2d 63 (Tenn., 1971) where sovereign immunity defense does not apply to nuisances; and see *Callaway v. City of Odessa*, 602 S.W.2d 330 (Tex., 1980) where the city may be liable when negligence becomes a nuisance although immune for negligence. “Sovereign immunity has also not been a defense to governmental violation of constitutional rights, including violation of due process and taking of private property.” On the state and local levels, lawsuits involve the government when regarded in a proprietary role in connection with negligence.

See *Enghauser Manufacturing Company v. Eriksson Engineering Ltd.*, 451 N.E.2d 228 (Oh., 1983), for example of a judicial abrogation of sovereign immunity doctrine. In this case, the Ohio Supreme Court abolished municipal immunity and held that a municipality could be held liable for negligently planning, designing and constructing a bridge and roadway that resulted in flooding of industrial property. Equally or even more important, Congress and state legislatures have adopted Tort Claim Acts and other legislation that restricts the defense of sovereign immunity with regard to tort claims. The trend is to duty to the individual versus public duty.

There are four situations in which governments are generally subject to a special duty of care to a particular plaintiff or class of plaintiffs:

- legislative intent: when the terms of a legislative enactment evidence an intent to identify and protect a particular and circumscribed class of persons;
- failure to enforce: where governmental agents responsible for enforcing statutory requirements possess actual knowledge of a statutory violation, fail to take corrective action despite a statutory duty to do so, and the plaintiff is within the class the statute intended to protect;
- rescue doctrine: when governmental agents fail to exercise reasonable care after assuming a duty to earn or come to the aid of a particular plaintiff;
- special relationship: where a relationship exists between the governmental agent and any reasonably foreseeable plaintiff, wetting the injured plaintiff from the general public and the plaintiff relies on explicit assurances given by the agent or assurances inherent in a duty vested in a governmental entity. (Id. at 1260)

See also Glannon (1982).

Statutory exceptions include acts and modifications:

- Federal Statutory Exceptions and the jurisdiction of the Court of Claims were expanded by the Tucker Act in 1887 and by later acts to follow, including claims based upon the Constitution, law of Congress, regulations of executive departments or contracts with the U.S., and patent infringements. 24 Stat. 505 (1887); 36 Stat. 85 (1910); 28 U.S.C.A. 1498 (1973); 28 U.S.C.A. 1346 (1976).
- In 1946, Congress adopted the Federal Tort Claims Act, which was a general waiver of sovereign immunity for “injury or loss of property or personal injury or death caused by the negligent or wrongful act or omission of any employee of the Government while acting within the scope of his office or employment, under circumstances where the United States, if a private citizen, would be liable to claimant in accordance with the law of the place where the act or omission occurred,” 60 Stat. 812, title 4 (1946); 28 U.S.C.A. at 2672 (1965). This act is mentioned because it contains 13 exceptions, 2 of which are particularly relevant to claims that are a result of natural hazards. The first and more important is the “discretionary function” exception, which excepts from the act any claim based upon the failure to exercise or perform a discretionary function or duty, whether or not the discretion involved involves abuse (emphasis added), 28 U.S.C.A. 2680(a) (1965). The second exception excepts from the act any claim “arising out of misrepresentation, deceit, or interference with contract rights”(emphasis added), 28 U.S.C.A. 2680(h) (1965).

U.S. courts are deciding if weather forecasts are the exercise of a discretionary function. The courts have consistently held that forecasts are, in themselves, discretionary. See, e.g. *Brown v. United States*, 790 F. 2d 199 (1st Cir., 1986): N.O.A.A. could not be sued for failure to predict a hurricane. But, in *Pierce v. United States*, 659 F. 2d 617, 621 (6th Cir.,

1982), the 6th Circuit held that “(s)ince the FAA has undertaken to advise requesting pilots of weather conditions, thus engendering reliance ... it is under a duty to see that information which it furnishes is accurate and complete.”

An extremely important statutory exemption for negligence is contained in section 702c of the Federal Flood Control Act of 1936, 33 U.S.C.A. 702c (1986). Section 702c exempts the federal government for liability for “negligence” associated with the design, operation, and maintenance of any given federal flood control facility.

When federal flood forecasts and federal floodplain mapping are characterized as “flood control” measures by lower federal courts, they are not subject to tort actions for negligence. Flooding is by far the most common basis for hazard-related liability suits against the government; therefore, the federal government has been principally responsible for the construction of all major flood control dams, dikes, levees, sea walls, and channelization projects. It is no surprise that this exception has acted to bar many lawsuits and has been challenged a number of times by claimants involved. See *United States v. James*, 106 S. Ct. 3116 (S., Ct., 1986), where private tort actions for damages based upon federal negligence at a flood control facility was interpreted by the U.S. Supreme Court. The court held that the Corps of Engineers could not be held liable in situations where recreational water users were swept into dams when the Corps opened these structures in order to control flooding.

## 20.8 STATUTES OF LIMITATIONS

In general, statutes of limitations applying to architects and engineers now start to run from the time of construction rather than from an injury. See *Klein v. Catalano*, 437 N.E. 2d 514 (Mass., 1982).

Limitations that begin running at the time of design or construction provide a low probability of recourse for someone damaged by design errors or negligence during a severe but very infrequent flood, erosion event, or other natural disaster. The probability in these cases is only 1 in 20, according to Kusler, that a negligence action would arise for a 100-yr event within the time period allocated by a 5-yr statute of limitations where the statute begins to run from the initial design rather than from the time of injury.

## 20.9 HAZARD MITIGATION MEASURES BASED UPON TORT THEORIES

Courts have repeatedly held that governments at all levels must use reasonable care. Most successful cases against the government involve situations where mitigation measures increased natural hazards and damaged individuals not intended as the beneficiaries of such measures. A good example is a flood

control measure that floods upstream properties (a nonbeneficiary).

Examples where courts have held that the basic decision to protect or not is not subject to liability, under theories of either no duty or discretionary function, include the following cases:

- *Tri-Chem, Inc. v. Los Angeles County Flood Control District*, Los Angeles County, 132 Cal. Rptr. 142 (Cal. App., 1976), where the State has no duty to construct a flood control system for an area that acts as a natural sump.
- *Deville v. Calcasieu Parish Gravity Drainage Dist.* No. 5, 422 So. 2d 631 (La., 1982), where the city was not liable for a child falling into a storm drain where the drainage district normally maintained the drain and the city maintained it only during floods.
- *Goldstein v. County of Monroe*, 432 N.Y. S. 2d 966 (N.Y.A.D. 4th Dept., 1980), where a municipal corporation is not liable for failing to restrain waters between the banks of a creek or to keep a channel free from obstructions it did not cause.

A decision worth examining is the Supreme Court case *Julius Rothschild and Co. v. State of Hawaii*, 655 P. 2d 877 (Haw., 1982) due to in-depth discussion of factors concerning reconstruction of a two-span bridge with the capacity to convey a 25-yr storm. A flash flood caused warehouse damage and the plaintiff argued that the replacement span was inadequate in light of a hydraulic design report prepared by a firm contracted by the state prior to the reconstruction. The report had recommended replacement of the bridge deck consistent with a 50-yr frequency design criterion.

In another case, *PDTC Owners Ass'n v. Coachella Valley County Water Dist.*, 443 F. Supp. 338 (D. Cal., 1978), the court held that owners of land damaged by flooding could not recover compensation from the water district under the Fifth and Fourteenth Amendments for failure to construct a levee large enough to protect landowners from a 50-yr flood. The levee in question had been constructed of sand and provided protection only from a 30-yr flood. The court held that the landowners might be able to recover any damages for negligent construction and maintenance. Also, in *Vanguard Tours, Inc. v. Town of Yorktown*, 442 Y.Y.S. 2d 19 (N.Y., 1981) the city was not liable for failure to install a drainage system that adequately disposed of surface waters, but the city must rather use care in maintenance of such systems.

Such cases lead to the subject of adequacy of the design which all boils down to reasonableness of care and implied warranties. In cases where the actual construction of a government measure is faulty, nondiscretionary task and government forces may be held liable for negligence of government employees or contractors not properly supervised. See *Price v. United States*, 530 F. Supp. 1010 (S.D. Miss., 1981), where the Corps of Engineers was liable for the negligence of

a contractor who dredged an area subject to hurricane damage, thus creating a deep hole, and subsequently failed to provide warnings. In general, operation or administration of a hazard mitigation measure is considered ministerial and governments are responsible for negligence.

By the same token, maintenance of a mitigation measure is considered ministerial and governmental units are responsible for negligence. See *Carlotto Ltd. V. County of Ventura*, 121 Cal. Rptr. 171 (Cal., 1975), where a California court held a county liable for inadequate maintenance of a “debris basin.” “The county had failed to maintain the debris basin behind the dam with the result that only 2.5 acre feet of its entire 12.7 acre feet of water storage remained and damages resulted.”

## 20.10 MORE ON THE TAKINGS ISSUE: EXPANDED STATUS AND TRENDS IN TORT AND TAKINGS LAWS

Successful regulatory takings cases in connection with hazard-related regulations are outnumbered 500 to 1 by successful tort cases holding governmental units liable for increasing losses due to hazards. Lopsided fear of “taking” is out of proportion due to several factors:

**First**, takings cases are given inordinate attention by the press. Supreme Court decisions receive front-page press coverage across America. Unfortunately, it is a sign of the times, more often than not, that the press coverage is inaccurate, speculative, and paranoia-driven.

**Second**, there is a deep-seated belief that “taking” private property without just compensation is morally wrong. This ethic contrasts with negligence, breach of contract, or other typical torts that do not carry the same weight as a moral stigma. The U.S. Constitution prohibits “taking” without compensation.

**Third**, successful takings cases could have severe political repercussions for bureaucrats and legislators who authorize the very taking itself. These law abiders must answer to an electorate on this sensitive issue of “taking.”

**Fourth**, a regulatory “taking” has its limits mainly due to the fact that governments are not positioned with established administrative procedures or funding for payment in conjunction with a regulatory taking. Usually, each case is handled individually through legislative appropriation. Unappropriated funds prove disruptive to government operations. However, a large unanticipated expense for a blizzard or even a large tort liability award due to highway construction, for example, is usually not an issue because eminent domain funds already exist.

**Fifth**, misunderstandings abound on government levels due to unclear concepts of what is or is not a taking. This inability to adjust measures to avoid “takings” is partly due to a lack of clear judicial guidance on the takings issue. The case-by-case approach to taking issues utilized by the court system involves a variety of tests to determine whether actions to “take” property are contributing factors.

Almost all hazard-related takings cases (regulatory and nonregulatory) deal with flood losses or floodplain regulations. This is due to the pervasiveness of flood and erosion problems throughout the United States as well as the many contexts in which government actions may increase flood damages on privately held lands.

Courts have traditionally held that governments may, in some instances, destroy private property during a disaster to prevent the spread of the disaster or may require the razing or raze private structures which are dangerous after a disaster.

See *Boland v. City of Rapid City*, 315 N.W. 2d 496 (S.D., 1982) where the city had the power to destroy flood-damaged private houses after the Rapid City Flood of 1972 to alleviate public health problems but the city also had the burden to prove that houses created public health problems a nuisance. The city had not done this and was liable for a “taking.”

In *Oswalt v. County of Ramsey*, 371 N.W. 2d 241 (Minn., 1985) the court held that a landowner was entitled to compensation for the county’s refusal of a permit to repair a flood-damaged house. The house was a valid nonconforming use under an ordinance, but the county had failed to consider the “useful life” of the proposed improvement for purposes of amortization and had instead, in effect, condemned the use by refusing to issue a building permit.

## 20.11 UPSTREAM VERSUS DOWNSTREAM LEGAL ISSUES

Unlike land, water is transient and moves. It recognizes no political boundaries. Therefore, water is legally and historically a public resource although water rights can be obtained. Private rights to water are often incomplete and subject to the public’s common needs (CSI 1999). The transfer of water rights must go through the proper legal channels for the state; for example, *Tyler v. Wilkinson* is a case that adopted the reasonable use standard.

Other boundary disputes that went to the U.S. Supreme Court include the following:

- *Georgia v. South Carolina*, 497 U.S. 376 (1990), a suit over the location of a boundary along the Savannah River, downstream from the city of Savannah and at the river’s mouth, and the lateral seaward boundary. Historically, the treaty between these states declared

that “where there is no island in the river, the boundary is midway between the banks, and where there is an island, the boundary is midway between the island and the South Carolina shore (*Georgia v. South Carolina*).” The Special Master (above) submitted two Reports, making several boundary recommendations, but both states filed exceptions.

Either state stands to lose riverbed as a result of natural erosion by the river; likewise, each state has the potential of acquiring additional riverbed as a result of accretion and erosion. For example, if an island existed in 1787 but was subsequently eliminated by gradual erosion, the boundary would be moved to the advantage of South Carolina, and the riverbed previously owned by Georgia would then be owned by South Carolina (*Georgia Exceptions* 56).

Part of Georgia’s fourth exception included the small, unnamed islands upstream and downstream from Pennyworth Island. Georgia’s exception was overruled and The Special Master’s determination adopted a “forever after” boundary on behalf of South Carolina due to the theory that the South Carolina shore, over time, would create a regime of continually shifting jurisdiction, by creating a new “northern branch or stream” for even the smallest emerging island, thus frustrating the original state treaty [497 U.S. 376, 377]. The avoidance of sudden boundary changes and respect for settled expectations that generally attend the drawing of interstate boundaries, cf. *Virginia v. Tennessee*, 148 U.S. 503, 522–525, pp. 394–398, was cited.

- *Oklahoma v. New Mexico*, 501 U.S. 221 (1991), was concerned with an enlargement of the Ute Reservoir and a violation of the 200,000 acre-feet limitation law on New Mexico’s constructed reservoir capacity available for conservation storage downstream from Conchas Dam, and with a so-called “desilting pool” exempt from the Article IV limitation, because it was not allocated solely to “sediment control.” Floods from Canada affected the storage basin in the downstream states. The Court abandoned the literal text of the Compact and searched for a new interpretation of the “originating” due to the fact that the Compact would otherwise allow New Mexico to lay claim to any water originating above Conchas Dam, including tributaries that arose in boundary states.

## 20.12 ACT OF GOD DEFENSE

Since the sixteenth century, courts have recognized “act of God” as a common law defense to negligence, nuisance, trespass and even, in some instances, takings cases. The act of

God defense has also been incorporated into some statutes. See 33 U.S.C.A. 1321(a)(12)(1986), “an act occasioned by an unanticipated grave natural disaster.”

The “act of God” defense is based upon the belief that one should not be held responsible for what cannot be reasonably anticipated or guarded against. It is a defense that must be affirmatively pleaded and proven by the defendant. It is a defense that was at one time much more broadly allowed by the courts. Today the defense is most often narrowly construed. See, e.g., *Sabine Towing and Transp. Co., Inc. v. U.S.*, 666 F.2d 561 (Ct. Cl., 1981). (Spring runoff was not “act of God” which would excuse an oil spill.)

Cases dealing with “act of God” defenses focus on two important hazard issues that are common to all such cases: the predictability of various hazards, and the magnitude of events, such as destructive force and return frequency, which need to be addressed by public and private landowners.

Verifying “act of God” is another story. In order to prove such a case, the defendant must establish, to the satisfaction of the jury or court, that (1) the event falls within the legal definition of “act of God” and (2) the “act of God” and not the defendant’s negligence was the proximate cause of the disaster.

Courts are in agreement that the defendant must more specifically prove that

- the event is an act of mother nature (hurricanes, storms, earthquakes, floods), not caused by human agency;
- the event is “extraordinary” in magnitude or size;
- the event and resulting damages could not reasonably have been anticipated or prevented; and
- the event was the proximate cause of the damage or injury.

The difficulty arises in the proof. Was the event an act of nature? An “act of God” is defined as an event that is due directly and exclusively to natural causes without human intervention. Kusler cites *Northwestern Bell Tel. Co. v. Henry Carlson Co.*, 165 N.W. 2d 346, 349 (S.D., 1969). See also *Dempsey v. City of Souris*, 279 N.W. 2d 418 (N.D., 1979), as another example of events that fall under the “act of God” category. Although meteorological events (hurricanes, storms, tornadoes, lightening) and geological/geomorphological events (erosion, landslides, earthquakes) continue to occur as they have throughout history, the actual causative elements of many events are no longer totally natural. Rains fall naturally but the height, velocity, and volume of floodwaters depend upon watershed uses, dams, dikes, levees, and many other alterations. Similarly, erosion has often been greatly impacted by human activities, as have landslides, mudslides, and wildfires.

Some courts have required that in order for an event to be classified as an “act of God” the event must be “unprecedented.” An example cited is the Alabama Supreme Court decision in *Bradford v. Stanley*, 355 So. 2d 328, 330 (Ala.,

1978) which observed that: "In its legal sense an act of God applies only to events in nature so extraordinary that the history of climatic variations and other conditions in the particular locality affords no reasonable warning of such events." However, with historical techniques now available, the occurrence of events over the last several thousand years is sometimes documented. In much of the world as we know it, there are historical written records of catastrophic floods, hurricanes, earthquakes, and other terrible storms that date back thousands of years. Paleo-flood studies combined with carbon dating and supplementary dating methods provide additional documentation. In addition, studies of tree rings, sediments, and soil science are providing quite specific documentation for large-scale hazard events at given locations.

If events are not unprecedented, courts have held that they must be at least extraordinary from a scientific and not simply a layman's perspective. One example is the U.S. Court of Appeals, District of Columbia Circuit in *Shea-S&M Ball v. Massman-Kiewit-Early*, 606 F. 2d 1245 (1979), which rejected the "act of God" defense by a contractor where waters from his construction site overflowed during heavy rains resulting in damage on a second construction site. In this case, the court found insufficient evidence in the record to support a finding of an act of God and they noted that "The record is completely devoid of any evidence of the normal range of rainfall in Washington, D.C., and (they contended that) the amount of rain that actually fell during the time periods when the floods occurred" (Id. At 1248). The court, therefore, concluded that heavy rainfalls are not considered acts of God unless they are unusual and extraordinary and quoted with approval from an earlier case, *Garner v. Ritzenberg*, 167 A.2d 353, 354-65 (D.C., 1961):

We take judicial notice that rains of heavy intensity and average duration are occurrences of common experience. This event was described as a flash flood. People often use that expression in describing accumulations of rainwater running off along natural or artificial contours of the ground; but that imports no particular legal significance. Such events, though infrequent, are to be expected. They do not create the widespread devastation commonly associated with earthquakes, tornadoes, hurricanes or extraordinary floods. The occasional filling of low-level or basement areas by rainwater is a probable and foreseeable result of a heavy rain. To classify it as an act of God is an unwarranted extension of that doctrine not supported by the authorities.

Due to the fact that predictability of events has become more accurate through modeling techniques for flooding, earthquakes, volcano eruption, hurricane tracking, etc., courts do not require that such events be specifically predictable with a "foreseeable" date and place; it is enough that such events could have been expected. Therefore, events with particular assigned recurrence intervals have persuaded a number of courts to consider the foreseeability of hazard events in a new light.

One such example resulted in a rejection. In *Barr v. Game, Fish and Parks Commission*, 497 p. 2d 340 (Col., 1972) the Colorado Court of Appeals rejected an "act of God" defense for flooding, erosion, and silt deposition damage caused by construction of a dam with an adequate spillway by the Colorado Game, Fish and Parks Commission. The court held that a "maximum probable storm, by definition, is both maximum and probable." In the end, the court agreed (Id., at 344) with the lower court that had concluded,

(W)ith modern meteorological techniques, a maximum probable storm is predictable and a maximum probable flood is foreseeable. Thus being both predictable and foreseeable to the defendant in the design and construction of the dam, the defense of an act of God is not available to them. In short, the flood that occurred in June of 1965 could not be classified as an act of God.

Therefore, the court concluded that the above dam should have been designed to meet the requirements of the maximum probable flood—200,000 cfs at this point of the stream. Proving that the event in and of itself was the proximate cause of the damage or injury is often difficult due to the fact that the defendant's actions (as in a negligence case) may also be part of the proximate cause. For example, storm waves from a hurricane may badly erode a beach, but the actual damage may also be caused, at least in part, by defendants' construction of a groin or seawall along another portion of the same beach.

There is a general rule in place that states that when a natural event concurs with acts of the defendant to produce the injury, the defendant is not liable if the event would have independently produced the damage without the defendant's transactions. Some well-documented cases include *Fairbrother v. Wiley's, Inc.*, 331 P. 2d 330 (Kan., 1958). The Maryland Court of Appeals in *Mark Downs, Inc. v. McCormick Properties, Inc.*, 441 A. 2d 1119, 1128-29 (Md., 1982) noted that an "act of God" will excuse mortal man from responsibility "only if God is the sole cause ... where God and man collaborate in causing flood damage, man must pay at least for his share of the blame." Where the acts of man and the acts of God combine to cause damage, courts have generally held man responsible for the total damage. See also *National Weeklies, Inc. v. Jensen*, 235 N.W. 905, 906 (Minn., 1931) in which the court stated:

If the damage done was solely the result of an act of God, the city was not liable. If the negligence of the city approximately contributed and an act of God combined to produce the result, the city is liable.

"Act of God" has been a defense principally in tort cases. In some instances, however, it has been recognized as a defense in contract cases—for example, *Firpine Prods. Co. v. Atchison, T. and S. F. Ry.*, 124 F. Supp. 906 (D.C. Mo., 1954). Other courts have disagreed with its application in contract contexts. For example, the Alabama Supreme

Court in *Alpine Construction Company v. Water Works Bd. Of Birmingham*, 377 So. 2d 954, 956 (Ala., 1979) stated that

Where one by his contract undertakes an obligation which is absolute, he is bound to perform within the terms of the contract or answer in damages, despite an act of God, unexpected difficulty, or hardship, because these contingencies could have been provided against by his contract.

## 20.13 FORENSIC GEOLOGY

Some turning points in forensic geology include the extensive use of aerial photography. According to *Forensic Geology*, by Raymond C. Murray and John C.F. Tedrow, the American Society of Photogrammetry has listed over 100 ways in which aerial photography serves a useful function from archaeological discoveries to finding modern burial sites. Altered soil conditions are key during court cases.

During the course of an investigation, it is sometimes critical to establish the time of a certain activity, such as the filling in of wetlands, the digging of a borrow pit, the time a forest was cut, or when a structure was built or demolished. An aerial or ground photograph, with date, gives indisputable evidence as to the presence of physical features or landscape conditions at a specific time. (Murray, 1992)

Federal agencies such as the U.S. Geological Survey and the U.S. Department of Agriculture and military and commercial establishments take aerial photographs periodically. Aerial photographs are available through these various agencies, but the most comprehensive sets, including archives, may be obtained from the U.S. Department of Agriculture, ASCS, Aerial Photography Field Office, 2222 West 2300 South, Salt Lake City, Utah 84130.

## 20.14 FUTURE DIRECTIONS

The complex law of public liability for natural hazards is not easily summarized. According to Kusler, there are vast differences in the law of liability under tort, contract, and constitutional theories from state to state, particularly with regard to the sovereign immunity defense and the nuances of particular causes of action such as trespass. Although the precise theories and rules of law vary, overall theories of liability are identical, such as situations in which as government unit can be held liable for a particular act. A good example is found in local government, which in most states can be held liable for flooding private land by construction of public access. Of course, the law varies from state to state, but such an action could be based upon nuisance, violation of riparian rights, trespass, negligence, or inverse condemnation.

There is a general status of law throughout the nation, but particular attention should be rendered when it comes to jurisdiction. When it comes to reducing natural hazard losses through structural measures such as dams or nonstructural measures such as warning systems and regulations, officials, scholars and landowners are increasingly confused with regard to the liability potential of reducing natural hazards. It is a huge undertaking to reduce private losses from private use of public lands that are subject to flood, earthquake, or other hazards at the risk of damaging other private parcels. Flood control measures have a high potential for liability, while regulations are low-risk. However, a wide variety of low-cost measures are available to help reduce potential liability.

The majority of liability suits to date have involved governmental activities on public lands that cause damage to adjacent privately owned lands due to inadequate design, operation, or maintenance of roads, airports, utilities, reservoirs, dikes, dams, erosion-control structures, mudslide and landslide structures, or storm-water facilities. The lawsuits have been based upon nuisance, trespass, negligence, violation of riparian rights, strict liability, negligence or inverse condemnation theories of action.

Although there is the potential for successful negligent suits based upon various nonstructural mitigation actions not related to government ownership and use of land such as inaccurate hazard maps, inadequate warning systems, inaccurate hazard predictions, inadequate dissemination of hazard information, inadequate emergency services, and inadequate administration or enforcement of regulations, few suits based upon such inadequacies have succeeded to date for several reasons. These actions are considered "discretionary" in nature by the courts and are also partially or wholly protected by sovereign immunity or statutory exemptions. (Kusler, unpublished work, 1992)

The *takings* issue is popular with the press because it is a strong political issue, but courts have overwhelmingly upheld hazard regulations against constitutional challenges. In the hundreds of appellate-level cases that involve constitutional challenges to regulations, courts have only held regulations unconstitutional as a taking of property in a few cases where regulations prevented all uses in relatively low-risk areas or an attempt was made to apply regulations retroactively to abolish hazard-prone structures without adequate documentation of the nuisance aspects. It is clear that natural hazard regulations can reduce property values without a taking and that performance-oriented hazard regulations do not, in general, pose a threat of "taking." Theories and cause of action for tort and inverse condemnation actions have been expanded to hold government liable for "unreasonable" conduct, much like a private citizen. Defenses such as sovereign immunity and "act of God" have been narrowed (see the *Act of God* section).

Advances in hazard-related technology and science deem hazard events more predictable and susceptible to various sorts of mitigation. As these options increase, the standard of care for “reasonable” conduct and also the potential for successful suits increases. Because of this fact, the “sovereign immunity” defense has been judicially or legislatively modified, particularly with regard to the actions of local governments. Therefore, it is possible to suggest trends in sedimentation law and possible future directions:

- Government actions that increase flooding, drainage, erosion, and landslide, problems that arise on private owned lands, will likely continue to pose inverse condemnation threat to governments.
- Government defenses will most likely narrow to engulf liability suits that relate to sovereign immunity, act of God, and inverse condemnation.
- The U.S. Supreme Court and lower courts will scrutinize land use regulations in terms of their impact on private landowners.

It is suggested, in Kusler’s extensive work, that the best overall approach to reducing liability is through informed decision-making that considers the hazard-loss implications of government acts and takes actions based upon this analysis. The best way to avoid negligence-based liability is through “reasonable conduct in the circumstances.”

From a scientific and engineering perspective, disasters equal moratoria to assess damages in greater detail. This includes probability of reoccurrence, and development of a mitigation plan. Speed in such studies is essential but the undertaking is often limited by availability of experts who are often in short supply after a major disaster. However, precise design and location of development must often be modified and re-modified to reduce impacts on other lands and to ensure the safety and structural integrity of the damaged area.

Examples of theories that have been modified on the judicial level and that apply to the reasonableness standard include the following:

- The “common enemy” doctrine for surface waters has been replaced by a reasonable use standard in most states;

A recent case in Missouri, in fact, overturns the “common enemy rule”: “Landowners who erect levees and otherwise back up DSW [downstream water] onto their neighbors can only do so with immunity if their actions are ‘reasonable’ (common law approaches to water rights ‘invite’ lawsuits if certainty is sought.)” In addition, a cautionary as to DSW: common law includes a “line of cases” known as the Natural Drainage Rule which states that natural drainage patterns and flow rates cannot be altered unilaterally without consent of impacted neighbors (Missouri Water Law).

For example, drainage decisions for the Illinois wetlands have been affected by the passage of the wetlands provisions of the Food Security Act of 1985 due to the fact that the remaining wetlands have important ecological and hydrologic value. Federal policy discourages conversion of wetlands to farmlands. The Illinois Drainage Law was revised in December 1997.

- Strict liability for dams has been replaced with a reasonable use standard in some states.
- The doctrine of caveat emptor (“let the buyer beware”) has been replaced with one of implied warranty of suitability, incorporating a concept of reasonable anticipation of natural hazards on the part of sellers and protection of reasonable expectations of buyers.
- Reasonableness of activities has become a principal issue in many inverse condemnation suits.

The “reasonableness” standard is used more widely because it reduces each circumstance to a common denominator standard for liability assessment. It is flexible and fact-specific. In most cases, it incorporates basic concepts of fairness. In the context of natural hazards, it is consistent with the goal of responsible use of public or private lands.

In summary, Kusler recommends a status and certain trends prevalent in the courts at the time of his research (unpublished work, 1992). The bottom line, despite widespread concern about government liability for regulation of private activities in hazard contexts, is that virtually all successful liability cases to date (reported in thousands of decisions, some of which have been mentioned) have involved government activities that caused or increased natural hazard losses or failure of governments to remedy or warn of natural hazards on public lands.

Theories and grounds for tort and inverse condemnation actions have been expanded to hold government liable for “unreasonable” conduct, much like a private individual. Defenses such as sovereign immunity and “act of God” have been narrowed. Based on all factors considered, it is possible, according to Kusler, to suggest trends in law as well as a clear path for future of American sedimentation law and the physical processes thereof.

- The greatest tort liability or inverse condemnation threat to governments will continue to be liability suits; subsidence can also be predicted as mitigation measures improve causing more regulations to be adopted that will ultimately help establish a standard of “reasonable” care conduct.
- All other hazards fall under the same category (see recent developments in “Project Impact”).
- The government and the individual will most likely fall into the same standard of care for nondiscretionary “unreasonable conduct.”

- Governmental units will be expected to uphold an increasingly high standard of care for “reasonable” conduct.
- Foreseeability limits may occur along with counter legislative caps on government liability through “tort-claim acts.”
- The U.S. Supreme Court as well as the lower courts, will more carefully examine land use regulations, not just related to hazard (again, see Project Impact in Recent Developments, next section).

In reducing potential government liability, there is a broad range of options available to maintain government responsibility, including administrative actions, legislative changes, and judicial responses.

Kusler concludes his survey with the theory that courts should continue to take a factually-specific, pragmatic approach to natural hazard cases and should tackle many unresolved legal issues with “the goal of encouraging responsible, equitable, and reasonable private and public conduct.”

## 20.15 SUMMARY AND RECENT DEVELOPMENTS

In Arnold, Missouri, the total amount of Federal disaster assistance granted after the devastating floods of 1993 was well over \$2 million. After the floods of 1995, the fourth largest flood in the history of Arnold, the damage was less than \$40,000 due to the nonstructural mitigation, which culminated in the acquisition of flood-prone or flood-damaged properties (FEMA, 1995). The 1995 flood was much less severe due to the fact that most of the affected areas had been bought out by the government so the residents were no longer in harm’s way. Therefore, the Arnold, Missouri case illustrates the value of acquisition and highlights the value of planning as a mitigation tool.

The unprecedented flood of 1993 offered a long-term solution that included the creation of land use plans that included changes to lessen the impacts of future disasters by following organizational plans implemented as land use strategies. This, along with capital improvement plans to obtain the necessary funds to accomplish the desired goals, in combination with the city’s ability to facilitate a solution to sustaining flood damages, was documented in 1995 as part of an ongoing accomplishment.

FEMA’s effort to reduce risk through mitigation culminates in a reduction in potential damages. The community of Darlington, Wisconsin experienced indirect benefits in connection with FEMA’s mitigation efforts. Darlington’s environment was rendered safer, its aesthetic quality was heightened, and the natural function of its floodplain was restored resulting in the city’s economic development potential to increase.

The mitigation projects in the Midwest ranged in size and complexity from one to two home elevations to Valmeyer,

Illinois which relocated a significant portion of the town to a new location, to Wakenda, Missouri which acquired and demolished all the town’s structures, and disincorporated. What all these projects hold in common is that they reflect the communities’ visions of themselves. Communities must be aware of their risks and plan accordingly, weighing mitigation alternatives with community needs (FEMA, 1995).

In May of 1995, the most expensive floods in the history of the National Flood Insurance Program (NFIP) took place in Louisiana, when \$584 million was paid out in claims. The severe floods, which ravaged at least 14 states from Florida to Maine in mid-September 1999, culminated in claims averaging \$21,237 per claim. At this writing, more than \$310 million has been settled for 14, 614 flood damage claims. Although an unprecedented amount of claim money has been paid, the statistics report that the majority of Hurricane Floyd flood victims unfortunately did not have flood insurance; that, for example, in the state of North Carolina (the state hit hardest by Hurricane Floyd), only \$1,000 policies were in force at the time of the disaster. “Nationwide, only about one-fourth of households in special flood hazard areas have flood insurance,” then-Federal administrator Jo Ann Howard pointed out. She went on to say that the money paid out comes from premium income, and not tax dollars, and that the more that property owners take responsibility for their own protection against hazards by purchasing flood insurance, the fewer landowners will need to rely on disaster relief funded by U.S. taxpayers. She assured the public at large that flood insurance not only reduces government expenditures for disaster relief in great amounts, but provides victims of disasters with much greater compensation. She also said that while disaster grants are helpful, they are also very limited, and that disaster loans have to be repaid with interest. Therefore, it is a win-win situation when landowners take rainy day responsibility for future hazard damages by purchasing flood insurance. Howard noted that high-risk areas engulf properties currently located outside of known high-risk zones due to the fact that in recent years, floods (the most common type of natural disaster) have been reported in places that never experienced them in their histories.

Aside from the benefits of hazard insurance policies, Howard encouraged communities to get involved in further actions to reduce damage through FEMA’s public awareness effort, **Project Impact**—an effort devoted to building disaster resistant communities, its motto being “educating people to elevate, floodproof, or otherwise move structures out of harm’s way” (FEMA 2000a).

### 20.15.1 Project Impact

The Federal Emergency Management Agency (FEMA) is changing the way America deals with disasters. Project Impact assists communities to protect themselves from the devastating effects of natural disasters by taking actions to dramatically reduce disruption and loss of properties and life. Project Impact

operates on a common-sense damage-reduction approach, basing its work and planning skills on three simple principles:

- Preventive actions decided at the local level;
- Private sector participation; and
- Long-term efforts and investments in prevention measures.

This unique experiment began with seven pilot communities across the country that partnered with FEMA for expertise and technical assistance on national and regional levels to include federal agencies and states in the equation. FEMA, using all available mechanisms to put the latest technology and mitigation practices into the hands of local communities (businesses, schools, private sectors) and governments, has expanded from the original seven pilot communities to 200 Project Impact communities. More than 1,100 businesses have joined FEMA's growing partnerships. The incentive for disaster-resistant communities across the land has been able to bounce back from a natural disaster with far less loss of property and consequently much less cost for repairs. The estimates are in that for every dollar spent in damage prevention, two are saved in repairs. (FEMA 2000b).

Former FEMA Director James Lee Witt outlined key provisions to Congress of the Fiscal Year 2001 budget. Besides asking Congress to authorize \$971 million, FEMA also requested an additional \$2.6 billion in emergency contingency funds for future disasters. Witt reminded Congress that with their support, Project Impact communities were established in every state in the union. He requested \$30 million for the following fiscal year in order to continue expansion of this initiative for the express purpose of building a nation of disaster-resistant communities (FEMA 2000c).

As of February 15, 2000, Congress approved additional buyout funds from a separate emergency contingency fund for 13 states from Florida to Maine hit by Hurricanes Floyd, Irene and Dennis. FEMA announced that an additional \$215 million was made available for buyouts and relocation of properties damaged by these floods. These funds must be matched by 25 percent of nonfederal funding and can be used only for primary residences that are deemed uninhabitable due to the disaster(s) (FEMA 2000d).

In addition to extra government fundings, projects related to the removal of structures from flood hazard areas were undertaken, such as the state of Iowa's case study, entitled *The Benefit of Hazard Mitigation Projects in Iowa*, which tracked 128 hazard mitigation projects or initiatives pursued by Iowa communities, counties, or the state, resulting in an anticipated overall government savings of \$100 million. At this time, since 1993, Iowa has been impacted three times by floods. Many of the federally funded acquisition projects that removed properties avoided the subsequent impact of flooding, resulting in savings within a 2 to 3-yr period (FEMA 1999).

Successes in relation to reducing costs, overall costly court cases that result in taking of high-risk disaster prone

lands, and unforeseen flood damages such as erosion and sedimentation problems due to unforeseeable natural disasters in unknown risk areas rests on sound public policy and strong support systems, such as FEMA's *Project Impact*, the NFIP insurance claims programs, and a demonstration of reasonable use of private and public lands by the citizens as well as by the government.

The Government Performance and Results Act (GPRA) requires that agencies submit annual performance plans to Congress along with fiscal year budget requests, and they must also prepare an annual performance report at the end of each fiscal year (FY) on how well their goals were met. The FY 1999 Annual Performance Plan was the Department of the Interior's first official plan submitted to Congress and Interior's first opportunity to report on their accomplishments. Further, their current plan and their proposal for their subsequent plan have been combined into a single presentation in order for trends in performance to be measured side by side with trends according to current results.

To make use of today's science for America's tomorrow, and science in general for a changing world, the strategic direction for the U.S. Geological Survey combined and enhanced diverse programs, capabilities, and talents, increased customer involvement in an effort to strengthen science leadership, and continued its reputation for contribution to the resolution of complex issues. As a world leader in the natural sciences with a vision of scientific excellence and responsiveness to society's needs, the USGS continues to have a mission to serve the nation by providing reliable scientific information. Its linkage to the bureau strategic plan, budget, and departmental goals is housed in its main mission objective: hazards, and environment and natural resources. Its most important product is quality science that is both relevant to a changing world and effectively communicated. Peer reviews and program evaluations will continue to measure its capabilities. The USGS sums up the future of hazard-related industry in general with its plans to meet the challenges of the 21st century with renewed vigor and a clarified sense of purpose and mission. "Understanding the delicate balance between the earth's natural resources and America's need for continued growth will enable us to make better decisions for future generations' enjoyment of this precious land," said Dr. Charles Groat, then-USGS Director, in defense of budget increases for science to provide reliable information and tools in order to accurately forecast a better tomorrow (USGS 2000).

### 20.15.2 Polluted Sediments and Sediments as Pollutants

Since the creation of nationwide regulations, such as the Federal Water Pollution Control Act Amendments of 1972, amended in 1977 and heretofore referred to as the Clean Water Act, legal liability has been assigned to situations where pollutants attach to sediment particles. However, the

legal framework for polluted sediments has emerged primarily from relatively recent environmental laws rather than from the body of law that examines the effects of sedimentation processes on changes in geography. For this reason, on the subject of polluted sediments, the authors recommend consulting reference materials that pertain to environmental law.

In addition to pollutants that attach to sediment, the individual particles can sometimes be recognized as pollutants by certain regulations. For example, introduction of high silt concentrations through surface erosion can affect fisheries, other aquatic species or habitats. This area of law and regulation is similarly beyond the scope of this chapter.

## 20.16 CONCLUSION

Sedimentation policy, in connection with the problems of property rights and damages due to flood disasters, stems from the changing tide of sedimentation engineering concepts and how those efforts must accommodate a constantly changing world that effects any given community subject to disasters. Engineering—the core of the vast field of water law and sedimentation—plays a vital role when it comes to recent trends in American sedimentation law and the physical processes it is based on. Key trend-setting court decisions serve to remind the powers that be of reasonable use standards and ethical practices. When it comes to public liability and natural hazards, hazard mitigation and awareness programs, insurance plans, and cooperation between government agencies and private citizens are key. Although Statutes of Limitation draw a line in the sand after certain disclosures, if reasonable use can be challenged, inverse condemnation can be considered. For the most part, “act of God” defenses occur when flood damage is unprecedented. Forensic geology is a valuable accuracy tool for technically proving physical changes. Overall, the new wave of sedimentation engineering demonstrates the benefits of reasonable use and cooperative awareness for both private and public lands that are interwoven with social controls, government regulations, and other legal agreements.

## ACKNOWLEDGMENTS

We were fortunate to have knowledgeable references in the form of an unpublished draft book entitled *Public Liability and Natural Hazards: Common Law and Regulatory “Takings”*; *Future Directions*, compiled by legal expert Jon Kusler, who was generous enough to lend access to his extensive research to the world of civil engineering.

A portion of the research and the actual writing of this report was made possible through Grant No. CES-8612277 from the National Science Foundation. This funding and the help of Dr. William Anderson, project officer, is gratefully appreciated. In addition, a project advisory committee helped define the audience for the book and the level of analysis. Advisory committee members included, in addition to Dr. Anderson,

James Wright, The Tennessee Valley Authority; Frank Thomas, the Federal Emergency Management Agency; Ross McKay, the Federal Emergency Management Agency; Larry Larson, the Association of State Floodplain Managers; and Gilbert White, the University of Colorado. Their assistance is much appreciated. Also, law student assistants at the Albany Law School who provided research assistance included Alan Baum, Robert McCann, Dan McCormick, Peggy Seilkin, and Peter Hickey. Their help and the use of law school library facilities are also much appreciated.

## CHAPTER 21

### *Contaminant Processes in Sediments*

*Danny D. Reible*

#### 21.1 INTRODUCTION

Many of the most toxic and most persistent environmental contaminants in bodies of water are strongly associated with sediments, either suspended or settled to the bed. As a result, the transport and fate of sediments also often define the dynamics of associated contaminants. Contaminants are also influenced, however, by a variety of physical, chemical, and biological processes that involve no net movement of sediments. These processes include pore-water transport processes such as diffusion and advection and sediment mixing processes such as reworking by benthic organisms that involve no net downstream particle movement. Understanding these processes is critical to development of appropriate strategies for managing the risks these contaminants may pose to human health and the environment. Assessment of the processes that control contaminant migration and fate in a water body allows development of a conceptual model of the system and identification of intervention approaches that are most likely to succeed. Evaluation of these processes provides an assessment of the potential for natural attenuation of contaminants in a system. These processes are also critical to the evaluation of more active remedial approaches, such as dredging or capping, because the success of these approaches typically depends upon the fate of the residual contaminants in the water body. This paper will examine processes that influence the fate and transport characteristics of contaminants in sediments and interaction of these processes with common management or remedial approaches.

Any attempt to summarize and compare natural processes in sediments must recognize the different environments in which contaminated sediments are found. The relative importance of these processes differs significantly between lacustrine, riverine, estuarine, and coastal environments. The range and significance of natural processes are influenced heavily by site-specific characteristics. This paper attempts to identify all of the potentially important natural processes influencing

contaminants and build a matrix relating sediment and water-body characteristics to these processes. The individual processes are discussed, including a means of assessing the importance of each process in particular field situations.

The most important natural fate and transport processes at contaminated sediment sites are illustrated in Fig. 21-1 and include the following:

- In-bed fate processes, including irreversible adsorption and chemical or biological reactions;
- In-bed transport processes, including diffusion and advection as influenced by reversible sorption/desorption and colloidal transport;
- Interfacial transport processes (bed to water column or vice versa), including sediment deposition and resuspension, bioturbation, and water-side mass transfer.

Table 21-1 summarizes the relative importance of these processes in various sedimentary environments. These processes and their importance in the individual environments are discussed in more detail in subsequent sections. The most important factor in defining the fate and transport processes that influence contaminants in sediment beds is the energy of the overlying flow. In high-energy environments, bed sediment tends to be coarse-grained and noncohesive, with little sorptive capacity and low depositional rates. These sediments pose little barrier to advective transport and often allow oxygen transport deep within the sediment. In low-energy environments, significant deposits of fine-grained sediments exist, providing high sorptive capacity and significant slowing of advection and oxygen transport. Somewhat offsetting these differences is the fact that many organisms, especially head-down deposit feeders, prefer fine-grained sediments. Therefore, bioturbation (i.e., the mixing associated with the normal life-cycle activities of sediment-dwelling organisms) is often enhanced in areas of finer-grained sediments.

Fig. 21-1. Depiction of selected processes at the sediment-water interface.

## 21.2 CONTAMINANTS OF CONCERN

Relatively uncontrolled historical wastewater effluents often introduced priority pollutants and other contaminants of concern to the environment. Many of these compounds tended to accumulate in sediments because of persistence and hydrophobicity. Because wastewater effluents are now more controlled, the accumulation of contaminants in the sediments is reduced and other sources, such as atmospheric deposition and rural and urban runoff, may be equally or more important in contributing individual pollutants to the sediment. In addition, the sediments now often constitute a significant source controlling surficial water quality. Contaminants that do not strongly associate with solids, such as polar organic compounds or soluble metals, rarely accumulate in sediments, because these compounds are efficiently released to the overlying water. In this section we will examine some of the most important sediment contaminants and the physical

and chemical characteristics that relate to fate and mobility in the environment. These contaminants include conventional pollutants such as nutrients and oxygen-demanding contaminants, heavy metals, pesticides, polycyclic aromatic hydrocarbons (PAHs), and chlorinated organic compounds such as polychlorinated biphenyls (PCBs) and multiply chlorinated benzenes.

### 21.2.1 Conventional Pollutants

Conventional pollutants include nutrients, oxygen demanding contaminants, and undifferentiated oil and grease. Sediments may harbor a significant inventory of nitrogen and phosphorus, release of which may dramatically change the biological characteristics of the overlying water. A variety of organic and inorganic compounds in sediments consume oxygen. The cumulative effect of these reactions is measured by sediment oxygen demand, a parameter similar

**Table 21-1 Sediment Processes and Relationship to Various Sediment Environments**

Environment	Environmental characteristics	Key fate and transport processes
Lacustrine	Low-energy environment Generally depositional environment Groundwater interaction decreasing away from shore Organic matter decreasing with distance from shore Often fine-grained sediment	Sediment deposition Water-side mass transfer limitations Groundwater advection in near-shore area Bioturbation (especially in near-shore area) Diffusion in quiescent settings Metal sorption Aerobic and anaerobic biotransformation Biotransformation of organic matter (e.g., gas formation)
Riverine	Low- to high-energy environment Depositional or erosional environment Potential for significant groundwater interaction Significant variability in flow and sediment characteristics within and between rivers	Local and generalized groundwater advection Sediment deposition and resuspension Aerobic biotransformation processes in surficial sediments (anaerobic at depth) Bioturbation
Estuarine	Generally low-energy environment Generally depositional environment Generally fine-grained sediment Grading to coarse sediment at ocean boundary	Bioturbation Sediment deposition Water-side mass transfer limitations Aerobic and anaerobic biotransformation of contaminants Biotransformation of organic matter (e.g., gas formation)
Coastal marine	Relatively high-energy environment, decreasing with depth and distance from shore Often coarse sediments	Bioturbation Sediment erosion and deposition Localized advection processes

in significance to oxygen-demanding measures in the overlying water. Sediment oxygen demand serves to reduce available oxygen and encourage anaerobic conditions within the sediment. This may affect the rate of fate processes, such as biological degradation of contaminants in the sediments, and the chemical state of metals, influencing mobility. The sediment oxygen demand can also impact oxygen levels in the overlying water. There are no specific levels of oxygen demanding constituents that are considered problematic. The impact of these contaminants depends upon the dynamics of the sediment, associated groundwaters, and overlying water column.

Long-chain nonpolar organic compounds, such as oil and grease, associate strongly with solids and sediments. Measures of these compounds include both oil and grease concentration and total petroleum hydrocarbon concentration. The source of these compounds is generally petroleum hydrocarbon production or processing facilities, or facilities that use or process significant amounts of these compounds. In addition, municipal and industrial wastewater-treatment effluents can lead to significant accumulation of hydrocarbons in sediments over time. Because many of these sources are much more carefully controlled than in times past, oil and grease or total petroleum hydrocarbons levels in sediments often represent excellent indicators of historical pollution.

### 21.2.2 Heavy Metals

The toxic metals and metalloids include antimony, arsenic, beryllium, cadmium, copper, lead, mercury, nickel, silver, thallium, and zinc. Importantly, these pollutants are nonbio-degradable, toxic in solution, and subject to biomagnification. The chemistry of many of these compounds is complex in sediments. A portion is generally chemically fixed and largely unavailable to fish and other organisms without significant chemical changes in the sediment. Often a portion is ion-exchangeable and may become available simply with the substitution of a more surface-active contaminant. Finally, a portion is soluble, mobile, and directly available for uptake by organisms.

Historically, the metals extraction and processing industries, as well as urban and rural runoff, provided the most significant sources of these elements. Lead was widely distributed in the environment as a result of the use of tetraethyl-lead in gasoline to control premature ignition (knocking). These sources have largely been controlled. Some sources of metals, however, are only poorly controlled and represent a continuing source of metals to sediments. These sources include leaching from abandoned mining sites and urban runoff. Unlike oxygen-demanding wastes, these pollutants are not easily neutralized or assimilated by natural processes.

### 21.2.3 Polycyclic Aromatics

The polycyclic aromatic hydrocarbon compounds are used as chemical intermediates and are present in fossil fuels. Polycyclic aromatics tend to be present in coal liquids and the heavier oil stocks as a result of lesser volatility. Many of the compounds have been found to be carcinogenic in animals and are assumed to be carcinogenic in humans. These tend to be intermediate in persistence and bioaccumulation potential compared with monocyclic aromatics/halogenated aliphatics and the PCBs. Production during combustion of industrial fuels and oils (diesel, coal liquids, heavy fuel oils) has resulted in the presence of PAHs at old industrial sites where contamination levels might be especially high. Sediment contaminant with PAHs is often associated with historical release of oils in wastewater but atmospheric deposition contributes to widespread contamination and specific locations may be influenced by oil seeps. Examples of PAHs include naphthalene, fluoranthene, pyrene, and chrysene. The compounds composed of two aromatic rings (naphthalene) tend to be the most volatile, soluble, and mobile, while solubility and volatility tend to decrease as the number of rings increases.

### 21.2.4 Pesticides

Priority pesticides are generally chlorinated hydrocarbons. These include such compounds as aldrin, dieldrin, DDT (dichlorodiphenyltrichloroethane), DDD (dichlorodiphenyl-dichloroethane), endosulfan, endrin, heptachlor, lindane, and chlordane. These organic compounds are readily assimilated by aquatic animals, and are subject to *bioaccumulation* and *biomagnification*. Bioaccumulation is the uptake and partitioning of contaminants by organisms, whereas biomagnification is the concentration of pollutants by natural processes such as the food chain. Greater amounts of pollutants may be accumulated higher in the food chain. These particular pesticides are also persistent contaminants. DDT, for example, remains an environmental contaminant many years after being banned in the United States.

DDT is an excellent example of the potential problems associated with these compounds. Although not considered extremely toxic and despite decreased usage during the 1960s, DDT use was banned in the United States in 1972 (although production and export continued after 1972) as a result of persistence and potential for biomagnification. Hickey et al. (1966), for example, reported biomagnification of DDT by more than 170,000 times between Lake Michigan sediments and fish-eating birds. Bottom-feeding crustacea exhibited about 30 times sediment concentrations, where as the fish that fed off the crustacea exhibited concentrations about 10 times still higher than found in the crustacean. Finally, fish-eating birds exhibited concentrations of DDT 500 times higher than observed in the fish. The magnification at each level is dependent on the feeding habits

and animal metabolism and, because the organochlorines tend to build up in the lipid or fat fraction of the body, the proportion of body fat.

### 21.2.5 Chlorinated Organic Compounds

Multiply chlorinated, high-molecular-weight organic compounds such as hexachlorbenzene and PCBs tend to be strongly hydrophobic and therefore partition into sediments. Due to low degradation rates, tendency to sorb, and high molecular weight, these compounds tend to exhibit low mobility in the environment and are persistent in sediments. PCBs are complex mixtures of organochlorines that are extremely stable. In addition, as with the organochlorine pesticides, PCBs are readily assimilated by aquatic animals and soluble in body fats and will biomagnify in the food chain. Although the toxicity of many of the individual PCBs is relatively low, specific isomers plus trace contamination with other chlorinated compounds give rise to significant health concerns. As a result, PCB production was banned in the United States in 1979. It should be emphasized that PCBs are a complex mixture of compounds and, in fact, are generally named only by the total percentage of chlorine in the mixture. Specific PCB mixtures are referred to as Aroclors, and Aroclor 1254 is 54% chlorine and Aroclor 1260 is 60% chlorine.

Again, as a result of persistence, significant quantities remain in the environment. Industrialized harbor areas in the Great Lakes and northeastern United States are often contaminated with PCBs. Fish advisories exist in many of the Great Lakes as a result of health concerns from eating PCB-contaminated fish. Because of the potential for PCBs to sorb onto organic materials in sediments and in fish lipids, such advisories are aimed primarily at fatty, bottom-feeding fish where PCB concentration is the highest, and will biomagnify in the food chain.

## 21.3 CONTAMINANT RELEASE AND EXPOSURE PATHWAYS

The risks of sediment contaminants to higher organisms such as fish and animals that feed off fish can arise via one of the following three pathways:

- Exposure by contaminant release due to erosion and resuspension of the sediment bed;
- Exposure by predation and harvesting of plants and animals living directly exposed at the contaminated sediment-water interface or by incidental ingestion of contaminated bed sediments;
- Exposure by contaminant release in dissolved or other form from a stable sediment bed by any of a variety of stable bed processes including advection, diffusion, and bioturbation.

Each of these pathways involves interaction of the higher organisms with the contaminants of and near the sediment-water interface. The absolute and relative importance of these pathways largely depends upon the rate of the various fate and transport processes that influence the pathway. Each of these will be examined in more detail.

These pathways are largely limited to the upper few cm of sediment, and thus exposure and risk due to sediment contaminants is largely related to surficial sediment concentrations. Due to significant erosion, it may be that the dynamics of the surface layer may result in exposure of previously buried contaminants, but at any given time, the surficial sediment concentrations largely define exposure and risk to organisms in the overlying water. In recognition of this fact, the surface-area-weighted average concentration ( $\langle W_s \rangle$ ) has come to be used as a good indicator of exposure and risk:

$$\langle W_s \rangle = \frac{\int_A W_s(0) dA}{\int_A dA} \quad (21-1)$$

where

$W_s(0)$  = Surficial sediment-contaminant concentration (e.g., in  $\mu\text{g/g}$ ), which may vary in space over the area  $A$ .

Similarly, the time-integrated  $\langle W_s \rangle$  is related to the time-integrated exposure, or dose,

$$\text{Integrated exposure} \sim \int_t \langle W_s \rangle dt \quad (21-2)$$

The assessment of exposure is thus largely reduced to defining quantitatively the relationship between exposure and  $\langle W_s \rangle$  (or time-integrated  $\langle W_s \rangle$ ) for the different processes relevant to a particular environmental system. Especially challenging is the definition of future exposure associated with contaminants currently buried below the surface layer. The use of a relationship such as Eq. (21-1) does not imply that currently buried contaminants will not become a source of exposure and risk at some point in the future.

### 21.3.1 Exposure by Contaminant Release from Resuspended Sediment

The dominant characteristic that controls direct exposure of fish and other animals to contaminated sediment is resuspension and erosion of particles from the sediment bed. Since most persistent sediment contaminants are associated with the solid phase, any mobilization of this phase dramatically increases contaminant mobility. As a result, contaminants can be distributed over large areas, and significantly increased water-column concentrations can be observed relative to less active sediment-water transport. Erosion and resuspension

conditions also hinder natural recovery that might occur in less active environments through deposition and burial of the contaminated sediment.

Under high-energy conditions in a stream, significant sediment transport occurs and individual sediment particles can be carried downstream either by bed-load or by suspended-load transport. This process normally results in the formation of dunes, ripples, and antidunes that progress downstream by erosion on the upstream face and deposition on the downstream face. During this overturning and migration process, sediment particles are exposed and either scoured and suspended in the stream or reburied by other sediment particles. During exposure to the stream water, contaminants sorbed to the sediment particles can desorb, and contaminants in the adjacent pore water can be released into the overlying water.

Should significant erosion and resuspension occur, the water-column concentration tends to approach the equilibrium defined by desorbable contaminants in the resuspended sediment. If  $K_{sw}$  is a distribution coefficient of the sorbed contaminant between the sediment and the water (units of volume per mass, e.g.,  $\text{cm}^3/\text{g}$ ), the aqueous phase concentration,  $C_w$  (mass/volume, e.g.,  $\mu\text{g}/\text{cm}^3$ ), is a function of the resuspended sediment concentration in the overlying water,  $C_s$  (mass/volume, e.g.,  $\text{g}/\text{cm}^3$ ). If the sediment carries an initial contaminant concentration,  $W_s$  (mass/mass, e.g.,  $\mu\text{g}/\text{g}$ ), the contaminant concentration in the overlying water is given by

$$C_w = \frac{C_s W_s}{1 + C_s K_{sw}} \quad (21-3)$$

For a hydrophobic organic compound, the distribution coefficient is often assumed to be given by the product of the organic carbon based partition coefficient,  $K_{oc}$ , a compound-specific parameter, and the fraction of organic carbon in the sediment,  $f_{oc}$ , a sediment-specific parameter. Theoretical predictions normally assume linearity, as indicated in Eq. (21-3), and complete reversibility, but deviations are often observed in practice. Equation (21-3) may still prove useful, however, if measured, rather than predicted, values of the effective partition coefficient are employed.

Equation (21-3) shows that for complete desorption (low suspended-sediment concentrations), the water concentration is simply the suspended-sediment concentration times the initial contaminant concentration in the sediment. At high suspended concentrations, however, the overlying water approaches equilibrium with the contaminated sediment bed as given by the equation

$$C_w = \frac{W_s}{K_{sw}} \quad (21-4)$$

For metals and other elemental species, the equilibrium state is much more complicated and depends on the chemical state of the water and sediment, particularly the pH and

oxidation-reduction conditions. The ratio of sediment loading to equilibrium water concentration is often very large for metals because only a small fraction of the metals is typically available for partitioning. Myers et al. (1996) indicate that the leachable fraction of metals is typically less than 10%, sometimes much less, and that the partition coefficient between the leachable fraction and the water is typically between 3 and 10 L/kg. For both organic and metal species, a site-specific measurement of the sediment-water partition coefficient is preferred.

As shown by Eq. (21-3), the concentration and exposure in the overlying water is a function of the concentration of sediment resuspended. The concentration of resuspended sediment is a function of the rate and depth of erosion. The ability to predict the rate of erosion based solely upon physical characteristics of the sediment such as grain size and density remains largely limited to cohesionless, coarse-grained particles. Site-specific measurements of sediment response to shear flows are needed to characterize erosion of cohesive, fine-grained sediment. Erosion of both cohesive and non-cohesive sediments is discussed in detail in Chapters 2 and 4.

Because contaminants tend to be strongly associated with fine-grained sediments, the discussion of Chapter 4 is especially relevant. As discussed there, erosion of a sediment bed can occur via one of four processes: surface erosion, mass erosion, fluid mud generation, and fluid mud entrainment. Of these, surface erosion is likely to be the most important except in specific locations where mass erosion (erosion of clumps of bottom material) or fluid mud entrainment (mobilization of very soft sediments) may be important.

For cohesive sediments, the friction velocity required to produce particle motion is significantly larger for a given particular particle size than for noncohesive sediments. Offsetting this is the fact that cohesive sediments tend to be very fine-grained and thus may be subject to significantly more erosion than coarse-grained noncohesive sediments. The property of cohesiveness is a complicated function of particle size, bulk density, mineralogy, organic content, and salinity. These properties vary significantly with position and time. Often, due to the lack of sufficient data on the deposit properties with position and time, these variations are not fully incorporated in sediment transport models. Instead, the rate of erosion,  $E$  (i.e., the sediment erosion flux in  $\text{g}\cdot\text{cm}^{-2}\cdot\text{hr}^{-1}$ ), is related to the local bed density,  $\rho_s$ , and the probability of a particle becoming resuspended,  $P_{\text{ero}}$ , which for a cohesive sediment is related to the bottom shear stress,  $\tau_b$ , and the bed density,

$$E = P_{\text{ero}} \tau_b^N \rho_s = A \tau_b^n \rho_s^m \quad (21-5)$$

The exponent on the bottom shear stress depends on the bed properties but is typically between 2 and 3 for cohesive sediments. This implies that the erosion rate depends on the fourth to sixth power of stream velocity, because bottom shear stress typically depends on the square of velocity. The strong dependence on stream velocity emphasizes that a

critical component of any effort to model sediment dynamics is knowledge of the stream hydrodynamics. Although it is not yet possible to predict the relationship between erosion rate and shear stress for cohesive sediments, it is possible to make measurements from which the values of  $A$ ,  $n$ , and  $m$  can be determined (McNeill et al. 1996). The flux of contaminants returned to the sediment column,  $F_{\text{ero}}$  (e.g., in  $\mu\text{g}\cdot\text{cm}^{-2}\cdot\text{hr}^{-1}$ ), as a result of erosion is then given by

$$F_{\text{ero}} = E W_s \quad (21-6)$$

where

$W_s$  = sediment contaminant concentration (e.g., in  $\mu\text{g/g}$ ).

When sediment is dredged, an artificial situation is created that is equivalent to high flow-related erosion of the sediment bed. Under such conditions, the water again tends to equilibrate with the sediment resuspended by the dredge head (DiGiano et al. 1993). Therefore, the approach outlined also can be used to assess exposure and risks due to dredging, at least for organic compounds, if an estimate or measurements of sediment resuspension are available. DiGiano et al. (1995) also developed an experimental protocol for estimating metals release and equilibration with a body of water during dredging.

Deposition may serve to isolate contaminants from the overlying water column and reduce the influence of erosion. The net sediment transport is the difference between the erosion rate, defined above, and the deposition rate. In general, the rate of deposition,  $D$ , can be modeled with relationships of the form

$$D = P_{\text{dep}} w_s C_s \quad (21-7)$$

where  $P_{\text{dep}}$  is the probability of capture of the depositing particle,  $w_s$  is the vertical settling velocity of the particles, and  $C_s$  is the suspended-sediment concentration. The probability of deposition tends to decrease as the bed shear stress increases. The local particle concentration can be modeled as a decreasing exponential function of height above the bed (Jones and Lick 2000). There are also significant differences between cohesive (flocculating) sediment and noncohesive (i.e., sandy) sediment. Sandy sediment deposition can be modeled employing the formulation of Cheng (1997). In cohesive sediments, deposition is affected by aggregation and/or disaggregation processes that are complex functions of sediment and stream conditions (Lick and Lick 1988). The flux of contaminants,  $F_{\text{dep}}$ , carried by deposition to the sediment bed is given by

$$F_{\text{dep}} = D K_{\text{sw}} C_w \quad (21-8)$$

Here the contaminant concentration on any depositing particles is assumed to be given by equilibrium with the overlying water concentration. The quantity  $K_{\text{sw}} C_w$  is the sediment concentration that would be in equilibrium with the overlying water,  $W_s^*$ . The net contaminant flux from the

sediment bed due to erosion and deposition processes can thus be written by combining Eqs. (21-4) and (21-6) to give

$$F_{\text{net}} = E W_s - D W_s^* \quad (21-9)$$

For a sediment bed in a state of quasi-equilibrium where the average erosion and deposition rates are equal, the net contaminant flux can be written as proportional to the difference between the actual surficial sediment concentration and the surficial sediment concentration that would be in equilibrium with the overlying water.

### 21.3.2 Exposure by Ingestion of Sediments or Organisms at the Bed Surface

The evaluation of the ingestion exposure pathway involves two steps: (1) the assessment of the contaminant concentrations in plants and animals living at the sediment-water interface as a result of exposure to the sediments, and (2) the assessment of uptake of these organisms by fish and other higher animals. In this paper we are focused on the processes within sediments and so will largely limit our discussion to the first step, that is, defining the relationship between the sediments and the accumulation of contaminants in the sediment-dwelling organisms. Plants and animals living at the sediment-water interface are often assumed to be in equilibrium with the surficial sediments. Similarly, incidental ingestion of sediments by fish or higher animals involves direct exposure to the surficial contamination. Thus uptake into fish and higher animals by these mechanisms depends upon the rate of ingestion of sediments or benthic organisms and the sediment concentration that is bioavailable. The contaminant capable of partitioning into the adjacent pore water from the sediment solids is often assumed to define the portion that is available for uptake by the plants and animals (USEPA 1993b). In principle, therefore, partitioning measurements or predictions can largely define the quantity of contaminant available to sediment-dwelling organisms or to higher organisms coming into direct contact with or ingesting sediments. It is important to note, however, that the contaminant concentration in the surficial sediments may not be represented well by a depth-averaged composite concentration, even though that is what is typically measured. Freshwater benthos, for example, may only populate the upper 5 to 10 cm of sediments in significant quantities. In marine sediments, animals living at the sediment-water interface tend to be larger and influence a somewhat greater depth of sediment, although the bulk of the activity remains within 15 cm of the surface. More than 90% of the 240 observations of the layer depth effectively mixed by organisms reported by Thoms et al. (1995) were 15 cm or less and more than 80% were 10 cm or less. It is the sediment concentrations within this layer that are expected to control the body burden of sediment-dwelling organisms.

If the upper sediment layers are assumed in equilibrium with the adjacent pore water and if uptake is assumed to be defined by porewater concentrations, the contaminant concentration available to plants and animals living at the sediment-water interface is as given by Eq. (21-4). The rate of uptake to a benthic or higher organism depends upon the rate of uptake or ingestion but will ultimately approach a steady state defined by a balance between uptake and elimination mechanisms. The ratio of the concentration in the organism,  $W_b$ , to that in the sediment,  $W_s$ , is termed the biota-sediment accumulation factor (BSAF). For hydrophobic organic compounds, the partitioning of the contaminant is assumed to be controlled by the organic "solvent" fraction that exists within a particular phase. Thus, a more useful biota-sediment accumulation factor for such compounds is one that normalizes the concentration in each phase with the organic fraction in that phase. For the biota, this is the lipid fraction,  $f_{\text{lipid}}$ , and for the sediment, it is the organic carbon fraction,  $f_{\text{oc}}$ . Benthic organisms are in intimate contact with the sediment and pore water and often exhibit only slow metabolism or elimination of the contaminants of interest. Thus benthic organisms rapidly approach equilibrium with these phases. The BSAF then approaches the ratio of the organic-carbon-normalized partition coefficients,

$$\text{BSAF} = \frac{W_b / f_{\text{lipid}}}{W_s / f_{\text{oc}}} = \frac{K_{\text{lipid}} C_w}{K_{\text{sw}} / f_{\text{oc}} C_w} \approx \frac{K_{\text{lipid}}}{K_{\text{oc}}} \quad (21-10)$$

In the final relationship,  $K_{\text{sw}}/f_{\text{oc}}$  is equal to the commonly tabulated organic-carbon-based partition coefficient,  $K_{\text{oc}}$ , only if the desorption is governed by linear, reversible sorption to the sediment organic fraction. As indicated below, the effective partition coefficient,  $K_{\text{sw}}$ , may not be equal to  $K_{\text{oc}} f_{\text{oc}}$  due to desorption resistance or nonlinear sorption-desorption equilibrium. The BSAFs for organic contaminants vary as a function of sediment, organism, and time of exposure, but the value for benthic organisms, especially those that ingest sediment as food, tends to approach unity (e.g., Ingersoll et al. 1997), suggesting that the organic-normalized partition coefficients in lipids and sediment are approximately equal ( $K_{\text{lipid}} = K_{\text{sw}}$ ). It is important to note that BSAFs in organisms not intimately associated with the sediment may vary considerably from unity. In addition, no equivalent basis for the estimation or normalization of the accumulation of metals in organisms exists.

The normalization by organic carbon content assumes that essentially all of the hydrophobic organic contaminant in the sediment and organism is available for partitioning. A significant fraction of the contaminant, though, is often unavailable and is held in a desorption-resistant fraction. The results of many laboratory and field observations indicate, though, that a significant fraction of soil- and sediment-bound contaminants desorb slowly, if at all, are not biodegraded, and are difficult to remove by extraction with surfactants or cosolvents. For example, Pereira et al. (1988) found that the concentration of halogenated organic compounds in native

water, suspended sediments, and biota was far below the values predicted from concentrations in the contaminated bottom sediments collected from Bayou d'Inde, Louisiana. Similarly, McGroddy and Farrington (1995) and Readman and Montoura (1987) observed a fraction of PAHs in river sediments not available for desorption. For most of these sediments, the contamination source had ceased for many years, yet the sediment-bound contaminants persisted over tens of years without significant reduction in concentration or changes in the compound distribution.

The sorption of organic chemicals to soils and sediments is a complex process, given the diversity, magnitude, and activity of chemical species, phases, and interfaces commonly present in contaminated subsurface environments, which may also be quite variable in particle size and organic carbon content. The quantity sorbed is often found to be well represented by the combination of a compartment exhibiting linear, reversible sorption and a compartment that exhibits nonlinear and thermodynamic irreversible sorption. Note that thermodynamically irreversibility simply means that the desorption process does not occur at the same rate or extent as sorption and does not imply that desorption does not occur. In addition to biphasic equilibrium behavior, the approach to equilibrium is controlled by different kinetics in the reversible and irreversible compartments. The kinetics of sorption and desorption in the reversible compartment are typically on the order of a day or less whereas desorption of the sequestered fraction may take weeks or months to approach completion (White et al. 1999).

Pignatello and Xing (1996) have presented a slow-sorption model in which sorption and desorption can be divided into a slow and a fast fraction. The quantity sorbed in each fraction can be described using a Freundlich isotherm or, if the fast release fraction is assumed linear and reversible and given by the organic-carbon-based partition coefficient, by

$$W_s = (W_s)_f + (W_s)_s = K_{oc} f_{oc} C_w + K_w C_w^{n_s} \quad (21-11)$$

Here

$W_s$  = sorbed quantity of solute;  
 $C_w$  = adjacent porewater concentrations;  
 and the subscripts f and s represent fast and slow, respectively.

$K_s$  and  $n_s$  are fitting parameters. Slow sorption may be strongly nonlinear and, combined with entrapment of contaminants in desorption-resistant compartments, is expected to be responsible for the effect of contaminant age on desorption and reduced bioavailability. Pignatello and Xing (1996) have related the different rates of sorption and desorption to the quality of the organic matter (i.e., soft and rubbery versus diagenetically aged hard and glassy).

Huang and Weber (1997) have presented the dual-reactive-domain model (DRDM), which is focused on this difference in sorbent character, to describe hysteresis in sorption-desorption. The soft, rubbery carbon that represents diagenetically young

soils exhibits linear, reversible sorption, whereas aged, hard glassy carbon represents a nonlinear contribution to sorption-desorption. The degree of nonlinear desorption phenomena and contaminant sequestration is presumably related to the fraction of aged carbon. For many sediments, the fraction of diagenetically aged carbon is relatively small, although the capacity of that material for contaminant sorption may be large. Assuming Langmuir-type sorption in the nonlinear domain and that the linear reversible sorption is defined by the organic-carbon-based partition coefficient, the sorbed quantity for the dual-reactive domain-model can be written

$$W_s = (W_s)_\ell + (W_s)_s K_{oc} f_{oc} C_w + \frac{QbC_w}{1+bC} \quad (21-12)$$

where  $\ell$  represents linear or labile fraction and  $s$  represents slow or sequestered fraction.  $Q$  and  $b$  represent the Langmuir fitting parameters of capacity factor and site energy, respectively. The model of Tomson and coworkers (Hunter et al. 1996; Kan et al. 1997; Kan et al. 1998) also assumes a biphasic sorption-desorption model that combines the linear and Langmuir sorption isotherms for the quantity sorbed.

Note that the net effect of a biphasic sorption model such as described by Eq. (21-11) or Eq. (12-12) is that the effective partition coefficient  $W_s/C_w$  increases:

$$K_{sw} \frac{W_s}{C_w} = K_{oc} f_{oc} + \frac{Qb}{1+bC_w} \quad (21-13)$$

This can be used to estimate the steady-state accumulation in benthic organisms in which  $K_{lipid}^{-1} K_{oc}$ . The effect of the desorption-resistant fraction is an effective increase in the sediment-water partition coefficient and reduction in the pore-water concentration. Thus the effect of the desorption-resistant-related reduction on pore-water concentration is a decrease in the BSAF according to

$$BSAF = \frac{K_{lipid}}{K_{sw} f_{oc}} \approx \frac{K_{oc}}{K_{oc} + \frac{Qb}{f_{oc}(1+bC_w)}} \quad (21-14)$$

As noted by Pignatello and Xing (1996), the rate of release from the desorption-resistant contaminant fraction is significantly lower than that from the more labile fraction. Thus the normalized accumulation may be significantly lower than shown in Eq. (21-14) due to kinetic limitations in some plants or animals or under some environmental conditions.

The bioaccumulation behavior of metals and ionic species is significantly more complicated; however, the dissolved pore-water concentration in the sediment has been seen increasingly as the best indicator of metals and ionic species in both plants and animals. As indicated previously, the fraction that is ultimately leachable into the pore water is typically less than 10% of the total metal loading on the sediment, and the effective partition coefficient for this leachable fraction is typically 3 to

10 (Myers et al. 1996). Another indicator for specific metal contaminants is the ratio of the acid volatile sulfides (AVS) to the simultaneously extractable metals (SEM). A number of metals, including cadmium, copper, lead, nickel, and zinc, tend to form insoluble metal sulfides in reduced sediments. As long as the AVS exceeds the SEM, these metals are in reduced form and essentially unavailable in dissolved form to living organisms (SAB 1995). For some metals, however, such as arsenic, the reduced form may be of more environmental consequence than other forms. Considerably more complicated is mercury, which undergoes biologically mediated reduction reactions that may encourage the formation of methylmercury.

As a result of the complex and varied behavior of metal species and other chemicals, toxicity tests, rather than specific physicochemical tests, are often used to assess the potential for adverse sediment effects. The USEPA Assessment and Remediation of Contaminated Sediments (ARCS) Program performed a comparative evaluation of a number of toxicity tests for sensitivity and discriminatory power (USEPA 1994). Discussion of the individual tests and their ability to identify severely contaminated sediments is beyond the scope of the present discussion.

Thus, the assessment of the contaminant levels entering the food chain via uptake into plants and animals at the sediment-water interface is largely a question of contaminant availability. In the absence of site-specific toxicity information, measurements or predictions of pore-water concentrations or the AVS/SEM for some metals are useful indicators of availability under steady-state conditions, such as might apply for benthic animals that process large amounts of sediments. For organisms in the water column or for benthic plants and animals with only passive contact with sediments, the kinetics of release from the sediments and uptake and elimination from the organism significantly complicate assessment of exposure and risk.

### 21.3.3 Exposure by Release from Stable Bed Sediments

The rate of contaminant movement into the water column through either of the two previous pathways was controlled by processes that are largely unrelated to the presence of the contaminant (i.e., erosion of the sediment bed and the rate of ingestion of sediment or benthic organisms). The dominance of these external factors led to the usefulness of approximations based on local equilibrium between any resuspended sediment and the overlying water and between benthic organisms and surficial sediments. The direct exposure of fish and higher animals to contaminants in stable, noneroding beds, however, is a rate-limited process controlled by a variety of natural fate and transport processes, as depicted in Fig. 21-1. Among the most important of these in-bed fate and transport processes are biotransformation, sorption, diffusion, advection, and bioturbation. Under specific circumstances, a variety of other processes identified in Fig. 21-1 may be important.

The local flux from the sediment to the overlying water is related to the sediment concentration and an overall mass-transfer coefficient that lumps the effects of the individual processes. The relationship between sediment contamination and exposure in the overlying water by these processes is controlled by the surficial sediment concentrations. Deep in-bed processes may be responsible for transport of contaminants to the sediment-water interface, but release into the overlying water column is still controlled by the interfacial concentration. Thus, the surficial average sediment concentration remains a useful indicator of the potential release to the overlying water. The average flux from the sediment by stable bed-sediment processes,  $F_{\text{bed}}$  (e.g., in  $\mu\text{g}\cdot\text{cm}^{-2}\cdot\text{h}^{-1}$ ) can then be estimated by

$$F_{\text{bed}} = K_s \rho_s (<W_s> - K_{sw} C_w) \quad (21-15)$$

where

$\rho_s$  = bulk (or dry) density of the sediments ( $\text{g}/\text{cm}^3$ ) and  
 $K_s$  = average sediment bed-mass transfer coefficient  
 (e.g., in  $\text{cm}/\text{h}$ ).

The concentration driving force in this equation is the deviation between the actual surficial sediment concentration ( $<W_s>$ ) and that which would be in equilibrium with the overlying water ( $K_{sw} C_w$ ). Alternatively, a water-based overall coefficient,  $K_w$ , can also be defined by  $F_{\text{bed}}/(<W_s>/K_{sw} - C_w)$ , where  $K_w = K_s \rho_s / K_{sw}$ . In general,  $K_s$  is a combination of sediment- and water-side mass transfer resistances, as characterized by sediment- and water-side mass transfer coefficients  $k_s$  and  $k_w$ , defined by

$$k_s = \frac{F_{\text{bed}}}{\rho_s (<W_s> - W_i)} \quad k_w = \frac{F_{\text{bed}}}{C_i - C_w} \quad (21-16)$$

where the subscript  $i$  defines the hypothetical interfacial concentrations at the sediment-water interface. Assuming that the resistances act in series and that the interfacial concentrations are in equilibrium,  $W_i = K_{sw} C_i$ , the overall mass transfer coefficient,  $K_s$ , can be written

$$K_s \rho_s = \frac{1}{1/k_s \rho_s + K_{sw}/k_w} \quad (21-17)$$

Thibodeaux et al. (2001) showed that a range of both laboratory and field data were consistent with  $12.5 \text{ cm}/\text{day} < k_w < 33.3 \text{ cm}/\text{day}$  and  $2 \text{ cm}/\text{yr} < k_s < 3.6 \text{ cm}/\text{yr}$ .

It is perhaps easiest to characterize the effect of the various natural processes depicted in Fig. 21-1 that make up  $K_s$  by the time required to achieve specified reductions in contaminant concentration. Because the surficial sediments are typically mixed by the action of benthic organisms or other processes, the response of the surficial-area-averaged sediment concentration can be modeled as

$$\frac{d}{dt}(\langle W_s \rangle \rho_s A h) = -K_s \rho_s \langle W_s \rangle A \quad (21-18)$$

assuming that there are no fate processes other than release by transport processes to the overlying water and the overlying water is always at zero concentration. Thus,

$$\frac{\langle W_s \rangle}{\langle W_s \rangle(0)} = e^{-\frac{K_s}{h}t} \quad (21-19)$$

From the above equation, the concentration half-life (time to 50% reduction) and the time to 95% reduction (5% remaining) in the surficial area averaged sediment concentration is given by

$$\tau_{0.5} = 0.693 \frac{h}{K_s} \quad \tau_{0.05} = 3 \frac{h}{K_s} \quad (21-20)$$

As indicated previously, the depth of the surficial sediment layer that is relatively well-mixed by the action of benthic organisms is typically 5 to 10 cm. The average value of  $K_s$  reported by Thibodeaux et al. (2001) in several laboratory experiments and in the Hudson River is approximately 1.3 cm/yr. Similarly, a surface area of 3,300 acres of the Lower Fox River, Wisconsin, containing an average surficial sediment concentration of 3.1 mg/kg PCBs accounts for the bulk of the approximately 125–280 kg/yr estimated to be transported into Green Bay (WDNR 2001). This is equivalent to a  $K_s$  of between 0.47 and 1.0 cm/yr. Employing  $K_s \approx 1$  cm/yr and a 10-cm surface layer, the contaminant half-life, assuming no exposure of freshly contaminated material and no resupply from upstream sources, is  $\tau_{0.5} = 6.9$  yr and the time to 95% reduction in contaminant concentrations  $\tau_{0.05} = 30$  yr. These estimates make no attempt to differentiate between the individual mechanisms that contribute to the average mass transfer coefficient. Estimates of the times required to achieve 50% and 95% recovery of the surficial sediment concentrations based upon individual mechanisms are provided in Section 21-5, and allow the mechanisms to be compared and ranked in their importance. The estimates of overall mass-transfer coefficients presented by Thibodeaux et al. (2001) and in the Fox River, however, incorporate mass-transfer resistances in both the sediment bed and in the benthic boundary layer of the water. Before the in-bed transport processes are assessed, the water-side mass-transfer resistances should be examined in more detail.

## 21.4 WATER-SIDE MASS TRANSFER PROCESSES

The relative importance of water-side mass transfer resistances increases as the hydrophobicity and  $K_{sw}$  of the contaminants increase, as shown by Eq. (21-17). If the overlying

water-transport processes control the rate of release from the sediment, measurements of in-bed processes are less important. It is often incorrectly assumed that the intrinsically slower sediment-side processes always control mass transfer to the overlying water. As shown by Thibodeaux et al. (2001), however, the effective coefficient mass transfer from the sediments approaches a limiting value defined by the water-side mass transfer resistances.

From Eq. (21-17), the water-side mass transfer resistances control overall mass transfer as long as

$$k_w < k_s \rho_s K_{sw} \quad (21-21)$$

thus  $k_w \gg k_s$ , which is normally true, does not necessarily mean that water-side resistances are negligible. Illustrative models of the water-side mass transfer coefficient under flowing and quiescent (generally wind-driven circulation) conditions are given by Thibodeaux (1996) as

$$k_w = \frac{\sqrt{v_w v_*^{1/2}}}{Sc^{2/3} y_o^{1/2}} \quad \text{flowing, typically } \leq 10 \text{ cm/h}$$

$$k_w = \left(0.031 \frac{\text{sec}}{m^2}\right) \frac{\rho_a v_a^2 d^2}{\rho_w M_w^{1/2} L} \quad \text{wind-driven,} \quad (21-22)$$

typically  $\leq 1$  cm/h

where

$v_w$  is the kinematic viscosity of water (0.01 cm<sup>2</sup>/s at 20 C);  
 $Sc$  is the Schmidt number (typically  $O(1000)$  for hydrophobic contaminants);  
 $y_o, v_*$  are the flow parameters surface roughness and friction velocity, respectively (m, m/s);  
 $\rho_a, \rho_w$  are the density of air and water, respectively;  
 $v_a$  is the wind velocity (m/s);  
 $d$  is the water depth (m);  
 $L$  is the fetch of the lake or water body in the direction of the wind (m);  
 $M_w$  is the molecular weight of the contaminant of interest (g/mol).

As indicated previously, Thibodeaux et al. (2001) showed that a range of both laboratory and field data from streams were consistent with 12.5 cm/day  $< k_w < 33.3$  cm/day and 2 cm/yr  $< k_s < 3.6$  cm/yr. Using these estimates of magnitude for  $k_w$ , this suggests that the water-side mass transfer is of equal importance to the sediment side processes for a sediment-water partition coefficient of

$$K_{sw} = \frac{k_w}{k_s \rho_s} = \frac{12.5 - 33.3 \text{ cm/h}}{(2 - 3.6 \text{ cm/yr})(\sim 1 \text{ kg/L})} \quad (21-23)$$

$\approx 30,000 - 150,000 \text{ L/kg}$

Strongly sorbing compounds such as PCBs and heavy PAHs may exhibit partition coefficients in this range for moderate organic carbon content (4–6%). Water-side mass transfer

resistances may thus be important for strongly sorbing compounds even in relatively rapid flowing streams. In lakes and impoundments stirred by wind-driven circulations, the water-side mass transfer resistance may be important for less strongly sorbing compounds. The mobile fraction of most metals in sediments exhibits a partition coefficient much less than this, suggesting that their release from stable sediments is controlled by sediment-side processes.

## 21.5 ANALYSIS OF SEDIMENT BED FATE AND TRANSPORT MECHANISMS

Fate and transport processes are examined separately to determine the most important mechanisms influencing contamination mobility in sediment. Fate and transport mechanisms are separated into two categories: those operating in stable, immobile beds and those operating in an active bed. For this purpose, an active bed is one in which either the pore water or the sediment grains are in motion.

### 21.5.1 Passive Sediment Fate and Transport Processes

Sediment fate and transport involve the following passive processes:

**21.5.1.1 Molecular Diffusion** Molecular diffusion is a ubiquitous chemical transport process within a sediment bed. Molecules are in a constant state of motion, characterized by random molecular velocities (directions and magnitudes) and frequent collisions involving both the solvent (i.e., water) and contaminants. The net result is the movement of contaminant molecules from pore-water regions of high concentration to those of low concentration.

The existence of a concentration gradient within the pore water of a porous sediment bed is sufficient to initiate transport by this molecular process. The magnitude of the contaminant flux is

$$F^{\text{diff}} = -D_{sw} \frac{\partial C_w}{\partial z} \quad (21-24)$$

$F^{\text{diff}}$  is quantified by Fick's first law and couples the concentration gradient to the diffusion coefficient.

The effective diffusion coefficient in the porous medium,  $D_{sw}$ , is less than the diffusion coefficient in water due to the porosity and tortuosity of the sediment. Often a constitutive relationship similar to that proposed by Millington and Quirk (1961) is used to relate the diffusion coefficient in the sediment to that in water,  $D_{sw} = D_w \epsilon^{4/3}$ . Here  $\epsilon$  represents the sediment porosity and  $D_w$  is the molecular diffusion coefficient of the contaminant in water, typically on the order of  $10^{-5} \text{ cm}^2/\text{s}$ .

Field investigations in sediment beds typically involve analytical measurements averaged over sediment depth and reflect a mixed sample from a few cm to 30 cm of core length. Profiles of concentration based on thin slices less

than 1 cm in depth spanning the entire depth of contamination are rarely measured. Available concentration profile data usually are limited to a snapshot in time and seldom reflect trends over time. Typically, only single measurements for a particular year are available for hydrophobic organics and metals. These measurements are not very useful in assessing the influence of diffusion, which is manifested over long time periods and may only influence concentration profiles in thin layers. In addition, diffusion normally occurs at significant rates only within the pore-water phase, and bulk sediment concentrations may not reflect the mobile fraction of contaminants. For metals, in particular, total sediment concentration measurements are not very useful in defining the rates of passive transport processes.

A better approach to both conceptual and quantitative fate and transport model development is the use of high-resolution coring with both total and speciated measurements via phase and constituent. In this manner, the fraction of the available contaminant dissolved in the pore water is identified. By discrimination between soluble and insoluble fractions of metals, a much better assessment of potential adverse effects can be made. High-resolution coring makes possible comparison to detailed mathematical models and can be very useful in identifying the most important transport processes. For example, diffusional processes give rise to concentration profiles that are quite different from those produced by advective transport.

**21.5.1.2 Adsorption and Desorption Equilibrium between the Solid Surface and Pore Water** Organic compounds that are hydrophobic by nature are capable of being adsorbed onto the organoclay fractions of the sediment. Thus, an adsorption-desorption equilibrium exists at the sediment and pore-water interface. In the case of transport into clean sediment, adsorption on the particles retards the movement of a concentration front due to transient accumulation of material in the sorbed phase. Adsorption slows transient pore-water processes (including diffusion) according to a retardation factor,  $R_f$ , that is essentially the ratio of the total concentration in the sediment to the concentration in the mobile pore-water phase:

$$R_f = \frac{\text{Total concentration}}{\text{Mobile phase concentration}} = \epsilon + \rho_s K_{sw} \quad (21-25)$$

Here  $\epsilon$  is the void fraction (porosity) of the sediment bed,  $\rho_s$  is the bulk (dry) sediment density, and  $K_{sw}$  is the effective sediment water-partition coefficient. Many authors define the retardation factor as  $R_f/\epsilon$ , where  $R_f$  is as defined by Eq. (21-25). Care must be taken to define the retardation factors and the conservation equations in which they arise in a consistent manner.

A simple estimate of the time required for attenuation of a contaminant in the sediments as a result of retardation is the product of  $R_f$  and the time required for the attenuation to occur by diffusion assuming no retardation. The

effect of retardation can be quite large. For a compound such as pyrene ( $K_{oc} = 10^5$  L/kg), assuming 1% organic carbon,  $\rho_s = 1$  kg/L, and  $K_{sw} = K_{oc} f_{oc}$ , the retardation factor is about 1,000. As described earlier, a significant fraction of the contaminants may not readily desorb. Under such conditions the partition coefficients used in Eq. (21-25) must be measured via desorption experiments and not simply assumed to be given by  $K_{oc} f_{oc}$ . It is also important to recognize that retardation affects only transient processes. Under steady contaminant transport, there is no further accumulation of contaminants in the sorbed phase and, therefore, there is no retardation.

Diffusion is an extremely slow process if retarded by sorption. If diffusion is the primary transport process or can be made to be the primary process through elimination of active processes, contaminant release and exposure are generally negligible. The time for diffusion to reduce 50% and 95% of the contaminant within a layer,  $h$ , is defined by

$$\begin{aligned}\tau_{0.5}^{\text{diff}} &= \frac{1.94}{\pi^2} \frac{h^2 R_f}{D_{sw}} \\ \tau_{0.05}^{\text{diff}} &= \frac{11.2}{\pi^2} \frac{h^2 R_f}{D_{sw}}\end{aligned}\quad (21-26)$$

This assumes no migration of contaminants into the layer from below and assumes that the overlying water provides no resistance to mass transfer.

Although sorption onto an immobile phase can retard contaminant migration in the sediment, sorption onto a mobile particulate phase (e.g., fine particulate, colloidal matter) can enhance or facilitate transport. Natural organic colloids are fine particulate suspensions that are primarily decomposition products of plant and animal life. Colloids form in a marine sediment through fermentation reactions of degraded cellular material to form low-molecular-weight dissolved organic matter such as amino acids. Condensation reactions then give rise to higher-molecular-weight dissolved organic matter such as fulvic and humic acids. These higher-molecular-weight compounds generally constitute what is referred to as dissolved organic matter (DOM). DOM is generally operationally defined as the organic fraction that passes a 0.45- $\mu\text{m}$  filter and consists of humic and fulvic acids, among other things. Colloidal matter is composed of groups of these fulvic and humic acid molecules that form large-diameter suspensions in water. The suspensions typically have a negative electrical surface charge and the stability is dependent on the structure of the electrical double layer formed, van der Waals forces, hydration phenomena, and the effects of adsorbed substances. Organic colloids represent a sink for hydrophobic organic contaminants in the water. They effectively increase the solubility by increasing the mass of contaminants that can partition into the mobile phase containing both water and colloidal material. In this manner, the mobility of organic contaminants can be enhanced. Colloids can enhance the effective

solubility of metal and ionic contaminants. Various metals and metal complexes also form colloidal species.

The net effect of the increased effective solubility of a contaminant is a change in the retardation factor (Reible et al. 1991; Thoma et al. 1991),

$$R_f = \frac{\text{Total}}{\text{Mobile}} = \frac{\varepsilon + \rho_b K_{sw} + K_{cw} C_c}{1 + K_{cw} C_c} \quad (21-27)$$

Here

$C_c$  = concentration of colloidal particles in the water and  
 $K_{cw}$  = partition coefficient between the colloids and the water.

The effective retardation factor represented by Eq. (21-27) assumes that the colloidal particles are transported through the sediment pore water at the same rate as the water molecules themselves. This may not be a good assumption, due to filtration or preferential retention or exclusion of the polar colloidal molecules. A commonly used but approximate estimate of the partitioning of an organic contaminant to colloidal or dissolved organic carbon is that  $K_{cw}$  equals  $K_{oc}$ . The concentration of dissolved organic carbon in sediments is typically in the range of 10 to 100 mg/L. These values suggest that the effect of colloidal organic carbon, for example for pyrene, is to decrease the retardation factor by a factor of 2 to 10. Thus, the presence of colloidal matter can decrease the time for diffusion to result in recovery of a pyrene-contaminated sediment layer by a factor of 2 to 10.

**21.5.1.3 Chemical Reaction and Biodegradation** A stable sedimentary environment does not lend itself to rapid degradation dynamics. Many organic compounds of concern in sediments are persistent and not subject to rapid degradation by either abiotic or biological processes. Only the upper few cm of a fine-grained sediment may be aerobic; the remainder of the sediment column is generally anaerobic. Organic compounds that are subject to microbial degradation generally degrade more slowly under anaerobic conditions. Although degradation may be slow, the persistence of contaminants over decades or centuries may be of interest. Unfortunately, very little information exists about the persistence of sediment contaminants over these time-scales.

Hughes et al. (1997) have reviewed the potential for PAH degradation in sediments and identified some of the limitations in achieving significant degradation in the field. PAHs degrade most rapidly under aerobic conditions, but some degradation under anaerobic conditions has also been observed (Zhang and Young, 1997). Anaerobic conditions are important for biotransformation of chlorinated organic compounds. Chlorine can interfere with the action of oxygenating enzymes, meaning that reductive dechlorination is often necessary before aerobic transformation can proceed. For example, reductive dehalogenation under reducing conditions converts dichlorodiphenyltrichloroethane (DDT) to dichlorodiphenyldichloroethene (DDE) and lindane to benzene. Pesticides such as toxaphene have

been known to be anaerobically degraded in soils and salt marsh sediments. Anaerobic dechlorination of PCBs can also occur (Tiedge et al. 1993) and has been observed under field conditions (Brown et al. 1984). Dechlorination of highly chlorinated PCBs encourages subsequent aerobic degradation of the less chlorinated PCB or biphenyl (NRC 2001).

In the absence of site-specific quantitative information on the rates of these reactions, the conservative assumption of negligible degradation rates is normally applied. With no degradation, attenuation of contaminant concentrations can only result from transport processes.

## 21.5.2 Active Sediment-Transport Processes

Diffusion, sorption, and reactions were considered in the absence of sediment or bulk pore-water movement. If sediment or pore water is moving, an advective flux generally dominates any diffusive flux. Mechanisms resulting in advective transport in sediments and their implications for contaminant transport are discussed below. The focus of this discussion remains on stable sediments and slowly moving dunes and ripples (i.e., complete scouring of the sediment bed is not considered). The situation of high suspended-sediment loads was discussed previously while the influence of resuspended sediment on water-column concentrations and exposures was examined. Sediment-transport processes emphasized here are such that the basic character of the sediment bed remains largely intact and the resulting changes in contaminant concentration are slow. "Slow", in this case, implies that the dynamics of the overlying water concentration remains controlled by the sediment-bed processes and not simply the steady-state suspended-sediment load, as discussed previously.

**21.5.2.1 Deposition or Erosion** Sediment deposition or erosion rates are likely to vary significantly over space and time (see Chapters 2 and 4). On average, or in specific locations, however, it may be possible to characterize erosion or deposition by an average velocity  $U = D/\rho_s$  or  $U = E/\rho_s$ , where  $E$  and  $D$  are the erosion and deposition rates defined by Eqs. (21-5) and (21-7), respectively. The growth of the sediment bed by deposition of clean sediment causes burial of contaminated sediment from the surficial mixed layer at a rate  $\langle W_s \rangle D/\rho_s$ . Similarly, the process of erosion removes contaminated sediment from the surficial sediment layer at a rate  $\langle W_s \rangle E/\rho_s$ . In either case, processes such as bioturbation mix the entire depth of the surface layer so that Eq. (21-19) applies as long as the rate of erosion or deposition is low compared to the rate of surficial layer mixing. If the contamination is initially limited to a uniformly mixed depth  $h$ , the times to 50% and 95% reduction in concentration in the layer for deposition or erosion at an average velocity  $U$  are given by

$$\tau_{0.5}^{\text{ero}} = 0.693 \frac{h}{U} \quad \tau_{0.05}^{\text{ero}} = 3 \frac{h}{U} \quad (21-28)$$

Deposition rates can sometimes be measured by sediment traps placed at the sediment-water interface, although these may not indicate net deposition rates, because they do not allow erosion. Thus sediment traps would track only the deposition portion of a deposition-and-erosion cycle driven, for example, by diurnal tidal variations. Deposition rates can also be estimated by the depth of burial of certain radionuclides, such as  $^{210}\text{Pb}$  and  $^{137}\text{Cs}$ :  $\gamma$  spectroscopy can be used to measure activities of excess  $^{210}\text{Pb}$  (source: U-series,  $t_{1/2} = 22$  yrs, 46.5-KeV peak), and  $^{137}\text{Cs}$  (source: nuclear fallout and reactors,  $t_{1/2} = 31$  yr, 661.6-KeV peak). The presence of a particular radionuclide can be used to date a layer in an undisturbed sediment core, and the location of this layer relative to the sediment surface defines the amount of deposition that has occurred.  $^{137}\text{Cs}$  was introduced into the atmosphere as a result of above-ground nuclear testing in 1954 and peaked in 1964.  $^{210}\text{Pb}$  decreases to background in surficial sediments, with the decrease indicating age since deposition. Changes in the geochemical character of depositing sediment and sediment erosion and mixing patterns, however, can greatly complicate the interpretation of profiles of these radionuclides.

**21.5.2.2 Dune Formation and Transport by Bed Load** In the previous section, deposition and erosion were assumed to occur at a uniform rate from an essentially flat surface. While this may be valid under low water velocity or in a low-energy environment in an estuary, this view of erosion and deposition does not hold under high-energy or high-velocity conditions. Under high-energy conditions, dunelike structures are formed that generally progress downstream by erosion on the upstream face and deposition on the downstream face, as shown in Fig. 21-2. During this overturn and migration process, sediment particles are exposed and either scoured or reburied by other sediment particles (see Chapter 2). During exposure to the stream water, contaminants sorbed to the sediment particles can be desorbed and contaminants in the adjacent pore water diluted mixed into the water column.

To quantify the rate of transport of sorbed and dissolved contaminants from the sediment bed, it is necessary to determine the spatial dynamics of the particle relocation process. The locations of particles as a function of time allow definition of the location of contamination as a function of time, the exposure time at the surface of the dune, and the total time required to overturn the dune. Savant-Malhiet and Reible (1993) developed a model of contaminant dynamics under these conditions that provides a means of estimating sediment recovery rates by bed-load transport of noncohesive sediment. The model is beyond the scope of the present paper, but results emphasize that bed turnover and contaminant release can be rapid (compared to processes such as diffusion) even under relatively low sediment-migration rates.

**21.5.2.3 Advection Due to Groundwater Flow** Streams, lakes, and estuaries are hydraulically connected to groundwater aquifer systems. These surface-water bodies can gain or lose water depending on the water level relative to the adjacent

**Fig. 21-2.** Depiction of bed-load sediment flow over dunelike sediment structures.

water table. The bulk flow through the sediment can result in an advective flux of contaminant that complements the diffusive flux described above. The relative magnitudes of advective and diffusive transport can be quantified with a Peclet number,

$$P_{pe} = \frac{Vh}{D_{sw}} \quad (21-29)$$

Here  $V$  is the superficial, or Darcy, velocity perpendicular to the contaminated layer of height  $h$ . For low values of the Peclet number, the transport is dominated by diffusion and the previous discussion applies. For large values of the Peclet number, advection dominates and the characteristic times for reduction in concentration of a layer of sediment of height  $h$  are

$$\tau_{0.5}^{adv} = 0.693 \frac{hR_f}{V} \quad \tau_{0.05}^{adv} = 3 \frac{hR_f}{V} \quad (21-30)$$

Note that the advective processes are assumed to be sufficiently slow so that the upper layer remains mixed by bioturbation or other processes. It is also important to note that the retardation factor arises in Eq. (21-30). Advection is a pore-water process subject to retardation due to accumulation on the immobile solid particles and enhancement by sorption onto mobile fine and dissolved particulate matter.

The measurement of groundwater flow velocities and, in particular, stream-bed seepage velocities is difficult. Seepage meters (i.e., containers covering a portion of the sediment bed, which collect any water that seeps through the sediment) are commonly used. It is particularly important that such measurements reflect the seasonal nature of groundwater flow. Unfortunately, the wide variability in sediment characteristics (e.g., permeability) makes interpretation of such data difficult. In addition, it is difficult to measure seepage

rates of less than about  $0.1 \text{ cm}^3/\text{cm}^2/\text{day}$  with typically available meters. An alternative means of detecting slow vertical transport by groundwater flow is through tracers, such as described by Cornett (1989). The groundwater flow in the surrounding aquifer can also be a useful measure because it represents an average inflow or outflow from the water body. The general direction of the groundwater flow can be measured by piezometers placed at different elevations below the bed of the water body. If the underlying water head is greater than the head in the stream, inflow occurs; outflow occurs in the reverse situation. In addition to defining direction, this information is used to estimate flow rate if the permeability of the medium can be measured.

**21.5.2.4 Advection due to Local Pressure Variations on the Sediment Surface** Even in the absence of a mean hydraulic gradient, an advective flux may still be observed. Local pressure variations on the order of 100 to  $1,000 \text{ N/m}^2$  can be observed between the upstream and downstream faces of the triangular-shaped dunelike sediment structures that typically form at the sediment-water interface. Figure 21-2 includes a depiction of the basic character of the flow over these dunes. The flow is a simple turbulent shearing flow on most of the upstream face and a recirculating wake on the downstream face which also influences a portion of the subsequent sediment dune. It is the weak and poorly organized flow in the wake that results in the leeward deposition of sediment grains under bed-load conditions. In addition to modifying the sediment dynamics, the formation of a separated recirculating wake on the downstream face results in an observed pressure difference. Thibodeaux and Boyle (1987) approximated the dunes as simple geometric shapes such as cylinders and showed that measured pressure data on those simple shapes are sufficient to generate a potentially significant in-bed advective flow.

Savant et al. (1987) used the pressure-profile data generated by Vittal et al. (1977) to predict head distributions and, through Darcy's law, velocity profiles in triangular sediment dunes in a laboratory flume. The relatively high pressure on the upstream face resulted in a flow down and into the dune, turning upward and out of the lower-pressure downstream face, as shown in Fig. 21-3. The experiments and modeling indicated that the induced in-bed flow could extend as much as four to five dune heights into the sediment. Elliot and Brooks (1997a, 1997b) also analyzed this mechanism and achieved similar results. This mechanism likely is important mostly in sediment beds subject to significant organism burrowing activity and in permeable, sandy sediments such as might be observed on the continental shelf of the coastal United States. Note that pressure differences in bends and under other flow irregularities may also cause advective flow in the adjacent sediments.

**21.5.2.5 Bioturbation-Induced Transport** The previous discussion largely considered sediment as a collection of particles separated by water-filled pore spaces. In reality, a variety of plants and animals reside in sediments. Root systems and animal burrows can provide channels for pref-

**Fig. 21-3.** Numeric simulation of the in-bed flow due to pressure variations on the surface of a dune (after Savant 1987).

erential water flow and contaminant transport. Even more important, the near-surface sediment is often continuously mixed by the activities of benthic organisms such as clams and worms. Sediment processing by animals residing in the upper layers includes burrowing, ingestion and defecation, tube building, and biodeposition. Taken together, these processes are termed bioturbation; a depiction of the type of animals that can be present and the interaction with sediments is provided in Fig. 21-4. The net result of bioturbation is the vertical and horizontal movement of sediment particles and pore water. Contaminants on the particles or in the pore spaces likewise are transported in the bioturbation process, which is especially important in the transport of hydrophobic contaminants that are heavily retarded by sorption in pore-water processes.

The possibility of bioturbation as a transport mechanism has long been recognized. Boudreaux (1986a) cites work on the effect of biological activity on sediment composition and properties as old as Davison (1891). A wide variety of animal organisms live on and in the upper sediment layer and interact with sediments in a variety of ways. If the scale of the individual organism mixing is very small compared to the depth and area of the sediment of interest (e.g., the depth and area of a box core sample of a sediment), then bioturbation has the appearance of a diffusive process. Boudreaux (1986a) examined the conditions under which a diffusive model of bioturbation is appropriate. Because of the decrease in organism density and activity with depth in sediment, some investigators have speculated that a

**Fig. 21-4.** Illustration of the variety of benthic organisms that interact with the sediments and solids associated contaminants (after Rhoads 1974).

depth-dependent biodiffusion coefficient is appropriate. However, as Boudreaux (1986b) noted, it is often difficult to differentiate between a constant and a depth-dependent biodiffusion coefficient on the basis of available data.

If the scale of the individual organism-related mixing is not sufficiently small so that the appearance of a random, diffusive process is achieved, other models must be postulated. For example, worm tubes and other macroscopic animal burrows can significantly enhance the contaminant transport rate across the sediment-water interface on larger scales. In addition, some marine and freshwater worms ingest sediment at depth and deposit the fecal matter at the surface, a process that has been called conveyor-belt feeding (Rhoads 1974). Neither of these processes can be described on a fundamental basis as a diffusive process. However, even nonlocal (i.e., macroscale) mixing events of this sort often give rise to contaminant profiles that have the appearance of a diffusive transport process.

Therefore, although diffusion characterized by a constant biodiffusion coefficient is not an adequate description of the actual physical processes that constitute bioturbation, it can be used to correlate the overall characteristics of the observed contaminant transport. The primary difficulty with such an approach is that due to the inadequacy of the assumption of a diffusive process, biodiffusion coefficients that adequately describe a particular sediment may not be applicable to another site, even a nearby site, if the density, distribution, and type of organisms are different.

Despite this, biodiffusion coefficients can show surprising similarity between different sites. For example, Aller (1982) estimated an effective biodiffusion coefficient of 5 to 32 cm<sup>2</sup>/yr in Narragansett Bay, Brownawell (1986) estimated a biodiffusion coefficient of 9.4 cm<sup>2</sup>/yr in Buzzards Bay, and, finally, Thibodeaux (1989), using the data of Spaulding (1987), observed an essentially identical biodiffusion coefficient of 9 to 13 cm<sup>2</sup>/yr in the upper estuary of New Bedford Harbor. An analysis of the data of Matisoff (1982) suggests that more than 2/3 of the available measurements in both freshwater and salt-water conditions suggest an effective particle diffusion coefficient of 0.3 to 30 cm<sup>2</sup>/yr. This can be restated as effective mass transfer coefficients of 0.03 to 3 cm/yr using an average effective layer depth  $h_{\text{bio}}$  of 10 cm. The vast majority of these measurements of effective bioturbation diffusivities were made by estimating particle-reworking rates using strongly sorbed radionuclides associated with nuclear testing. The times and amounts of the release of particular radionuclides and the current distribution within sediment allow estimation of the reworking rates in stable sediments.

The measurement range of 0.3 to 30 cm<sup>2</sup>/yr is consistent with the measurements of Reible et al. (1996) of effective bioturbation mass transfer coefficients,  $k_{\text{bio}} \sim D_{\text{bio}}/h$ , equivalent to 1 to 10 cm<sup>2</sup>/yr for tubificid worms at field densities in freshwater sediments. Tubificid worms are typically found at very high densities and often represent the bulk of the biomass in sediment bioassays (e.g., USEPA 1993a). These

worms are head-down deposit feeders capable of processing 10 or more times their own weight in sediment every day. The high density of these organisms, along with the ability to process large amounts of sediment, leads to relatively high mass-transfer rates. Some organisms may also degrade certain contaminants, further speeding the attenuation of contaminant concentrations.

Focusing specifically on the transport effect of bioturbation, the diffusive models discussed previously can be applied. The time required for 50% and 95% reduction in concentration in a surface layer of depth  $h$  due solely to bioturbation at an effective particle reworking diffusion coefficient,  $D_{\text{bio}}$ , is given by

$$\tau_{0.5}^{\text{bio}} = \frac{1.94}{\pi^2} \frac{h^2}{D_{\text{bio}}} \quad \tau_{0.05}^{\text{bio}} = \frac{11.2}{\pi^2} \frac{h^2}{D_{\text{bio}}} \quad (21-31)$$

Because biodiffusion typically involves particle movement, there is no effect of retardation by sorption onto an immobile phase. Therefore, for a hydrophobic contaminant that is strongly sorbed to the sediment, bioturbation is a much more effective mixing process than molecular diffusion in the pore water.

As stated previously, effective molecular diffusion coefficients in sediments are on the order of 10<sup>-6</sup> cm<sup>2</sup>/s, which corresponds to approximately 30 cm<sup>2</sup>/yr, or about the same as the largest of the typical effective bioturbation diffusion coefficients. For many elemental species, whose leachable fraction may partition only weakly into the solid phase, the enhancement by bioturbation is minimal. For a hydrophobic contaminant such as pyrene, however, bioturbation is expected to control contaminant migration in the upper layers of a stable sediment bed. In general, bioturbation is the primary migration mechanism of strongly sorbing contaminants in stable surficial sediments unless the physical character of the sediment or its level of contamination precludes significant colonization by benthic organisms.

## 21.6 ENGINEERING MANAGEMENT OF CONTAMINATED SEDIMENTS

The goal of remedial efforts at a contaminated sediment site is to manage the risks that they pose. The processes already described define the rate of natural attenuation of contaminants in the surficial sediment layer but also define the attenuation of any residual remaining from more active remediation.

Thus the above discussion of the fate and transport processes provides a basis for the assessment and implementation of natural attenuation. To ensure the effectiveness of natural attenuation as a management option, it is necessary to design a monitoring plan that tests and updates the conceptual model of contaminant release and exposure from the sediments and demonstrates the attenuation of concentration

and risk that is predicted by it. The design of such a monitoring plan is beyond the scope of this chapter, but the general approach must be consistent with the most important process or processes that influence contaminant behavior.

Engineered efforts to control exposure and risk beyond natural attenuation can be placed into two broad categories:

1. Containment and/or treatment in situ;
2. Removal and ex situ treatment or disposal.

The feasibility of sediment or dredged material treatment approaches is strongly dependent on the contaminants and the characteristics of the sediment and the environmental setting. Evaluation and the presentation of design approaches for treatment processes are beyond the scope of this work. The initial step in applying any treatment approach, however, is either containment by capping with clean sediments or removal by dredging. In some cases, the body of water can be diverted or contained, allowing removal by dry excavation. Dry excavation will not be considered here because of its similarity to conventional soil removal. Instead, the basic features and key design constraints of capping and wet dredging will be discussed.

### 21.6.1 Contaminated Sediment Containment by in Situ Capping

Capping is the placement of clean sediment or similar materials over contaminated sediment. For ease of placement, sand or other coarse media are normally used as capping material. Geomembrane material may be used beneath a cap in soft sediments to aid in the support of the cap, and stones or other large material may be employed as armoring on top of the cap to reduce cap resuspension and erosion. The purpose of a cap is to contain the contaminated sediment physically, separate the contaminants from organisms living at the sediment-water interface, or isolate the chemical contaminants from the overlying water by reducing flux. The design of a cap to meet each of these goals is discussed below.

**21.6.1.1 Containment of Contaminated Sediment** The goal of sediment containment is to armor the sediment bed and eliminate the resuspension and erosion that may control contaminant release. Contaminants tend to be associated with fine-grained sediments that are often cohesive and exhibit low shear strength or load-bearing capacity. A more coarse-grained cap can provide significant stabilization if placement can be achieved. In addition, since such a cap is generally composed of granular, noncohesive sediment, for which erosion properties are well known, uncertainties associated with the stability of the underlying cohesive sediment become irrelevant.

The ability to place a cap over a sediment with low load-bearing capacity can be estimated by considering local shear failure (Palermo et al. 1998). The thickness of a cap that can be supported for a certain strength sediment is given by

$$h_{\text{cap}} = (2 + \pi) \frac{2}{3} \frac{C_{\mu}}{\gamma} \quad (21-32)$$

where

$C_{\mu}$  = the shear strength of the sediments and  
 $\gamma$  = the specific weight of the cap materials.

If the cap is made of sand with a specific weight of 5 kN/m<sup>3</sup> and the sediments are at the liquid limit ( $C_{\mu} \sim 2.5$  kN/m<sup>2</sup>; Das 1979), a load of almost 1.7 m or 5.6 ft may be placed without local shear failure of the sediment. A thinner cap may be required to ensure a factor of safety, or for weaker sediments. A thicker cap may be placed, if desired, by placement in multiple lifts to allow consolidation and strengthening of the sediment prior to placement of the entire cap.

The long-term stability of an armoring cap layer depends upon the erosion characteristics of the cap and the hydraulic forces to which it may be exposed. For simple preliminary design, the Transportation Research Board (1970) established a criterion for the onset of erosion of noncohesive granular media of particle size  $d_p$  that is dependent upon bed shear stress,  $\tau_b$ :

$$\begin{aligned} \tau_b &= 4 d_p \quad (\tau_b \text{ in lbf/ft}^2, \quad d_p \text{ in ft}) \\ \tau_b &= 58.4 d_p \quad (\tau_b \text{ in N/m}^2, \quad d_p \text{ in m}) \end{aligned} \quad (21-33)$$

Another approach, employing flow velocity rather than bed tractive force, may be found in Palermo et al. (1998). Use of Eq. (21-33) or the methods in Palermo et al. (1998) requires specification of a design flow condition. This is typically a major rare flood event such as a 100-yr flood or a maximum design flood. In addition, however, special care must be taken to ensure that such a flood event controls the potential for cap instability. Wind-driven seiche flows, wave action, or ice scouring of the sediments may challenge cap integrity more than a major flood event.

Simple relationships such as Eq. (21-33) do not recognize the spatial variability in shear stresses and the resulting cap erosion. Localized erosion of a cap, however, is unlikely to significantly affect overall cap effectiveness, which is proportional to the total area of sediment capped.

Palermo et al. (1998) also includes approaches to the evaluation of a stable grain size when a body of water is subjected to commercial or recreational navigation traffic. Regular exposure to high-powered traffic, especially in relatively shallow water, may limit the feasibility of capping as a management alternative. However, irregular recreational boat traffic outside of dock and marina areas, may not pose a significant challenge to cap integrity because any cap erosion may be localized.

Eq. (21-33) assumes that the cap grain size is uniform. Other criteria on cap materials may be required to ensure stability and eliminate the potential for fine-grained material to be lost through the cap, including (Palermo et al. 1998)

- A nonuniform particle-size distribution, e.g.,  $d_{85}/d_{15} \sim 4$ ;
- Angular shapes for coarse-grained particles such as gravel and cobbles;
- A maximum particle size of not more than  $2 d_{50}$  (USBR 1973);
- A minimum particle size of not less than  $0.05 d_{50}$  (USBR 1973);
- A minimum layer thickness of approximately  $1.5 d_{50}$ ;
- Maintaining a ratio of particle sizes between upper and lower layers of a multilayered cap such that  $d_{15}^{\text{upper}}/d_{85}^{\text{lower}} \leq 5$  (this criteria also defines an upper bound for the ratio of particle sizes in the cap layer immediately adjacent to the sediment layer desired to be contained); and
- Limiting placed cap slope to the stable angle of repose of the cap material (Palermo et al. 1998 suggested a vertical to horizontal slope of 1:1.88 for clean sand, although a factor of safety of 2 to 3 might be applied).

**21.6.1.2 Separate Benthic Organisms from Contaminated Sediment** The adequacy of a cap to physically separate organisms from contaminated sediment depends upon the thickness of the cap and the depth of penetration of the organisms. The depth and intensity of interaction of organisms with sediments is strongly dependent upon the type of organism and environmental characteristics such as sediment texture. Freshwater benthos, for example, may only populate the upper 5 to 10 cm of sediments in significant quantities. In marine sediments, animals living at the sediment-water interface tend to be larger and influence a larger sediment depth. Deposit feeders typically prefer fine-grained sediment high in organic carbon content, whereas burrowing filter feeders may prefer coarse-grained sandy sediment. More than 90% of the 240 observations of bioturbation mixing depths in both fresh and salt water reported by Thoms et al. (1995), however, were 15 cm or less and more than 80% were 10 cm or less. Almost all of these estimates were based upon measurements of the vertical distribution of various radionuclides, which have proven to be very useful tools in identifying the degree of mixing within the upper layers of sediment. Short-term mixing in this regard can be effectively assessed with beryllium ( $^7\text{Be}$ , cosmogenic source,  $t_{1/2} = 52$  days, 477 KeV peak), which is mixed downward from the water column by the benthic organisms.

Certain organisms may penetrate significantly deeper than 15 cm. The importance of these penetrations at the population level depends upon the density and intensity of organism behavior at the deeper levels. As indicated by the measurements reported by Thoms et al. (1995), however, 90% of the observations showed minimal mixing below 15 cm, leading to the conclusion that population-level impacts are generally limited to that depth. Deeper penetrations by individual organisms, however, may be important in particular environmental settings or when the organisms of concern are those that tend to penetrate more deeply.

If the depth of concern for organism penetration is  $h_{\text{bio}}$ , and the cap consolidation is given by  $\Delta h_{\text{cap}}$ , the depth of cap,

$h_{\text{cap}}$ , necessary for separation of benthic organisms and the contaminated sediments is given simply by

$$h_{\text{cap}} > h_{\text{bio}} + \Delta h_{\text{cap}} \quad (21-34)$$

Cap consolidation may be estimated by conventional consolidation measurements and models such as PCDDF (Stark 1991).

**21.6.1.3 Reduce Contaminant Flux to the Overlying Water** The final objective of a cap is reduction of chemical flux to the overlying water. If the criterion for cap stability is achieved, only pore-water processes are effective below the zone of bioturbation. Thus the pore-water concentration,  $C_{pw}$ , controls the driving force for flux to the overlying water. This flux is usually described by a combination of advective and diffusive processes,

$$F_{\text{cap}} = V C_w - D \frac{dC_w}{dz} \quad (21-35)$$

Here  $V$  is the superficial or Darcy velocity driven by local or mean hydraulic gradients and  $D$  is an effective coefficient including both diffusion (Eq. 21-24) and dispersion. Wang et al. (1991) and Thoma et al. (1993) demonstrated the applicability of flux models of the form of Eq. (21-35) and defined a modeling framework that was later extended by Palermo et al. (1998).

If it is assumed that the cap poses essentially the only mass transfer resistance and the pore-water concentration beneath the cap,  $C_0$ , remains constant, the flux at the top of the effective cap thickness,  $h_{\text{cap}}$ , is given by

$$F_{\text{cap}} = \frac{C_0 V}{2} \operatorname{erfc} \left\{ \frac{R_f h_{\text{cap}} - V t}{2 \sqrt{R_f D_{sw} t}} \right\} + C_0 \sqrt{\frac{D_{sw} R_f}{\pi t}} \exp \left\{ - \frac{(V t - R_f h_{\text{cap}})^2}{4 R_f D_{sw} t} \right\} \quad (21-36)$$

where  $R_f$  is given by Eqs. (21-25) or (21-27) and defined by cap properties. The effective cap thickness is the cap thickness minus allowances for consolidation and bioturbation. The effective cap thickness is the thickness of the chemical isolation layer. For times long compared to  $R_f h_{\text{cap}}/V$ , the flux through the chemical isolation layer approaches  $VC_0$ . For  $V \ll D_{sw}/h_{\text{cap}}$ , however, the migration through the cap is diffusion controlled and the flux at the top of the chemical isolation layer is given by

$$F_{\text{cap}} = \frac{C_0 D_{sw}}{h_{\text{cap}}} \left[ 1 + 2 \sum_{n=1}^{\infty} (-1)^n \exp \left( - \frac{D_{sw} \{n\pi\}^2 t}{R_f h_{\text{cap}}^2} \right) \right] \quad (21-37)$$

For times long compared to  $R_f h_{\text{cap}}^2 / (\pi^2 D_{sw})$ , the flux through the cap approaches  $C_0 D_{sw} / h_{\text{cap}}$ .

Both Eqs. (21-36) and (21-37) predict minimal flux through the cap from the time of placement until times approaching

the characteristic time for the advective or diffusion-dominated process that controls migration through the cap. That is, the time until some contaminants have migrated over most of the cap can be estimated by

$$\begin{aligned}\tau_{\text{cap}}^{\text{adv}} &\sim \frac{R_f h_{\text{cap}}}{V} && \text{advective conditions} \\ \tau_{\text{cap}}^{\text{diff}} &\sim \frac{R_f h_{\text{cap}}^2}{\pi^2 D_{\text{sw}}} && \text{diffusive conditions}\end{aligned}\quad (21-38)$$

At times short compared to these characteristic times, the flux through the cap is effectively zero. Note that the flux through the cap, even after these times, may still be significantly less than the flux from the exposed sediment prior to cap placement. The uncapped sediment is typically subject to bioturbation and erosion that a well-designed cap will eliminate. Under diffusive conditions, the cap provides a longer diffusion path that effectively reduces flux even at steady state (long time).

The flux through the chemical isolation layer, defined by Eqs. (21-36) or (21-37), controls the flux through the bioturbation layer as well. This provides a basis for estimating the concentration in the bioturbation layer, which is defined by the balance of the flux in from the chemical isolation layer and out into the overlying water. If  $k_{\text{bio}}$  is the effective mass transfer coefficient in the bioturbation layer,  $k_w$  is the benthic water layer mass transfer coefficient, and  $V$  is the seepage velocity, assumed independent of either the bioturbation-layer or benthic-water-layer mass transfer processes, the water-phase concentration in the bioturbation layer is

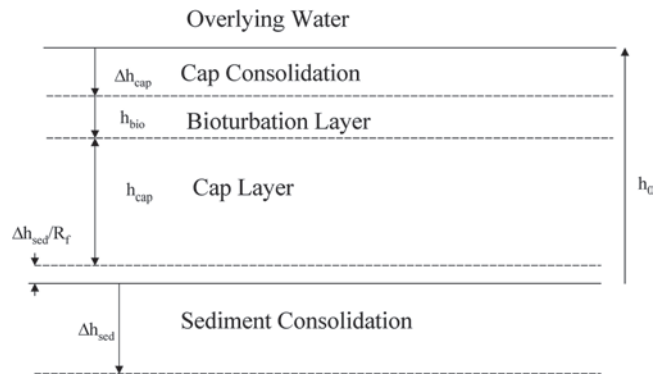

$$C_{\text{bio}} = F_{\text{cap}} \left( \frac{1}{k_{\text{bio}} R_f + V} + \frac{1}{k_w} \right) \quad (21-39)$$

and the corresponding solid-phase concentration, which can be compared to sediment quality standards, is

$$W_{\text{bio}} = K_{\text{sw}} C_{\text{bio}} \quad (21-40)$$

Examination of Eqs. (21-36) and (21-37) shows that as the effective cap thickness increases, the flux decreases and the time required to achieve the steady state (maximum) flux increases. The cap thickness is initially defined by the placement thickness,  $h_0$ , which is reduced by consolidation of the cap,  $\Delta h_{\text{cap}}$ , mixing of the upper layers of the cap by bioturbation,  $h_{\text{bio}}$ , and consolidation of underlying sediment,  $\Delta h_{\text{sed}}$ , which expresses contaminated pore water over a portion of the cap. The contaminants expressed with the pore water due to underlying sediment consolidation, however, are subject to retardation. It is assumed that the time of consolidation and the time for bioturbative mixing of the upper layers of the cap are very small compared to the time required for contaminant transport through the cap. Thus the effective cap thickness for use in Eqs. (21-36) and (21-37) can be written

$$h_{\text{cap}} = h_0 - \Delta h_{\text{cap}} - h_{\text{bio}} - \frac{\Delta h_{\text{sed}}}{R_f} \quad (21-41)$$

**Fig. 21-5.** Depiction of the different layers present in a cap as defined by the effective cap thickness.

The relationship of these terms within the cap is shown in Fig. 21-5.

In either the advection-dominated case or the diffusion-dominated case, it is possible to compare this flux to that estimated from the uncapped sediment-water interface to determine the effectiveness of the cap. Alternatively, it may be desired to design a cap by selecting the thickness necessary to achieve a desired reduction in flux or a time until significant migration through a cap might occur.

## 21.6.2 Dredging Contaminated Sediments

Options that involve removal of contaminated sediments from a water body are significantly more complicated than in situ approaches. Removal options require controls to minimize contaminant loss during sediment removal and transportation, pretreatment of produced dredged material for dewatering and equalization, treatment or transport and disposal of the dredged material, and management of the residual contamination in the sediment and treatment effluents. Thus removal options involve not only dredging but several other component technologies to manage the dredged material.

**21.6.2.1 Dredging Technologies** Dredges fall into one of two basic categories: hydraulic dredges that primarily use suction and hydraulic action to remove sediments, and mechanical dredges that remove sediments by direct, mechanical action. Hydraulic dredges are generally preferred for high production rates and to minimize sediment resuspension. Solids content of dredge material produced by hydraulic dredging, however, is typically less than 15% and in some environmental dredging operations has been as low as 1%. Hydraulic dredges with a rotating cutterhead or a horizontal auger are commonly used in contaminated-sediment removal. Mechanical dredges, such as a clamshell or cable-arm bucket dredges, are generally preferred for high solids content, low water production, improved performance in the presence of debris and obstructions, and greater accuracy. Close to in situ densities have been generated during mechanical dredging operations. Hybrid dredges have also been used that are predominantly mechanical in action but also withdraw water to control migration of a resuspension plume.

**21.6.2.2 Resuspension of Contaminants** One of the most significant factors in the selection of dredges for removal of contaminated sediments is the resuspension potential. Sediment characteristics such as grain size largely control resuspension. Fine-grained sediments settle the most slowly and result in the most resuspension in and around a dredgehead. Dredging effectiveness is also limited by residual sediment contamination not targeted or captured by the dredging operation, and by the influences of debris, sediment heterogeneity, and dredge type. In the presence of large debris, certain hydraulic dredges may be ineffective or lead to increased resuspension rates. Hard, consolidated sediment layers, or hardpan, may make dredging overlying contaminated sediments extremely difficult and of limited effectiveness. Sediments also tend to settle back into the cuts of mechanical dredges, leading to increased resuspension rates and residuals in the surface sediments.

Sediment resuspension and associated contaminant loss during dredging operations have been the focus of much attention. Limited data preclude reliable a priori predictions for all except conventional cutterhead and bucket dredges operating under near-normal conditions. Available data for conventional cutterhead and bucket dredges show resuspension rates generally less than 1% of the sediment dredged (Hayes et al. 2000). Whereas available data for smaller dredge types (USACE 1990; Foth and Van Dyke 2000; 2001) show resuspension and contaminant loss rates generally in excess of 1%.

If the contaminant is assumed to be largely associated with the sediment particles, a 1% sediment loss translates directly into a 1% contaminant loss. The mass of contaminant released per unit area of sediment dredged is given by

$$F_{\text{sus}} = f_{\text{sus}} h_{\text{dredge}} W_s \rho_s \quad (21-42)$$

where  $h_{\text{dredge}}$  is the depth of dredging,  $\rho_s$  is the sediment bulk density,  $W_s$  is the contaminant concentration, and  $f_{\text{sus}}$  is the fractional resuspension rate.

**21.6.2.3 Residual Sediment Contamination** The portion of sediments that remains as a residual contaminated layer may be a more significant source of long-term exposure and risk. Typically, removal of this contaminated residual is attempted by “overdredging,” the process of removing an additional layer of less contaminated underlying sediment. Complete removal of the contaminated layer is not possible, however, due to the mixing of this layer with the less contaminated underlying sediment even during overdredging. Removal of the residuals is especially difficult where overdredging is hindered by debris or by “hardpan” or bedrock that limits the depth of the dredging cut.

It is not possible to predict with certainty either the depth or the concentration of the residual contaminated layer or its relationship to sediment and operational variables. Problems posed by residual contaminated sediment from dredging, however, have been demonstrated in a variety of dredging

projects. The dredging of PCBs near a GM facility in Massena, New York required 15–18 dredge passes to reduce sediment concentrations below 500 mg/kg in areas where initial concentrations exceeded 500 mg/kg (BBL 1996). In some areas, a cap was ultimately placed over the residual contamination because repeated dredging passes could not reduce the sediment concentrations below 10 mg/kg. In an area of the Grasse River, also near Massena, removal of as much as 98% of the PCBs from the sediment column reduced the average PCB concentrations in surficial sediments (upper 8 in.) by only 53% (Thibodeaux et al. 1999). Both of these efforts were hindered by the presence of bedrock or hardpan, limiting the extent of overdredging, and by the fact that the highest PCB concentrations were observed at depth rather than at the sediment surface. Demonstration projects in the Lower Fox River of Wisconsin also indicate the potential for residual PCB contamination in the surficial sediments after cessation of dredging (BBL 2000).

Although no definitive approaches to estimating residual contaminant concentrations or residual sediment depths have been developed, mechanical mixing associated with dredging suggests that the residual layer would exhibit a concentration similar to the depth-averaged concentration in the layer being dredged,

$$\bar{W}_s \approx \frac{\int_0^{h_{\text{dredge}}} W_s(z) dz}{h_{\text{dredge}}} \quad (21-43)$$

The thickness of this residual layer is uncertain and dependent upon the presence of hardpan or debris but is likely to be at least 1–4 in. given the significant concentrations typically observed in 4- to 12-in. surficial sediment samples after dredging. Multiple passes can significantly reduce this residual concentration if the dredge is not limited by hardpan or debris.

The attenuation of concentrations in this thin surface layer may be very rapid in that the contaminants may be quickly removed by erosion, or bioturbation may rapidly mix the contaminants over at least the mixed layer of the sediments. A conservative estimate (i.e., an overestimate protective of human health) of the flux immediately after dredging is that the surficial sediment concentration is given by Eq. (21-43). That is, the flux to the overlying water due to the residual contamination immediately after dredging is then

$$F_{\text{res}} = K_s \bar{W}_s \rho_s \quad (21-44)$$

**21.6.2.4 Dredged Material Handling** In addition to management of resuspension losses and residuals from dredging, the dredged material requires significant handling. The additional required steps include pretreatment of produced dredged material for dewatering and equalization, treatment or transport and disposal of the dredged material,

and management of the residual and treatment effluents. Although it is beyond the scope of this paper to evaluate these steps, the cost and difficulty of onshore management of the contaminated sediments may exceed that in water and should be considered in any comparative analysis of in situ versus ex situ management options for contaminated sediments.

## 21.7 SUMMARY

Exposure and risk of sediments to higher trophic organisms (e.g., piscivorous birds and mammalian predators) are controlled by the type and extent of the contamination and the relative rates of the various natural fate and transport processes. Contaminants that are buried, sequestered, or degraded pose less risk, whereas contaminants that can be mobilized by natural physical, chemical, and biological processes can pose significant risks. This discussion quantitatively summarizes the most important fate and transport processes that attenuate contaminant levels and exposure in river, estuarine, lacustrine, and marine sediments. The key factors influencing contaminant release and exposure during the application of common remedial approaches, including in situ capping and dredging, were also summarized.

Exposure and risks to fish and higher animals were attributed to one of three contaminant pathways. The first pathway, direct exposure to resuspended sediment, can often be described by assuming chemical equilibrium between the suspended sediment load and water. The rate of resuspension of surficial sediments would then be needed to predict water-column concentrations. The second pathway, indirect exposure to contaminated sediment through the food chain, can often be described by chemical equilibrium between the bed sediment and the benthic organisms that inhabit the sediment-water interface. The rate of predation on these organisms would then indicate the rate of uptake by fish and higher organisms. The third pathway, direct exposure to contaminants released from stable sediments, requires analysis of the fate and transport processes in the sediment.

Although many of the fate and transport processes vary significantly in importance from site to site, it is possible to rank the potential importance of each mechanism depending upon the rate at which the process can influence contaminant concentrations. Relationships were presented for estimation of the time required to achieve 50 and 95% reductions in contaminant concentrations by the various mechanisms. Processes that exhibit a shorter characteristic time are likely to be the most important transport processes.

In general, active sediment processes in which contaminants are transported by bulk movement of pore water or particles exhibit the shortest characteristic transport times and, therefore, the shortest sediment-concentration attenuation times. These processes also exhibit the highest sediment-to-water fluxes and the potential for relatively high exposure and attendant risk to fish and higher animals. In

high-energy environments, sediment resuspension and movement are likely to be dominant factors in particle transport; in low-energy environments, bioturbation is likely to dominate contaminant movement in the upper layer of sediments. It is important to note that each site is different and that only through detailed studies can the dominant process or processes at a particular site be identified and quantified, allowing the evaluation of the effect of these processes on natural attenuation and active remedial options. In all cases, the nature of the physical environment (e.g., sediment texture, water depth and flow velocities, temperature effects, and climatographic effects, as well as sediment chemistry and heterogeneity), the nature of the contaminants (e.g., hydrophilic versus hydrophobic, persistent versus ephemeral), and the biotic elements of the environmental setting all contribute to the fate of the contaminants in sediments.

There are few options for reducing exposure by active intervention rather than passive natural attenuation, largely removal or containment. There are limited in situ treatment options. Both removal and containment leave residual contamination and risks that must be assessed to appropriately select or design either option.

## CHAPTER 22

# *Sediment Oxygen Demand (SOD) in Rivers, Lakes, and Estuaries*

*Miki Hondzo and Nancy Steinberger*

### 22.1 INTRODUCTION

Sediment oxygen demand (SOD) is defined as the rate of oxygen consumption exerted by the bottom sediment on the overlying water (Lee et al. 2000b). The uptake of dissolved oxygen (DO) by sediment is usually attributed to the aerobic decomposition of organic material by microorganisms at the sediment surface and the reaction of oxygen with anaerobic respiration by-products (Sweerts et al. 1991). Because the sediments are a repository for decaying organic material, SOD is often a major contributor to DO depletion in rivers and lakes (Ellis and Stefan 1990; Sweerts et al. 1991; Nakamura and Stefan 1994; Seiki et al. 1994).

The amount of DO in a water body is an indication of the level of microbiological activity and the amount of decaying organic matter present, and often limits the amount of waste that a water body can safely assimilate from municipal and industrial discharges (Hatcher 1986; Lung and Soback 1999). In addition, DO is critical for the sustainability of fish habitat in temperate rivers and lakes. Low DO levels influence the composition of fish fauna, favoring species with tolerance for low oxygen levels, such as common carp (*Cyprinus carpio*), and can cause winterkill in ice-covered lakes (Moyle and Cech 2000). Because SOD is often a major component of the DO budget, accurate estimation of the flux of DO across the sediment-water interface is of paramount importance.

Davis and Lathrop-Davis (1986) have provided a brief history of the early investigations in SOD. Early reports relating water quality to sediments described the effects of wastewater sanitation practices and settled sludge deposits on surface-water quality in heavily populated areas (Hering et al. 1887; Stearns and Drown 1890; Forbes and Richardson 1913; Metcalf and Eddy 1916; Richardson 1928; Purdy 1930). Studies of oxygen dynamics in lakes considered the influence of bottom sediments on DO depletion (Birge 1906; Birge and Juday 1911; Alsterberg 1922; Welch 1935).

Early models of DO dynamics include the work of Streeter and Phelps (1925), Wisely and Klassen (1938), Jansa and Akerlindh (1941), and Bouldin (1967).

Experimental investigations of SOD have considered chemical, biological, and hydrodynamic influences on the rate of DO consumption by sediments (Baity 1938; Fair et al. 1941; Lardieri 1954; Odum 1956; Hayes and MacAulay 1959; Teal and Kanwisher 1961; Isaac 1962; Edwards and Rolley 1965; O'Connell and Thomas 1965; Knowles et al. 1962; Lenard et al. 1962). More recently, the effect of velocity and boundary-layer interactions has become a major focus for SOD research (NCASI 1978; Jorgensen and Revsbech 1985; Whittemore 1986; Hall et al. 1989; Rahm and Svensson 1989; Sweerts et al. 1991; Dade 1993; Nakamura and Stefan 1994; Maran et al. 1995).

Current work related to DO dynamics and SOD is extensive and is being performed in many disciplines. Ecologists and aquatic biologists have recently published several studies on the effect of oxygen stress on the growth and survival of aquatic organisms (Matthews and Berg 1997; Sparks and Strayer 1998; Hale 1999; Harris et al. 1999; Lowell and Culp 1999; Rosas et al. 1999; Buentello et al. 2000; Ruggerone 2000), the effect of DO on habitat utilization and the distribution of organisms (McKinsey and Chapman 1998; Sellers et al. 1998; Elliott 2000), and the relationships between DO in nesting areas and mate selection and reproduction (Jones and Reynolds 1999a; 1999b; Takegaki and Nakazono 1999). In addition, biologists have been interested in the diurnal variation in DO as it relates to metabolism (Guasch et al. 1998; Marzolf et al. 1998; Young and Huryn 1998), the influence of benthic activity on DO consumption (Brekhovskikh et al. 1998; Moodley et al. 1998; Schallenberg and Burns 1999; Schol et al. 1999; Caraco et al. 2000), and relationships between ecosystem functioning and DO (Moore and Townsend 1998; Nishri et al. 1998).

Other recent work of biological importance includes studies of DO and SOD in estuaries, tidal rivers, and oceans (Bertuzzi et al. 1997; Borodkin and Makkaveev 1997; Najjar and Keeling 1997; Summers et al. 1997; Tishchenko et al. 1998; Boyer et al. 1999; Chen et al. 1999; Engle et al. 1999). Additional studies have recently been published on DO and SOD in large regulated rivers and ancient lakes (Martin et al. 1998; Bachmann and Usseglio-Polatera 1999).

Modeling DO dynamics and SOD for management and regulation of water quality continues to be an active area of research in environmental engineering (Chambers et al. 1997; Houck et al. 1997; Chaudhury et al. 1998; Leu et al. 1998; Neal et al. 1998; Sun and Wakeham 1998; Chapra and Runkel 1999; Park and Jaffe 1999; Lung and Sobock 1999; Ansa-Asare et al. 2000; Kayombo et al. 2000). Thermal stratification in DO-limited systems also continues to be an important area of research, especially in relation to climate change (Fang and Stefan 1997; Jonas 1997; Chapman et al. 1998; Fang et al. 1999; Kelly and Doering 1999; Fang and Stefan 2000). Engineers are also concerned with the effect of velocity and turbulence on SOD as it relates to the physical mechanisms of DO mass transfer (Parkhill and Gulliver 1997; Guss 1998; Hondzo 1998; Mackenthun and Stefan 1998; Josiam and Stefan 1999; Steinberger and Hondzo 1999; Lee et al. 2000a; 2000b).

## 22.2 DIFFUSIVE SUBLAYER THICKNESS

The mechanisms of mass transfer at the sediment-water interfaces in rivers and lakes involve a combination of molecular diffusion and turbulent transport of DO from the overlying water to the sediment bed. Consider the physical effects occurring in the region adjacent to an interface (Fig. 22-1). In the near-bed region lies the diffusive sublayer, where molecular diffusional transport dominates over

turbulent transport (Levich 1962; Dade 1993). The diffusive sublayer thickness has been reported as  $\delta_c = 10 \frac{\nu}{u_*} \text{Sc}^{-1/3}$ , where  $\nu$  is the kinematic viscosity,  $u_*$  is the shear stress velocity,  $\text{Sc} = \nu/D$  is the Schmidt number, and  $D$  is the molecular diffusion coefficient. The dependence of the Schmidt number on water temperature is displayed in Fig. 22-2. According to this relationship, the Schmidt number decreases with increasing water temperature. A typical magnitude of the Schmidt number for DO in water is about 500 at 20°C (Fig. 22-2).

Therefore, the diffusive sublayer is on the order of one tenth the thickness of the viscous sublayer. The presence of this diffusive sublayer can act as a region of resistance to mass transport, and thus may limit chemical reactions occurring at the sediment-water interface (Jorgensen and Revsbech 1985; Hall et al. 1989; Rahm and Svensson 1989; Dade 1993; Steinberger and Hondzo 1999).

Consider a turbulent flow between two parallel plates as an example of shear dispersion (Fig. 22-3). The lower plate is a DO sink, whereas the upper plate constitutes a no-flux boundary condition. The boundary layer between the plates is considered to be either developed, or so slowly varying that the absence of variation in the streamwise direction can be assumed. For developed flow the mean velocity in the vertical direction,  $y$ , is zero (note that the turbulent velocity fluctuation  $v'$  is not zero), and streamwise velocity is a function only of  $y$ . As the fluid moves along the channel, DO diffuses from the fluid to the lower plate, causing the growth of the diffusive sublayer (Fig. 22-3). The bulk DO concentration at any distance  $x$  can be expressed as

$$C_B - C_w = \frac{\int_0^{2H} u (C - C_w) dy}{\int_0^{2H} u dy} \quad (22-1)$$

**Fig. 22-1.** Conceptual sketch for near-bed concentration and velocity distributions ( $\delta_c$  is the diffusive sublayer;  $\delta_v$  is the viscous sublayer).

**Fig. 22-2.** Relationship of Schmidt number ( $Sc$ ) for dissolved oxygen in water to temperature.

where

- $C$  = mean (time-averaged) DO concentration;
- $C_w$  = DO concentration at the sediment-water interface;
- $u$  = mean velocity in the  $x$  direction; and
- $H$  = the half-distance between the plates.

For developed flow the diffusive sublayer experiences no further growth in the streamwise direction. This suggests that the local mass-transfer coefficient is constant in the streamwise direction. The constant mass-transfer coefficient condition is equivalent to the condition that the concentration profiles at all  $x$  stations are mappable onto a single curve. This mapping is accomplished by the use of a concentration similarity group  $\frac{C-C_w}{C_B-C_w}$ . Note that  $C$ ,  $C_w$ ,  $C_B$  may vary with  $x$ , but not the group  $\frac{C-C_w}{C_B-C_w}$ . From the invariance condition

$$\frac{\partial}{\partial x} \left( \frac{C-C_w}{C_B-C_w} \right) = 0, \quad (22-2)$$

it follows that

$$\frac{C-C_w}{C_B-C_w} = f(y) \quad (22-3)$$

Therefore, the concentration gradient follows from Eq. (22-3) as

$$\frac{\partial C}{\partial y} = (C_B - C_w) \frac{df}{dy} \quad (22-4)$$

The local mass flux per unit area from the fluid to the sediment-water interface can be evaluated as

$$\begin{aligned} M &= -D \frac{\partial C}{\partial y} \Big|_{y=0} = -D (C_B - C_w) \left( \frac{df}{dy} \right) \Big|_{y=0} \\ &= \frac{D}{\delta_c} (C_B - C_w) \end{aligned} \quad (22-5)$$

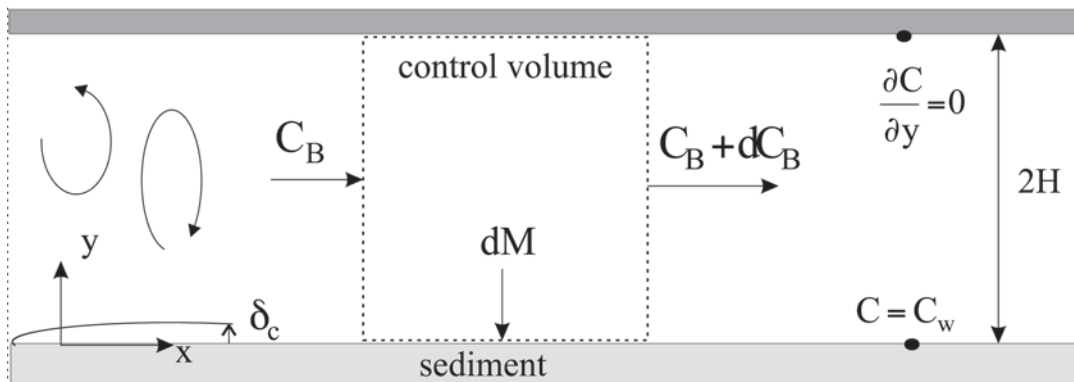

where  $M$  is the mass flux across the sediment-water interface, and  $\delta_c$  is the diffusive-sublayer thickness or the “unstirred-layer” thickness. The diffusive-sublayer thickness is given by

$$\delta_c = \frac{1}{\left( \frac{df}{dy} \right) \Big|_{y=0}} \quad (22-6)$$

The first derivative of the DO concentration similarity variable profile  $\frac{C-C_w}{C_B-C_w}$  is evaluated at the sediment-water interface. The derivative represents the slope of the similarity group in the diffusive sublayer region. The local mass-transfer coefficient is related to the diffusive sublayer thickness by

$$k = \frac{D}{\delta_c} \quad (22-7)$$

The diffusive-sublayer thickness is constant in a developed flow. Therefore, for a given fluid temperature, the mass-

**Fig. 22-3.** Definition sketch for flow between two parallel plates.

transfer coefficient is constant as well. Once the diffusive-sublayer thickness is available the mass-transfer coefficient can be estimated from the above expression. The constant mass-transfer coefficient and concentration-profile similarity are important characteristics of the developed flow regime. Note that the DO flux across the sediment-water interface should always occur across the diffusive sublayer thickness. The thickness of this layer may be determined by turbulent activity, i.e., by mean frequency of large or small eddies in the fluid above the unstirred layer. The time-averaged micro-DO concentration profiles of natural sediments are shown for four experimental runs in Fig. 22-4 (Steinberger and Hondzo 1999). The data acquisition system, operating at 25 Hz, obtained a minimum of 200 readings at each vertical step. These readings were then averaged as represented by a single measurement point denoted by a circle in Fig. 22-4. The consistent shape of the microprofiles is an indication of the high level of repeatability of the experiments. As shown on the DO microprofiles, all DO arriving at the sediment bed was quickly utilized within the first few millimeters of the surface, indicating that the experiments were water-side-controlled as opposed to reaction-limited. The concentration-sublayer

thickness near the sediment-water interface is the thin diffusive region within which the DO concentration changes rapidly. The diffusive-sublayer thickness ranged from 0.12 to 1.23 mm. In Fig. 22-4 it can be seen that  $\delta_c$  decreased with higher Reynolds number. This smaller thickness corresponds to an increase in the flux of DO to the sediment bed.

Scaling arguments (Steinberger and Hondzo 1999) yield an expression for  $\delta_c$  (Fig. 22-5) of the form

$$\delta_c = (19.4 \pm 5.5) \frac{V}{u_*} S_c^{-1/3} \quad (22-8)$$

where

$\delta_c$  = diffusive-sublayer thickness in mm

and  $\pm 5.5$  are the 90% confidence intervals for the mean slope. Prasad and Russell (2000) derived a similar expression,  $\delta_c = 14.5 \nu / u_* S_c^{-1/3}$ , that falls within the 90% confidence limits of Eq. (22-8). This result is not in close agreement to

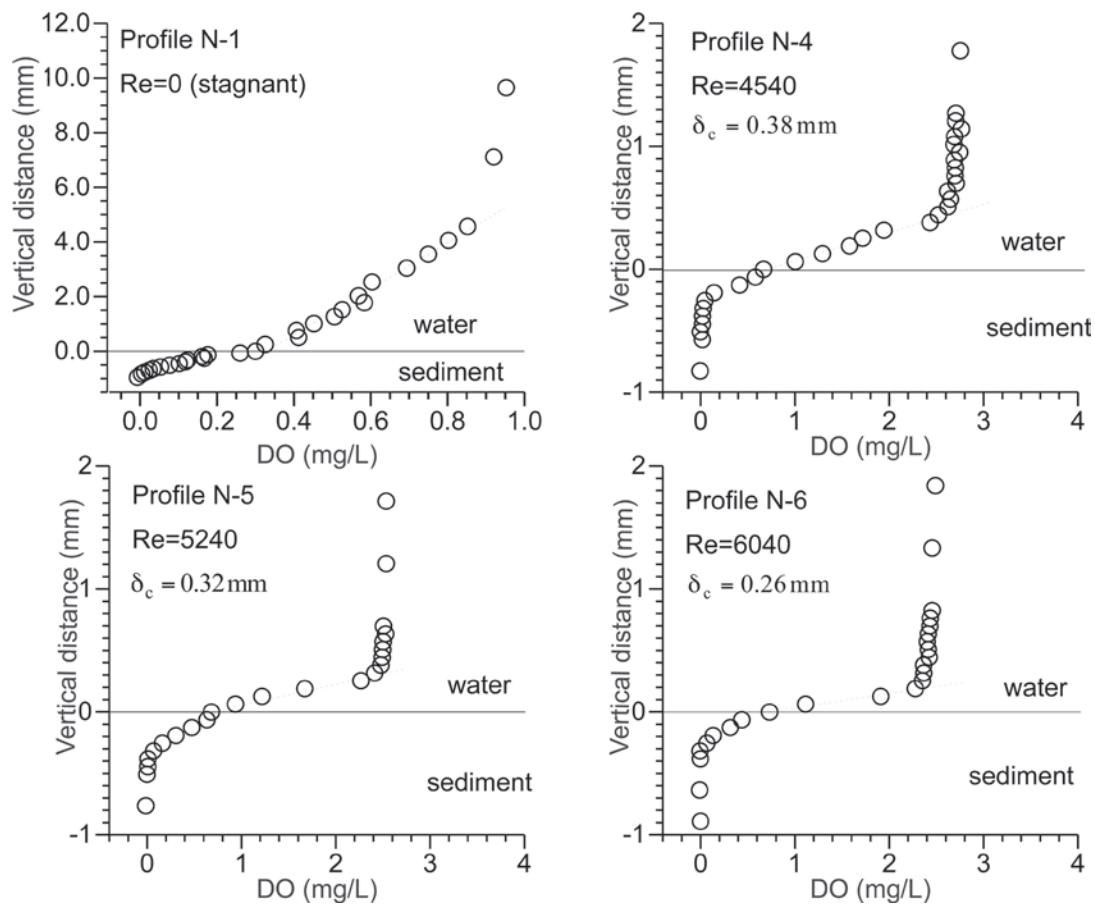

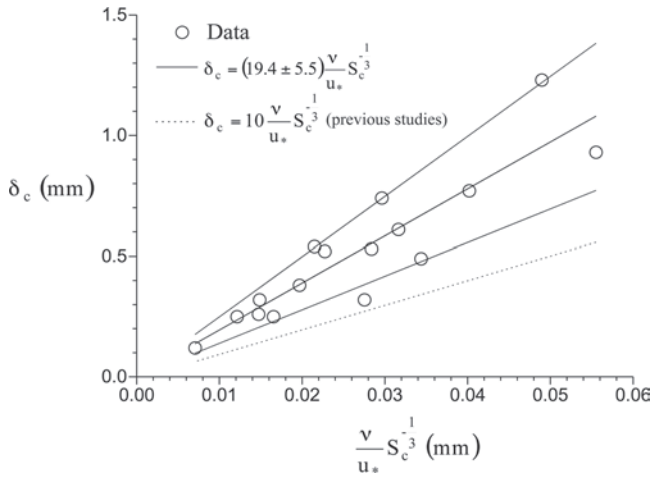

Fig. 22-4. Dissolved oxygen concentration profiles in near-bed region.

**Fig. 22-5.** Experimental data for diffusive sublayer thickness ( $\delta_c$ ) as function of viscous length scale ( $\nu/u_*$ ) and Schmidt number ( $Sc$ ).

the theoretical formulation of previous studies (e.g., Levich 1962; Dade 1993), as presented by the dashed line in Figure 22-5. The cited studies provided useful scaling parameters and an order-of-magnitude estimate for the diffusive sublayer thickness; however, the nature of the function  $\delta_c$  was not verified by experiment in the previous work. In Fig. 22-5 it can be seen that  $\delta_c$  decreased with shear stress velocity. An increase in mean flow velocity produces a corresponding increase in the shear stress velocity, and therefore a decrease in the diffusive sublayer thickness.

## 22.3 MASS-TRANSFER COEFFICIENT

### 22.3.1 Dimensional Analysis: Bulk Flow

To relate the mass flux of DO to relevant system parameters, dimensional analysis was invoked. Let us consider the situation shown in Fig. 22-1, where a reaction at the sediment surface is causing a reduction in DO concentration of the turbulent water above it. It is assumed that the concentration at the sediment-water interface and the average bulk concentration are known. The remaining independent variables that influence the mass-transfer coefficient appear in the expression

$$k = f(D, H, U, \rho, \mu) \quad (22-9)$$

where

- $H$  = plate half-spacing (boundary layer thickness);
- $\rho$  = density; and
- $\mu$  = dynamic viscosity.

The quantity of interest that is dependent upon these parameters is the mass-transfer coefficient. Using  $k$  as the dependent variable and  $D$ ,  $H$ , and  $\rho$  as the repeating independent variables,  $\pi$ -theorem analysis can be used to obtain the following dimensionless variables, which are important to this system:

$$Sh = \frac{kH}{D}; \quad R = \frac{UH}{\nu}; \quad Sc = \frac{\nu}{D} \quad (22-10)$$

where  $Sh$  is the Sherwood number,  $R$  is the Reynolds number based on  $H$  and  $U$ , and  $Sc$  is the Schmidt number. It therefore follows that the mass-transfer coefficient of oxygen to the sediment bed can be represented by an expression of the form

$$Sh = f(R, Sc) \quad (22-11)$$

Investigators have reported mass-transfer data in terms of Sherwood-Reynolds-Schmidt number correlations of the form  $Sh = aR^bSc^{1/3}$ . The values for the constants  $a$  and  $b$  are typically determined from experimental measurements. In the next section, we will derive a Sherwood-Reynolds-Schmidt number correlation for DO transport in a turbulent flow between two parallel plates.

### 22.3.2 Mass-Transport Analysis

The mean DO concentration between two parallel plates (Fig. 22-3) is governed by the equation (Fischer et al. 1979)

$$\begin{aligned} \frac{\partial C}{\partial t} + u \frac{\partial C}{\partial x} + v \frac{\partial C}{\partial y} = \frac{\partial}{\partial x} \left[ (D_{cx} + D) \frac{\partial C}{\partial x} \right] \\ + \frac{\partial}{\partial y} \left[ (D_{cy} + D) \frac{\partial C}{\partial y} \right] \end{aligned} \quad (22-12)$$

where  $t$  is time and  $D_{cx}$  and  $D_{cy}$  are the turbulent diffusion coefficients. Neither biological oxygen demand nor primary production-respiration is considered in the fluid between the plates. From the invariance condition  $\frac{\partial}{\partial x} \left( \frac{C - C_w}{C_b - C_w} \right) = 0$ , it follows that  $\frac{\partial C}{\partial x} = \frac{\partial C_b}{\partial x} = \text{constant}$  (Appendix). Therefore, for steady developed flow Eq. (22-12) reduces to the form

$$u \frac{dC_b}{dx} = \frac{\partial}{\partial y} \left[ (D_{cy} + D) \frac{\partial C}{\partial y} \right] \quad (22-13)$$

This two-process model implies a first-order balance between the advection and vertical diffusion in a developed flow. Equation (22-13) is subject to the boundary conditions

$$C = C_w \text{ at } y = 0 \quad \text{and} \quad \frac{\partial C}{\partial y} = 0 \text{ at } y = 2H \quad (22-14)$$

Equation (22-13) may be integrated twice subject to the boundary conditions (22-14) so that

$$C - C_w = \frac{dC_B}{dx} U \int_0^{y'} \frac{y - 2H}{D_{cy} + D} dy \quad (22-15)$$

where

$U$  = discharge velocity.

To facilitate closed-form solution, we assumed that  $u = U$ .

The slope of the variation of the streamwise bulk concentration,  $dC_B/dx$ , is obtainable from the conservation-of-mass equation for the control volume shown in Fig. 22-3. The net mass flux into the control volume yields

$$\frac{dC_B}{dx} = - \frac{M}{2UH} \quad (22-16)$$

Substituting Eq. (22-16) into Eq. (22-15) yields

$$C - C_w = -M \int_0^{y'} \frac{\frac{y}{2H} - 1}{D + D_{cy}} dy \quad (22-17)$$

Introducing  $\tilde{y} = yu_*/\nu$  into Eq. (22-17) as the independent variable yields

$$\tilde{C} = \frac{(C - C_w)u_*}{M} = - \int_0^{\tilde{y}'} \frac{\frac{\tilde{y}\nu}{u_*} \frac{1}{2H} - 1}{\frac{1}{S_c} + \frac{D_{cy}}{\nu}} d\tilde{y} \quad (22-18)$$

The integral in Eq. (22-18) can be evaluated using different degrees of approximation. We will neglect the terms  $D_{cy}/\nu$  and  $\tilde{y}\nu/u_*$  in the diffusive sublayer and we will neglect  $1/S_c$  in the region outside the sublayer. The diffusive sublayer extends to  $\tilde{\delta}_c = 19.4S_c^{-1/3}$  (Eq. 22-8). When these approximations are taken, the following equation for the concentration profile results:

$$\tilde{C} = \frac{(C - C_w)u_*}{M} = - \left( \int_0^{\tilde{\delta}_c} S_c d\tilde{y} + \int_{\tilde{\delta}_c}^{\tilde{y}'} \frac{\tilde{y}\nu}{u_*} \frac{1}{2H} - 1 d\tilde{y} \right) \quad (22-19)$$

The turbulent diffusion of DO for the entire region outside the diffusive sublayer is expressed as (Hondzo 1998)

$$\frac{D_{cy}}{\nu} = \frac{\kappa \tilde{y}}{4Sc_t} \left( 2 - \frac{y}{H} \right) \left[ 1 + 2 \left( 1 - \frac{y}{H} \right)^2 \right] \quad (22-20)$$

where  $\kappa$  is the von Karman constant, taken as equal to 0.4, and  $Sc_t$  is the turbulent Schmidt number, taken as equal to 1.0. Substituting Eq. (22-20) into Eq. (22-19), integrating, evaluating the value of  $\tilde{C}$  at the half distance between the plates ( $y = H$ ), and defining  $R_* = u_*H/\nu = R\sqrt{C_f}$  where,  $C_f$  is the friction coefficient, yields

$$\begin{aligned} \tilde{C}_c = 19.4S_c^{-2/3} + 10S_{ct} \left\{ \frac{1}{6} \ln \left( \frac{19.4S_c^{-1/3}}{R\sqrt{C_f}} \right) \right. \\ \left. + \frac{1}{2} \ln \left( \frac{4.5}{3 + 752S_c^{-2/3} \frac{1}{R^2 C_f} - 77S_c^{-1/3} \frac{1}{R\sqrt{C_f}}} \right) \right. \\ \left. + \frac{\sqrt{2}}{6} \operatorname{atan} \left[ \left( \frac{19.4S_c^{-1/3}}{R\sqrt{C_f}} - 1 \right) \sqrt{2} \right] \right\} \end{aligned} \quad (22-21)$$

The local mass-transfer coefficient can be represented by an expression of the form

$$Sh = \frac{R\sqrt{C_f} Sc}{\tilde{C}_c} \frac{(C_c - C_w)}{(C_B - C_w)} \quad (22-22)$$

The ratio  $C - C_w / C_B - C_w \approx 1$ ; thus the nondimensional mass-transfer coefficient follows from Eq. (22-22) as

$$Sh = \frac{R\sqrt{C_f} Sc}{\tilde{C}_c} \quad (22-23)$$

where  $\tilde{C}_c$  is given by Eq. (22-21) and  $C_f$  is the friction coefficient (e.g.,  $C_f = 0.0791 \times R^{-1/4}$ ; Dawson and Trass 1972).

A comparison of Eq. (22-23) with experimental data for DO transfer at the sediment-water interface (Steinberger and Hondzo 1999) is given in Fig. 22-6. Linear regression of the experimental data yields a mean exponent of 0.89 on  $R$  in the equation

$$Sh = (0.012 \pm 0.001) R^{0.89 \pm 0.05} Sc^{0.33} \quad (22-24)$$

where

$\pm 0.001$  and  $\pm 0.05$  = the 90% confidence intervals for the mean coefficient and the mean exponent, respectively.

The exponents of 0.89 closely match the reported values of: 0.87 (Probstein et al. 1972), 0.91 (Harriott and Hamilton 1965), and 0.80 (Colburn 1933; Incropera and DeWitt 1990).

**Fig. 22-6.** Experimental data for Sherwood number ( $Sh$ ) as function of Reynolds number ( $Re$ ) with  $Sc = 500$ .

The results of the cited studies were not based specifically on diffusional DO transfer at the sediment-water interface. They were based on a semianalytical integral theory for electro dialysis (Probstein et al. 1972), benzoic acid dissolution in glycerine-water solutions (Harriott and Hamilton 1965), and heat transfer data (Colburn 1933; Incropera and DeWitt 1990). The model developed in this study (Eq. (22-23)) compares very well with the data. The predicted values of the Sherwood number are within the 90% confidence intervals of the empirical relationships. Using Eq. (22-24) or Eq. (22-23), it is possible to estimate the mass-transfer coefficient,  $k$ , from the bulk measured quantities such as the mean flow velocity, the flow depth, and the mean water temperature.

**Example:** Consider a wide irrigation channel with a smooth channel bed. The channel has the following characteristics: mean depth  $H = 0.5$  m, cross-section average velocity  $U = 0.5$  m/s, and mean water temperature  $T = 20^\circ\text{C}$ . Using Eqs. (22-23) and (22-24) estimate the mass-transfer coefficient and DO flux at the sediment-water interface.

**Solution:** For water temperature at  $20^\circ\text{C}$  the kinematic viscosity is  $1.005 \times 10^{-6} \text{ m}^2/\text{s}$ . The Schmidt number (Fig. 22-2) is  $S_c = 8.809 \times 10^4 - 566.85 \times (20 + 273.15) + 0.914 \times (20 + 273.15)^2 = 464$ . The DO diffusion coefficient in water is

$$D = \frac{\nu}{S_c} = \frac{1.005 \times 10^{-6}}{464} \approx 2.16 \times 10^{-9} \text{ m}^2/\text{s}.$$

The Reynolds number for the wide channel is

$$R = \frac{UH}{\nu} = \frac{0.5 \times 0.5}{1.005 \times 10^{-6}} \approx 2.5 \times 10^5.$$

The mass-transfer coefficient can be estimated from Eq. (22-24) as

$$\begin{aligned} k_1 &= 0.012 \frac{D}{H} R^{0.89} S_c^{0.33} \\ &= 0.012 \frac{2.16 \times 10^{-9}}{0.5} (2.5 \times 10^5)^{0.89} 464^{0.33} \\ &= 2.5 \times 10^{-5} \text{ m/s}. \end{aligned}$$

With the mass-transfer coefficient, it is possible to estimate the DO flux using values for DO concentration at the bed and in the bulk flow. Assuming that  $C_w = 0$  and  $C_b = 6 \text{ mg/L}$ , and using Eq. (22-5), the DO flux is

$$\begin{aligned} M_1 &= k_1 (C_w - C_b) = 2.5 \times 10^{-5} (0 - 6) \times 10^3 \\ &= -0.15 \text{ mg/m}^2\text{s}. \end{aligned}$$

The minus sign designates DO flux from water toward the sediment (downward flux).

The nondimensional mass-transfer coefficient from Eq. (22-23) is

$$\begin{aligned} Sh &= \frac{R \sqrt{C_f} S_c}{C_c} \\ &= \frac{2.5 \times 10^5 \times \sqrt{(0.0791 \times (2.5 \times 10^5 \times 4)^{-1/4} \times 464)}}{1151.03} \\ &= 5043.22. \end{aligned}$$

The mass-transfer coefficient is

$$k_2 = \frac{Sh \times D}{H} = \frac{5043.22 \times 2.16 \times 10^{-9}}{0.5} = 2.18 \times 10^{-5} \text{ m/s}.$$

The DO flux is

$$\begin{aligned} M_2 &= k_2 (C_w - C_b) = 2.18 \times 10^{-5} (0 - 6) \times 10^3 \\ &= -0.13 \text{ mg/m}^2\text{s}. \end{aligned}$$

The relative difference between the DO flux and the corresponding mass-transfer coefficient is

$$\left( \frac{M_1 - M_2}{M_1} \right) = \left( \frac{-0.15 + 0.13}{-0.15} \right) \times 100 = 13\%.$$

## APPENDIX: DEVELOPED FLOW CONCEPTS

The statement that the DO concentration similarity variable is invariant with  $x$  can be expressed as

$$\frac{\partial}{\partial x} \left( \frac{C - C_w}{C_B - C_w} \right) = 0. \quad (22-25)$$

Differentiating and solving for  $\frac{\partial C}{\partial x}$

$$\frac{\partial C}{\partial x} = \frac{dC_w}{dx} + \frac{C - C_w}{C_B - C_w} \frac{dC_B}{dx} - \frac{C - C_w}{C_B - C_w} \frac{dC_w}{dx} \quad (22-26)$$

The constant DO flux and mass-transfer coefficient are characteristics of the developed regime.

$$M = k(C_B - C_w) = \text{const} \quad (22-27)$$

where  $M$  is the DO flux at the sediment water interface, and  $k$  is the mass-transfer coefficient. Therefore, if  $k$  is a constant, then  $C_B - C_w = \text{const}$ . From this condition

$$\frac{dC_B}{dx} = \frac{dC_w}{dx} \quad (22-28)$$

Thus, substituting Eq. (22-28) into Eq. (22-26),

$$\frac{\partial C}{\partial x} = \frac{\partial C_B}{\partial x} = \frac{\partial C_w}{\partial x} \quad (22-29)$$

From Eq. (22-29), it follows that  $\partial^2 C / \partial x^2 = 0$  in the developed regime.

## CHAPTER 23

# *Development and Application of Numerical Models of Sediment Transport Associated with Dam Removal*

*Yantao Cui and Andrew Wilcox*

### 23.1 INTRODUCTION

Numerous dams have been removed in recent decades in the United States for reasons including economics, safety, and ecological restoration. For example, Edwards Dam, on the Kennebec River, Maine, was removed in 1999 to assist Atlantic salmon recovery efforts. In the Pacific Northwest, proposals to remove or breach dams on the Elwha River, Washington, and the Snake River, Idaho, to resuscitate declining stocks of anadromous salmonids have received national attention.

A key concern in many dam removal proposals is the routing of sediment stored behind reservoirs, including downstream channel response and release of contaminated sediments (e.g., Randle 2003). No studies have been completed to document and quantify channel response to the removal of large dams (Graf 1996), although field observations following the removal of small dams have intensified in recent years (e.g., Pizzuto 2002; Doyle et al. 2003). In addition, development of predictive models to estimate the effects of sediment release following dam removal has been limited until very recently. Decommissioning processes for dams, especially those with relatively large sediment deposits, have been hindered by shortcomings in our capacity to quantitatively predict sediment-transport dynamics following dam removal, and in the face of such uncertainties, costly dredging operations are often proposed before dam removal.

In this chapter we will discuss several issues in developing sediment-transport models following dam removal, including previous numerical modeling efforts relevant to dam removal, coupled modeling of reaches upstream and downstream of dams, reservoir sediment erosion, selection of sediment transport equations, and modeling of pre-dam-removal baseline conditions. We then present the development and application of numerical models for sediment transport following removal of Marmot Dam, a hydroelectric facility on the Sandy River,

Oregon, that is scheduled for decommissioning. The Marmot Dam removal modeling example is used to demonstrate the development and application of numerical modeling of sediment transport following dam removal, thereby illustrating many of the general issues related to dam-removal modeling discussed in the following section.

### 23.2 DAM REMOVAL AND SEDIMENT-TRANSPORT MODELING

Many of the principles developed for modeling the transport of fluvial sediment are applicable to modeling sediment transport associated with dam removal. Effective numerical models of sediment transport following dam removal should have the capability to route both fine and coarse sediment downstream, account for abrasion of gravel, and simulate transient flows. In developing and applying sediment-transport models for dam removal, modelers must address several unique issues, including the difficulties of coupled modeling of reaches upstream and downstream of dam sites, uncertainties surrounding the channel morphology that will develop within the eroding reservoir sediments, selection of sediment-transport equations that account for the complex nature of reservoir sediment deposits, and the large spatial and temporal scales required for modeling the downstream transport of large volumes of reservoir sediment following dam removal. In the following section, we describe previous numerical modeling efforts relevant to dam removal and discuss special considerations in developing sediment-transport models for dam removal.

#### 23.2.1 Previous Numerical Modeling Efforts Relevant to Dam Removal

Because reservoir sediment deposits behave as large sediment pulses once dams are removed, previous simulations of the evolution of sediment pulses in rivers have provided

a basis for modeling sediment transport associated with dam removal. In the sediment pulse model of Cui and Parker (2005), multiple lithology heterogeneous sediment pulses were routed downstream with full consideration of particle abrasion. The model has been applied successfully to simulate the evolution of a large landslide in the Navarro River, California (Hansler 1999; Sutherland et al. 2002). A simplified version of the Cui and Parker (2005) model has also been used to simulate evolution of gravel pulses in a laboratory flume (Cui et al. 2003).

The first adaptations of the Cui and Parker (2005) model to dam removal projects were applied to the potential removal of two dams in Oregon, Soda Springs Dam on the North Umpqua River and Marmot Dam on the Sandy River. This chapter presents the Marmot Dam removal modeling effort as a case study of the application of sediment-transport modeling to dam removal. Cui et al. (2006a; 2006b) further developed the Dam Removal Express Assessment Models (DREAM): DREAM-1 for simulation of dam removal with the reservoir sediment composed of primarily fine sediment, and DREAM-2 for simulation of dam removal with the top layer of the reservoir sediment composed of primarily coarse sediment (gravel and coarser).

Off-the-shelf sediment-transport models have also been applied to dam removal evaluations. For example, the U.S. Army Corps of Engineers' HEC-6 model was used to simulate sediment release associated with proposed dam removals on the Elwha River, Washington (Bureau of Reclamation 1996a; 1996b). Such models are usually not capable of simulating the upstream and downstream reaches of a dam simultaneously, however, because the models were not originally written for dam removal applications, and the code of the models may not be accessible to users for modification. Modelers may overcome these obstacles without access to and modification of the code in certain cases using two approaches: (1) modeling the upstream and downstream reaches of the dam separately, with the results of the upstream simulation providing input to the downstream reach; and (2) assuming that sediment-transport capacity is controlled at a critical cross section somewhere downstream of the dam, and assuming unlimited sediment supply to that location until all the reservoir sediment is exhausted. Simulating upstream and downstream reaches of the dam separately can be an effective solution in certain cases in which some physical separation between reaches upstream and downstream of the dam site is maintained during or after dam removal. Examples of such cases include dam removal methods in which sediment is metered out by an outlet structure with the dam still in place; early stages of a staged removal, where the remaining portion of the dam separates the two reaches; and a cohesive reservoir sediment deposit with limited potential for deposition immediately downstream of the dam. When the upstream and downstream reaches of the dam are connected and sediment is

deposited downstream of the dam, as will normally be the case in dam removal modeling, such a technique will usually result in erroneous predictions, because the assumption that sediment transport upstream of the dam site is independent of that in the downstream reach becomes invalid. Using a critical cross section further downstream of the dam to meter out sediment may provide useful back-of-the-envelope estimates of suspended-sediment concentration in certain cases. Overall, however, this technique is problematic because sediment deposition following dam removal will inevitably alter the sediment-transport capacity, potentially by orders of magnitude.

Sediment-transport modeling following dam removal is as yet limited to one-dimensional models. One-dimensional models cannot simulate multidimensional effects such as lateral distribution of sediment deposition. This is true even if channel cross sections are used in simulations or if modeling rules are used to distribute sediment deposition and erosion across the cross section. One-dimensional models also cannot simulate local features such as topography generated by alternate bars and pool-riffle sequences and associated fine-scale effects on sediment deposition. As a result of the latter limitation, the best spatial resolution in the results of a one-dimensional model is on the order of several channel widths, i.e., the length of an alternate bar or pool-riffle sequence. Because of the coarse spatial resolution of one-dimensional models, professional judgment and general knowledge of sediment-transport dynamics should be applied to interpretation of one-dimensional model results in order to provide insight into finer-scale effects.

### 23.2.2 Coupled Modeling of Upstream and Downstream Reaches

A key challenge in any dam removal modeling exercise is the simultaneous modeling of sediment-transport processes upstream of the dam, in the reservoir-influenced reach from which sediment is eroded, and downstream of the dam, in the river reach to which the reservoir sediment is delivered. Simultaneous modeling of reaches upstream and downstream of the dam must address the difficulties in simulating flow over very steep bed slopes, such as would be expected, to characterize the downstream portion of the reservoir sediment wedge immediately following dam removal. In this important transition area between reaches upstream and downstream of the dam, very steep slopes can produce transient flow conditions (Fig. 23-1), potentially resulting in numerical instabilities.

Several techniques can be used in coupled modeling of upstream and downstream river reaches. For example, flow near the dam site can be simulated using a fully coupled model that retains the unsteady terms in the St. Venant shallow-water equations (Eq. (14-1)). Applying a fully coupled model to simulate the transient flow will involve the application of artificial viscosity terms in seeking a solution (e.g., Chaudhry 1993).

Fig. 23-1. Sketch demonstrating potential transient flow near a dam site following dam removal.

Even with the introduction of artificial viscosity terms, there will still be high-frequency oscillation in the solution for water depth and flow velocity, which, in turn, may result in instability in the solution for bed elevation. Thus, an artificial viscosity term will likely have to be introduced into the Exner equation as well. Cui et al. (2006b) found that applying a viscous term to the Exner equation may introduce artificial waves in bed elevation that can be on the same order of magnitude as the disturbance itself, resulting in an unacceptable solution. Model developers and users developing or applying fully coupled models for sediment-transport simulation following dam removal should therefore be cautious in the treatment of artificial viscosity terms and should be cognizant of the potential for artificial waves on the channel bed during model testing or application. Another method for modeling transient flow is a shock-fitting method, in which the program locates each hydraulic drop or jump and then solves different sections with different methods (e.g., Cui and Parker 1997). This method, however, is unlikely to be successful in application to dam removal simulation because of the complexity of natural rivers.

The U.S. Army Corps of Engineers HEC-6 model can simulate flow with transitions between subcritical and supercritical flow conditions. In the HEC-6 model, flow parameters are calculated with the standard energy conservation equation for subcritical flow conditions, and a quasi-normal assumption is applied for supercritical flow conditions (USACE 1993). The dam removal model presented in this chapter and those of Cui et al. (2006a; 2006b) applied similar principles as those used in HEC-6, whereby the standard backwater equation is applied for low Froude-number flow conditions and a quasi-normal flow assumption is applied for higher Froude-number flow conditions, as described further below in the Marmot Dam case study. In addition, Cui et al. (2006a; 2006b) applied a relatively coarse grid system so as to be compatible with the general resolution of one-dimensional sediment-transport modeling, although they applied an adaptive and much finer subgrid system for flow simulation whenever the channel bed is very steep. This method has been used successfully to simulate sediment-

transport conditions in a laboratory experiment (Cui et al. 2006b).

### 23.2.3 Reservoir Sediment Erosion

In typical sediment-transport modeling applications, sediment and water discharge tend to be confined within a well-defined channel, whose characteristics can be quantified prior to model implementation. In dam removal modeling, the morphology of the channel that will develop within the reservoir following dam removal is unknown in advance, necessitating assumptions by modelers about how channel morphology will evolve within reservoir reaches. The dynamics of channel incision through a reservoir deposit following dam removal depends on how the dam will be removed, reservoir sediment characteristics (e.g., volume, grain-size distribution, and cohesion), the width of the reservoir sediment deposit relative to stable channel width, and water discharge during and after dam removal.

Dam removal methods will significantly affect subsequent patterns of reservoir erosion. Gradual lowering of the reservoir level (e.g., through notches or lower level outlets) prior to dam removal may produce a channel that is much wider than its stable channel form, as demonstrated in the Lake Mills drawdown experiment on the Elwha River, Washington (Childers et al. 2000). Complete dam removal within a short time span, however, may result in rapid incision into reservoir sediment and creation of a channel that is either similar to or slightly narrower than its stable channel form before the channel begins to migrate laterally when its gradient becomes relatively stable. In cases of cohesive sediment deposits or relatively small discharges, the erosion of reservoir sediment may be characterized by head-cutting or gully-like morphology (Fig. 23-2). In such cases, reservoir erosion is likely to be governed by the rate of head-cut retreat, as has been observed following removal of many small dams (e.g., Pizzuto 2002; Doyle et al. 2003). In contrast, head-cutting or gully-like morphology in reservoir sediment deposits is unlikely where these deposits are not cohesive

**Fig. 23-2.** Head cut developed following the removal of the Maple Gulch Dam, Evens Creek, Oregon, courtesy of Greg Stewart. The relatively small discharge before and at the time of the photograph after the dam was removed was probably responsible for the formation of the head cut. The strength from dense tree roots may also have contributed to the formation of the head cut.

and where postremoval river discharges are adequate to transport reservoir sediment. For example, head cutting was not observed following removal of Saeltzer Dam on Clear Creek, California, where reservoir sediments were relatively coarse and river discharges were relatively large (Fig. 23-3). The implications of both reservoir-sediment and river-discharge characteristics for reservoir erosion dynamics must therefore be taken into account in modeling sediment transport following dam removal.

Modelers should also be conscious of the inadequacies of current sediment-transport theory for addressing certain reservoir erosion processes. For example, we know of no theory to address the head-cut process as a result of inadequate water discharge, and thus it may be difficult to build a numerical model to accurately simulate the downstream effect in such cases.

**Fig. 23-3.** (a) Saeltzer Dam on the Clear Creek, California, removed in 2000, courtesy of Geoff Fricker; and (b) former impoundment area of the Saeltzer Dam, photo taken in 2003, courtesy of Peter Miller. No head cut was observed in the reservoir deposit following the removal of the Saeltzer Dam (Matt Brown and Jess Newton, personal communication, 2003).

#### 23.2.4 Selection of Appropriate Sediment-transport Equations

The complex nature of reservoir sediment deposits can complicate sediment-transport modeling. The size distribution of reservoir sediments is typically wide, ranging from boulders to clay, and reservoir deposits are often stratified, with a coarse top layer and fine bottom layer. Modelers must therefore select sediment-transport equations and

make other assumptions that are appropriate to the particular reservoir sediment characteristics of the case in question. Until recently, no sediment-transport equations were available to handle mixtures of coarse sediment (gravel and coarser) and fine sediment (sand and finer), such as are typical of reservoir sediment deposits; this complicates efforts to model transport of such sediments. The sediment-transport equation of Wilcock and Crowe (2003) provides the first attempt to calculate transport of coarse and fine sediment simultaneously while accounting for the grain-size distribution of the coarse sediment. The equation calculates gravel-transport rate by size fractions and sand transport rate based on known shear stress and surface grain-size distribution, including the fraction of sand on the bed surface. Development of a relation that links the grain-size distribution, including the fraction of fine sediment, in the subsurface to that on the channel surface and to the sediment load would facilitate incorporation of the Wilcock and Crowe (2003) equation into a sediment-transport model.

In lieu of using a sediment-transport equation that simultaneously calculates coarse- and fine-sediment transport, one approach to modeling a wide size range of sediments is to employ separate models of fine- and coarse-sediment transport that calculate coarse- and fine-sediment transport independently. This approach, which was adopted for the Marmot Dam removal study presented below, is based on the assumptions that (1) coarse sediment is transported primarily as bed load during high-flow events, when fine sediment is transported primarily as suspended load, and (2) most fine sediment is transported during the intermediate-flow events, when coarse sediment transport is limited. Observations that suggest that coarse- and fine-sediment transport may be only weakly correlated, and that modeling using independent equations for coarse- and fine-sediment transport is therefore defensible, are suggested by Cui et al. (2006b). These include the observations that (1) the fraction of fine sediment in gravel-bed sediment samples is relatively stable and insensitive to the amount of fine-sediment transport, and (2) the fraction of fine sediment in a clast-supported sediment deposit seems to be inversely correlated with the standard deviation of the particle grain-size distribution of the coarse sediment (Fig. 23-4), indicating that the fraction of fine sediment is dependent on the available space of the coarse-sediment deposit (Cui et al. 2006b). Although applying separate equations for coarse and fine sediment is not a perfect solution because gravel and sand transport likely affect each other, this approach may provide an acceptable approximation.

If the approach of using separate models of coarse- and fine-sediment transport is adopted, modelers must select from the array of published transport equations for sand and gravel. For example, in the modeling of the Marmot Dam removal, we used Parker's surface-based bed-load equation (Parker 1990) to model coarse-sediment transport and

**Fig. 23-4.** Fraction of sand in gravel/sand deposit as a function of standard deviation of the gravel grain-size distribution in the sediment deposit. Data were derived from a large-scale flume experiment (SAFL downstream fining Run 3) by Toro-Escobar et al. (1996), and the diagram was presented in Cui and Parker (1998).

Brownlie's (1982) bed-material equation for modeling transport of fine sediment, as discussed further in Section 23.3.2.

### 23.2.5 Reproducing the Pre-dam-removal Longitudinal Profile and Other Background Conditions

Because large volumes of sediment may be released downstream following dam removal, downstream sediment impacts may be spatially and temporally extensive. To predict the nature of these impacts, numerical models therefore must be capable of simulating long river reaches for multiple years, and modelers should be conscious of the potential for propagation of errors for such simulations. For example, the simulation of the Marmot Dam removal presented below was applied to a 50-km river reach for a 10-yr duration following dam removal.

Accurate simulation of a river reach over a long period of time requires that the model be capable of reproducing background conditions in the system of interest. Although reproduction of background conditions is a key task in sediment-transport modeling, this can be difficult to achieve because of a lack of sediment-transport theory, a lack of understanding of the system in question, and/or a lack of field data. In most cases the background condition can be treated as a quasi-equilibrium state, under which the channel bed experiences very limited amounts of aggradation and degradation over time. The process of trying to reproduce this quasi-equilibrium state, which we term the "zero process," provides a frame of reference from which subsequent changes predicted by modeling can be attributed to changes in input or boundary conditions, such as the removal of a dam. The zero process itself also provides model developers and users with an opportunity to test and adjust certain assumptions and input parameters used in modeling.

### 23.3 NUMERICAL SIMULATION OF SEDIMENT TRANSPORT FOLLOWING THE REMOVAL OF MARMOT DAM, SANDY RIVER, OREGON

The remainder of this chapter will present an application of one-dimensional numerical modeling simulation of sediment transport following dam removal. Our treatment of the issues detailed above, including selection of sediment-transport equations, modeling of reservoir erosion, and reproduction of background conditions (the zero process), will be described, and modeling results from the example application will be presented. The following sections provide background information on Marmot Dam and on the physical setting of the Sandy River basin, descriptions of the numerical models and their governing equations, discussion of the input data used in application of the models to the Sandy River, and results and discussion of the modeling.

#### 23.3.1 Project Background

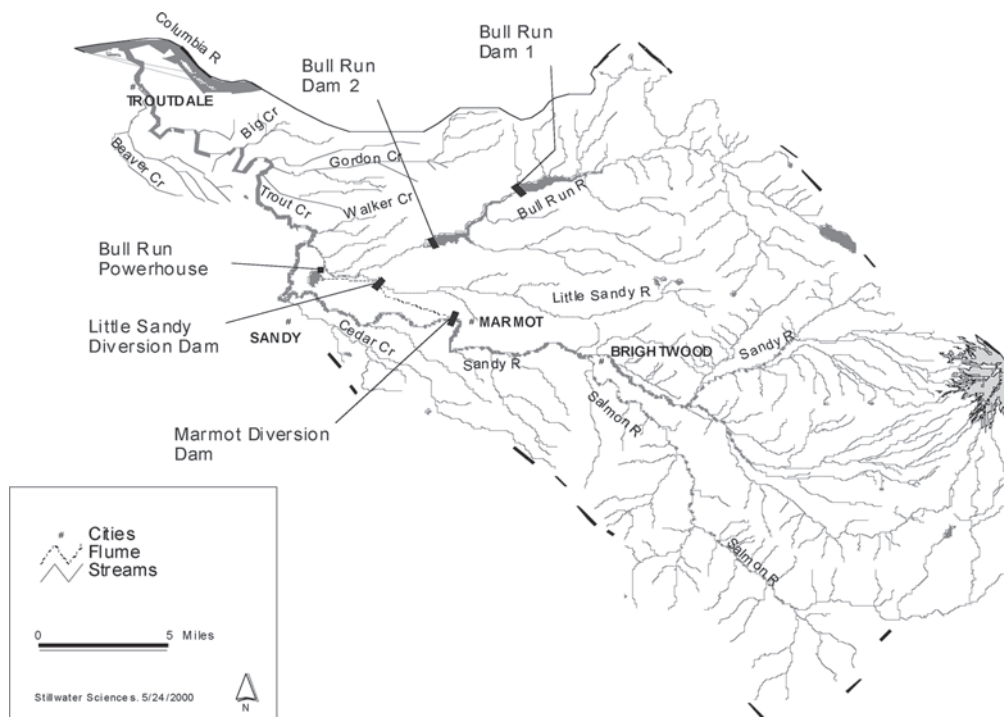

Marmot Dam is located on the Sandy River approximately 48 km upstream of its confluence with the Columbia River. The dam was originally completed in 1913 as a wood crib rock-filled structure, and it was replaced in 1989 with a 14-m-high, 104-m-wide concrete dam (Fig. 23-5). Approximately 750,000 m<sup>3</sup> of sediment is stored behind Marmot Dam, about two-thirds of which is primarily gravel/pebble and one-third of which is primarily sand (Squier Associates 2000). The Sandy River originates from Mt. Hood on the

**Fig. 23-5.** Marmot Dam, Sandy River, Oregon, scheduled for removal in 2007 (photo courtesy of Portland General Electric).

western slopes of the Cascade Range and has a drainage area of 1,316 km<sup>2</sup>, about half of which is upstream of Marmot Dam (Fig. 23-6). A detailed description of the geology, hydrology, and geomorphology of the Sandy River basin is provided in Stillwater Sciences (2000).

Marmot Dam is scheduled to be voluntarily removed by Portland General Electric (PGE), the holder of the Federal Energy Regulatory Commission (FERC) license for this project. Removal of Marmot Dam will provide unrestricted upstream and downstream passage for anadromous salmonids and other aquatic organisms, restore natural flows in the

**Fig. 23-6.** Map of the Sandy River basin.

Sandy River from Marmot Dam to the Bull Run River confluence, and, under some removal alternatives, release sediment stored behind Marmot Dam. Several alternative methods for removal of Marmot Dam have been developed, which differ in the amount of sediment accumulated behind the dam that would be released downstream. These removal alternatives are described in detail in Portland General Electric (2000) and are summarized as follows:

- Single-season dam removal with minimal sediment removal;
- Removal of top of dam in year 1, followed by complete dam removal in year 2 with sand-layer excavation;
- Single-season dam removal after dredging of sediment to 830 m upstream of the dam;
- Single-season dam removal after dredging of 95,600 m<sup>3</sup> of sediment;
- Single-season dam removal after dredging of 229,400 m<sup>3</sup> of sediment.

The portion of the Sandy River likely to be affected by removal of Marmot Dam extends from the reservoir-influenced reach upstream of Marmot Dam downstream to the Sandy River's confluence with the Columbia River. For purposes of studying the potential geomorphic effects of removing Marmot Dam, the pertinent river reach was delineated into six subreaches (Fig. 23-7) according to their distinctive geomorphic characteristics, as described below and in Table 23-1:

- *Reach 0 (reservoir area)*: The Sandy River upstream of the Marmot Dam is affected by the backwater effect of the dam for a distance of approximately 2 to 4 km.

The impoundment formed by the dam has filled to the dam's crest with sediment and now functions as an alluvial river reach. Compared to upstream and downstream reaches, this reach currently has a lower gradient and finer bed substrates as a result of the grade control provided by the dam and the backwater effect of the dam's impoundment. The reservoir is believed to have filled with sediment in the early years following dam closure. Marmot Dam may continue to partially trap coarse sediment, although coarse- and fine-sediment transport over the dam do occur during high-flow events.

- *Reach 1*: Reach 1 extends from Marmot Dam to the mouth of the Sandy River gorge and has moderately pronounced forced pool-riffle morphology. This reach has an armored cobble/boulder bed surface with limited gravel, possibly due to supply reductions caused by Marmot Dam.
- *Reach 2*: Reach 2 is the Sandy River gorge, a steep (0.01 gradient) section of the river that is confined by 20- to 30-m-high bedrock strath terraces with steep hillslopes above. The steep gradient and high confinement in this reach create very high shear stresses, resulting in high sediment-transport capacity. Few deposition areas are therefore present in this reach, and bedrock exposure in the channel bed is common. The reach is characterized by long, deep bedrock pools that are separated by coarse-bedded riffles and boulder rapids, and large (house-sized) boulders are common in the channel.
- *Reach 3*: Reach 3 extends from the downstream end of the Sandy River gorge to the Bull Run River confluence. This reach is considerably wider and lower-gradient than Reaches 1 and 2, reducing sediment-transport capacity and increasing the potential for sediment deposition.

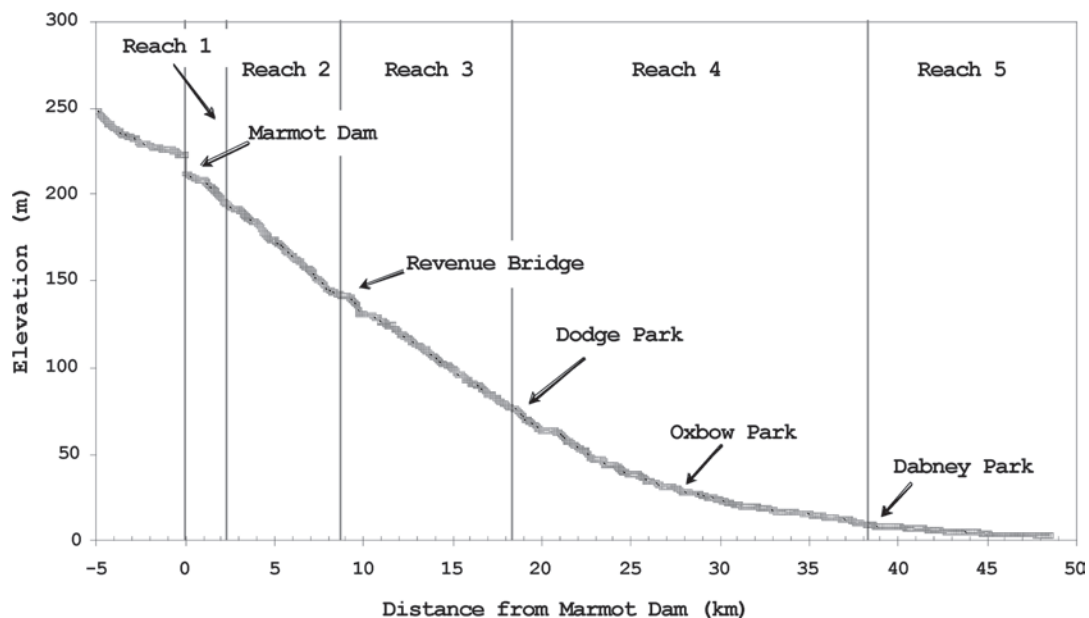

Fig. 23-7. Sandy River longitudinal profile, based on PGE 1999 photogrammetric data.

- *Reach 4:* Reach 4 extends from the Bull Run River confluence to Dabney State Park. In Reach 4, channel confinement, gradient, and bed particle size decrease further compared to upstream reaches, with these tendencies particularly evident in the lower half of the reach. Large cobble/gravel bars, side channels, and islands are common in Reach 4, which is bounded by high (mostly alluvial) terraces. Sand content in the bed subsurface, on the active bed, and on bars is high in the lower portion of the reach.
- *Reach 5:* Reach 5 extends from Dabney State Park to the confluence with the Columbia River. This reach is characterized by a highly mobile sand and gravel bed surface with large gravel/sand alternate and medial bars. In the Sandy River delta, which forms the downstream-most portion of Reach 5, the channel is sand-bedded and depositional dynamics are strongly influenced by the backwater effect of the Columbia River.

### 23.3.2 Numerical Model Development for Application to Marmot Dam Removal

One-dimensional numerical models of fine- and coarse-sediment transport were developed to predict the routing of sediment from behind Marmot Dam downstream through the Sandy River. Numerical models were completed to examine a variety of alternatives for removing Marmot Dam. Model results provide estimates of the time required for sediment to be cleared from the reservoir area, time required for sediment to travel out of the Sandy River (including various subreaches), thickness of downstream sediment deposits in various reaches (on a reach-averaged and cross-section-averaged basis), changes in deposition thickness through

time, and total suspended-sediment concentrations through time along the river's longitudinal profile following dam removal. Questions explored with the numerical models for different dam removal alternatives include the following:

- Will substantial bed aggradation occur following dam removal, or is the sediment-transport capacity downstream of the Marmot Dam high enough to minimize aggradation? How long will any aggradational effect persist and in what reaches will it be most prominent?
- How much will suspended-sediment concentrations downstream of Marmot Dam increase following dam removal, and how long will any such increases persist?
- How does transport distance from the dam affect suspended-sediment concentration and coarse- and fine-sediment accumulations following dam removal? Is there a distance downstream of which no detectable changes are expected?
- How will dredging of varying amounts of sediment from Marmot Reservoir prior to dam removal affect downstream sediment deposition and suspended-sediment dynamics?
- How will discharge conditions during and following dam removal affect downstream sediment transport and deposition characteristics?

Because unified theory and transport equations for gravel/sand mixtures are still in a developing stage, as discussed above, two separate models were developed for application to the removal of Marmot Dam: a gravel model for simulation of

**Table 23-1 Summary of Geomorphic Characteristics of Sandy River Reaches That Will Be Affected by Removal of Marmot Dam**

Reach	Length (km)	Average width (m)	Average gradient	Confinement	Morphology	Dominant grain size
Upstream of Marmot dam (Reach 0)	2–4	50	0.0024	High	Pool-riffle	Gravel-sand
Marmot Dam to gorge (Reach 1)	2.4	45	0.008	Medium	Forced pool riffle/plane bed	Cobble-boulder
Sandy River gorge (Reach 2)	6.4	30	0.01	High	Step pool/forced pool riffle	Bedrock-boulder
Downstream end of Sandy River gorge to Bull Run River (Reach 3)	9.6	50	0.006	Medium	Forced pool riffle/plane bed	Cobble-gravel
Bull Run River to Dabney Park (Reach 4)	20	70	0.0025	Medium/low	Pool riffle/plane bed	Gravel-cobble-sand
Dabney Park to mouth (Reach 5)	9.6	100	0.0007	Medium/low	Pool riffle	Sand-gravel

the erosion of the reservoir deposit and downstream deposition of coarse sediment (diameter  $> 2$  mm), and a sand model for simulation of suspended-sediment concentration and downstream deposition of fine sediment (diameter  $< 2$  mm). The use of separate models assumes that (1) as the sediment is released from the reservoir deposit, gravel particles will be transported as bed load and sand will be transported mostly as suspended load because of the steep slope of the Sandy River, and (2) gravel and sand transport occur over different time scales (years versus days; i.e., a gravel particle may take years to travel the same distance that a sand particle travels in several days). In reality, use of separate models may create errors because transport of gravel and sand will each influence the transport rate of the other.

The gravel-transport model was developed based on Parker's surface-based bed load equation (Parker 1990) and is similar to the model of Cui and Parker (2005), with adjustments to accommodate the specific conditions of the Sandy River and Marmot Dam. The Parker equation calculates gravel-transport rate and bed-load grain-size distribution based on the grain-size distribution of the surface layer and the boundary shear stress. The Parker equation was developed to apply to gravel-bed streams (particles larger than 2 mm in diameter) and was not intended for application to sand or for suspended material of any size. Application of the Parker equation to a mixture with a relatively large amount of sand, such as the sediment accumulation behind Marmot Dam, may therefore create some error in predictions of the gravel-transport rate.

The one-dimensional model of sand transport was developed based on Brownlie's (1982) bed-material equation. Brownlie's equation was developed for sand-bedded rivers but is used here because no sediment-transport equations exist to calculate sand transport in a bedrock- or coarse-sediment-dominated river such as the Sandy River. In applying Brownlie's equation of sediment transport and friction, we modified the roughness height to account for the bedrock, boulders, and gravel present along the bed of the Sandy River. Calibration and validation of this approach are required, however, and the error associated with applying Brownlie's equation to a gravel-bed river, even with roughness adjustments, is not known. Our model of sand transport assumes the following: (1) sand transport can be represented as transport over a rough bedrock surface (i.e., the existing gravel bed of the Sandy River remains immobile with respect to sand transport); (2) silt is transported as throughput load that is carried in suspension and cannot be deposited in the channel bed; (3) reservoir sediment is not cohesive; and (4) sand transport is not affected by the amount of coarse-sediment aggradation and degradation downstream of the dam (i.e., the changes in channel gradient resulting from gravel deposition or scour are not accounted for in modeling sand transport). This last assumption may create some errors in reaches where significant coarse-sediment deposition occurs, such as immediately downstream of the dam.

As discussed in Section 23.2.3, simulation of reservoir erosion is a key challenge in dam removal modeling. In the Sandy River model, a number of simplifying assumptions were made to simulate sediment release from Marmot Reservoir. The model assumes laterally uniform sediment transport out of the reservoir, with sediment mobilization and transport derived by the gravel model from Parker's (1990) sediment-transport equation. In the reservoir area, the model assumes that erosion is exclusively dependent on the transport capacity of gravel and the amount of gravel that can be provided through erosion of reservoir sediment deposit. As the gravels within a layer are mobilized, the sand volume within that layer is also mobilized and transported downstream; it is assumed that sand is not available for transport until the gravel within the same layer as the sand is mobilized. Volumetric estimates of sand release from the reservoir deposit that are generated by the gravel model using this method are subsequently used as the upstream boundary condition for the sand model. The model further assumes that, because the reservoir-influenced reach upstream of Marmot Dam (Reach 0) is relatively narrow, all the sediment will be eroded downstream following dam removal (i.e., there will be no long-term storage of reservoir sediment in Reach 0 following dam removal). Sensitivity tests were performed to address uncertainties in modeling of sediment transport from the reservoir and to qualitatively assess the potential effects of incision, as described in Section 23.3.4 below.

The numerical models of fine- and coarse-sediment transport entail equations for calculating downstream changes in flow depth, Exner equations of sediment continuity for sand and gravel, transport-capacity equations, and flow-friction relations. The governing equations used in these models are introduced below; additional details are presented in Stillwater Sciences (2000; 2002).

To calculate downstream changes in flow depth, the standard backwater equation is used for low-Froude-number flows and a quasi-normal assumption is applied for high-Froude-number flows:

$$\frac{dh}{dx} = \frac{S_0 - S_f}{1 - F^2}, \quad F < F_c \quad (23-1a)$$

$$S_0 = S_f, \quad F \geq F_c \quad (23-1b)$$

where

$h$  = water depth;

$x$  = downstream distance;

$S_0$  = slope of the channel bed;

$S_f$  = friction slope;

$F$  = local Froude number; and

$F_c$  = a user-defined Froude number that is smaller than and close to unity and that is used to differentiate between low- and high-Froude-number conditions in the application of Eqs. (23-1a) and (23-1b) (see also Cui and Parker 2005).

In the Marmot Dam removal simulation,  $F_c$  was set equal to 0.75; below this value, Eq. (23-1a) is used; otherwise Eq. (23-1b) is applicable. The approach of alternating the backwater equation and the quasi-normal flow assumption based on a Froude number threshold has been used in the HEC models (USACE 1993) and in the models of Cui et al. (2003) and Cui and Parker (2005).

Local Froude number is calculated using the equation

$$F^2 = \frac{Q_w^2}{gB^2h^3} \quad (23-2)$$

in which

$Q_w$  = water discharge;  
 $g$  = acceleration of gravity; and  
 $B$  = local channel width.

The Exner equations of sediment continuity for gravel used here are variants of those in Parker (1991a; 1991b) and (Chapter 3, Eqs. (3-95a) to (3-95i)) and take the following form:

$$(1-\lambda_p)f_g B \frac{\partial \eta}{\partial t} + \frac{\partial Q_g}{\partial x} + \beta Q_g \left( 2 + \frac{1}{3\ln(2)} \frac{p_j + F'_j}{\Delta \psi_j} \right) = 0 \quad (23-3a)$$

$$\begin{aligned} (1-\lambda_p)f_g B \left( \frac{\partial(L_a F_j)}{\partial t} + f_{lj} \frac{\partial(\eta - L_a)}{\partial t} \right) \\ + \frac{\partial(Q_g p_j)}{\partial x} + \beta Q_g (p_j + F'_j) \\ + \frac{1}{3\ln(2)} \beta Q_g \left( \frac{p_j + F'_j}{\Delta \psi_j} - \frac{p_{j+1} + F'_{j+1}}{\Delta \psi_{j+1}} \right) = 0 \end{aligned} \quad (23-3b)$$

where

$\lambda_p$  = porosity of the channel-bed deposit;  
 $f_g$  = volumetric fraction of gravel in the channel-bed deposit;  
 $\eta$  = deposition thickness above an arbitrary datum;  
 $t$  = time;  
 $Q_g$  = volumetric transport rate of gravel;  
 $\beta$  = volumetric abrasion coefficient of gravel;  
 $p_j$  = volumetric fraction of the  $j$ -th size range in bed load;  
 $F_j$  = volumetric fraction of the  $j$ -th size range in the surface layer;  
 $F'_j$  = an adjusted value of  $F_j$  providing an estimate of relative surface area exposure of gravel of the  $j$ th size range at the surface (Parker 1991a; 1991b);  
 $f_{lj}$  = volumetric fraction of the  $j$ th size range in the interface between bed load and the channel-bed deposit;  
 $L_a$  = surface layer thickness; and  
 $\psi$  = grain size in the  $\psi$ -scale, which is the negative of the  $\phi$  scale (also see Chapter 3, Eqs. (3-1a) and (3-1b)).

Equation (23-3a) represents the mass conservation of total gravel, and Eq. (23-3b) represents the mass conservation of the gravel in the  $j$ -th size range.

The full grain-size distribution of coarse sediment (gravel and coarser) is discretized into a number of groups, represented by  $\psi$  and grain size  $D$  in such a way that grain size  $\psi_j(D_j)$  and  $\psi_{j+1}(D_{j+1})$ , from finer to coarser, bound the  $j$ -th size group. The average grain size of the  $j$ -th range is then

$$\bar{\psi}_j = \frac{\psi_j + \psi_{j+1}}{2}, \quad \bar{D}_j = \sqrt{D_j D_{j+1}} \quad (23-4a,b)$$

and

$$\Delta \psi_j = \psi_{j+1} - \psi_j \quad (23-5)$$

The parameter  $F'_j$  in Eqs. (23-3a) and (23-3b) is estimated with the relation provided by Parker (1991a; 1991b):

$$F'_j = \frac{F_j / \sqrt{\bar{D}_j}}{\Sigma (F_j / \sqrt{\bar{D}_j})} \quad (23-6)$$

The Exner equations of sediment continuity for sand that were used in modeling of sand transport take the forms

$$\frac{1}{B} \frac{\partial \eta_s}{\partial t} + \frac{1}{(1-\lambda_s)\lambda_g} \frac{\partial Q_s}{\partial x} = 0, \quad 0 < \eta_s \leq k_{s0} \quad (23-7a)$$

$$\frac{1}{B} \frac{\partial \eta_s}{\partial t} + \frac{1}{1-\lambda_s} \frac{\partial Q_s}{\partial x} = 0, \quad \eta_s > k_{s0} \quad (23-7b)$$

in which

$\eta_s$  = thickness of the sand deposit;  
 $\lambda_s$  = porosity of the sand deposit;  
 $\lambda_g$  = porosity of the roughness elements;  
 $Q_s$  = volumetric transport rate of sand; and  
 $k_{s0}$  = height of roughness elements.

Equation (23-7a) applies to cases where the thickness of the sand deposit is less than the height of the roughness elements (in which case sand aggradation fills in the interstices of the roughness elements). Equation (23-7b) is applied when the thickness of the sand deposit is greater than the height of the roughness elements.

As discussed above, two sediment-transport equations were used for calculation of sediment-transport capacity: the surface-based bed-load equation of Parker (1990) for coarse sediment and the bed-material equation of Brownlie (1982) for sand. The surface-based bed-load relation of Parker (1990) is also described in Section 3.7.5 (Chapter 3), and minor adaptations of the bed-material equation of Brownlie (1982) can be found in Stillwater Sciences (2000) and Cui et al. (2006a; 2006b). It is important to note that both

equations are used to calculate sediment-transport capacities rather than sediment-transport rates. Actual sediment-transport rates at any location were evaluated based on upstream sediment supply, local sediment-transport capacity, erodibility of the channel bed, and sediment mass conservation. The application of the sediment-transport equations of Parker (1990), for gravel transport, and Brownlie (1982), for sand transport, requires the use of different friction relations. A Keulegan-type resistance relation (modified from Keulegan 1938) is used for gravel and Brownlie's (1982) friction formulation is used for sand, as detailed in Stillwater Sciences (2000) and Cui et al. (2006a; 2006b).

In addition to evaluating coarse and fine sediment-transport rates, this modeling effort includes estimates of total suspended-sediment (TSS) concentration following dam removal, to assist evaluation of biological impacts. The suspended-sediment concentration is calculated by combining the portion of sand that is transported in suspension with the entire silt and clay load (sediment finer than 62.5  $\mu\text{m}$ ) in transport. All of the silt and clay from the reservoir deposit is treated as throughput load that is carried in suspension once it has been mobilized from the reservoir. The criterion set for suspension of sand is given as follows (e.g., van Rijn 1984):

$$\frac{v_s}{\kappa u_*} < 1 \quad (23-8)$$

in which

$v_s$  = particle settling velocity calculated with the procedure given by Dietrich (1982);

$u_*$  = shear velocity; and

$\kappa$  = von Karman constant, with a value of approximately 0.4.

TSS therefore is composed of all the particles finer than 62.5  $\mu\text{m}$  from the reservoir deposit and those satisfying Eq. (23-8).

### 23.3.3 Input Data and Zero Process

The sediment-transport models developed for the simulation of the removal of Marmot Dam use input data on channel gradients, channel widths, water discharge at each section of the river for the duration of the simulation, grain-size distribution of the sediment deposit in the reservoir and in the downstream channel, and the sediment supply and associated grain-size distribution upstream of the Marmot reservoir. The modeling of total suspended sediment following dam removal also requires an order-of-magnitude estimate of the background average sediment concentration in the Sandy River. These input parameters and their sources are described in the following sections.

**23.3.3.1 Channel Gradient and Width** Data on channel gradients, and an associated longitudinal profile of the Sandy River from 4.8 km upstream of Marmot Dam

downstream to the Columbia River, were derived from 1999 photogrammetric measurements of the Sandy River. The photogrammetric data measure water-surface elevation with an accuracy of  $\pm 0.6$  m and were averaged over a 0.8-km distance to further smooth the longitudinal profile (Figs. 23-7 and 23-8).

Channel widths were measured from 1:6,000-scale aerial photographs of the Sandy River corridor. Field checking of randomly selected cross sections with a laser distance finder found that channel widths measured from aerial photographs were generally within 10% accuracy. One exception is in Reach 2 (the Sandy River gorge), where widths cannot be measured from aerial photographs due to the narrow channel and valley in this reach. A channel width of 30 m was applied to all of Reach 2 in the model, based on the average of field-measured widths in the Sandy River gorge. In all other reaches of the Sandy River, channel width was varied in the model according to the aerial photographic measurements.

**23.3.3.2 Discharge Data and Hydrologic Scenarios Used in Numerical Modeling** A daily discharge series spanning the length of model runs was also required as input. Daily discharge data used as input for the modeling are from the USGS Sandy River near the Marmot gauge (Station 1413700), which was assumed to represent the reach from Marmot Dam downstream to the Bull Run River confluence, and the Sandy River below the Bull Run River gauge (Station 14142500), which was assumed to represent discharge from the Bull Run River to the mouth (Fig. 23-6). The Bull Run River is the largest tributary that enters the Sandy River downstream of the Marmot Dam. Other tributaries have small drainage areas, and therefore are likely to create only small increases in water discharge in the Sandy River.

Numerical modeling was performed for three different hydrologic scenarios to evaluate the effects of various flow regimes following dam removal on sediment transport and deposition dynamics. The flows occurring following dam removal, particularly in the first year after removal, will have an important influence on the time required for downstream transport of reservoir sediment, on subsequent deposition patterns, and on the duration of impacts on aquatic organisms. Scenarios for wet, average, and dry hydrologic conditions were developed for input into the numerical modeling, with the flows in the first year after removal varying in each scenario (i.e., hydrologic scenarios were defined according to the discharge conditions in the first year of the model run). The hydrologic scenarios account for both peak flow magnitude and overall water yield, both of which influence sediment-transport dynamics. The peak and annual daily average discharges from the Marmot gauge were fit to a log Pearson III distribution and a normal distribution, respectively, to predict the return period of future discharges. Based on this analysis, daily discharge records were selected as input for Year 1 of model runs from three representative

Fig. 23-8. Sandy River channel slope downstream of Marmot Dam.

water years, with exceedance probabilities for both annual peak discharge and average daily discharge corresponding to wet, average, and dry hydrologic conditions. In the scenarios for dry, average, and wet conditions, flows used as input for Year 1 had both peak flows and average annual discharges with exceedance probabilities of approximately 90% (1.1-yr return period), 50% (2-yr return period), and 10% (10-yr return period), respectively (Table 23-2). The years following the first year were selected randomly from all of the water years in the period of record using a numerical random generator, and the same water years for years 2 through 10 were used in the three different hydrologic scenarios (Table 23-2).

In each model run the simulation starts on the day of the water year (after 1 October) when discharge at the Marmot gauge first exceeds 48 m<sup>3</sup>/s. This is because removal of Marmot Dam will be carried out with a cofferdam that can hold up to 48 m<sup>3</sup>/s in place, and the cofferdam will be removed (allowing downstream sediment release) when flow reaches this threshold.

**23.3.3.3 Surface Grain-Size Distribution of the Channel Bed and Abrasion of Coarse Sediment** Estimates of the grain-size distribution of the channel-bed surface layer and of abrasion effects are necessary inputs to the gravel model. The surface grain-size distributions were collected at seven locations, shown in Fig. 23-9. The volumetric abrasion coefficient for gravel and coarser material is estimated to be on the order of 0.02/km based on abrasion values reported

by Collins and Dunne (1989) from the Satsop River basin, Washington, for basaltic colluvium, which is geologically similar to river gravels in the Sandy River basin. Detailed input data on surface grain-size distribution are not important for this modeling effort, however, because the model quickly adjusts the grain-size distribution of the channel bed during model simulations.

Effects of abrasion on grain size can be characterized using a modification of Sternberg's (1875) law that can be derived from the Exner equations in Parker (1991a; 1991b), as follows:

$$D_x = D_0 \exp\left(-\frac{2}{3}\beta x\right) \quad (23-9)$$

where

- $D_0$  = grain size (diameter) at an upstream section;
- $D_x$  = grain size at a downstream section;
- $\beta$  = volumetric abrasion coefficient (fraction of gravel volume lost due to abrasion per unit distance); and
- $x$  = distance between the two sections.

The abrasion coefficient used in the model dictates the rate of attrition of gravel released from the reservoir and therefore influences predicted deposition (i.e., if attrition is greater, less deposition will occur because fewer coarse particles will

**Table 23-2 Water Year Series Selected for Use in Simulation**

Year in model run	Water year	Peak flow (cms)	Exceedance probability of peak flow (%)	Annual average discharge (cms)	Exceedance probability of annual average discharge (%)
1a (Dry)	1987	230	83	28	91
1b (Average)	1991	371	55	37	59

10	1948	546	29	46	15

**Fig. 23-9.** Surface grain-size distributions in the Sandy River, based on selected pebble counts by stillwater sciences.

be available for deposition). Parker's (1991a; 1991b) modification of Sternberg's law considers the abrasion of both bed load and sediment on the channel surface. This modification is seen in Eqs. (23-3a) and (23-3b), which are the variants of the Exner equations of sediment-transport continuity for

gravel suggested by Parker (1991a; 1991b). Integration of Eq. (23-3a) for the case of equilibrium conditions by ignoring the production of sand (the last term on the right-hand side of the equation) and then converting volume to diameter yield Eq. (23-9).

Because this modeling effort focuses on evaluation of channel aggradation following sediment release from the reservoir deposit (rather than degradation/incision in the downstream channel bed), results are not sensitive to subsurface grain-size distribution in the channel bed downstream of the dam. For simplicity, it is assumed that downstream of the reservoir area, the subsurface grain-size distribution is the same as that of the surface layer.

**23.3.3.4 Grain-Size Distribution of the Reservoir Sediment** The grain-size distribution of the sediment accumulation stored behind Marmot Dam, which will influence downstream sediment-transport and deposition patterns, was determined based on sampling conducted in October 1999. Sampling of the reservoir sediment consisted of drilling a series of cores within 1 km upstream of the dam and manual and mechanical excavation further upstream (Squier Associates 2000). A summary of the resulting interpretation of grain-size distribution in the reservoir deposit is given in Fig. 23-10. The reservoir sediment consists of two main units, with the predam channel bed representing a third distinct unit (Squier Associates 2000). The uppermost unit (Unit 1) ranges from approximately 2 to 5.5 m in thickness and is composed of sandy gravel with a small amount of cobbles and boulders, becoming thicker toward the dam. The next unit (Unit 2) is predominantly fine sediment (silty sand to sand with a small amount of gravel, ranging from 4 to 11 m thick). Unit 3, the

predam channel, consists primarily of coarse sediment and is 0.8 to 3 m thick. Approximately 750,000 m<sup>3</sup> of sediment is stored behind the dam, of which 490,000 m<sup>3</sup> is primarily gravel/pebble and 260,000 m<sup>3</sup> is primarily sand (Squier Associates 2000).

The grain-size distribution of upstream sediment supply is also required as model input. The grain-size distribution of gravel in upstream sediment supply is assumed to be the same as that of the gravel portion of Unit 1 of the reservoir deposit. This assumption was based on the likelihood that as the reservoir filled in, all or most of the upstream bed load was captured in the reservoir. The grain-size distribution of the sand in sediment supply is assumed to be the same as that of the sand portion of Unit 2 of the reservoir deposit (Fig. 23-10).

The roughness height without sand coverage ( $k_{s0}$  in Eqs. (23-7a) and (23-7b)) is assumed to be 0.4 m at Marmot Dam and to decrease exponentially to 0.25 m at the Columbia River confluence. These values are estimates based on field observation and correspond to roughly 4 to 10 times the geometric mean grain size. A model run in which the roughness heights were doubled (i.e., 0.8 m at Marmot Dam and 0.5 m at the Columbia River confluence) was also performed to test the sensitivity of model results to the assumed roughness height. Doubling the roughness heights results in an increased likelihood that sand deposition will be initialized but has only a limited effect on the overall thickness of predicted sand deposition.

**Fig. 23-10.** Sediment deposit in Marmot Reservoir. Three grain-size distributions are shown for each unit, representing upper and lower bounds and their average values. Diagram developed based on information provided by Squier Associates (2000).

### 23.3.3.5 Background Gravel and Sand Transport

**Rates** Background rates of gravel and sand transport in the Sandy River upstream of Marmot Dam are required inputs to the gravel and sand models, but no data are available for reference. To derive a gravel-transport rate, we assumed that the Sandy River's gravel-transport capacity upstream of Marmot Dam exceeds the supply, based on the abundance of bedrock outcrops and boulders in the channel. Thus it is possible to assume that the actual sediment-transport rate upstream of Marmot Dam is some fraction of the transport capacity. This fraction was determined by the model using trial and error as part of the "zero process," whereby various gravel-transport rates were plugged into reference-condition runs so that downstream aggradation and degradation are minimized over the entire river reach. This zero process is discussed in more detail below.

A rough estimate of background suspended-sediment concentration was developed based on an estimate of the long-term average sediment-transport rate and water discharge. For input to the model, the long-term average sediment-transport rate in the Sandy River at Marmot Dam is estimated to be about 250,000 tn/yr (roughly 350 tn/km<sup>2</sup>/yr), of which the majority is fine sediment. This is a rough estimate based on review of sediment-yield data from other rivers in Oregon's western Cascade Range, which suggest average sediment yields that range from 100 to 500 tn/km<sup>2</sup>/yr for undisturbed and disturbed basins (Curtiss 1975; Swanson and Dyrness 1975; Larsen and Sidle 1980; Swanson et al. 1982; McBain and Trush 1998). In the Sandy River basin, sediment yields may be substantially higher on average than elsewhere in the western Cascades due to Mt. Hood glaciers, the presence of semiconsolidated lahar deposits, steep topography, and land uses. The estimated sediment yield of 350 tn/km<sup>2</sup>/yr translates to an average suspended-sediment concentration of about 200 mg/l, which was used as the background suspended-sediment concentration at Marmot Dam in this modeling effort. If the sediment flux from reservoir erosion following removal of Marmot Dam is much higher than the background value, as it is expected to be, model output is not sensitive to the accuracy of the background concentration assumed for model input.

**23.3.3.6 Zero Process** A "zero process" is generally required for long-term, large-scale sediment-transport simulation. The purpose of the zero process used in this modeling effort is to generate a starting point for the modeling and to evaluate certain input parameters. In the zero process, the model is run repeatedly under a reference condition, in which input data such as discharge are the same as for the simulation of dam removal, but neither Marmot Dam nor any sediment pulse from the reservoir deposit is considered. If the model is fed with raw input data (e.g., channel gradient, width) without modification, it typically will not produce quasi-equilibrium results under reference conditions. The goal of the zero process is to run the model, modifying certain input parameters if necessary, until the model produces quasi-equilibrium results, whereby

the river experiences aggradation and degradation in different reaches over different periods of time and hydrological events, but overall, long-term aggradation or degradation is limited. If a quasi-equilibrium condition is established as the baseline for modeling, changes in the system can be interpreted as a direct result of the introduced disturbances, in this case the release of the sediment pulse from Marmot Dam. Boundary conditions in the model are given by (1) discharge at the upstream end of the modeled reach (4 km upstream of Marmot Dam) and along the Sandy River in a downstream direction, (2) background gravel transport at the upstream end (given as a fraction of the potential gravel-transport rate, as described above), (3) the assumed grain-size distribution of the background gravel load, and (4) a fixed bed elevation at the downstream end of the modeled reach (the confluence of the Sandy River with the Columbia River). The water-surface elevation at the downstream end is acquired by the normal flow assumption.

In the zero process for this modeling effort, channel width is modified in such a way that certain extremely wide sections are reduced to no less than 80% of the original value. The model is then run repeatedly, with the output of the channel bed elevation (slope) as the input of the subsequent run, until the channel bed reaches quasi-equilibrium. The zero process is also used to estimate the background gravel-transport rate upstream of Marmot Dam (which is needed as input to the model). Large-scale deposition (aggradation) will occur if the input sediment-transport rate is too high and large-scale erosion (incision/degradation) will occur if the input sediment-transport rate is too low. The input gravel-transport rates selected for modeling, based on trial and error in the zero process, vary with hydrology and, for the hydrologic conditions shown in Table 23-2, vary from about 7,000 to 72,000 tn/yr at Marmot Dam. These results suggest an average long-term gravel-transport rate of about 25,000 to 30,000 tn/yr (roughly 10% of the total sediment yield estimated above). Assuming a bulk sediment density of 1.7 tn/m<sup>3</sup>, this average annual gravel-transport rate would have completely filled Marmot reservoir in about 30 yr following dam closure. The actual length of time required for the reservoir to fill is unknown but 30 yr appears to be a reasonable estimate, based on regional sediment-yield data and on the rapid sedimentation of an area of the reservoir that was excavated to facilitate reconstruction of the dam in 1989.

The "zeroed" bed slope is given in Fig. 23-8 along with the original photogrammetric data. This figure shows that the zero process retains the general overall channel slope but modifies local gradients to convey the background sediment load through all reaches of the Sandy River.

### 23.3.4 Model Results

Numerical modeling was used to simulate sediment-transport processes both for background conditions in the Sandy River and for the dam removal alternatives listed in Section 23.3.1. Results are presented for background conditions and for the

alternative entailing single-season dam removal with minimal sediment removal. Sensitivity tests to evaluate certain model assumptions and approaches are also summarized. Results for modeling of other removal alternatives, as well as additional details on sensitivity testing, are presented in Stillwater Sciences (2000; 2002).

**23.3.4.1 Reference Runs of Numerical Models** For both the gravel and sand models, model runs were performed for reference conditions assuming that no dam exists and downstream sediment transport is equivalent to estimated background (natural) conditions, with no release of reservoir sediment. Reference runs of the model are a component of the

zero process described above and depict aggradation and degradation in the Sandy River in the absence of sediment release from Marmot Dam. Reference runs therefore provide a basis of comparison for interpretation of model predictions of deposition patterns following various dam removal alternatives.

For the gravel model, a 10-yr simulation was performed for reference conditions. In the reference run of the gravel model, a small amount of coarse sediment aggradation (and degradation) is indicated in Reaches 3 and 4, even without sediment release from Marmot reservoir (Figs. 23-11 and 23-12). The reference run indicates that up to about 1 m of aggradation would periodically occur in certain reaches.

**Fig. 23-11.** Annual change in bed elevation from gravel erosion and deposition: reference run of the gravel model.

In particular, about 1 m of deposition is observed downstream of the gorge outlet in Year 6 of the model run (which uses water year 1949, a wet year with only moderate peak flow, as input flow data). This result indicates that under certain hydrological conditions, local aggradation or degradation

could occur in certain reaches under reference conditions in the Sandy River.

Reference runs of the sand model indicate background suspended-sediment concentrations fluctuating between approximately 90 and 150 ppm at the site of Marmot Dam,

**Fig. 23-12.** Cumulative change in bed elevation from gravel erosion and deposition: reference run of the gravel model.

**Fig. 23-13.** Simulated suspended-sediment concentration downstream of Marmot Dam under reference conditions.

with lower concentrations further downstream (Fig. 23-13), based on the assumed background sediment concentration. Reference runs also show sand aggradation occurring in Reach 5, which is in agreement with field observations of the sand-bedded nature of this reach.

**23.3.4.2 Modeling of Sediment Transport Associated with Single-Season Dam Removal and Minimal Sediment Excavation** Under one of the alternatives being considered for removal of Marmot Dam, only a minimal amount of sediment (i.e., enough to facilitate dam removal activities) would be excavated from the reservoir prior to dam removal, which would be accomplished in one season. All of the remaining reservoir sediment would be released downstream following dam removal. Model runs for this alternative assumed that a slightly greater amount of sediment was in the reservoir and would be released downstream (800,000 m<sup>3</sup>) than the sediment volume of 750,000 m<sup>3</sup> suggested by the Marmot reservoir coring study (Squier Associates 2000). This volume difference was arrived at based on review of PGE photogrammetric data (Fig. 23-7), which suggests that the reservoir deposit may extend further upstream than indicated by the coring study (Squier Associates 2000).

Figures 23-14 and 23-15 illustrate model predictions of the downstream movement of coarse sediment out of the reservoir and resulting increases in bed elevation (aggradation) downstream of Marmot Dam, under average hydrologic conditions and over a 10-yr period. These model results indicate that, in the first year following removal, coarse sediment would move downstream into the portion of Reach 1 immediately downstream of the dam, creating

a depositional wedge up to a maximum of about 4 m thick, with small amounts of deposition predicted further downstream in Reach 1 and in Reach 3. In subsequent years, additional sediment would move out of the reservoir, resulting in a gradual increase in deposition thickness in the downstream portion of Reach 1, reaching a maximum of about 1 m on a reach-averaged basis. The aggradational wave is predicted to travel quickly through most of the gorge (Reach 2), with aggradation increasing at the downstream end of the gorge and the upstream end of Reach 3 from Years 1 through 10. Aggradation is predicted to gradually build to a maximum predicted thickness of about 1.5 to 2 m in the upper portion of Reach 3 (9–13 km downstream of the dam), where the channel widens and decreases in gradient (Fig. 23-15). In Reach 1, the greatest amount of aggradation would be expected in the early years following dam removal, whereas in Reach 3, aggradation would be expected to show gradual increases through the first 7 yr. After the first 7 yr, deposition thickness in Reach 3 would gradually decrease as the sediment wave is transported downstream. The model predicts small amounts of aggradation (typically <0.5 m) downstream of the Bull Run River confluence, although this aggradation is similar in magnitude to aggradation predicted in a reference run of the model and is not likely to be distinguishable from natural depositional processes.

Figure 23-16 shows the predicted change in bed elevation in a longitudinal profile view in the reservoir reach and in Reach 1 following dam removal. This figure shows how, following dam removal, the slope in the reservoir reach would gradually flatten out and return to that of the predam channel

**Fig. 23-14.** Annual change in bed elevation following dam removal for single-season dam removal with minimal dredging.

bed. Model results show that under average hydrologic conditions, the depth of the sediment deposit in the reservoir would decrease from about 11 m at the time of dam removal to about 8 m after 30 days, 7 m after 60 days, 6 m after 1 yr, 3 m after 5 yr, and 1 m after 10 yr (Fig. 23-15).

After the dam is removed and the channel begins to incise into the reservoir deposit, sand and finer sediment will be mobilized from the reservoir deposit. The magnitude of sand transport out of the reservoir is predicted to be greatest in the first winter following dam removal, although sand transport out of the reservoir continues for the duration of the model runs. Modeling of sand transport indicates that

sand aggradation is most likely to occur in the lower 10 km of the Sandy River (Reach 5) and that negligible aggradation would occur further upstream. Reach 5 has the lowest transport capacity of any reach in the Sandy River, reflecting its greater width and low gradient, and is currently sand-bedded in its lower portion. The model predicts deposition thicknesses of up to about 0.4 m in Reach 5 (Fig. 23-17), with the greatest aggradation expected to occur in the first year following removal of Marmot Dam. If stages are high enough in the Columbia River to create a backwater effect in the Sandy River during periods of sand transport in the Sandy River, however, the thickness of sand deposition in

**Fig. 23-15.** Cumulative change in bed elevation following dam removal for single-season dam removal with minimal dredging.

the lower Sandy River could be much greater than predicted here. Because the model does not account for this backwater effect, there is considerable uncertainty in model predictions of deposition thickness in Reach 5.

Figures 23-17 and 23-18 show the pattern of sand deposition at selected locations in Reach 5 during the first 2 yr

following removal of Marmot Dam and indicate that the magnitude of sand aggradation would fluctuate both seasonally and between years. Aggradation in Reach 5 is predicted to occur mainly in the lower 3 km of the Sandy River (with less aggradation in the upper part of the reach), which roughly corresponds to the location of the gravel/sand transition area

**Fig. 23-16.** Simulated bed elevation in the vicinity of the reservoir area following dam removal, for single-season dam removal with minimal dredging.

**Fig. 23-17.** Simulated thickness of sand deposit for single-season dam removal with minimal dredging. The diagram depicts the general areas and magnitudes of sand deposition. No attempt is made to identify individual lines on the diagram.

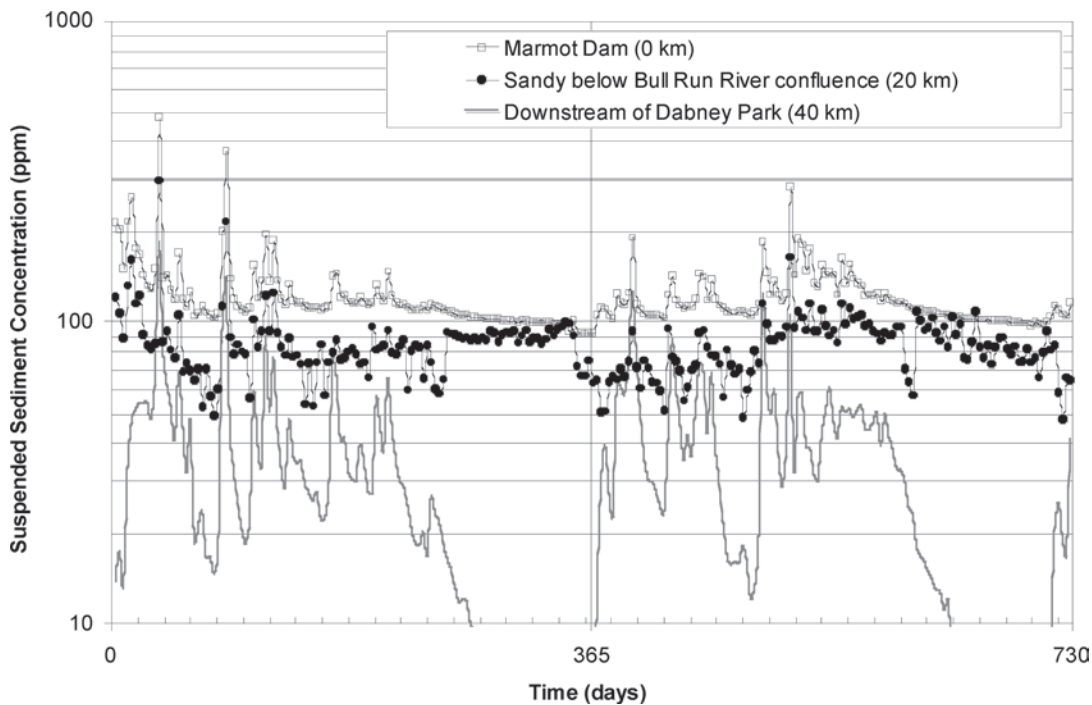

**Fig. 23-18.** Simulated thickness of sand deposit at four locations for the first two years following dam removal: single-season dam removal with minimum dredging.

in the Sandy River (i.e., very little gravel is found in the channel bed downstream of this portion, whereas upstream the bed contains both sand and gravel). Observations in other river systems suggest that the gravel/sand transition zone is typically an area of active deposition (Dietrich et al. 1999).

Model results also suggest that sand release from the reservoir would produce relatively small increases in total suspended-sediment (TSS) concentrations. Modeling indicates that, between Marmot Dam and the Bull Run River confluence, peak TSS of about 500 ppm would occur in the first winter following dam removal under average hydrologic conditions (Fig. 23-19). Suspended-sediment concentrations would generally remain between 100 and 200 ppm during the first 2 yr after removal, with periodic increases above this level during high flows. Downstream of the Bull Run River, suspended-sediment levels would be lower because of the dilution effect of flows from the Bull Run River. Suspended-sediment levels associated with dam removal are predicted to be relatively low because of the nature of the reservoir sediment deposit, in which fine sediment deposits are armored by a coarser surface layer (Fig. 23-10) and are therefore released gradually, rather than as one large pulse. Background suspended-sediment levels in the Sandy River are not known; modeled results should be considered indicative of potential increases in suspended-sediment concentration above background levels due to sediment release from Marmot Reservoir.

**23.3.4.3 Sensitivity Tests** Sensitivity tests were also performed to characterize the potential uncertainties in model results as a result of uncertainties either in model input data or in basic assumptions. Sensitivity tests were performed for the Marmot Dam removal simulation to evaluate uncertainties in (1) future hydrologic conditions, (2) grain-size distributions in the reservoir deposit, and (3) erosion rates from Marmot Reservoir. The results of these sensitivity tests are summarized below, and additional details are presented in Stillwater Sciences (2000; 2002). Cui et al. (2006a) present additional sensitivity tests for a hypothetical case study.

Modeling was completed to test the effects of “wet,” “average,” and “dry” hydrologic conditions in the first year following dam removal on sediment-transport dynamics; descriptions of the input data used for these scenarios are provided in Section 23.3.3. These model runs suggest that varying hydrology in the first year following dam removal strongly affects the rate of sediment transport out of the reservoir reach, with more rapid reservoir erosion under wetter conditions. For example, modeling indicates that after 1 yr, the thickness of the reservoir deposit would be about 3 m based on wet hydrologic conditions, compared to about 6 m based on average hydrology. Compared to average hydrologic conditions (results of which are described above), the more rapid movement of sediment out of the reservoir in Year 1 expected under wet conditions is predicted to slightly

**Fig. 23-19.** Simulated suspended-sediment concentration at three locations for the first two years following dam removal: single-season dam removal with minimum dredging.

reduce overall gravel aggradation in Reach 1 in the years following removal, to alter the temporal pattern of aggradation in Reach 3 (with thicker deposition in the first several years after removal, but with similar magnitude of aggradation over a 10-yr scale), and to slightly increase aggradation in Reach 4. Model runs based on dry hydrologic conditions in Year 1 suggest that sediment would initially move more slowly out of the reservoir area compared to average hydrologic conditions, but that after 5 yr, the thickness of the deposit at the dam site would be the same as for average hydrologic conditions. Downstream patterns of predicted aggradation are similar for dry and average hydrologic scenarios, with aggradation concentrated in Reach 1 and Reach 3. The sensitivity of TSS levels to hydrologic conditions was also evaluated: predicted TSS levels are lowest for dry hydrologic conditions in Year 1, generally remaining below 200 ppm, and are similar in average and wet conditions.

In addition to varying the hydrologic input data, we also conducted model runs with different assumed grain-size distributions for the reservoir deposit. The model runs described above assumed an “average” grain-size distribution (Fig. 23-10). Using the “upper bound” (i.e., coarser) and “lower bound” (i.e., finer) grain-size distributions shown in Fig. 23-10 causes only very small changes in the predicted pattern of coarse sediment deposition. Predictions of TSS concentration are somewhat sensitive to the assumed grain-size distribution: TSS levels are highest for the assumed lower-bound distribution and lowest for the assumed upper-bound distribution.

Sensitivity tests were also used to evaluate simplifying assumptions used to simulate reservoir erosion, which is a key uncertainty in this modeling effort. As discussed in Section 23.3.2, basic model runs assume laterally uniform erosion of reservoir sediment from Marmot Reservoir. In reality, however, incision of a channel through the reservoir reach will likely occur to some extent following dam removal. A sensitivity analysis was performed to assess how an increase in the rate of gravel transport out of the reservoir resulting from channel incision could affect downstream deposition patterns. It was assumed that channel incision in the reservoir reach would be most likely when the local channel bed slope was high, as would be the case at the downstream end of the reservoir deposit immediately following dam removal, and that this could result in a gravel-transport rate that was greater than predicted by Parker’s bed load transport equation. The increase in sediment-transport rate resulting from downcutting is therefore hypothesized to be an incremental function of bed slope. To simulate this, we applied a multiplier that varied with bed slope to the gravel-transport rate calculated by the Parker equation for channel bed slopes above 0.01. The transport rate out of the reservoir calculated by the Parker equation is thereby increased by a factor of up to 10 in this sensitivity test, depending on local bed slope. The results of this sensitivity test indicate that, if the down-cutting process affects the gravel-transport rate as is assumed in this sensitivity test, there will be only a short term effect on the pattern of gravel erosion from the reservoir and downstream deposition. This is because slopes

will be steepest immediately following dam removal at the downstream end of the sediment deposit, but downstream transport of this material would result in reduced bed slopes (and sediment-transport rates) within a short time, even if channel incision does occur. This sensitivity test does not fully simulate the effects of channel incision on sediment-transport patterns out of the reservoir reach, but it does capture one potential effect of incision (i.e., transport rates that are higher than calculated by the Parker equation when channel incision occurs).

The model also employs simplifying assumptions with respect to the mechanism of sand release from the reservoir, assuming that sand will be metered out of the reservoir in association with transport of gravel, as described in Section 23.3.2. To address the considerable uncertainties in this method, we completed sensitivity tests in which the rate of sand release from the reservoir was increased 5-fold and 10-fold over the rates of sand release predicted by the model based on predicted shear stresses and laterally uniform transport in the reservoir reach. Increasing the rate of sand release by a factor of 5 or 10 would result in complete sand evacuation from the reservoir in about 4 or 2 yr, respectively. The sensitivity analysis for the 10-fold increase indicates that sand release from the reservoir at 10 times the expected rate would result in a peak TSS concentration of approximately 4,000 ppm in the first winter following dam removal (compared with a maximum of about 500 ppm for basic model runs), with other spikes in TSS above 500 ppm during storm events. Otherwise TSS would generally remain between 100 and 400 ppm between Marmot Dam and the Bull Run River confluence, resembling assumed background conditions during late summer and early fall low-flow conditions. Increasing the rate of sand release 10-fold would also result in additional deposition downstream, including sand aggradation of approximately 0.2 to 0.4 m at the downstream end of Reach 4 (where no deposition is predicted for basic model runs), and aggradation predicted throughout Reach 5, with a maximum of about 1 m in this reach (compared to about 0.4 m in basic model runs).

### 23.3.5 Discussion

The case study presented in this chapter illustrates key considerations in the development of sediment-transport models for dam removal simulations. The model presented here and those of Cui et al. (2006a; 2006b) provide a framework for development of future models, either as a reference or as a starting point for modifications.

Numerical modeling of a process as complex as transport of a large volume of coarse and fine sediment following dam removal contains a number of uncertainties. The modeling approach presented here includes both uncertainties that are specific to the Marmot Dam removal application and those that would likely affect any dam removal modeling effort. Many hypotheses are incorporated in the models, in terms

of both theoretical development (i.e., reflecting uncertainties in current scientific understanding about the mechanics of sediment transport) and input data. Key areas of uncertainty in this modeling effort, each of which is discussed further below, include modeling of reservoir erosion processes, selection of appropriate sediment-transport equations, uncertainty arising from the use of one-dimensional modeling, and uncertainty in input parameters.

A key source of uncertainty in this modeling approach arises from simplifying assumptions used to model reservoir erosion. Whereas the model assumes that transport out of the reservoir would be laterally uniform, erosion of reservoir sediment would in fact likely result in incision of a channel within the valley walls, potentially accelerating exposure of the underlying sand layer in the incised area and increasing the time (compared to model predictions) required for sediment on the margins of the reservoir deposit to be eroded downstream. Uncertainties also arise from the use of the Parker equation to model erosion of the mixed sand and gravel layers in the reservoir. The Parker equation is used to predict mobilization of the coarse fraction of various sediment layers in the reservoir, treating those layers as if fine sediments were not present. In fact, although the overall stratification of the reservoir results in a larger proportion of fine sediment in the lower layers of the reservoir and more coarse sediment in the upper layers, each layer in the deposit typically contains a range of grain sizes. The presence of a large amount of fines may create error in the use of the Parker equation because it is not intended for application to particles smaller than 2 mm. The model also assumes that fine sediments within each layer of the reservoir deposit are not transported out of the reservoir until shear stresses are sufficient to mobilize the gravel (>2-mm) component of the layer, as indicated by the Parker equation. Some fraction of the fine sediments in the reservoir, however, will likely be mobilized and transported at discharges lower than those that transport the coarse sediments found in the same layer as the fine sediments, resulting in more rapid transport of sand from a given layer in the reservoir deposit than of the gravel in that layer. In addition, sand following the gravel leaving the reservoir could smooth the bed and increase the mobility of the leading gravel front downstream (T. Lisle, personal communication, 2000). Sensitivity tests to address uncertainties related to reservoir erosion processes are described in Section 23.3.4.

Selection of appropriate sediment-transport equations is an important consideration in sediment-transport modeling of dam removal and, because of the complexities of dam removal modeling and incomplete knowledge of sediment-transport mechanics, the transport equations selected can be a potential source of uncertainty. The Marmot Dam removal case study involves simulation of transport of a mixture of coarse and fine sediment over a primarily coarse existing river bed. Because of the relatively undeveloped nature of transport equations for sand/gravel mixtures, we developed

separate transport models for sand and gravel components in the Marmot case study, rather than simultaneously modeling a sand/gravel mixture. Although sand and gravel transport are treated separately, they do likely affect each other, creating some uncertainty in model results. Moreover, the transport equation used here to model the downstream transport of fine sediment (Brownlie 1982) was developed for sand-bedded channels, and we know of no equations for sand transport over a coarse bed. Because most of the Sandy River has coarse bed materials downstream of Marmot Dam, use of the Brownlie equation (or of a comparable equation for sand transport) creates additional model uncertainty.

One-dimensional numerical modeling, such as the Marmot Dam removal model, provides results that are most applicable on a reach-scale and time-averaged basis, including estimates of sediment-transport rates and cross-section and reach-averaged depths of sediment deposits over the existing channel bed. Current state-of-the-art modeling, however, typically cannot predict complex three-dimensional geomorphic responses over long river reaches and time scales, such as depositional patterns in channel cross section, local changes in sediment particle size distribution, infiltration of sand into the channel bed, or changes in the mobility of the existing channel bed. The Marmot Dam removal model assumes a simplified, rectangular channel, and model predictions do not account for local variations in shear stress caused by features such as deep pools, bedrock outcrops, or large boulders. The modeling of fine sediment transport also does not account for the production of sand and silt from gravel abrasion (i.e., suspended load estimates do not include products of gravel abrasion). The amount of sediment actually deposited may therefore be substantially higher or lower than predicted by the model in localized areas of the channel. Because of the one-dimensional nature of modeling results, professional judgment and field observations of the system being evaluated should be used to interpret model results in terms of expected geomorphic effects.

Numerical models of dam removal, such as the model presented here for the Marmot Dam removal application, require input parameters on a range of physical characteristics that influence sediment transport. Modeling results typically will have varying levels of sensitivity to different types of input data, and input data typically contain varying levels of uncertainty. Modeling accuracy and efficiency will therefore be enhanced if the effort devoted to quantifying input parameters is commensurate with model sensitivity to these parameters. For the Marmot Dam removal application, data were collected specifically for this project or were already available for those input parameters to which the model is most sensitive (i.e., channel gradient, channel width, grain-size distribution of reservoir sediment, and water discharge). In addition, sensitivity analyses were performed to examine the effects of varying certain input data (hydrologic conditions, grain-size distribution of reservoir sediment) on model results, as described above. For other input parameters, such as background gravel- and

sand-transport rates, size distribution of bed load, and abrasion rates in the Sandy River, existing data were not available and new data were not collected for this project. For many of these input parameters, only order-of-magnitude estimates are required for the models, and rough assumptions based on field observations of the Sandy River and on published data from elsewhere in the region were therefore used.

Despite the uncertainties in the modeling effort described here, this numerical modeling approach does provide predictions of sediment transport and deposition following dam removal over large temporal and spatial scales and can be used to compare sedimentation impacts associated with various dam-removal alternatives. Modeling efforts such as this one can be improved if field data describing the phenomena being modeled are collected and compared to modeling results. Monitoring of processes such as reservoir erosion, sand and gravel aggradation, and total suspended-sediment concentrations following dam removal is critical to improving upon nascent efforts to simulate sediment-transport dynamics following dam removal.

## ACKNOWLEDGMENTS

We would like to thank the following reviewers for comments on this work: Jim Pizzuto (University of Delaware), Tom Lisle (U.S. Forest Service), Steve Wiele (U.S. Geological Survey), Bill Dietrich (University of California, Berkeley), and Marcelo Garcia (University of Illinois). Suggestions from Brian Cluer on this manuscript are gratefully appreciated. Discussions and helps from Stillwater Sciences employees, Christian Braudrick, Frank Ligon, Bruce Orr, Martin Trso, Jennifer Vick, and many others, too many to mention individually, are gratefully acknowledged. Funding for the Marmot Dam removal sediment-transport study was provided by Portland General Electric (PGE).

## APPENDIX A

### *Rock Scour*

*George W. Annandale and Erik F. R. Bollaert*

#### INTRODUCTION

Rock scour can occur when the erosive capacity of water exceeds the ability of rock to resist it. Typical environments where rock scour is a concern are downstream of overtopping dams, downstream of spillways, in plunge pools, around bridge piers, in unlined rock tunnels, and in channels and at other structures constructed in rivers and marine environments. Development of technology to predict scour of rock commenced in 1991 and has seen significant growth since then.

This appendix provides a summary of technology that can be used to determine the potential for and the extent and rate of rock scour. The latest technology in this field is explained in more detail in Schleiss & Bollaert (2002) and in Annandale (2006). Both works provide a detailed exposition of rock scour technology, explains methods for applying it, and provides a number of case studies validating the technology and demonstrating its application.

Two quantitative approaches, known as the Erodibility Index Method (EIM; Annandale 1995, 2006) and the Comprehensive Scour Model (Bollaert 2002, 2004; Bollaert & Schleiss 2005), can be used to predict the potential for and the extent of scour. While both approaches allow estimating the ultimate possible scour depth, only the latter model is capable of predicting scour evolution as a function of time. By following these approaches, the practitioner can cross-check results and identify failure modes leading to scour of rock.

The EIM is basically a semi-empirical model that is based on a scour threshold relating the relative magnitude of the erosive capacity of water to the relative ability of rock to resist it (Annandale 1995). When using this method, the relative ability of rock to resist erosion is quantified by a geomechanical index known as the erodibility index. The erosive capacity of water is determined by quantifying the stream power of the flowing water. The universality of the scour threshold relationship offered by the EIM and the use of stream power

to quantify the relative magnitude of the erosive capacity of water provide practitioners with the ability to solve almost any scour problem in a global manner (Annandale 2006) for its ultimate depth. No rate of scour is available, however.

The Comprehensive Scour Model (CSM) developed by Bollaert (2002, 2004) is a completely physically based model that consists of two principal components: the comprehensive fracture mechanics (CFM) method and the dynamic impulsion (DI) method. Application of the CFM is focused mainly on fissured rock where brittle fracture or failure by fatigue dominates. Brittle fracture occurs instantaneously, while failure by fatigue is time dependent and thus allows estimating the time evolution of scour formation. The DI method is used principally to assess scour of intact blocks of rock formed by joints and fractures, but can also be used to predict sudden failure of concrete slab linings of stilling basins (Bollaert, 2004b). In some cases, large blocks of rock delineated by joints and fractures may also contain fissures within the principal mass of the rock and all three failure mechanisms; that is, brittle fracture, failure by fatigue, and removal by dynamic impulsion may be relevant. Application of both the CFM and the DI method requires quantification of the mean and fluctuating dynamic pressures acting within fissures, joints, and fractures. These pressures are caused by turbulence in flowing water. The method can in principle be applied to any type of turbulent flow situation and any type of fractured media, provided that turbulent pressure fluctuations and the strength of the fractured media can be reasonably estimated. The model not only provides the ultimate scour depth but also an estimate of the rate of scour during the lifetime of the structure in question.

#### OVERVIEW OF ROCK SCOUR

Rock scour occurs when the erosive capacity of water flowing over the rock exceeds its ability to resist scour. It is therefore

necessary to not only understand the characteristics of flowing water leading to scour of rock but also devise practical methods to quantify its erosive capacity. Similarly, it is necessary to investigate and understand the failure mechanisms in rock leading to scour and devise practical approaches for quantifying its ability to resist the erosive capacity of water. A relationship between the erosive capacity of water and the ability of rock to resist it at the threshold of motion is known as a scour or erosion threshold.

### Erosive Capacity of Water

Most engineers interested in the interaction between flowing water and earth materials opine that the shear stress exerted by the flowing water on the material results in erosive action. Bollaert (2002) proves that the erosive capacity of turbulent flow on fractured rock is the result of fluctuating pressures and not shear stress, while Annandale (2006) demonstrates that use of shear stress is correct for laminar flow only. These are important observations, as application of a shear stress concept cannot explain how large blocks of rock can be removed from a rock formation or how turbulent flow can break rock blocks into smaller pieces.

To state this, Bollaert (2002) and Bollaert and Schleiss (2003; 2005) conducted detailed research into pressure fluctuations of turbulent plunging jets and determined how these pressure fluctuations interact with rock joints and fissures. They developed methods that can be used to quantify the relative magnitude of fluctuating pressures due to turbulent jet flows, which are very useful when investigating scour of rock in plunge pools or stilling basins downstream of hydraulic structures. They also showed that free air in the water can play a significant role in causing resonance of fluctuating pressures in close-ended rock fissures, increasing pressure magnitudes by up to 20 times. Such amplification plays an important role when rock scour occurs because of brittle fracture or fatigue failure. Bollaert (2002) also showed that block removal by dynamic impulsion occurs because of the transient effect of pressure waves introduced into rock joints and depends on the time persistency of the net uplift forces.

Pragmatic methods to quantify the relative magnitude of fluctuating pressures due to turbulent flow (Fig. A-1) are available for turbulent jets, hydraulic jumps and horizontal and vertical river constrictions, such as for example bridge abutments or bed sills (Hoffmans & Verheij, 1997). Other flow situations such as bridge piers are currently under investigation. For flow scenarios where the turbulence intensity of the flow cannot be readily estimated, indirect techniques can be used to quantify the relative magnitude of pressure fluctuations. Annandale (1995) used a direct relationship between stream power and the relative magnitude of turbulent pressure fluctuations. The other approach relies on findings by Hinze (1975), that is, that the magnitude of fluctuating pressures can be correlated to boundary shear stress caused by flowing water.

Stream power is equivalent to the rate of energy dissipation in flowing water, which is high when flow is very turbulent and decreases when flow is less turbulent. Turbulence in flowing water is the principal reason for energy dissipation.

A general expression for stream power is

$$SP = \int_{x_2}^{x_1} \rho g \cdot Q \cdot \Delta E(x) \cdot dx \quad (A-1)$$

$SP$  = total stream power between locations  $x_1$  and  $x_2$ ;

$t$  = time;

$\Delta E(x)$  = energy head loss of flow at location  $x$ ;

$Q$  = discharge;

$\rho$  = mass density of water;

$g$  = acceleration due to gravity.

Equation (A-1) is often of little use to most practitioners, who wish to have simple techniques to quantify the magnitude of stream power. Annandale (2006) has developed a suite of equations allowing practitioners to quantify stream power for varying flow conditions, including plunging jets, hydraulic jumps, flow around bends, flow around bridge piers, flow in tunnels and over knickpoints, as well as flow in channels.

Alternatively, should a practitioner be interested in estimating the relative magnitude of pressure fluctuations, and the shear stress exerted by the flowing water is already known, the following equations can be used. Hinze (1975) found that the root mean square of fluctuating pressures in turbulent flowing water can be correlated to the shear stress as

$$p' = 3 \cdot \tau \quad (A-2)$$

where  $p'$  = root mean square of the turbulent fluctuating pressures;  $\tau$  = boundary shear stress.

In addition to this one also wishes to know the magnitude of the maximum pressure peaks that can result due to turbulence. Emmerling (1973) found that the maximum pressure peaks can be as high as  $6 \cdot p'$ ; that is,

$$p_{\max} = 18 \cdot \tau \quad (A-3)$$

**Fig. A-1.** Mean dynamic pressure, root mean square of the fluctuating dynamic pressure, and maximum fluctuating dynamic pressure in turbulent flow.

An important observation when applying either of Equations (A-2) or (A-3) is that these are merely simple correlations relating pressure fluctuations to shear stress. It does not mean that scour is caused by shear but merely is a procedure to estimate the relative magnitude of pressure fluctuations if shear stress is known.

## Rock Scour Mechanisms

Rock can scour by means of four mechanisms: block removal, brittle fracture, subcritical failure, and abrasion.

### • Block Removal

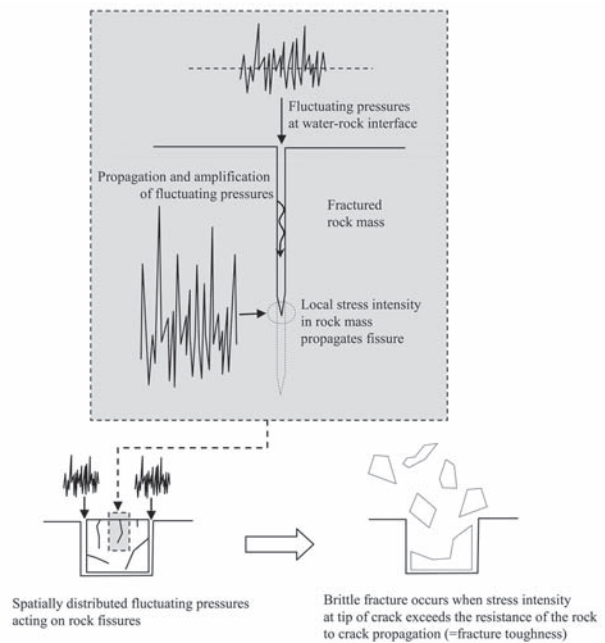

Fluctuating pressure magnitudes resulting from turbulent flow vary as a function of space and time. The pressures introduced into rock joints due to turbulent flow can result in increased pressure directly underneath the rock. When upward pressure underneath the rock exceeds the weight of the rock block and the friction forces along its sides, the rock will start being removed from the rock formation (Fig. A-2). Depending on the time persistency of the uplift forces, this phenomenon can lead to imminent failure and occurs as soon as the upward forces exceed the downward forces for a minimum time duration (Bollaert 2002, 2004b). An example of uplift failure of concrete slabs has been observed at Gebidem Dam (Switzerland).

### • Brittle Fracture

Brittle fracture of rock occurs when the stress intensity at the edges of close-ended fissures, resulting from the introduction of fluctuating pressures into the fissures, is greater than the fracture toughness of the rock (Bollaert, 2002, 2004a). When this occurs the rock fails in an explosive manner (Fig. A-3). Such failure typically results in the rock breaking up into smaller pieces. An example of rock scour by brittle fracture has been found at Santa Luzia Dam, Portugal (Annandale 2006). This failure type occurs instantaneously.

**Fig. A-2.** Rock scour by block removal (also known as dynamic impulsion) (based on Bollaert 2002).

**Fig. A-3.** Scour of rock by brittle fracture (based on Bollaert 2002, 2004a).

### • Subcritical Failure

Scour of rock by subcritical failure occurs when the stress intensities at the edges of close-ended fissures do not exceed the fracture toughness of the rock. Continued application of the fluctuating pressures in the close-ended rock fissures eventually results in breakup of the rock due to fatigue (Fig. A-4). This failure type is time dependent and both theory and practical implementations have been extensively described by Bollaert (2002, 2004a) and Bollaert and Schleiss (2005). An example of subcritical failure is the well-known scour at Kariba Dam in Zambia-Zimbabwe (Bollaert 2005).

**Fig. A-4.** Rock scour by subcritical failure, also known as fatigue failure (based on Bollaert 2002, 2004a; Bollaert & Schleiss 2005).

- Abrasion

Scour by abrasion can occur if the fluid interacting with the rock is abrasive enough relative to the resistance offered by the rock to cause it to scour in a layer-by-layer fashion. An example of abrasion damage on concrete slabs has been observed at Gebidem Dam (Switzerland).

## COMBINED APPLICATION OF METHODS

Rock scour by abrasion can currently only be analyzed by making use of laboratory testing. This type of scour is currently believed to be less prevalent than scour by sudden block removal (dynamic impulsion), brittle fracture, and fatigue failure (subcritical failure). The latter three scour mechanisms can be separately analyzed by making use of the CSM developed by Bollaert (2002, 2004), while the EIM only provides a global assessment of rock scour.

It has been found that scour analyses using the EIM and the CSM respectively provide comparable global results (Bollaert 2002; Bollaert and Annandale, 2004; George and Annandale, 2006). Comparison leads to the conclusion that the EIM predicts scour in a global manner, inherently accounting for all possible mechanisms of break-up but without any noticeable insight into which mechanism is most feasible. On the other hand, the CSM allows a much more detailed description of the type of scour as well as the scour rate.

Knowledge of how scour will occur is important for development of economical design solutions. For example, if a rock scour analysis concludes that scour will occur by brittle fracture and dynamic impulsion only, it is necessary to develop mitigation measures to protect against scour. If, in another case, an analysis indicates that scour will occur by subcritical failure (fatigue) only, it might not be necessary to design mitigation measures. This might be the case if it is found that the rock will only scour after, say, 30 days of continuous submission to fluctuating pressures. If the design flood would only submit the rock to, say, 10 hours of fluctuating pressures, the rock is unlikely to experience damage during such a flood, and protection against scour may not be warranted.

## THE EIM

Hydraulic erodibility of natural and engineered earth materials can be evaluated in terms of a rational correlation between the stream power of flowing water and a geomechanical index. The relative ability of earth materials to resist scour can be characterized in terms of an erodibility index,  $K$ . The parameters of the index represent key material properties including mass strength, block/particle size, discontinuity/interparticle bond shear strength, and shape and orientation relative to flow. The relative magnitude of erosive power of flowing water as used in this method is represented by the stream power of flowing water.

Annandale (1995) developed a scour threshold relationship based on this approach by analyzing 137 field

observations of spillway performance collected by the U.S. Department of Agriculture; observations at Bartlett Dam, Salt River Project, Arizona; and at four South African dams and published data related to initiation of sediment motion. This threshold relationship was established for a wide range of earth materials, ranging from noncohesive granular soils, cohesive soils, vegetated soils, and rock. The information presented in this appendix focuses on the erodibility of rock only. Application of this method to solve scour of other earth materials is discussed in Annandale (2006).

The observation that turbulence in flowing water is related to both energy loss and pressure fluctuations provides a convenient way to quantify the relative magnitude of the erosive capacity of water. This can be done by calculating the rate of energy dissipation (also referred to as stream power in this appendix), which has been shown to correlate to the relative magnitude of pressure fluctuations (Annandale 1995, 2006).

The correlation between rate of energy dissipation ( $P$ ) and a material's resistance to erosion ( $f(K)$ ) can be expressed by the function

$$P = f(K) \quad (\text{A-4})$$

at the scour threshold. If  $P > f(K)$ , the scour threshold is exceeded, and the material is expected to erode. Conversely, if  $P < f(K)$ , the erodibility threshold is not exceeded, and erosion is not expected. The relationship between stream power and the Erodibility Index  $K$  is presented in Figure A-5. The data shown on the figure represent events that experience scour when subjected to flowing water and events that did not experience scour. The relationship between these values indicates a region that separates events that experienced scour from those that did not experience scour. The dashed line in this region indicates the possible location of the erosion threshold. When assessing rock scour potential, this graph is used to relate stream power to the relative ability of the rock to resist scour. If the relationship between stream power and the erodibility index for a case under consideration is located above the erosion threshold line, it is concluded that scour could occur. Alternatively, if it is located below the threshold line, it is concluded that scour is unlikely. Methods to quantify the relative magnitude of the erosive capacity of water and the relative ability of rock to resist scour are presented in the following sections.

## Stream Power

A primary objective in the development of a method to calculate the relative magnitude of the erosive power of water associated with the EIM is to select parameters that reasonably represent the relative magnitude of the fluctuating pressures causing scour that can concurrently be calculated with ease. Rate of energy dissipation (or stream power) is such a parameter, and its selection can be justified per the following

**Fig. A-5.** Example of scour estimation at a dam foundation resulting from overtopping by combined use of the EIM and CSM methods. Both methods are used to calculate the total scour extent. The CSM method moreover identifies the scour type (i.e., whether scour occurs by block removal, brittle fracture or fatigue failure) as well as the rate of scour.

reasoning. Turbulence causes both pressure fluctuations and energy loss, and increases in turbulence intensity concurrently result in increased rates of energy dissipation and increases in the magnitude of peak fluctuating pressures. Estimates of the rate of energy dissipation could therefore be expected to represent the relative magnitude of fluctuating pressure and thus the erosive power of the water.

Annandale (2006) presents a suite of equations to calculate the rate of energy dissipation for various flow conditions encountered in practice, including headcut formation, hydraulic jumps, channel grade change, and open channel flow. All these equations are based on a general equation that represents the rate of energy dissipation per unit area. If the energy loss is  $\Delta E$  per unit length of flow ( $L$ ), the unit discharge is  $q$ , average flow velocity is  $v$ , and flow depth is  $D$ , the rate of energy dissipation per unit area of the channel bed can be expressed as

$$P = \gamma \cdot q \cdot \Delta E / L = \gamma \cdot v \cdot D \cdot S_f = \tau \cdot v \quad (\text{A-5})$$

where  $\tau$  = shear stress,  $S_f$  = energy slope.

The equations for particular flow conditions are not repeated in this appendix but can be found in the cited reference.

### Erodibility Index

The erodibility index  $K$  (Eq. [A-6]) represents a measure of an earth material's resistance to erosion. The index is based on Kirsten's ripability index, for which a rational relationship was established between flywheel power of excavation equipment and the ripability of earth materials (Kirsten 1982, 1988). The primary geological parameters that are used to

calculate the erodibility index are mass strength, rock block size, discontinuity/interparticle bond shear strength, and shape and orientation of rock blocks relative to the direction of flow. The index is calculated as

$$K = M_s \cdot K_b \cdot K_d \cdot J_s \quad (\text{A-6})$$

where  $M_s$  = mass strength number,  $K_b$  = block size number,  $K_d$  = discontinuity shear strength number, and  $J_s$  = relative ground structure number. All parameters can be assessed rapidly in the field by using simple identification tests and measurements. The paper by Kirsten (1982) provides standard tables quantifying these geological parameters that are also presented in Tables A-1 through A-5.

The value of  $M_s$  for rock can be determined by equating it to the unconfined compressive strength (UCS) in megapascal (MPa) if the strength is greater than 10 MPa and equal to  $0.78 \times UCS^{1.05}$  when the strength is less than 10 MPa and then multiplying it with the coefficient of relative density. The latter is the ratio of a material's unit weight over  $27.0 \text{ kN/m}^3$ . Alternatively, if the unconfined compressive strength is unknown, field descriptions of the rock can be used to select values of  $M_s$  from Table A-1.

The block size number,  $K_b$ , is calculated as follows:

$$K_b = \frac{RQD}{J_n} \quad (\text{A-4})$$

where  $RQD$  = rock quality designation, a standard parameter in drill core logging (Deere and Deere 1988), and  $J_n$  = the joint set number, which is a function of the number of joint sets in a rock mass (Table A-2).  $K_b$  ranges between 1 and 100 for rock.

**Table A-1 Mass Strength Number for Rock ( $M_s$ )**

Hardness	Identification in profile	Unconfined compressive strength (MPa)	Mass strength number ( $M_s$ )
Very soft rock	Material crumbles under firm (moderate) blows with sharp end of geological pick and can be peeled off with a knife; is too hard to cut tri-axial sample by hand.	Less than 1.7	0.87
		1.7–3.3	1.86
Soft rock	Can just be scraped and peeled with a knife; indentations 1 mm to 3 mm show in the specimen with firm (moderate) blows of the pick point.	3.3–6.6	3.95
		6.6–13.2	8.39
Hard rock	Cannot be scraped or peeled with a knife; handheld specimen can be broken with hammer end of geological pick with a single firm (moderate) blow.	13.2–26.4	17.70
Very hard rock	Handheld specimen breaks with hammer end of pick under more than one blow.	26.4–53.0	35.0
		53.0–106.0	70.0
Extremely hard rock	Specimen requires many blows with geological pick to break through intact material.	Larger than 212.0	280.0

**Table A-2 Joint Set Number  $J_n$** 

Number of joint sets	Joint set number ( $J_n$ )
Intact, no or few joints/fissures	1.00
One joint/fissure set	1.22
One joint/fissure set plus random	1.50
Two joint/fissure sets	1.83
Two joint/fissure sets plus random	2.24
Three joint/fissure sets	2.73
Three joint/fissure sets plus random	3.34
Four joint/fissure sets	4.09
Multiple joint/fissure sets	5.00

The discontinuity or interparticle shear strength number,  $K_d$ , is determined by the ratio  $J_r/J_a$ , where  $J_r$  = joint roughness number and  $J_a$  = joint alteration number. Joint roughness refers to the roughness condition of the facing walls of a discontinuity. The joint alteration number reflects the weathering condition of the joint face material. Shear strength of a discontinuity is directly proportional to the shear strength of the gouge and inversely proportional to the degree of alteration of the joint wall material. Values for the joint roughness and joint alteration numbers are found in Tables A-3 and A-4.

In addition to representing the effective dip of the least favorable discontinuity with respect to the flow, the relative ground structure number,  $J_s$ , accounts for the shape of the material units that affects the ease with which the stream can penetrate the ground and dislodge individual units. The effective dip is the apparent dip of a discontinuity adjusted for the slope of the stream channel relative to the direction of flow. Table A-5 contains values of the relative ground structure number for various ratios of joint spacing.

## Scour Assessment

The extent (depth) of scour is determined by comparing the stream power that is *available* to cause scour with the stream power that is *required* to scour the earth material under consideration. The available stream power represents the erosive power of the water discharging over the earth material, whereas the required stream power is the stream power that is required by the earth material for scour to commence. If the available stream power is exactly equal to the required stream power, the material is at the threshold of erosion. In cases where the available stream power exceeds the required stream power, the material will scour. If the available stream power is less than the required stream power, the rock will remain intact.

Figure A-7 shows how the available and required stream power, both plotted as a function of elevation beneath the original ground surface, are compared to determine the extent of scour. Scour will occur when the available stream power exceeds the required stream power. Once the maximum scour elevation is reached the available stream power is less than the required stream power, and scour ceases.

The required stream power is determined by first indexing geologic core or borehole data. The values of the erodibility index thus determined will vary as a function of elevation, dependent on the variation in material properties. Once the index values at various elevations are known, the required stream power is determined from Figure A-6. The available stream power is calculated as a function of elevation by making use of methods presented in Annandale (2006).

## THE CSM

Bollaert (2002, 2004) developed a physically based engineering model for prediction of the ultimate scour depth of fissured

**Table A-3 Joint Roughness Number  $J_r$** 

Joint separation	Condition of joint	Joint roughness number
Joints/fissures tight or closing during excavation	Discontinuous joints/fissures	4.0
	Rough or irregular, undulating	3.0
	Smooth undulating	2.0
	Slickensided undulating	1.5
	Rough or irregular, planar	1.5
	Smooth planar	1.0
	Slickensided planar	0.5
Joints/fissures open and remain open during excavation	Joints/fissures either open or containing relatively soft gouge of sufficient thickness to prevent joint/fissure wall contact on excavation	1.0
	Shattered or microshattered clays	1.0

**Table A-4 Joint Alteration Number  $J_a$** 

Description of gouge	Joint alteration number (J.) for joint separation (mm)		
	1.0 <sup>1</sup>	1.0–5.0 <sup>2</sup>	5.0 <sup>3</sup>
Tightly healed, hard, nonsoftening impermeable filling	0.75	—	—
Unaltered joint walls, surface staining only	1.0	—	—
Slightly altered, nonsoftening, noncohesive rock mineral or crushed rock filling	2.0	2.0	4.0
Nonsoftening, slightly clayey noncohesive filling	3.0	6.0	10.0
Nonsoftening, strongly overconsolidated clay mineral filling, with or without crushed rock	3.0*	6.0**	10.0
Softening or low friction clay mineral coatings and small quantities of swelling clays	4.0	8.0	13.0
Softening moderately overconsolidated clay mineral filling, with or without crushed rock	4.0*	8.0**	13.0
Shattered or microshattered (swelling) clay gouge, with or without crushed rock	5.0*	10.0**	18.0

*Notes:*<sup>1</sup> Joint walls effectively in contact.<sup>2</sup> Joint walls come into contact after approximately 100-mm shear.<sup>3</sup> Joint walls do not come into contact at all on shear.<sup>4</sup> \*\* Also applies when crushed rock occurs in clay gouge without rock wall contact.

**Table A-5 Relative Ground Structure Number  $J_s$** 

Dip direction of closer spaced joint set (degrees)	Dip angle of closer spaced joint set (degrees)	Ratio of joint spacing, $r$			
		1:1	1:2	1:4	1:8
180/0       In direction of stream flow	90	1.14	1.20	1.24	1.26
	89	0.78	0.71	0.65	0.61
	85	0.73	0.66	0.61	0.57

	-50	0.53	0.56	0.59	0.61
	-60	0.63	0.68	0.71	0.73
	-70	0.84	0.91	0.97	1.01
	-80	1.26	1.41	1.53	1.61
	-85	1.39	1.55	1.69	1.77
	-89	1.50	1.68	1.82	1.91
	-90	1.14	1.20	1.24	1.26
	180/0	1.14	1.20	1.24	1.26

Notes:

<sup>1</sup> For intact material, take  $J_s = 1.0$

<sup>2</sup> For values of  $r$  greater than 8, take  $J_s$  as for  $r = 8$ .

and jointed rock. The CSM incorporates two major failure modes of fissured and jointed rock. The first mode, described by the comprehensive fracture mechanics (CFM) method, determines the ultimate scour depth by expressing instantaneous or time-dependent crack propagation. The second mode, described by the dynamic impulsion (DI) method, determines ultimate scour depth by calculation of the ejection of rock blocks due to sudden net uplift impulsions. The CFM method is applied principally to fissured rock and the DI method to jointed rock. However, individual rock blocks in a jointed rock mass can contain fissures that can fail in brittle fracture or by fatigue, which can lead to formation of smaller rock blocks that can be removed by dynamic impulsion with less effort. Hence, both methods are strongly related to each other.

The structure of the CSM, specifically developed for predicting scour by plunging or submerged jets, distinguishes between three modules: the falling jet, the plunge pool, and the rock mass. The latter module allows simulation of the previously mentioned failure mechanisms, that is,

brittle fracture, failure by fatigue, and dynamic impulsion. Emphasis is placed on the description of physical parameters that are necessary to accurately describe the different processes. This is presented in a way that allows practicing engineers to implement the concepts while still honoring the basic principles of physics.

### The Module of the Falling Jet

This module describes how the hydraulic and geometric characteristics of the jet are transformed from its point of issuance from the dam down to the plunge pool (Figure A-8). Three main parameters characterize the jet at issuance: the velocity  $V_j$ , the diameter (or thickness)  $D_j$ , and the initial jet turbulence intensity  $Tu$  (Bollaert, 2004a).

The trajectory calculation for the jet through the atmosphere is based on ballistics and drag forces encountered by the jet as it plunges through the air and will not be further outlined herein. The basic output is the impingement

Fig. A-6. Scour threshold relating stream power and the Erodibility Index (Annandale 1995).

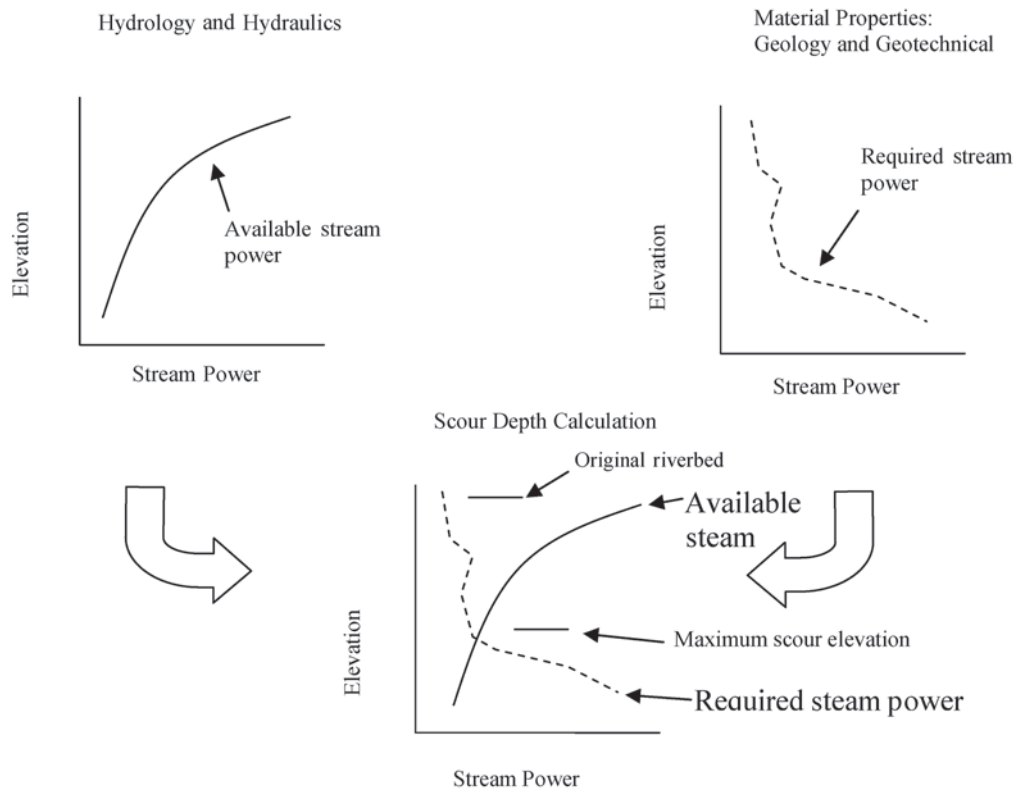

Fig. A-7. Determination of the extent of scour by comparing available and required stream power.

**Fig. A-8.** Definition sketch of the main parameters of a free overfall jet plunging into a pool and breaking up the rock mass (Bollaert 2004a).

location of the jet at impact, the jet trajectory length  $L$ , and the jet velocity at impact  $V_j$ . Knowledge of the jet trajectory length  $L$  is used to determine the contraction of the jet due to gravitational acceleration. This allows calculation of the jet diameter or thickness at impact  $D_j$ . This diameter is essential to determine the  $Y/D_j$  ratio in the plunge pool.

Second, the turbulence intensity  $Tu$  defines the lateral spread of the jet  $\delta_{out}$  (Eq. [7]; Ervine et al. 1997). Superposition of the outer spread to the initial jet diameter  $D_i$  results in the outer jet diameter  $D_{out}$ , which is used to determine the extent of the zone at the water–rock interface where severe pressure damage may occur. The corresponding expressions are

$$\frac{\delta_{out}}{X} = 0.38 \cdot Tu \quad (A-7)$$

$$D_j = D_i \cdot \sqrt{\frac{V_i}{V_j}} \quad (A-8)$$

$$V_j = \sqrt{V_i^2 + 2gZ} \quad (A-9)$$

$$D_{out} = D_i + 2 \cdot \delta_{out} \cdot L \quad (A-10)$$

in which  $\delta_{out}$  is the half angle of outer spread,  $X$  the longitudinal distance from the point of issuance, and  $Z$  the vertical fall distance of the jet. When using Equation (A-7), it is important to note that the angle  $\delta_{out}$  is in degrees and  $X$  in meters.

The turbulence intensity  $Tu$  is dimensionless, expressed as a decimal. Typical outer angles of jet spread are 3% to 4% for rough turbulent jets (Ervine and Falvey 1987). The corresponding inner angles of jet spread are 0.5% to 1%. When

investigating scour in practice,  $Tu$  is usually unknown. Under such circumstances, an estimation can be made based on the type of outlet structure (Table A-6, Bollaert 2002, 2004a).

This classification constitutes a simplification of reality.  $Tu$  may depend largely on specific geometric characteristics of the outlet, the flow pattern immediately upstream of the outlet, and so on. Whenever possible, all these aspects should be accounted for, and appropriate engineering judgment is necessary.

Furthermore, the angle of the jet at its point of impact is neglected in the present analysis, which is reasonable for impingement angles that are close to the vertical (70–90°). For smaller impingement angles, it is proposed to use the same hydrodynamic parameters as for vertical impingement but to redefine the water depth in the pool  $Y$  as the exact trajectory length of the jet through the water cushion and not as the vertical difference between water level and pool bottom.

Calculation of the other relevant variable when analyzing the plunging jet can be accomplished with Equations (A-8) to (A-10).

It is obvious that this module can be replaced by any type of turbulent flow structure that allows determining its main hydraulic and geometric characteristics (diameter, width, velocity, turbulence intensity). Types of flow already applicable are hydraulic jumps, vertical and horizontal river constrictions (abutments, sills, etc.), horizontal jet flows, etc. The module is actually being updated to account for bridge pier scour situations.

### Plunge Pool Module

The second module refers to the hydraulic and geometric characteristics of the plunge pool downstream of the dam and defines the statistical characteristics of the hydrodynamic loading at the water–rock interface. The water depth  $Y$  in the plunge pool is an essential parameter of the scour model, because it defines the diffusion length of the impacting turbulent flow. During scour formation, the water depth  $Y$  has to be increased with the depth of the already formed scour  $h$ . Prototype observations indicate possible mounding at the downstream end of the pool. The mounding of rock results when the detached rock blocks are swept away and deposited immediately downstream. This can raise

**Table A-6** Estimation of the Initial Jet Turbulence Intensity  $Tu$  Based on the Type of Outlet Structure (Bollaert 2002b)

Type of outlet	$Tu$
1. Free overfall	0–3 %
2. Ski-jump outlet	3–5 %
3. Intermediate outlet	3–8 %
4. Bottom outlet	3–8 %

the tailwater level. The effect is not described in the present model but can easily be added to the computations.

Knowledge of the water depth  $Y$  and the jet diameter at impact  $D_j$  (defined in the falling jet module) determines the ratio of water depth to jet diameter at impact  $Y/D_j$ . This ratio is directly related to diffusion characteristics of the jet.

The root-mean-square values of the pressure fluctuations at the water-rock interface, expressed by the  $C'_{pa}$  pressure coefficient, depend on the  $Y/D_j$  ratio and on the initial turbulence intensity  $Tu$ . Experimental data measured at near-prototype jet velocities (Bollaert 2002b) have been approximated by a polynomial regression (Eq. [12]) and are presented in Table A-7 for different turbulence intensity levels. Each curve corresponds to a degree of jet stability. The key issue is that  $Tu$  is considered to be fully representative of low-frequency instabilities of the jet. The curves are valid up to a  $Y/D_j$  ratio of 18 to 20. For higher ratios, the  $C'_{pa}$  value that corresponds to a ratio of 18 to 20 should be used. The range of values in Table A-7 is representative of the range of jet characteristics encountered in practice. Compact jets are smooth as they fall through the atmosphere, with no significant source of turbulence leading to low-frequency instability. Very turbulent jets are characterized by  $Tu$  values greater than 5%. In between these two outer bounds, other curves have been defined. They are applicable to low and moderately turbulent jets:

$$C_{pa} = 38.4 \cdot (1 - \alpha_i) \cdot \left( \frac{D_j}{Y} \right)^2 \quad \text{for } Y/D_j > 4-6 \quad (\text{A-11})$$

$$C_{pa} = 0.85 \quad \text{for } Y/D_j < 4-6 \quad (\text{A-12})$$

$$\alpha_i = \frac{\beta}{1 + \beta} \quad (\text{A-13})$$

$$C_{pa} = a_1 \cdot \left( \frac{Y}{D_j} \right) + a_2 \cdot \left( \frac{Y}{D_j} \right)^2 + a_3 \cdot \left( \frac{Y}{D_j} \right)^3 + a_4 \quad (\text{A-14})$$

**Table A-7 Polynomial Coefficients and Regression Coefficient for Different Turbulence Intensities of Jets (Bollaert 2002b; Bollaert & Schleiss 2005)**

$Tu$ [%]	$a_1$	$a_2$	$a_3$	$a_4$	Type of Jet
<1	0.000220	-0.0079	0.0716	0.000	Compact
1-3	0.000215	-0.0079	0.0716	0.050	Low turbulence
3-5	0.000215	-0.0079	0.0716	0.100	Moderate turbulence
>5	0.000215	-0.0079	0.0716	0.150	High turbulence

The nondimensional mean dynamic pressure coefficient  $C_{pa}$ , defined by Equations (A-11) to (A-13), decreases with increasing air content in the plunge pool and with increasing root-mean-square values of pressure fluctuation. The fluctuating dynamic pressure coefficient is calculated with Equation (A-14).

Similar to the falling jet module, any other type of turbulent flow impacting the water-rock interface can be used as input to the model, provided that the statistical parameters of the pressure fluctuations can be reasonably described (mean, RMS, extreme values).

## Rock Mass Module

The plunge pool module defines the principal parameters of the hydrodynamic loading at the water-rock interface. This is used as input for determination of the hydrodynamic loading inside open- and closed-ended rock joints. The governing parameters are defined as (Fig. A-4, Bollaert 2002, 2004a)

1. maximum dynamic pressure coefficient  $C_p^{\max}$
2. characteristic amplitude of pressure cycles  $\Delta p_c$
3. characteristic frequency of pressure cycles  $f_c$
4. maximum dynamic impulsion coefficient  $C_I^{\max}$

The first parameter is relevant to brittle propagation (immediate failure) of closed-ended rock joints. The second and third parameters are used to calculate time-dependent failure (failure by fatigue) of closed-ended rock joints. The fourth parameter is used to define dynamic uplift of rock blocks formed by open-ended rock joints.

The maximum dynamic pressure coefficient  $C_p^{\max}$  is obtained through multiplication of the root-mean-square pressure coefficient  $C'_{pa}$  with the amplification factor  $\Gamma^+$  and by superposition with the mean dynamic pressure coefficient  $C_{pa}$ . The product of  $C'_{pa}$  times  $\Gamma^+$  results in a pressure coefficient  $C_{pa}^+$ . The distinction between  $C_{pa}$  and  $C_{pa}^+$  is necessary because the amplification of the root-mean-square pressures influences only the fluctuating part of the dynamic pressures. As such, the maximum pressure value is written (Bollaert 2002) as

$$P_{\max} [\text{Pa}] = \gamma \cdot C_p^{\max} \cdot \frac{\phi \cdot V_j^2}{2g} = \gamma \cdot (C_{pa} + \Gamma^+ \cdot C'_{pa}) \cdot \frac{\phi \cdot V_j^2}{2g} \quad (\text{A-15})$$

As a first approximation, the  $\phi$  value for nonuniform velocity profiles is chosen equal to one. The main uncertainty of Equation (A-15) lies in the amplification factor  $\Gamma^+$ . Near-prototype scaled experiments resulted in the relationship for the amplification factors shown in Figure A-9.

The characteristic amplitude  $\Delta p_c$  of the pressure cycles is determined by the characteristic maximum and minimum pressures of the cycles. The minimum pressures are relatively constant and always close to standard atmospheric pressure. The maximum pressures are chosen equal to the  $C_p^{\max}$  value.

**Fig. A-9.** Amplification factor  $\Gamma^+$  as a function of  $Y/D_f$ . The measured data are circumscribed by a maximum curve and a minimum curve, and represent core (+) and developed jet impact (♦) (Bollaert 2002).

The characteristic frequency of the pressure cycles  $f_c$  follows the assumption of a perfect open-closed resonator system and, thus, depends on the air concentration in the joint  $\alpha_i$  and on the length of the joint  $L_f$ . The air content inside the joints can be directly related to the air content in the plunge pool (Bollaert and Schleiss 2003). This air content depends on the velocity of the jet at impact and on the plunge pool depth. The joint length depends on the distance between the different joint sets. For practice, a preliminary estimate of  $f_c$  can be made by assuming a mean celerity of 100 to 200 m/second (depending on the concentration of free air in the water) and joint lengths of typically 0.5 to 1 m. This results in frequencies of 25 to 100 Hz.

Besides the pressure loading inside the rock joints, the resistance of the rock to failure also has to be determined. The cyclic character of the pressure loading generated by the impact of a high-velocity jet on a closed-ended rock joint makes it possible to describe joint propagation by fatigue stresses occurring at the tip of the joint. This can be defined by linear elastic fracture mechanics (LEFM), assuming a perfectly linear elastic, homogeneous, and isotropic rock mass (Bollaert and Schleiss 2005). Despite these simplifying assumptions, its application to fractured rock becomes quite complicated when accounting for all the relevant parameters (Atkinson 1987; Whittaker et al. 1992; Andreev 1995).

Bollaert (2002, 2004a) developed a simplified methodology known as the comprehensive fracture mechanics (CFM) method for investigating rock scour that honors the underlying theory. Using this approach, pure tensile hydrodynamic loading inside rock joints is described by a stress intensity factor  $K_I$ . This parameter represents the amplitude of the rock mass stresses that are induced by the water pressures at the tip of the joint. The corresponding resistance to crack propagation offered by the rock mass is expressed by its fracture toughness  $K_{Ic}$ .

The challenge is to develop a comprehensive and physically representative implementation of the complex and dynamic conditions encountered in scour of fractured rock. Crack propagation distinguishes between brittle (or instantaneous) crack propagation and time-dependent crack propagation, subject to failure by fatigue. The former occurs when the stress intensity factor is equal to or greater than the fracture toughness of the material. The latter occurs when the maximum possible water pressure results in a stress intensity that is less than the material's resistance. Cracks can then be propagated by fatigue. Failure by fatigue depends on the frequency and the amplitude of the load cycles. The implementation of the fracture mechanics approach as it relates to hydrodynamic loading consists of a transformation of the water pressures  $\sigma_{\text{water}}$  in the joints into rock mass stresses at the joint end. The approach that was followed is based on the following simplifying assumptions: 1) the dynamic character of the loading has no influence, 2) the water pressure distribution inside the joints is constant, 3) only simple geometrical joint configurations are considered, and 4) joint surfaces are planar.

These stresses are characterized by the stress intensity factor  $K_I$  as follows:

$$K_I = P_{\max} \cdot F \cdot \sqrt{\pi \cdot L_f} \quad (\text{A-16})$$

in which  $K_I$  is in  $\text{MPa}\sqrt{\text{m}}$  and  $P_{\max}$  in MPa. The boundary correction factor  $F$  depends on the type of crack and on its persistency, that is, its degree of cracking defined as  $a/B$  or  $b/W$  in Figure A-9. This figure presents three basic configurations for partially jointed rock, and simplifying assumptions are that the water pressure in the joints are assumed to be applied from outside, and no geometries with multiple joints are considered.

The choice of the most relevant geometry depends on the type and the degree of jointing of the rock. The first type of crack shown in Figure A-9 is of semielliptical or semi-circular shape and, pertaining to the laterally applied water pressure  $P_{\max}$ , partially sustained by the surrounding rock mass in the two horizontal directions. As such, it is the geometry with the highest possible support of surrounding rock. Appropriate stress intensity factors should be used in case of low to moderately jointed rock. The second type of crack is a single-edged notch that is of a two-dimensional nature. Support from the surrounding rock mass is exerted only perpendicular to the plane of the notch, and, as a result, stress intensity factors will be substantially higher than for the first case. Thus, this crack type is relevant to significantly to highly jointed rock. The third geometry type is center cracked throughout the rock. Similar to the single-edge notch, only one-sided rock support can be accounted for. This support, however, should be slightly higher than that of the single-edged notch. The second and third configurations correspond to a partial destruction of the first one. They are more sensitive to stresses and have to be used for significant to highly jointed rock.

**Fig. A-10.** Main geometrical configurations of jointed rock: (a) semi-elliptical (EL) joint; (b) single edge (SE) joint; (c) center-cracked (CC) joint (Bollaert 2004a).

A summary of  $F$  values is presented in Figure A-10. For practical purposes, values of  $a/B$  or  $b/W$  greater than or equal to 0.5 are considered to correspond to completely broken-up rock; that is, the DI method is considered to be more applicable than the CFM method. For values of 0.1 or less, it is considered that a pure tensile strength approach is more plausible than a fracture mechanics approach. The  $F$  values for fissured rock where the CFM is assumed relevant are those associated with the range of  $a/B$  or  $b/W$  values between 0.20 and 0.40. This determination also depends on the type and number of joint sets, the degree of weathering, joint spacing, and so on.

The fracture toughness  $K_{Ic}$  depends on a wide range of parameters. Its determination has been simplified below by relating it to tensile strength  $T$  or unconfined compressive strength UCS and the in-situ stress field of the rock mass ( $\sigma_c$ ). Based on a regression of data available in the literature,

the in-situ fracture toughness  $K_{Iins}$  can be defined as (Bollaert 2002):

$$K_{Iins, T} = (0.105 \text{ to } 0.132) \cdot T + (0.054 \cdot \sigma_c) + 0.5276 \quad (\text{A-17})$$

$$K_{Iins, UCS} = (0.008 \text{ to } 0.010) \cdot UCS + (0.054 \cdot \sigma_c) + 0.42 \quad (\text{A-18})$$

The units of  $T$ ,  $UCS$ , and  $\sigma_c$  are expressed in MPa.

Instantaneous or brittle crack propagation will occur if

$$K_I \geq K_{Iins} \quad (\text{A-19})$$

If this is not the case, crack propagation is time dependent. This is expressed by an equation of the type originally proposed to describe fatigue crack growth in metals (Bollaert 2002, 2004a):

$$\frac{dL_f}{dN} = C_r \cdot (\Delta K_I / K_{Ic})^{m_r} \quad (\text{A-20})$$

in which  $L_f$  is the joint length and  $N$  the number of pressure cycles.  $C_r$  and  $m_r$  are rock material parameters that can be determined by fatigue tests and,  $\Delta K_I$  is the difference of maximum and minimum stress intensity factors at the joint tip. To implement time-dependent crack propagation into a comprehensive engineering model, the parameters  $m_r$  and  $C_r$  are summarized at Table A-8 for different rock types. First-hand calibration of these parameters resulted in an  $m_r$  value of 10 to 12 and a  $C_r$  value of  $1\text{E-}07$  for granite rock. Hence, while the  $m_r$  values can reasonably be used for practical purposes, the value of the  $C_r$  coefficients appears to be not as well defined. It could be one to two orders of magnitude higher than the theoretically proposed values in Table A-8.

The fourth hydrodynamic parameter is the maximum dynamic impulsion  $C_I^{\max}$  in an open-end rock joint (underneath a rock block). This parameter is obtained by a time integration of the net forces on the rock block (Bollaert 2002, 2004a):

$$I_{\Delta \text{tpulse}} = \int_0^{\Delta \text{tpulse}} (F_u - F_o - G_b - F_{sh}) \cdot dt = m \cdot V_{\Delta \text{tpulse}} \quad (\text{A-21})$$

**Fig. A-11.** Comparison of different boundary correction factors  $F$  for the computation of the stress intensity at the tip of a rock joint (Bollaert 2004a).

**Table A-8 Fatigue Exponent  $m_r$  and Fatigue Coefficient  $C_r$  for Different Rock Types (Bollaert 2002b)**

Type of Rock	Exponent $m_r$	Coefficient $C_r$
Arkansas novaculite	0.5	1.0E-8
Mojave quartzite	10.2–12.9	3.0E-10
Tennessee sandstone	4.8	4.0E-7
Solenhofen limestone	8.8–9.5	1.1E-8
Falerans micrite	8.8	1.1E-8
Tennessee marble	3.1	2.0E-6
Westerley granite	11.8–11.9	8.0E-10
Yugawara andesite	8.8	1.1E-8
Black gabbro	9.9–12.2	4.0E-9 to 5.0E-10
Ralston basalt	8.2	1.8E-8
Whin Sill dolerite	9.9	4.0E-9

in which  $F_u$  and  $F_o$  are the dynamic forces under and over the block,  $G_b$  is the immersed weight of the rock block, and  $F_{sh}$  represents the shear and interlocking forces. The shape of a block and the type of rock define the immersed weight of the block. The shear and interlocking forces depend on the joint pattern and the in-situ stresses. As a first approximation, they can be neglected by assuming that progressive dislodgment and opening of the joints occurred during the breakup phase of the rock mass. The pressure field over the block is governed by the turbulent shear layer of the jet. The pressure field under the block corresponds to transient pressure waves inside open-ended rock joints.

The pressures and forces are considered independent of block movement, which is a simplification of reality because shear and interlocking forces can vary considerably, depending on changes in block position and orientation. These forces depend on the points of contact between the blocks and on the in-situ horizontal stress field and are difficult to assess. Also, the pressure forces under the block may decrease because of the cavity that is formed once the latter starts moving. This, however, is difficult to formulate. As a firsthand approximation, the transient pressures under the block are assumed to be independent of the movement of the block. This seems plausible for a high peak pressure value during a small time interval but is less evident for lower pressures during a relatively long time period.

The first step is to define the instantaneous differences in forces over and under the block. By integrating the net uplift forces over a small time period  $\Delta t$ , the net impulses  $I$  and a maximum net impulse  $I^{\max}$  can be obtained.

Second,  $I^{\max}$  is made nondimensional by defining the impulse as the product of a net force and a time period. For this, the net force is firstly transformed into a pressure. This means that the problem is solved for a unit surface area of

the block ( $1 \text{ m}^2$  depending on the units). This pressure can then be made nondimensional by dividing it by the incoming kinetic energy  $\phi \cdot V^2/2g$  as was done for the surface pressures. This results in a net uplift pressure coefficient  $C_{up}$ . The time period is made nondimensional by the travel period characteristic for pressure waves inside open-ended rock joints, that is,  $T = 2 \cdot L_j/c$ , in which  $L_j$  stands for the total joint length and  $c$  for the mean wave celerity. This results in a time coefficient  $T_{up}$ . Following this line of reasoning, a nondimensional impulsion coefficient  $C_i$  can be defined by the product  $C_{up} \cdot T_{up} = V^2 \cdot L/g \cdot c$  [m·s], presented in Figure A-12 as a function of  $Y/D_j$ .

The maximum net impulse  $I^{\max}$  is then obtained by multiplication of the value for  $C_i$  by  $V^2 \cdot L/g \cdot c$ . For jet velocities  $V_j$  greater than 20 m/second, a relatively constant value for  $C_i$  of 0.35 was observed during experiments (Bollaert 2002b). When expressed as a function of the  $Y/D_j$  ratio, the observable scatter is quite low. For core jets, a value of 0.6 to 0.8 seems plausible. For developed jets, the values are between 0.2 and 0.5. For practice, it is proposed to use the following polynomial expression:

$$C_i = 0.0035 \cdot \left( \frac{Y}{D_j} \right)^2 - 0.119 \cdot \left( \frac{Y}{D_j} \right) + 1.22 \quad (\text{A-22})$$

Failure of a rock block is then expressed by the displacement it undergoes due to the net impulse (Eq. [A-21]). This kinetic energy is transformed into a net uplift displacement  $h_{up}$ . The displacement that is necessary to eject a rock block from its matrix is difficult to define. It depends on the degree of interlocking of the blocks, which depends on the in-situ stress field of the rock mass. A very tightly jointed rock mass will need a displacement that is equal to or higher than the height of the block. Less tightly jointed rock will probably be uplifted more easily. The necessary displacement is a model parameter that needs to be calibrated. Firsthand calibrations performed on the well-known Cabora-Bassa scour

**Fig. A-12.** Non-dimensional impulsion for pressures inside open-end rock joints:  $C_i$  as a function of  $Y/D_j$ ; (Bollaert 2002).

case in Mozambique (Bollaert 2002) resulted in a necessary displacement equal to 0.20 times the block height.

## SUMMARY

The current state-of-the-art in rock scour technology is represented by the EIM (Annandale 1995, 2006) and the CSM (Bollaert 2002, 2004a; Bollaert and Schleiss 2005). Both these methods can be used to determine scour thresholds and extent. However, the CSM offers the additional ability to calculate rate of scour, which is particularly relevant in the case of fissured media, such as rock, concrete of stilling basins or strongly cohesive soils. Also, the DI method incorporated into the CSM allows describing sudden failure of anchored concrete slabs of stilling basins (Bollaert 2004b).

Comprehensive descriptions, examples, and case studies demonstrating application of these methods to assess scour of rock and other earth and engineered earth materials are presented in Bollaert (2004b) for dynamic uplift of stilling basin concrete slabs, in Bollaert (2005), (2006), Bollaert et al. (2006) and Bollaert and Mason (2006) for time-dependent scour of rock in plunge pools, and in Annandale (2006) for applications of the EIM.

Theory and applications of most other existing methods to predict rock scour can be found in Schleiss and Bollaert (2002).

The EIM is based on an erosion threshold that is defined by relating the relative magnitude of the erosive capacity of water (expressed in terms of steam power) to the relative ability of rock to resist scour (expressed in terms of a geomechanical index known as the erodibility index). The scour threshold relationship can be used concurrently with estimates of the rate of change of stream power in scour holes, as they develop, to calculate the extent of scour.

The CSM addresses two failure modes of rock scour: scour of fissured rock and scour of jointed and fractured rock. In both cases, the erosive power of water is represented by pressure fluctuations that can easily be calculated in practice for plunging jets using methods proposed by Bollaert (2002, 2004a) and for any other type of turbulent flow whenever mean and fluctuating pressure values can be readily estimated. As an example, the method has already been applied to hydraulic jumps and is actually being extended towards scour of bridge piers founded in rock. The ability of rock to resist scour when using the CSM is determined by making use of LEFM approaches in the case of fissured rock and a force balance in the case of jointed and fractured rock. Fissured rock can fail by brittle fracture or in a time-dependent fashion in subcritical failure mode. In the case of brittle fracture, the stress intensity within a fissure exceeds its fracture toughness. Time-dependent failure is subject to the amplitude of pressure fluctuations and its frequency and the ability of the rock to withstand these forces to prevent

fatigue failure. Dynamic impulsion of rock blocks occurs when net uplift pressures occur during a certain time interval. This impulsion method is also applicable to uplift of concrete slab linings.

Joint application of the EIM and CSM provides improved understanding of rock scour potential and extent. The geomechanical index used by the EIM provides a means to represent varying rock properties in an empirical manner using borehole and core data. It can be used to calculate scour potential and scour extent for varying flow conditions. The CSM uses basic fracture mechanics approaches and basic principles of physics to assess rock scour potential. In addition to providing the ability to assess scour threshold and extent, it can also be used to calculate the rate of rock scour. As such, it provides a much more detailed assessment of the phenomenon. A sound and complete parametric comparison of both models has been developed, allowing combined application in a fully consistent manner (Bollaert and Annandale 2004; Annandale and George 2006).

## APPENDIX B

### *Riprap Design*

*Steve Maynard and Charles Neill*

#### B.1 INTRODUCTION

##### B.1.1 Objective and Scope

The objective of this appendix is to present methods of designing riprap protection for rivers and open channels, including methods for determining stone sizes and other important factors. Design against wave action is not addressed in detail, but pertinent references are presented. References to more detailed design information are cited throughout the text.

Riprap, mostly in the form of natural stone, is one of the most commonly used materials for erosion protection in revetments, dikes and groins, toe protection, and other types of hydraulic structures. Riprap consists of loose, coarse elements whose stability is derived mainly from their submerged weight and in some cases from interlocking forces with adjacent elements. The use of stone to prevent erosion or provide stability has a long history. A still widely used equation by Isbash (1935), relating the required stone diameter to the square of the velocity, was apparently anticipated by a similar relationship presented by A. Brahms in 1753 (Forchheimer 1914).

##### B.1.2 Advantages and Disadvantages of Riprap

The primary advantages of riprap are flexibility, tendency to be self-healing, relative ease of construction, and extensive experience and design guidance to support its use. In many parts of the world, stone is one of the most abundant and long-lasting building materials: Roman aqueducts built in Spain in the first century A.D. are still standing today. Local failures are easily repaired if done promptly. To some, riprap has a reasonably natural appearance, and vegetation can be incorporated into it to provide a more natural appearance.

Disadvantages of riprap include its limited availability and relatively high cost in some areas, environmental restrictions on use, variations in quality, and difficulties of transport and placement in some locations.

##### B.1.3 Design Factors

Existing engineering literature on riprap focuses predominantly on the stable sizes required to resist movement from waves and currents. However, size is only one of many important aspects of riprap design. Thorne et al. (1995a) present five requirements in the design of riprap structures:

- The structure must be capable of withstanding the combined impact of all the forces of water flow and wave attack responsible for erosion and destabilization. This determination is based on such factors as stable stone size, lateral and vertical extent of protection, and alignment.
- The structure must be safe with regard to geotechnical stability, foundation settlement, and groundwater seepage.
- The structure must be built using sufficiently durable materials to retain the required erosion resistance and mass stability over the design life of the project.
- The ecological impacts and aesthetics of the structure have to be acceptable to today's society.
- The structure must be economical to build using available materials, equipment, and labor.

#### B.2 RIPRAP STRUCTURE TYPES

##### B.2.1 Bank Revetment

In many applications, riprap bank revetments have traditionally been placed from the toe of the slope to the top of the bank and have generally been kept relatively free of vegetation. There are exceptions, however. On some large rivers such as the Mississippi, riprap on the upper part of the bank is often combined with articulated concrete mattress on the lower portion, because of the difficulty and uncertainty of placing riprap underwater in large depths and of high velocities. On some small to intermediate streams, on the

other hand, riprap is used on the lower portion of the bank, with planted or adventitious vegetation on the upper portion (Fig. B-1). Reasons for these mixed treatments include reduced costs and environmental benefits.

Riprap bank revetment is also used to control the effects of rapid water-level drawdown caused by large-displacement vessels in confined navigation channels (Schulz 1995). In these applications, special attention must be paid to filters and to layering within the revetment. This is also important where revetments are designed to prevent piping due to water surcharge into streambanks, either from overbank sources or from rising river levels.

### B.2.2 Revetment Adjacent to Hydraulic Structures

Riprap is widely used to protect zones upstream and downstream of hydraulic structures such as spillways and outlet works. Many forms of energy dissipators use riprap downstream of the structures to resist streambed scour.

In some cases, riprap is used to form grade control structures on small to intermediate streams. Riprap is also widely used to prevent scour downstream of culverts.

### B.2.3 Toe Protection and Launchable Stone

Because of its flexibility and self-healing nature, riprap is often used as toe protection for bank revetments and other channel control works. Toe protection can be placed either down to the anticipated maximum scour depth, or in an enlarged section at the toe of the bank that will “launch” as scour occurs.

Various forms of launchable riprap used by the Corps of Engineers include weighted riprap toe, placed at the toe of the slope; trenchfill revetment, placed at the low-water reference

plane, often around midbank height; and windrow revetment, placed on the top of the bank. The launching action should be gradual, causing the rock to creep rather than avalanche down the slope—generally, this requires that launchable riprap be restricted to noncohesive beds and banks.

According to Simons (1995), the launchable stone method was first used for large alluvial rivers in India—“falling aprons” were described by Spring (1903). A somewhat similar concept in the wave environment is the dynamic revetment, designed to be reworked by wave activity into a stable, relatively flat slope (Ahrens 1995).

### B.2.4 Dikes, Groins, and Bendway Weirs

Riprap is often used to form or cover dikes, groins, and bendway weirs for river training and bank protection. In large rivers, these structures may be used to improve navigation depth and alignment. In major rivers such as the Mississippi, dikes are often constructed in stages, allowing the response of the river to be monitored at each stage.

Bendway weirs have been used on the Mississippi River to allow a wider navigation channel in bendways. They form submerged sills attached to the outer bank and angled upstream, with lengths of one-third to one-half of the channel width. On smaller streams, bendway weirs may be used for bank protection, to redirect flow away from eroding banks (Derrick and Northcutt 1996). A relatively short type of riprap groin called a hardpoint has been used to resist bank erosion in moderately curved reaches of the Missouri River (USACE 1981).

On rivers like the Mississippi, riprap gradation for these types of structure is generally “quarry-run”: the stone receives little quarry processing other than removing the largest sizes. Besides reducing costs, quarry-run riprap is considered by many to have the advantage of providing its own filter.

### B.2.5 Bridge Piers and Abutments (See Chapter 11)

### B.2.6 Wave Protection Including Boat Waves

Riprap design in the marine-wave environment (which has been the main focus of wave riprap research) is not covered in this appendix; however, some wave problems occur in the riverine environment. Riprap is frequently used to protect the upstream faces of dams from wind-generated waves and to protect navigation channels from boat-generated waves.

On most rivers, where fetch is generally limited, maximum short-period wave heights are caused by boat waves rather than wind waves. Few river revetments, however, have been constructed solely as protection against boat waves.

### B.2.7 Steep Chutes and Channels

The term “steep” refers here to slopes of 2 to 50%. Riprap applications on steep slopes include resisting the overtopping

**Fig. B-1.** Riprap protection on lower bank only. Photo by author.

of dams, levees, and roadways and capping and sealing waste-disposal impoundments.

On a steep chute, the flow remains supercritical for a significant distance down the slope. Supercritical flow has a tendency to concentrate in any locally weak spots, leading to local erosion and further concentration. Flow concentration may also result from less-than-ideal entrance conditions at the top of the slope. The problem of flow concentration and channelization can be addressed by using conservatively high estimates of unit discharge for design, with relatively uniform riprap gradations. If more widely graded rock is used, strict quality control is required to prevent size segregation during construction.

Grouted riprap is often used on steep slopes, especially if unit discharges are so high that stable riprap sizes become impracticably large.

### B.2.8 Bed Protection

Riprap may be used as bed protection for berthing and fleeting areas in navigation channels, around bridge foundations, and over pipelines and as a cap for contaminated sediments. Such protection may have to resist river and tidal flows, wave attack, and wash from vessel propellers and jets. Filters are normally incorporated into the design.

### B.2.9 River Closure Structures

River closures using dumped stone may proceed by horizontal closure, vertical closure, or a combination of both. The best-known publication is by Isbash (1935). Isbash's equation relating stone size to velocity still serves as a basis for riprap design in river closures and elsewhere.

## B.3 PHYSICAL CHARACTERISTICS OF RIPRAP STONE

### B.3.1 Rock Type/Sources

Riprap is mostly obtained from rock quarries. Other sources and substitutes include boulder-containing deposits of glacial and fluvial origin, broken concrete or soil cement, and slag from mining operations.

A European publication (CUR 1995) lists rock geological types used in hydraulic engineering, with their advantages and disadvantages. Geological rock type alone is not a useful guide to acceptability, because of the wide variation in properties within a given type.

### B.3.2 Testing/Sampling

Difficulties are often experienced in ensuring that in-place riprap meets specified size gradations. Compliance testing generally involves taking one sample per so many units of weight or volume placed. Laan (1995) states: "With large

batches a check may be carried out every 10,000 to 30,000 tonnes." The USACE (1990d) suggests a gradation test for every 10,000 cu yds (7651 cu m).

Another sampling question involves the size of each sample. In most sampling to check gradation, each particle is weighed rather than measured. According to (USACE 1990d), a sample should weigh about 100 times the average stone weight, assuming a maximum riprap size of about 0.9 m (36 inches). Laan (1995) recommends that samples of rock smaller than 300 kg maximum weight should contain a minimum of 200 pieces. These guidelines refer generally to relatively uniform riprap; widely graded mixtures may require a larger number of pieces. Additional information on testing and sampling is given by CUR (1995) and Thorne et al. (1995a).

### B.3.3 Stone Density

According to (USACE 1994), stone should have a specific weight of 2,400 kg/m<sup>3</sup> (150 lb/ft<sup>3</sup>) or greater. Most stone used for riprap has a unit weight between 2,500 and 2,700 kg/m<sup>3</sup>. The densities of various rock types are given in Table 2–2 of Chapter 2.

### B.3.4 Shape and Porosity

Riprap stone should be blocky rather than elongated, and angular rather than rounded. Tests by Olivier (1967) and by Abt and Johnson (1991) confirmed that for equivalent stability, rounded stone must be larger in dimension than angular stone.

Stones can be considered to have three mutually perpendicular axes:

- The major axis  $a$ , representing the maximum length.
- The intermediate axis  $b$ , defining the maximum width. (The major and intermediate axes define the orientation of the minor axis.)
- The minor axis  $c$ , defining the thickness. CUR (1995) defines  $c$  as the minimum distance between two parallel planes between which the stone could pass.

It is often specified that the ratio  $a/c$  should be less than 3, except for a small percentage of stones (USACE 1994; CUR 1995).

The relationship between stone size and weight may be computed on the basis of a sphere, or a cube, or halfway between—depending on typical shapes of the material in question.

Porosity is usually in the range of 40 to 45% for uniform riprap, and 25 to 35% for graded riprap.

### B.3.5 Durability

Riprap durability is a key consideration. Riprap should be able to withstand transport, handling, placement, and

freeze-thaw without significant size deterioration. Problems with durability increase with increasing stone size and become very important for the large stone sizes used in many coastal projects. CUR (1995) reports that durability is well correlated with density, and that breakage of stone is of two types: (1) along existing flaws; and (2) along new fractures, usually involving loss of edges and corners. For rock weights less than 300 kg, the first type is more common. USACE (1990b) gives additional information on durability.

### B.3.6 Gradation

Riprap gradation affects many aspects of revetment design including stability, filter requirements, unit cost, and placement. The degree of nonuniformity is usually expressed by the ratio  $D_{85}/D_{15}$ . Gradation types can be classified as shown in Table B-1.

Very widely graded stone has a relatively low unit cost at the quarry, and the substantial proportion of fines usually present is considered by some to provide a filter. Quarry-run stone with a  $D_{85}/D_{15}$  ratio of about 6 has been widely used in the lower Mississippi River basin for dike construction. A disadvantage of widely graded riprap, however, is its tendency to segregate during placement—if this occurs, the effective size for stability may be highly uncertain. Flume tests have consistently shown that for the same median size and layer thickness, hydraulic stability decreases with wider gradations (Anderson et al. 1970; Abt et al. 1988; Maynard 1988). As a general rule, very widely graded riprap must be placed to greater thicknesses to achieve equivalent protection.

Although uniform riprap gradations exhibit relatively greater stability, their higher porosities can allow hydraulic action to reach the underlying soil. They may require several mineral filter layers to bridge the size gap between the smallest riprap stones and the underlying material. Where it is impracticable to provide a filter, as with launchable riprap, wider gradation is preferable.

Riprap gradation is often specified in the form of upper and lower limit curves, any intermediate gradation being regarded as acceptable. Generally, the narrower the specified limits, the higher the production costs. Rock sizing procedures discussed subsequently should be used to define the lower limit curve.

**Table B-1 Gradation Types**

Descriptive term	$D_{85}/D_{15}$
Uniformly or narrowly graded	<1.5
Widely graded	1.5 to 2.5
Very widely graded, including quarry-run	>2.5

A typical gradation plot based on standard gradations used in USACE (1994) is shown in Fig. B-2. Standardized gradations are frequently used on a local basis, but have not been adopted on a national basis in the United States.

A European reference (CUR 1995) classifies rock gradations as follows:

- *Heavy*: requiring handling of individual pieces.
- *Light*: often processed using “grizzlies” or large bar sieves.
- *Fine*: processed by screens with square openings less than 200 mm.

The light CUR gradations are similar to the USACE (1994) gradations shown in Fig. B-2. This Figure also shows gradations by AASHTO (Brown and Clyde 1989) and by Simons and Senturk (1977), as well as a very wide gradation used for dikes on the Mississippi River.

### B.3.7 Revetment Thickness

Up to a point, revetment thickness has an effect on the stability and durability of riprap protection. Thickness is generally specified as a multiple of maximum size  $D_{100}$  or of median size  $D_{50}$ . For relatively low-turbulence applications such as bank protection, USACE (1994) specifies a minimum thickness of  $D_{100}$  or  $1.5 \times D_{50}$ , whichever is greater. For high-turbulence applications, such as below energy dissipators, the same reference specifies  $1.5 \times D_{100}$ . Escameia (1998) recommends a minimum thickness of  $2 \times D_{50}$ .

**Fig. B-2.** Standard gradation curves. Adapted from USACE (1994), Simons and Seuturk (1977), and Brown and Clyde (1989).

Stability tests (Abt et al. 1988; Maynard 1988) show that additional thickness above these minima generally results in increased stability—consequently, a greater thickness of a smaller gradation may sometimes provide equivalent stability. The increase in stability with thickness is greatest for very wide gradations and relatively small for uniform gradations. According to Simons (1995), the improvement in stability with increasing thickness results because more material is available to move to damaged areas, and more energy has to be dissipated before the filter or underlying soil is exposed.

It is common practice to use 50% greater thickness under water, because of uncertainties in placement. On the basis of flume studies, Hunt (1998) presented relations for the required excess thickness as a function of depth and velocity.

### B.3.8 Roughness

Hydraulic roughness and flow resistance are covered generally in Chapter 2.

Most riprap applications involve relatively high relative roughness, with fully rough turbulent flow. The Strickler equation relating roughness to grain size is therefore applicable. The Manning/Strickler roughness coefficient for riprap is formulated in USACE (1994) as

$$n = K \times D_{90}^{1/6} \quad (\text{B-1})$$

where  $D_{90}$  is in feet and  $K = 0.036$ , assuming slopes less than 2% depth/ $D_{90}$  ratios from 3 to 30, and above-water placement. For underwater placement,  $K$  is increased by about 15%.

Alternatively, CUR (1995) uses the logarithmic form of the flow formula, where  $k_s = 2 D_{90}$  is used to define grain roughness height. Other values of  $k_s$  are given in Table 2-1 of Chapter 2.

For riprap on steep slopes, Rice, et al. (1998) present different equations for Manning's  $n$  and Darcy's  $f$ .

In the design of porous structures formed of riprap, it may be necessary to calculate head losses for through-flow. Guidance can be found in Keulegan (1973); Stephenson (1979); Jain et al. (1988); and CUR (1995).

## B.4 SIGNIFICANCE OF HYDRAULIC LOADING

Most stone-sizing equations make stone size dependent on velocity or wave height raised to a power of 2 or greater. This makes determination of the hydraulic loading a key element in design. For the coastal environment, accurate determination of wave loading has received detailed attention in the literature. In many river applications, on the other hand,

the data required for sophisticated formulations are often unavailable, and relatively simple methods for quantifying the hydraulic loading are required.

### B.4.1 Descriptors of Channel Type and Bend Severity

For the purpose of discussing the significance of channel cross-section and alignment for riprap design, channels can be classified as (1) natural irregular or (2) artificial trapezoidal:

- Natural irregular channels have irregular alignments and cross sections, with erodible beds and sediment transport leading to toe scour and bar building, often concentrating flow along the outer bank. In such channels, additional roughness due to bank riprap is usually of little hydraulic significance.
- Artificial trapezoidal channels do not usually exhibit bars or toe scour, because rates of sediment transport are generally low and the bed is usually formed in bed-rock or lined with riprap. If much of the perimeter is lined with riprap, the increase in roughness may be substantial, with effects on depth and velocity that affect riprap sizing. An iterative solution for riprap sizing is then required.

In channel bends, the most significant parameter with respect to riprap sizing and scour depth estimation is the ratio of centerline radius of curvature to water-surface width at the entrance to the bend. These dimensions should be based on flow in the main channel, excluding overbank areas. Another significant parameter is the total deflection angle.

### B.4.2 Parameters Defining Hydraulic Loading

The hydraulic loading classification shown in Table B-2 is due to Escameia (1998).

Escameia (1998) proposes that these classifications be used to assess which protection systems are appropriate for a given class of hydraulic loading: for example, bioengineering is considered appropriate only for light hydraulic loading, as tabulated. Other investigators, however, might rate bioengineering as sometimes suitable for heavier loading classes. Theoretically, riprap is appropriate for all loadings. In practice, however, it may be impracticable to obtain or handle stone sizes large enough for the heaviest loadings, unless grouting or other forms of reinforcement are used.

Hydraulic loading can be evaluated using various techniques: physical models and/or numerical models, empirical methods, and prototype data. Physical and numerical models are excellent tools for determining design velocities, but the necessary input data are not always available for projects such as local bank protection. Empirical methods use observed data; their most significant limitation is that prototype data can seldom be obtained for design flood conditions.

A possible exception is in multichannel or braided streams, where critical erosion conditions due to severe impingement on banks may occur under bank-full or other discharges considerably smaller than the maximum (Maynord 1993).

To characterize the hydraulic loading in an open channel, boundary shear stress is theoretically the most appropriate parameter because it represents forces exerted on the riprap that can easily be compared with other stabilizing forces. The average boundary shear stress is easily determined from simple open channel theory. However, riprap design should be based on local maximum values, for example along the outer bank of a bend.

To estimate maximum shear stress along the outer bank of a channel bend, USACE (1970) multiplies the average shear stress by a factor dependent on the ratio of radius to width ( $R/W$ ), as shown in Fig. B-3. Another method is to calculate local shear stress using velocity distribution relations given in Chapter 2. Data on near-bed velocity provide the best shear stress estimates, but are seldom available. Local depth-averaged velocity is an alternative, but difficulties arise over the appropriate choice for roughness height  $k_s$ , the location of the virtual bed or velocity-profile origin when the bed consists of large coarse particles, and the validity of velocity-profile equations for high relative roughness (van Rijn 1982).

Because of these difficulties in evaluating local boundary shear stress, many practitioners have a preference for velocity predictors. Velocity parameters that have been used include

- *Average cross-sectional velocity:* Riprap design equations using this parameter include those of Blodgett and McConaughy (1986) and Brown and Clyde (1989).
- *Local depth-averaged velocity:* Design equations using this parameter include USACE (1994) and Pilarczyk (1990).
- *Local near-bed velocity:* Design equations using this parameter include those of Isbash (1935) and Escarameia and May (1992).

Another advantage of velocity-based relations is that, generally, velocity can be visualized and measured more easily than shear stress.

**Fig. B-3.** Peak shear stress in bend/average shear stress. Reprinted by permission from USACE (1970).

To characterize hydraulic loading due to waves, wave height is the preferred parameter. Numerous studies have addressed selection of the most appropriate wave height. (USACE 1984a; CUR 1995).

#### B.4.3 Hydraulic Loading for Bank Protection Design

Use of average cross-sectional velocity ( $V_a = Q/A$ ) in a riprap design equation may be problematic because of wide variability in cross sections and in alignments. However, empirical methods are available to use  $V_a$  along with geometric parameters to estimate local depth-averaged velocity  $V$ .

USACE (1994) presents velocities along the outer bank of bends as a function of  $R/W$  and  $V_a$  for natural channels (Fig. B-4), and also for trapezoidal channels. The outer bank velocity is defined as the depth-averaged velocity at 20% of the bank length upslope from the toe—this definition was selected to accord with the location of maximum

**Table B-2** Classification of Hydraulic Loading

Hydraulic loading		
Mean channel velocity, $V_a$ , m/s	Significant wave height or maximum boat wave height, $H$ , m	Classification
<1	<0.15	Light
1–2.5	0.15–0.5	Moderate
2.5–4	0.5–1.0	Heavy
4–7	>1.0	Very heavy
Downstream of hydraulic structures, around sharp bends, bridge piers, transitions		High turbulence

NOTE:  $V_{ss}$  IS DEPTH-AVERAGED VELOCITY AT 20 PERCENT OF SLOPE LENGTH UP FROM TOE

**Fig. B-4.** Near bank velocity of natural channel. Reprinted by permission from USACE (1994).

side-slope shear stress as found in studies of straight channels (Chow 1959). In computing these parameters, dimensions and discharge should represent the main channel only, excluding overbank areas.

According to Thorne et al. (1995b), an analytical model by Bridge (1982) provides a good estimate of outer bank velocity in natural channel bends.

#### B.4.4 Hydraulic Loading for Steep Slopes and River Closures

For riprap on steep chutes or river-closure structures, velocity may not be an appropriate surrogate for shear stress. Because of the difficulty of defining the water surface and depth on steep slopes, design equations for these situations often use either unit discharge and slope, or head and slope, to represent hydraulic loading. Abt and Johnson (1991) reported that flow concentration factors ( $=$  local unit  $q$ /average unit  $q$ ) of up to 3 are possible and should be considered in design. Additional guidance is given by Robinson et al. (1997).

#### B.4.5 Hydraulic Loading below Energy Dissipators

In large projects, physical model studies are often used to determine or confirm riprap sizing, but for smaller projects this is often impracticable.

Near-bottom velocity is the most reliable parameter for riprap sizing, but is generally available only from physical model studies. Analytically, velocity distributions below end sills of energy dissipator basins cannot be predicted

reliably—there is no boundary layer development. Depending on discharge, hydraulic jump characteristics, basin length, baffle block geometry and arrangement, end sill configuration, and number of gates open, the location of maximum velocity can range from near the bottom to near the surface.

To characterize hydraulic loading, the average velocity over the end sill is often used. Where the spillway is nongated, the average velocity is calculated using total discharge, basin width, and minimum tailwater depth. Where the spillway is gated, a more conservative approach is advisable because operators may open only one or more gates to pass ice or debris. The tailwater is then lower than with all gates operating, and attack on riprap can be severe (USACE 1987).

#### B.4.6 Hydraulic Loading from Propeller Jets

Loadings from propeller jets should be based on a near-bottom velocity, because a depth-averaged velocity has little meaning for propeller jet flows. A difficulty is how to decide the value of propeller thrust to be used in the bottom velocity equation. If the maximum installed power of a vessel is used in every case, the resulting stone size may be larger than necessary. The duration of the design thrust is not taken into account in most design equations.

#### B.4.7 Hydraulic Loading from Waves

Guidance on hydraulic loading from wind waves can be found in USACE (1984a) and CUR (1995).

Guidance on hydraulic loading from boat waves can be found in PIANC (1987a), Bhowmik et al. (1992), CUR (1995), and Maynard (2005). According to Hemphill and Bramley (1989), in navigation channels the blockage ratio (BR), defined as vessel cross-section area over channel cross-section area, determines the dominant type of wave loading. For  $BR > 0.1$ , a long-period drawdown wave caused by the displacement effects of the vessel will be dominant. For  $0.05 < BR < 0.1$ , the drawdown wave and short-period secondary waves will be of similar magnitude. For  $BR < 0.05$ , secondary waves will likely dominate.

## B.5 GEOTECHNICAL REQUIREMENTS FOR RIPRAP

As stated by Thorne et al. (1995a), geotechnical requirements for riprap installations include safety against geotechnical instability, foundation settlement, and groundwater seepage. The first two items are beyond the scope of this appendix. Groundwater seepage effects, which may require a filter design, are addressed below.

### B.5.1 Seepage Effects

Seepage emerging from a streambank may be a major cause of bank instability (Hagerty 1991a; 1991b). Observed bank

failures due to seepage occurred in layered and lensed alluvial deposits. Water recharged by floods into streambanks, or derived from infiltration on overbank areas, can penetrate pervious alluvial layers and emerge from bank faces, eroding particles from sandy layers. Hagerty reports that failures due to seepage effects also occur at riprap revetments both with and without filters—filters over silty or gap-graded soils easily become clogged.

One Ohio River site experiencing significant seepage-induced bank instability was protected with an extensive filter overlain with riprap, and has performed well. W.A. Cutter and R.C. Waterman unpublished manuscript, November 1984. A section through this revetment is shown in Fig. B-5 (replotted from Cutter and Waterman 1984).

### B.5.2 Filter Objectives

Filters (mineral or fabric) are placed beneath riprap revetments to meet one or more of the following objectives:

- To prevent groundwater behind the revetment from transporting bank material through the riprap (piping). This is usually the primary purpose of a filter. Filters must meet two basic requirements: stability (to prevent piping) and permeability. The filter should be fine enough to prevent the base material from passing through, but more permeable than the base soil being protected. See Section B.5.1.

**Fig. B-5.** Minimum section recommended for Ohio River revetment to address seepage failure. Adapted from W.A. Cutter and R.C. Waterman unpublished manuscript November (1984).

- To prevent large-scale turbulence in front of the revetment from sucking bank material through the riprap. Turbulence is certainly capable of this in the wave environment and in high-energy zones below hydraulic structures and on steep slopes. In these environments, the filter dissipates the large-scale turbulence before it reaches the bank material. In the smaller-scale turbulence environments of typical streambank protection projects, through-erosion by turbulence is generally limited to banks composed of fine or weak material.
- To serve as a foundation to distribute load in poorly consolidated soils. Where soils have not been sufficiently compacted, filters can prevent individual stones or armor units from sinking into the base soil.

Filters are widely used beneath revetments in the wave environment, adjacent to hydraulic structures, on steep chutes, and in bed protections such as vessel berthing areas.

### B.5.3 Geotextile Filters

Filter fabrics have been widely used in bank and channel protection projects. Advantages include ease of installation; economy; consistent quality; tensile strength; general availability; and small thickness. Disadvantages include problems with placement underwater; unproven durability; bacterial activity, which can affect performance; relative movement between fabric and bank material; failure on steep slopes; requirements for edge protection; susceptibility to damage; difficulty of repair; and the careful design and installation needed to accommodate settlement.

Because of sliding problems with filter fabric, its use is generally limited to slopes of 1V:2H or flatter. To prevent damage during riprap placement, some designers specify a bedding layer of small rock or gravel on top of the fabric, or high-strength fabrics more resistant to puncture. Clogging of geotextile fabrics is a major concern, and proper selection of the fabric mesh to match the bank soil gradation is essential. Some fabrics incorporate a roughness layer attached beneath the geotextile, to restrict water movement beneath the fabric. This roughness layer makes the overall fabric 2 to 3 cm thick and increases overall strength and resistance to puncture.

Additional guidance for selection of geotextiles is given in USACE (1984b); USACE (1986a); Brauns et al. (1993); CUR (1995); and Escameia (1998).

### B.5.4 Mineral Filters

Advantages of mineral filters are that they are self-healing; generally durable; deformable without serious damage; and relatively easy to repair. Disadvantages include the careful control required to achieve specified gradation and thickness; difficulty of compaction on steep slopes; and difficulties in control of underwater placement. Mineral filters are more

widely used adjacent to hydraulic structures than geotextile filters due to concerns about clogging of geotextiles over the design life of the structure.

Traditional guidance for mineral filters used in dam construction requires consideration of stability and permeability (USACE 1986b). To prevent piping and ensure stability requires  $D_{15}(\text{filter})/D_{85}(\text{soil}) < 5$ , and  $D_{50}(\text{filter})/D_{50}(\text{soil}) < 25$ . To ensure adequate permeability requires  $D_{15}(\text{filter})/D_{15}(\text{soil}) > 5$ . CUR (1995) provides similar guidance. USACE (1986b) states that these criteria are applicable to all soils whose gradation curve is parallel to the chosen filter material. Application of these criteria can result in multiple filter layers being required when riprap is large and/or uniform and when the base soil is sand or silt.

Worman (1989) and Bakker et al. (1994) found that for revetments subjected primarily to stream turbulence, stability and permeability criteria can be relaxed using what are called “open” filter criteria. Worman’s equation, based on riprap around bridge piers, is

$$\frac{V^2}{gS} = 6 \frac{D_{85}(\text{base})}{D_{15}(\text{riprap})} \quad (\text{B-2})$$

where

$V$  = mean flow velocity above the revetment;

$g$  = acceleration due to gravity;

$S$  = revetment thickness;

$D_{85}(\text{base})$  = 85% passing size of the base material;

$D_{15}(\text{riprap})$  = 15% passing size of the riprap.

## B.6 ENVIRONMENTAL REQUIREMENTS FOR RIPRAP

CUR (1995) classifies environmental impacts into construction impacts and long-term impacts. Sources of construction impacts include the following:

- Quarrying and dredging of materials;
- Materials transport;
- Noise, vibration, dust, odor, and pollution from equipment;
- Effects on local community in regard to employment, commerce, recreation, and access to the site.

Long-term impacts include the following:

- Changes in bathymetry and landscape due to construction;
- Changes in existing processes such as littoral transport;
- Effects on ecology;
- Visual effects, e.g., how the structure fits in with the landscape;

- Socioeconomic effects, such as changes in local employment, changes in access and safety during access, and relief of risk of flooding;
- Geological, archeological, historical, and cultural impacts;
- Pollution of air, water, and soil.

Only the ecological aspects of riprap use are addressed herein.

### B.6.1 Ecological Impacts of Riprap

Shields et al. (1995) evaluated the effects of riprap and river-training structures on riverine fish and macroinvertebrates and related impacts to three spatial scales:

- At a microscale represented by median stone diameter, riprap supports dense, diverse populations of macroinvertebrates. Farabee (1986) found that uniform riprap supports higher fish biomass than graded riprap, presumably because the larger interstitial openings provide better habitat.
- At a mesoscale represented by channel width, intermittent structures such as dikes provide better habitat than continuous bank revetments.
- At a macroscale represented by a length of 10 or more channel widths, planform stabilization of large rivers can have significant effects, but these are not attributable to the use of riprap.

Lister et al. (1995) found certain species and life stages of salmon and trout of higher densities near large riprap than around small riprap or cobble structures. On the other hand, at Bodkin Island in Chesapeake Bay, a design concern was that ducklings leaving the island after hatching would fall into the interstices of large riprap used for wave protection.

### B.6.2 Reduced Riprap Protection—Lower Bank Only

Sotir and Nunnally (1995) observe that although erosion protection can be accomplished with vegetation only at some sites, most applications require some use of rock to be effective. Riprap revetments for bank protection have traditionally extended from toe of slope to top of bank, or to design water surface plus freeboard. However, ecological benefits and lower project costs can sometimes be obtained by restricting riprap to the lower bank only. On upper banks, flows are of lower duration and frequency and exert smaller hydraulic forces, so that riprap can sometimes be dispensed with.

The minimum required height of riprap depends on the magnitude and duration of hydraulic forces on the upper bank, on upper bank soil strength, and on the strength and flow resistance of bank vegetation used instead of riprap. Recent bioengineering techniques often use soil reinforcement above the riprap to ensure that the upper bank is not

damaged before vegetation becomes established (Sotir and Nunnally 1995; Sotir 1998). Benefits of less than full-height riprap include increased habitat in the riparian zone, shade from upper bank vegetation, and improved appearance.

### B.6.3 Vegetation in Riprap Revetments

The need to maintain or enhance riparian habitat frequently leads to the concept of allowing vegetation to grow through the riprap. Advantages may include less maintenance, environmental benefits, and velocity reduction due to increased resistance. Disadvantages may include inspection difficulty, increased water levels, large-scale turbulence around large isolated trees, and tree failure, leading to large holes in the revetment.

It is common practice to disallow vegetation on mainline levees or where the increased flow resistance will create unacceptable increases in stage. Shields et al. (1990) found that on a pilot reach of the Sacramento River, “damage rates for revetments supporting woody vegetation tended to be lower than for revetments of the same age and located on banks of similar curvature but without woody vegetation.”

On small to intermediate streams, the larger vegetation is often selectively removed from revetments. In some cases, however, vegetation is planted within the revetments to provide environmental benefits (Haltiner 1995; Sotir and Nunnally 1995; Dittrich 1998).

## B.7 SCOUR PROTECTION REQUIREMENTS FOR BANK REVETMENTS

The perimeter of a bank protection revetment is a zone of vulnerability for almost any protection technique. Once failure starts at the toe of the slope, at the top of the bank, or at the upstream or downstream end, the entire revetment may be in jeopardy. Although the flexibility and self-healing nature of riprap make it less susceptible than many alternative forms of protection, careful attention to perimeter details is necessary.

### B.7.1 Toe Scour alongside Bank Revetments

River-bed scour at the toe of riprap protection can sometimes result from longterm bed degradation due to upstream or downstream changes, or more frequently from various forms of local scour—at bends, at confluences, or in the vicinity of bridges and hydraulic structures.

Toe scour in bends is a common reason for failure of bank protection projects. (USACE 1981). Potential reasons for local bend scour include the following:

- Cross-sections may become deeper and narrower as a result of making the banks erosion-resistant. Revetments placed down to the preexisting bed level may then be undermined.

- Whether or not banks are protected, scour tends to occur near the outer banks of bendways in high flows. Protection placed down to the normal low-flow bed can then be undermined by high flows.

Notwithstanding the above remarks, Harvey and Sing (1989) reported no tendency for bends to deepen and narrow due to revetment construction, although the thalweg scoured on rising stages. Vanoni (1975) states that sufficiently rough revetments create a zone of low velocity and intensified turbulence that keeps the maximum scour away from the toe of the bank. In some bend reaches of the Missouri River where the elevation of maximum scour may be 9 m (30 ft) lower than the elevation of the revetment toe, no damage has occurred because the scour is far enough away from the toe. However, the zone of lower velocity but stronger turbulence near the toe may result in a greater tendency for bank material to leach through the riprap.

Estimation of local scour depth in bends is theoretically a complex problem involving planform, cross-section shape, hydraulic forces, water and sediment hydrographs, and bed material gradation. The level of effort that would be required to take account of all these factors cannot be justified for most bank protection projects. Consequently, several more empirical methods have evolved, as follows:

1. It is assumed that scour will occur below the existing bed. The maximum depth of scour is assumed to vary with stream size and is estimated on the basis of past experience with the same or similar streams.
2. Scour depth data are collected and plotted against pertinent cross-sectional and planimetric variables, as shown in Fig. B-6 (Maynard 1996). The vertical axis of this plot shows the ratio of the maximum *total* depth in the bend to the average water depth in the approach

channel. As shown in Fig. B-6, the aspect ratio (water surface width/average channel depth) has a significant effect on scour depth.

3. Blench (1969) presented a “regime” method for estimating maximum scour depth in alluvial channels. The method is based on estimating the unit discharge adjacent to the bank and then calculating a regime depth, which is a function of the unit  $q$  and a “zero bed factor.” The zero bed factor is a function of the median diameter of the bed material and is defined by a curve presented by Blench. The maximum scoured depth is determined by multiplying the regime depth by a “ $z$  factor” that varies from 1.5 to 2.75 depending on the geometry of the problem, such as flow parallel to a bank or at right angles. Additional information on the Blench method is given in Neill (1973).

Zimmerman (1997) states that analytical methods for scour depth estimation (such as Zimmermann and Kennedy 1978) are preferable to the empirical method embodied in Fig. B-6.

### B.7.2 Requirements for Toe Scour Protection

Two basic design alternatives are available for toe scour protection. The first is to extend the protection into the bed to the depth of maximum scour. This is relatively easy where construction is in the dry, but is difficult and expensive under water. The second alternative is to place some form of protection on the existing bed that will adjust to the maximum scour; suitable systems include riprap toe sections, gabion mattresses, and cabled concrete blocks.

Scour below a riprap toe section (Fig. B-7) causes the riprap to “launch” and protect the exposed material below. A schematic of the toe-launching process is shown in Fig. B-7. According to USACE (1994), launchable riprap should have  $D_{85}/D_{15} > 2$  to prevent large interstitial spaces after launching. With recommended toe shapes, riprap launches on non-cohesive sediments at a slope of about 1V:2H. The riprap thickness  $H_B$  before launching governs the rate at which rock is launched. If it is too thick, rock will be released at too high a rate and wasted in the process. If it is too thin, rock will be released too slowly and coverage of the slope will be sparse. The recommended thickness  $H_B$  (Fig. B-7 is 2.5 to 4.0  $T$  with an optimum value of  $3T$ , where  $T$  is the normal revetment thickness on the slope. The volume of riprap required per unit length of bankline is

$$\text{VOLUME/LENGTH} = T \times \text{SCOUR DEPTH} \times \sqrt{5} \quad (\text{B-3})$$

The  $\sqrt{5}$  converts the scour depth to a slope length for volume computation, assuming that the rock launches at a 1V:2H slope. To account for stone lost during launching and

**Fig. B-6.** Bend depth/average depth versus centerline radius/water surface width. Reprinted by permission from Maynard (1996).

**Fig. B-7.** Launched stone schematic. Before launch section can be placed above, on, or below streambed. Developed by author.

for the uncertainty of placement underwater, USACE (1994) and CUR (1995) recommend increasing the volume given by Eq. (B-3) by 25 to 75%.

### B.7.3 Scour and Protection at Revetment Ends and Tops

Scour at the downstream end of bank revetments presents a maintenance problem for many installations. In some cases, the protection was not carried far enough downstream, so that the unprotected banks is still subject to high velocities. This situation can be resolved only by extending the revetment farther downstream. In other cases, a reduction in hydraulic roughness from the riprap to the natural bank results in separation eddies at the downstream end of the revetment. As erosion progresses, the eddy strength grows, leading to faster erosion.

One technique to reduce eddy action is to terminate the revetment gradually by inclining its downstream end, so that the toe terminus is located three to four bank heights downstream of the top-of-bank terminus.

For both the ends and the top of the revetment, scour protection can be provided by placing a large thickness of riprap at the end or top. This technique uses the launching process to prevent undermining. Various designs of riprap end sections are presented in USACE (1994).

## B.8 SIZE REQUIREMENTS FOR RIPRAP

### B.8.1 Forces on Riprap

The key displacing forces on riprap particles on a level bed are instantaneous peaks of lift and drag, which are related to

near-bed instantaneous velocity components. The submerged weight is usually the main resisting force, but additional resistance may result from contact with adjacent particles. On side slope particles, the downslope component of weight also contributes to instability, but in compensation there may be greater inter-particle resistance.

Figure 2-16 shows the various forces acting on a loose particle. Equation 2-53 shows a theoretical balance of forces at first displacement, when the boundary shear stress equals the resisting force due to submerged weight. Lane (1955), Stevens et al. (1976), Ikeda (1982), and Christensen (1995) have all presented moment-balance equations. Some formulations introduce lift as well as drag and use different assumptions for side slopes and channel beds. Lane's equation, although it ignores lift, is widely used to derive the ratio  $K_{sl}$  of critical shear stress on a side slope to critical shear stress on a level bed:

$$K_{sl} = \frac{\tau_s}{\tau_b} = \sqrt{1 - \frac{\sin^2 \alpha}{\sin^2 \phi}} = \cos \alpha \sqrt{1 - \frac{\tan^2 \alpha}{\tan^2 \phi}} \quad (\text{B-4})$$

where

- $\tau_s$  = critical shear stress on side slope;
- $\tau_b$  = critical shear stress on bed;
- $\alpha$  = angle of side slope to the horizontal;
- $\phi$  = angle of repose of riprap material.

Equation (B-4) is plotted in Fig. B-8 using an angle of repose of  $40^\circ$ , which is commonly assumed for riprap.

**Fig. B-8.** Ratio of critical side slope to bed shear stress versus cotangent of side slope angle. Adopted from Lane (1955), USACE (1994), and Ulrich (1987).

Maynard (1988) conducted flume tests of riprap on level beds and on side slopes ranging from 1V:1.25H to 1V:4H. Measured near-bed velocities were used to compute the bed shear stress at failure. The best-fit curve of the data, shown in Fig. B-8 as the USACE (1994) curve, indicates that the Lane equation is conservative. For riprap on side slopes, Ulrich (1987) recommended using an angle of  $75^\circ$  instead of the actual repose angle in the Lane equation—the corresponding curve is also plotted in Fig. B-8: The Froehlich and Benson (1996) expression for  $K$ , using  $75^\circ$  instead of angle of repose, produces the same results as the Ulrich curve in Fig. B-8. Experimental results for sand-size particles in an air tunnel by Ikeda (1982) show that “the effects of lift force seem to be negligible in describing the most probable values of critical tractive forces of both level and laterally sloping boundaries.” On the other hand, some reformulations of moment-balance equations to include lift suggest that the Lane equation is nonconservative.

Fig. B-8 indicates that the effects of side slope on riprap stability are relatively small except when the slope angle increases to near the angle of repose. Correspondingly, riprap design procedures presented by Hughes et al. (1983) and by Escameia and May (1992) do not change rock size for side slopes of 1V:2H or flatter. Also, wave riprap equations by Hudson (1958), based on stability tests, are less sensitivity to slope angle than the Lane (1955) equation with a repose angle of  $40^\circ$ .

A reason that some theoretical formulations of riprap stability may be overconservative is that a steady gravity force

is used in conjunction with time-averaged values of hydraulic forces. In fact, however, riprap displacement may be sensitive to time-peak values of hydraulic forces, which can be several times higher than their time-averaged values. The result is to exaggerate the relative influence of downslope gravity forces for riprap on side slopes—at least when the slope is notably flatter than the angle of repose.

### B.8.2 Design for Maximum Force

Riprap should be designed for whatever hydraulic conditions determine the largest rock size. These conditions do not necessarily correspond to the design or maximum discharge—in some cases bank-full conditions may be critical.

In bendways, riprap sizing is normally based on the most severe flow conditions found along the bend. If the approach alignment is stable, bendway revetments could be designed with variable sizing along the length of the bend, and possibly up and down the slope. Such multiple gradations have not been common practice, however, usually because of cost and inspection difficulties in projects of limited scale.

### B.8.3 Effects of Velocity Profile and Turbulence on Stability

Two secondary factors that affect stone size are (1) the development and form of the velocity profile and (2) the turbulence characteristics of the flow:

- Velocity profile development refers to how well the velocity distribution has adjusted to the boundary roughness at the point of interest. At many riprap design locations, the velocity profile has not fully adjusted from the upstream channel boundary roughness to the greater roughness of the riprap. Also, in bendways, the flow may be accelerating up to the point of most severe attack, hindering normal boundary layer development. For the same depth-averaged velocity, near-bed velocity and bed shear stress will generally be greater if boundary layer development is incomplete. The vertical velocity profile can also be distorted in bendways, where secondary currents move the point of maximum velocity closer to the bed.
- Intensity and scale of turbulence can also affect required riprap size. Flow exiting from energy dissipators is a common case. Other examples are flow exiting from propellers and jets; downstream of dikes and groins; sharp bends with low radius/width ratios; bridge piers and abutments; and transitions in roughness or channel dimensions, particularly width expansions. In such high-turbulence areas, the ratios of peak to time-averaged values of velocity and shear stress may be much higher than in straight channels of uniform cross section. Escameia (1998) presents a riprap sizing design procedure in which turbulence intensity—but not scale—is included.

### B.8.4 Characteristic Size and Gradation Effects

In many studies and design procedures, the median riprap size  $D_{50}$  has been used to characterize the stability of a mixture. Many design procedures either use  $D_{50}$  for all types of gradation, or else restrict the procedure to a recommended range of gradations.

Other characteristic measures have also been used. USACE (1994) used  $D_{30}$ , assuming a thickness of  $1 \times D_{100}$ . The California Division of Highways (CDH 1970) used a characteristic weight  $W_{33}$ , than which 33% by weight of the mixture is lighter. Shen and Lu (1983) used  $D_{30}$  for armor layers. (In sediment-transport studies, Einstein (1950) used  $D_{35}$  and Ackers and White (1973) used  $D_{30}$ .)

Anderson et al. (1970) found in flume studies that uniform riprap was more stable than graded riprap of the same  $D_{50}$ . This conclusion was confirmed in flume studies by Abt et al. (1988), Ahmed (1988), and Maynard (1988). In their sizing equation, Abt et al. (1988) retain  $D_{50}$  as the characteristic size but add a gradation coefficient.

### B.8.5 Riprap Sizing Methods

Some methods such as those of CUR (1995) and Escaramela (1998) address riprap sizing for a range of applications. Other methods address specific applications only. The following sections describe various riprap sizing methods for different river applications.

The basic form of many sizing equations is given by

$$\frac{V_c}{[g(S_g - 1)D_c]^{1/2}} = C_{\text{ref}} \left( \frac{h}{D_c} \right)^{P_{\text{ref}}} \quad (\text{B-5})$$

where

$V_c$  = characteristic velocity (which may be near-bed velocity, depth-averaged velocity, or cross-sectional average velocity)

$S_g$  = specific gravity of riprap stone =  $\rho_s/\rho$ ,

where

$\rho_s$  = stone density and

$\rho$  = water density;

$C_{\text{ref}}$  = a numerical coefficient, usually based on experimental data;

$h$  = local water depth;

$D_c$  = characteristic particle size ( $D_{30}$  to  $D_{90}$  depending on investigator);

$P_{\text{ref}}$  = an exponent dependent on the hydraulic environment and the way the characteristic velocity  $V_c$  is defined.

$P_{\text{ref}}$  generally varies from 0 to 0.167. For problems having little or no boundary layer development, such as below energy dissipators or within propeller jets,  $P_{\text{ref}}$  is often taken as zero, which means no dependency on depth. Some

investigators suggest  $P_{\text{ref}} = 0$  even for bank protection. For a completely developed boundary layer,  $P_{\text{ref}} = 0.167$  when using the Manning-Strickler resistance equation.

In the following subsections, riprap sizing equations are presented in the form recommended by their authors. Values of  $P_{\text{ref}}$  and  $C_{\text{ref}}$  are quoted to show how each equation relates to the basic form of Eq. (B-5).

#### B.8.5.1 Bank and Bed Revetments (Not around Hydraulic Structures)

**B.8.5.1.1 CUR Manual** CUR (1995) present an equation developed by Pilarczyk (1990) for stability under current attack:

$$\Delta D_n = \phi_c k_t \frac{0.035}{\psi_{cr}} k_h k_{st}^{-1} \frac{V^2}{2g} \quad (\text{B-6})$$

where

$\Delta$  = relative submerged density of stone =  $(\rho_s - \rho)/\rho$ ;

$D_n$  = characteristic stone size =  $0.85 D_{50}$ ;

$\phi_c$  = geometry correction factor to account for edges or transitions: 0.75 for continuous protection, 1.0 to 1.5 for edges and transitions, 1.5 for exposed rock on a sill;

$k_t$  = turbulence factor: 1.0 for normal turbulence in rivers; 1.5 for increased turbulence as in bends; 2.0 for high-turbulence hydraulic jumps, sharp bends, local disturbances; and 3.0 for propeller jets;

$\psi_{cr}$  = Shields parameter = 0.035 for loose rock;

$k_h$  = depth factor dependent on velocity profile:  $2/(\log 10h/k_s)^2$  for fully developed boundary layer;  $(h/D_n)^{-0.2}$  for a velocity profile not fully developed;

$k_{st}$  = slope factor, for flow along or down a slope; defined for flow along a slope by the Lane (1955) equation.

The left side of the Pilarczyk (1990) equation represents the resisting strength of the revetment and the right side the load or disturbing force.

In relation to the basic form of Eq. (B-5), the Pilarczyk equation varies  $P_{\text{ref}}$  and  $C_{\text{ref}}$  depending on the application. A specific form of the Pilarczyk equation is used in PIANC (1987a) and Hemphill and Bramley (1989).

**B.8.5.1.2 California Bank and Shore Protection (CBSP) Manual** The basic equation of the California Division of Highways (CDH 1970) for stable stone weight is

$$W_{33} = \frac{0.00002 V_{\text{cbasp}}^6 S_g}{(S_g - 1)^3 \sin^3(\beta - \alpha)} \quad (\text{B-7})$$

where

$V_{\text{cbasp}}$  = velocity in ft/sec, defined as 2/3 of average channel velocity in straight reaches, and 4/3 of average velocity on the outsides of bends;

$\beta$  = angle for determining side slope effect,  $70^\circ$  for randomly placed rubble.

It is not clear how  $\beta$  relates to the more commonly used angle of repose. Other investigators also proposing a relatively large angle to address side slope effects are Froehlich and Benson (1996), who proposed a “particle angle of initial yield” of about  $70$ – $75^\circ$  for typical gradations, and Ulrich (1987), who used a “bearing angle” of  $75^\circ$ .

In relation to the basic form of sizing equation (B-5), the CBSP equation has  $P_{\text{ref}} = 0$  (no dependance on depth) and a variable  $C_{\text{ref}}$  depending on the application.

In a supplemental report, Racin (1996) explains that the CBSP approach emphasizes relatively uniform rock placed in two or more layers instead of graded rock and evaluates the CBSP procedure relative to field data and other procedures. The CBSP manual also provides guidance for shape, durability, specific gravity, layer thickness, gradation, filter requirements, and placement methods.

**B.8.5.1.3 Wallingford Design Manual for River and Channel Revetments** Escameia and May (1992) provide a general equation for riprap, loose or interlocking concrete blocks, and gabion mattresses,

$$D_{50} = C \frac{U_b^2}{2g(S_g - 1)} \quad (\text{B-8})$$

where

$D_{50}$  = characteristic particle size, related to weight on the basis of a cubical shape;

$C$  = coefficient dependent on turbulence intensity =  $12.3\text{TI} - 0.2$  for riprap bank or bed protection on side slopes of 1V:2H or flatter;

TI = turbulence intensity at 10% of flow depth above the bed;

$U_b$  = velocity at 10% of flow depth above the bed =  $(1.04 - 1.48\text{TI})V$ .

The incorporation of turbulence intensity TI is a unique feature of this equation.

For specific application to bed and bank protection, Escameia and May (1992) present an equation using local depth-averaged velocity, applicable to bank slopes of 1V:2H or flatter and normal river flow:

$$D_{50} = C \frac{V^2}{S_g - 1} \quad (\text{B-9})$$

where  $C = 0.05$  for continuous revetments, and  $0.064$  for the edges of revetments. For bank protection,  $V$  should be measured at the toe of the slope.

Relative to the basic form of sizing equation (B-5), the Escameia and May equations have  $P_{\text{ref}} = 0$  (no dependance on depth) and a variable  $C_{\text{ref}}$  depending on the application.

The general Eq. (B-8) uses bottom velocity, and the specific riprap Eq. (B-9) uses depth-averaged velocity.

**B.8.5.1.4 FHWA Manual—Design of Riprap Revetment (HEC-11)** Brown and Clyde (1989) combine the Manning-Strickler equation with the Shields relation to produce an equation for stable rock size. A similar approach was used earlier by Straub (1953); Grace et al. (1973); and Reese (1984). The Brown and Clyde equation is

$$D_{50} = C_{sg} C_{sf} \frac{0.001 V_a^3}{h_{\text{avg}}^{0.5} K_{sl}^{1.5}} \quad (\text{B-10})$$

where  $h_{\text{avg}}$  is the average depth in the main channel,  $C_{sg} = 2.12/(S_g - 1)^{1.5}$ , and  $C_{sf} = (\text{SF}/1.2)^{1.5}$ . SF is a stability factor dependent on the ratio  $R/W$  of radius of curvature to channel width. For  $R/W > 30$ , SF = 1.2; for  $R/W = 10$  to  $30$ , SF = 1.3 to 1.6; and for  $R/W < 10$ , SF = 1.7.

Relative to the basic form of sizing equation presented in Section B.8.5, the Brown and Clyde equation has  $P_{\text{ref}} = 1/6$  (generally applicable to complete boundary layer development) and a variable  $C_{\text{ref}}$  depending on the application.

**B.8.5.1.5 Safety Factor Methods** Most of the methods reviewed above address riprap stability in an overall sense, without considering in detail the stability of individual particles. The methods reviewed below involve more detailed consideration of forces and moments on an individual particle, including lift—which does not appear in the classical Lane (1955) equation.

Stevens et al. (1976) developed a safety factor method based on the hypothesis that a particle is stable if the sum of the moments acting to displace it is less than the moment of its submerged weight.

Wittler and Abt (1988) modified Stevens’s analysis to add contact and frictional forces from adjacent particles; they tested their equation against stability data for flow down slopes of 2 to 20% and found good agreement, but did not test it for flow along a side slope.

Ahmed (1988) compared seven safety factor methods (including two of his own but not the Wittler and Abt modification) against flume data for flow along a riprapped 1V:1.5H side slope, and found that all appeared to underestimate stability significantly. He reported that non-safety-factor approaches by Anderson et al. (1970) and by the California Division of Highways (CDH 1970) gave better results.

**B.8.5.1.6 Corps of Engineers Manual—Hydraulic Design of Flood Control Channels** The USACE (1994) method is intended for sizing riprap in rivers and channels, except immediately downstream of hydraulic structures that create highly turbulent flow. Source data were limited to slopes of 2% or less and to values of  $D_{30}/d$  exceeding 0.02. The sizing equation is

$$D_{30} = S_f C_s C_v C_T h \left[ \left( \frac{\gamma_w}{\gamma_s - \gamma_w} \right)^{1/2} \frac{V}{\sqrt{K_{slcoe} gh}} \right]^{2.5} \quad (\text{B-11})$$

where

- $D_{30}$  = riprap size for which 30% by weight is finer.  
 $S_f$  = safety factor, minimum = 1.1.  
 $C_s$  = stability coefficient for incipient failure = 0.30 for angular rock or 0.375 for rounded rock. A revetment thickness of  $D_{100}$  or  $1.5 D_{50}$ , whichever is greater, is assumed, and a gradation factor  $D_{85}/D_{15}$  in the range of 1.7 to 5.2.  
 $C_v$  = vertical velocity distribution coefficient = 1.0 for straight channels or inside of bends; 1.25 downstream of concrete channels or at the ends of dikes; and  $1.283 - 0.2 \log(R/W)$  for outsides of bends.  
 $C_T$  = thickness coefficient = 1.0 for a thickness of  $D_{100}$ , with smaller values for greater thickness depending on  $D_{85}/D_{15}$ .  
 $h$  = local depth, defined for side slope riprap at a point 20% upslope from toe for slope.  
 $\gamma_w$  = unit weight of water.  
 $\gamma_s$  = unit weight of stone.  
 $V$  = local depth-averaged velocity, symbolized as  $V_{ss}$  for bank protection riprap and defined at depth-average at a point 20% upslope from the toe.  
 $K_{slope}$  = side slope correction factor =  $-0.672 + 1.492 \cot(\alpha) - 0.449 \cot^2(\alpha) + 0.045 \cot^3(\alpha)$  where  $\alpha$  is angle to the horizontal.

Equations of basically similar form but without most of the modifying factors were presented by Neill (1967); Bogardi (1978); and Pilarczyk (1990).

In the USACE equation, an incipient failure criterion is used to determine the stability coefficient, and defined as the condition when the fabric or bank material beneath the riprap is first exposed. Incipient failure was used instead of incipient motion or displacement, to cover a wide range of gradations and to allow for the effects of blanket thickness.

Significant differences between the USACE method and others are the use of  $D_{30}$  as characteristic size, an empirical relation rather than the Lane equation to account for side slope, a coefficient for thickness, and the provision of guidance for determining the near-bank velocity  $V_{ss}$  (Fig. B-4). In relation to the basic form of stone sizing equation (B-5), the USACE equation implies  $P_{ref} = 0.1$  (intermediate between zero and complete boundary layer development), and a variable  $C_{ref}$  depending on the application.

**B.8.5.1.7 Method Based on Field Data** Blodgett and McConaughy (1986) developed a method based on analysis of field riprap stability data and presented the equation

$$D_{50} = 0.01 V_a^{2.44} \quad (B-12)$$

This relationship is intended for straight and curved channels having side slopes of 1V:1.5H or flatter. The Blodgett and

McConaughy report also addresses other factors important in riprap design. Equation (B-12) does not fit the standard form of the stone-sizing equation.

**B.8.5.1.8 Probabilistic Methods** Probability-based methods for design of riprap against currents have been presented by Li et al. (1976); PIANC (1987b); and Froehlich and Benson (1996). With increasing emphasis on risk-based design procedures, probability-based methods will see increased usage. One of their advantages lies in the ability to combine effects from different mechanisms, such as waves and currents. Although the probability of the hydraulic forces has been the focus of most probabilistic methods, the uncertainties in estimates of stone size, stone density, channel depth, etc. will also have to be addressed in a risk-based procedure.

**B.8.5.2 Riprap Sizing for Steep Slopes** Olivier (1967) developed an equation for stone size on steep slopes, specifically the downstream faces of through-and-overflow rockfill dams. By including  $g$ , the equation can be written in dimensionally homogeneous form as

$$D_{50} = \frac{5.63 q^{2/3} S^{7/9}}{(S_g - 1)^{10/9} g^{1/3}} \quad (B-13)$$

where

- $q$  = unit discharge and  
 $S$  = slope.

The equation is based on data for crushed rock on slopes from 8 to 45%. In relation to the basic form of stone-sizing equation (B-5), the Olivier equation has  $P_{ref} = 1/6$  and a variable  $C_{ref}$  depending on the application.

Knauss (1979) evaluated loose rock on slopes as steep as 67%. He reports that the Olivier equation is conservative for slopes steeper than about 20%, because of air entrainment that develops on steeper slopes. For slopes from about 20 to 67%, a stone specific gravity of 2.7, and typical placement methods, Knauss recommends the equation

$$D_{50} = \frac{q^{2/3}}{g^{1/3} [2.4 - 3 \sin(\eta)]^{2/3}} \quad (B-14)$$

where  $\eta$  is the slope expressed as the angle to the horizontal.

Abt and Johnson (1991) conducted large-scale flume studies on slopes from 1 to 20%, and presented the empirical relation

$$D_{50} = 5.23 S^{0.43} q^{0.56} \quad (B-15)$$

where  $D_{50}$  is in inches and  $q$  is in cfs/ft. Other variables incorporated into their design procedure include (1) definitions of conditions at both first movement and at complete

failure, (2) channelization, gradation, and thickness effects, and (3) rounded versus angular stone shape.

Design methods for riprap on steep slopes have also been presented by Stephenson (1979); USACE (1994); Robinson et al. (1997); and Chang (1998). Some of these methods should be used with caution outside the range of data used in their development, because of dimensional inconsistency in the presented relationships.

**B.8.5.3 Riprap around Hydraulic Structures** Most equations for sizing riprap around hydraulic structures use some form of the Isbash (1935) equation. For riprap below energy dissipators, the USACE (1987; 1990b) uses the equation

$$D_{50} = \frac{V_a^2}{C^2 2g \left( \frac{\gamma_s - \gamma_w}{\gamma_w} \right)} \quad (\text{B-16})$$

where

$C = 0.86$  for high turbulence (applicable to stilling basins) and

$C = 1.2$  for low turbulence (applicable to bank protection).

Average velocity over the end sill is used in the equation, except for structures where only one gate might be opened—see USACE (1987). In relation to the basic form of stone-sizing equation (B-5), the USACE equation has  $P_{\text{ref}} = 0$  (no dependence on depth) and a variable  $C_{\text{ref}}$  depending on the application.

Peterka (1963) presented a riprap-sizing curve used by the Bureau of Reclamation for riprap below energy dissipators. The curve gives results similar to those for the Isbash equation with  $C = 0.88$  and with  $D_{40}$  as the characteristic size. CUR (1995) presents the Pilarczyk (1990) equation discussed in Section B.8.5.1 for areas below energy dissipators.

Guidance references for riprap protection at highway drainage culverts include the FHWA's HEC-14 (Corry et al. 1983), and Shafei-Bajestan and Albertson (1993).

**B.8.5.4 River Closures** The study by Isbash (1935) represents the most widely known investigation of riprap structures for river closure. Further detailed guidance for closure structures can be found in CUR (1995) and Thorne et al. (1995a).

**B.8.5.5 Propeller Jets** Most equations for sizing riprap from protection against scour from propeller jets use some form of the Isbash (1935) equation. References providing guidance for near-bed velocity and stone sizing include Blaauw and van de Kaa (1978); Fuehrer et al. (1981); Bergh and Magnusson (1987); and PIANC (1987a). Because of wide variations in the definition of near-bed velocity, it is recommended that the near-bed velocity and stone sizing both be determined by a single investigator.

**B.8.5.6 Waves (Including Boat Waves)** Riprap sizing for wave conditions is not generally covered in this appendix. References providing detailed guidance include USACE (1984a); PIANC (1987a); Hemphill and Bramley (1989); CUR (1995); Thorne et al. (1995a); and Escameia (1998).

**B.8.5.7 Combined Action of Waves and Currents** Revetments sometimes undergo attack from both currents and waves. The combined action is complex, and a probability approach should be considered, because the probability of simultaneous maximum forces from the two sources is often quite small. As a rough design approach, Escameia (1998) suggests that the stone sizes determined separately for waves and currents be added together. This approximation seems rather conservative: at the waterline, where wave forces tend to be highest, current forces are often well below the maximum which occurs farther down the slope. Additional guidance for combined wave-current action may be found in CUR (1995).

## B.8.6 Ice and Debris Effects on Riprap Stability

Potential ice and debris effects on riprap stability are generally addressed by increasing size and/or thickness. The USACE (1994) suggests increasing thickness by 150 to 300 mm (6 to 12 in.) when heavy debris is present, and increasing rock size in proportion to the increased thickness.

Sodhi et al. (1996) summarize earlier guidance on ice and present results from flume tests. Ice can damage riprap slope protection by shoving action, or by plucking when water and ice levels rise. To avoid shoving damage, the maximum riprap size should be two times the ice thickness for 1V:3H side slopes, and three times the ice thickness for 1V:1.5H side slopes. To avoid plucking damage,  $D_{50}$  should be greater than the maximum winter ice thickness. Additional guidance is given by Wuebben (1995).

## B.9 CONSTRUCTION AND MAINTENANCE

As stated by Thorne et al. (1995a), constructibility and maintainability constitute one of five key factors in a successful riprap project. Some related considerations are as follows:

1. Cost of transportation is often a major portion of the total cost.
2. Excessive stockpiling and handling can lead to size degradation unless rock quality is high.
3. During placement, dumping and spreading may promote size segregation and breakage. Rock should be released from the equipment as close as possible to its final position.
4. In the case of underwater placement, rock tends to move in a downstream direction—see Prezedwojski et al. (1995). It also tends to disperse—see Hunt (1998).

5. A large, heavy plate is sometimes recommended to compact the riprap and thereby increase its stability (Maynard 1992; Simons 1995).
6. Riprap should be inspected annually and after each significant flood event.

Additional guidance on construction and maintenance can be found in USACE (1990ab); CUR (1995); and Escarameia (1998).

## APPENDIX C

### *Sediment Transport Scaling for Physical Models*

*Clifford A. Pugh*

#### C.1 INTRODUCTION

Reclamation experience with sediment models started in the early 1950s. Several predesign models were developed for the Missouri River Basin and Middle Rio Grande diversions. The sediment used for all these studies was a fine uniform sand with a mean diameter of 0.2 mm. It was recognized that settling velocity is very important in determining when a particle will remain at rest or how far it will travel once lifted into the flow. The 10% model sizes were scaled by settling velocity according to the Froude law, that is, by the square root of the length ratio (not by the geometric scale ratio).

These models were force fed with sediment to develop bed slopes sufficient to move sediment at rates estimated by theoretical sediment bedload equations. Bed slopes that were developed in this manner were generally exaggerated because of friction differences between model and prototype. However, at diversions, flow splits occur within a short reach in the direction of flow, and the structure does not need to be distorted.

Sediment concentration was measured in all the component flows of the models. Concentration ratios of the measured delivery rate to the river concentration were used to compare the relative amount of sediment in the delivery for different trial diversion arrangements (Carlson 1970).

#### C.2 MODELING CONSIDERATIONS

##### C.2.1 Similitude

Hydraulic models are used because of the large number of variables involved and because of complicated boundary conditions. Hydraulic models may be either true or distorted models. True models have all of the significant characteristics of the prototype reproduced to scale (geometrically similar) and satisfy model design restrictions (kinematic and dynamic similitude). Model-prototype comparisons have

shown that correspondence of behavior is often well beyond expectations, as has been attested by the successful operation of many structures designed from model tests.

A model and prototype are designed to be similar geometrically, kinematically, and dynamically. Geometric similarity exists when the ratios of all homologous dimensions between model and prototype are the same. The geometric scale ratio, or length ratio, is denoted by  $L_r$ , which is the ratio  $L_m/L_p$ , where the subscripts  $m$  and  $p$  refer to the model and prototype, respectively. Kinematic similarity, or similarity of motion, implies that the ratios of velocities and accelerations between model and prototype are equal. Dynamic similarity requires that the ratios of homologous forces between the model and prototype be the same. Possible hydraulic forces are caused by gravity, viscosity, pressure, surface tension, and elasticity.

For hydraulic modeling, the more important, dimensionless parameters are dimensionless ratios formed with respect to inertia.

The Reynolds number is the ratio of inertia and viscous forces:

$$R = \frac{VD}{\nu} \quad (C-1)$$

An open-channel model is normally operated according to the ratio of inertia and gravity forces. This ratio is represented by the Froude number:

$$F = \frac{V}{\sqrt{gD}} \quad (C-2)$$

The scale relationships for open-channel flow based on Froude scaling follow:

$$\text{Length} = L_r \text{ (geometric scaling)}$$

$$\text{Area} = L_r^2$$

$$\text{Volume} = L_r^3$$

$$\text{Time} = L_r^{1/2}$$

$$\begin{aligned}\text{Force} &= L_r^3 \\ \text{Shear} &= L_r \\ \text{Velocity} &= L_r^{1/2} \\ \text{Discharge} &= L_r^{5/2}\end{aligned}$$

### C.2.2 Similitude Deficiency of Froude Scaling

The tractive stress on a particle fluctuates because of turbulence. The drag force and turbulence are a function of viscous forces (Reynolds number). Vanoni (1975) discussed the important variables involved in the present knowledge of sediment transport in a section on "Fundamentals of Sediment Transport" in the *Sedimentation Engineering* handbook. He reduced the sediment discharge rate ( $Q_s$ ) to the following relationship (these symbols are defined in the glossary):

$$Q_s = f(Q, R, d, \nu, \rho, \rho_s, \sigma, \sigma_g, q, w, g) \quad (\text{C-3})$$

### C.2.3 Tractive Stress

Models involving erosion of noncohesive bed material must simulate tractive stress ( $\tau_0$ ), because the tractive stress causes the drag force required to overcome the gravity forces holding a particle in place (See Fig. C-1).

Froude scale models do not necessarily simulate the tractive forces and sediment erosion accurately because Froude

Fig. C-1. Forces holding sand grains in place.

scaling does not simulate viscous forces. However, sediment sizes can be adjusted (distorted) in some Froude scale models to compensate for a Reynolds number that is too low. The Reynolds number offset ratio ( $R_r$ ) of a Froude scale model can be determined by substituting the Froude scaled variables (velocity and length) into Eq. (C-1) for the Reynolds number (Pugh and Dodge 1991), resulting in

$$R_r = L_r^{3/2} \quad (\text{C-4})$$

This means that a 1/10 scale model would have a Reynolds number ratio ( $R_r$ ) of

$$(1/10)^{3/2} = 1/31.6$$

Fig. C-2. General resistance diagram for uniform pipe flow.

Therefore, if the prototype Reynolds number is, say,  $3 \times 10^6$ , the model Reynolds number for a Froude scaled model would be  $9.5 \times 10^5$ . If we refer to the Darcy-Weisbach friction diagram (See Fig. C-2) for an arbitrary relative roughness ( $4R/k$ ) of 10,000 (Rouse 1948), the model friction factor ( $f$ ) would be 0.0135 in the model and 0.0125 in the prototype. This indicates that the model should be designed to be smoother than geometrically scaled roughness (Kobus 1980) (or distorted to a steeper slope) to compensate for the relatively greater influence of viscous forces in the model.

#### C.2.4 Structural Modeling of Cohesive Sediment

If erosion of cohesive sediment occurs by chunking action such as cutback scour, or in a controlled manner, such as by the erosion of an impervious cohesive core in a fuse plug (Figs. C-3 and C-4), the model needs to include the effects of elastic forces of the cohesive sediment as well as of gravity (Pugh 1985). The ratio of the gravity and elastic forces results in the structural integrity number ( $M$ ), expressed as

$$M = \gamma \cdot L / E \quad (\text{C-5})$$

where  $E$  is the modulus of elasticity of the cohesive sediment material, and  $L$  is a characteristic length.  $M$  must be the same in the model and the prototype.

In the fuse plug model it was difficult to find an impervious material with the proper modulus of elasticity to satisfy Eq. (C-5), so the core was analyzed as a structural slab, with pieces breaking off due to the weight of sand and water above as the cohesionless material in the pilot channel and in the main shell during the lateral erosion process eroded downstream from the core. The clay portion was reduced in thickness to adjust the moment of inertia, to compensate for the relatively high  $E$  of the model core. This method was successful, since it qualitatively simulated the observed behavior of pilot channel erosion in prototype tests, such as the Oxbow experiment (Albrook 1959).

#### C.2.5 Shields Diagram

Shields developed a diagram (Fig. 2-18) relating dimensionless shear stress ( $\tau^*$ ) to a boundary or grain Reynolds number ( $R$ ). Shields used this diagram to define critical shear stress ( $\tau_c$ ) (the stress required for incipient motion of noncohesive sediment). This concept has been expanded by others (Fig. C-5) to include dimensionless unit sediment discharge ( $q_s^*$ ), where

$$q_s^* = \frac{q_s}{u^* d} \quad (\text{C-6})$$

#### C.2.6 Dimensionless Unit Sediment Discharge

Dimensionless unit sediment discharge should be the same in the model and the prototype to properly simulate sediment transport. The following procedure explains how to compute adjustments in model sediment size and/or weight, in order to compensate for a relatively low Reynolds number in a Froude-scaled model. These corrections should yield a near-uniform  $q_s^*$  in the model and the prototype.

Vanoni (1975) used Taylor's data to show that dimensionless unit sediment discharge at low transport levels falls very close to the Shields curve for incipient motion (Fig. C-5). To properly simulate sediment transport, the dimensionless unit sediment discharge rate ( $q_s^*$ ) must be approximately the same in the model and the prototype.

For a model with a grain Reynolds number ( $R^*$ ) greater than about 5 and less than 100, the unit sediment discharge rate for the model would be higher than that for the prototype (if the model sand grains are sized according to geometric scaling) because the dimensionless shear stress ( $\tau^*$ ) is about the same in the model and the prototype.

For grain Reynolds number

$$R^* = \frac{u^* d}{\nu} \quad (\text{C-7})$$

and dimensionless shear stress

Fig. C-3. Structural modeling of fuse plug core.

Fig. C-4. Fuse plug lateral erosion process.

Fig. C-5. Shields diagram, dimensionless unit sediment discharge curve ( $q_s^*$ ), versus dimensionless shear stress ( $\tau^*$ ) and grain Reynolds number ( $R^*$ ). Effects of settling velocity adjustments are shown.

$$\tau^* = \frac{\tau_o}{(\gamma_s - \gamma)d} \quad (\text{C-8})$$

it can be shown that dimensionless shear stress is a form of the Froude number, the submerged specific gravity of the sediment and the ratio between the flow depth and the particle diameter.

The shear velocity is

$$u^* = \sqrt{\frac{\tau_o}{\rho}} \quad (\text{C-9})$$

Therefore the tractive shear stress is,

$$\tau_o = \rho \cdot u^{*2} \quad (\text{C-10})$$

and the unit force (or weight) is

$$\gamma = \rho \cdot g \quad (\text{C-11})$$

Substituting equation (C-11) into Eq. (C-10):

$$\tau_o = \left[ \frac{\gamma \cdot u^{*2}}{g} \right] \quad (\text{C-12})$$

Substituting Eq. (C-12) into Eq. (C-8):

$$\tau^* = \left( \frac{u^{*2}}{gd} \right) \cdot \left( \frac{\gamma}{\gamma_s - \gamma} \right) \quad (\text{C-13})$$

The first term in Eq. (C-13) is in the form of a Froude number; the second term is the ratio of the densities of the water and the sediment, when gravity is factored out.

It is sometimes more convenient to compute  $\tau^*$  using a form of Eq. (C-13) relating to the Darcy-Weisbach friction factor ( $f$ ). Rouse (1948) has shown that the shear velocity is a function of the water velocity ( $V$ ) and the friction factor ( $f$ ),

$$u^* = \sqrt{gRS} = \sqrt{\frac{\tau_o}{\rho}} = V \cdot \sqrt{\frac{f}{8}} \quad (\text{C-14})$$

Substituting Eq. (C-14) into Eq. (C-13),

$$\tau^* = \left( \frac{V^2 f}{8gd} \right) \cdot \left( \frac{\gamma}{\gamma_s - \gamma} \right) \quad (\text{C-15})$$

To determine  $f$  in an open channel, the Reynolds number ( $R$ ) is computed according to the equation (Rouse 1948)

$$R = 4R \cdot V/\nu \quad (\text{C-16})$$

where  $R$  = the hydraulic radius and  $\nu$  is the kinematic viscosity. The relative roughness (needed to determine  $f$ ) is defined as

$$\text{relative roughness} = \frac{K_s}{4 \cdot R} \quad (\text{C-17})$$

where

$K_s$  = roughness height.

Kamphuis (1974) found that

$$K_s = 2 \cdot d_{90} \quad (\text{C-18})$$

where

$d_{90}$  = the particle diameter at which 90% of the grains are smaller in diameter.

The hydraulic radius ( $R$ ) can be taken as the flow depth, if the channel is relatively wide.

If a model is scaled geometrically according to Froude scaling ( $\tau_m^* = \tau_p^*$ ), the model unit sediment discharge rate ( $q_s^*$ ) will be too great in the range  $5 < R^* < 100$ . Therefore, the model sediment should be adjusted to properly simulate sediment transport in this range. A diagram of settling velocity ( $w$ ) of sand and silt particles in water (Fig. C-6) illustrates that small particles (<1 mm in diameter) settle at progressively lower velocities as the particles become smaller. For particle diameters larger than 1 mm, the settling velocity is a function of the particle diameter ( $d$ ) to the 1/2 power. This is consistent with Froude model scaling for velocity,  $V_r = L_r^{1/2}$ .

### C.2.7 Settling Velocity Adjustment

By increasing the size of a model sediment grain, the settling velocity can be corrected to the proper value for Froude scaling in the model for a grain Reynolds number in the range  $5 < R^* < 100$ . For example, according to geometric scaling, a 1:10 scale model of prototype sand 2.0 mm in diameter would use sand 0.2 mm in diameter. However, the settling velocity would then be about 0.02 m/s (see Fig. C-6), when it should be 0.049 m/s, according to Froude scaling. If the model particle diameter is adjusted from 0.2-mm to 0.4-mm, the settling velocity is corrected to 0.049 m/s, the proper value for Froude scaling. Fig. C-7 gives sample sediment size adjustments for a fuse plug prototype gradation curve of the sand and gravel zone of the embankment (1:10 and 1:25 scale models). Note that the model gradation curves are closer to geometric scaling in the larger sizes. After the model gradation is determined, the test material may need to be created by mixing uniform-sized sands, or an available natural sand gradation may be close enough to the design gradation to suit the purpose.

The effect of settling velocity adjustment on the dimensionless sediment discharge rate ( $q_s^*$ ) is shown in the examples for fuse plug model scaling plotted in Fig. C-5. Note that the model values of dimensionless shear ( $\tau^*$ ) for geometrically scaled particles, before settling velocity adjustments, are about the same as the prototype values they simulate (Froude scaling). Tests 1 to 5 simulate a 7.6-m (25-ft)-high prototype fuse plug embankment, and tests 6, 7, and 8 simulate a 3.8-m (12.5-ft)-high prototype embankment. However, the value of  $q_s^*$  must be the same in the model and prototype to properly

Fig. C-6. Settling velocity of sand and silt in 15° C water.

scale the time rate of sediment transport. When the model grain sizes are adjusted for settling velocity (as described above), the value of  $\tau^*$  decreases, whereas, the value of  $R^*$  increases (see the effect of the change in Fig. C-5). This adjustment brings the model value of  $q_s^*$  much closer to the estimated prototype curves for  $q_s^*$ . The method applies to noncohesive materials in the model and in the prototype, and must be checked for various ranges of grain sizes, locations, and model flow conditions. If model Reynolds number is less than 5, a lighter sediment weight is often substituted to approximate the proper model sediment transport rate. If the model  $d$  is greater than 1mm, no adjustment in sediment grain size is generally necessary. However, keep in mind that the model  $R^*$  values will be lower in certain zones in the model, so each area of interest to sediment transport in the model needs to be evaluated to properly simulate sediment-transport scaling. For instance, sediment is

sometimes drawn back into stilling basins by surging reverse currents at the end of energy-dissipation-type stilling basins. To simulate this movement in a physical model, the velocities should be measured and the procedure described above should be applied to determine the appropriate model sediment size and weight to simulate transport in this area.

It is desirable to make the model scale as close as possible to the prototype so that scale effects are minimized. This is why model sediment is sometimes simulated with a lightweight material, such as coal dust, in a model with a relatively small scale,  $R^* < 5$ .

### C.2.8 Model-Prototype Comparison

Photographs of the laboratory fuse plug tests are shown in Figs. C-8 and C-9. The lateral erosion process after the initial

**Fig. C-7.** Sample sediment size adjustments for fuse plug prototype gradation curves. Main sand and gravel shell (1:10 and 1:25 scale models).

**Fig. C-8.** Fuse plug test; lateral erosion in progress, initial breach is complete.

breach is shown in Fig. C-8. The rate of erosion is controlled by the embankment geometry and the material gradation and placement of the zoned embankment.

The erosion rate of the main 'shell,' downstream from the inclined impervious core, controls the lateral erosion rate. This zone (sand and gravel) was carefully modeled with the gradations shown in Fig. C-7. The gradations were obtained by mixing proportions of uniform-sized sands to

reconstruct the gradation curve determined by the scaling process described above. After the scaled gradations were mixed, they were tested with sieve analysis to confirm the proper gradation. The material was placed in lifts and compacted to 70% relative density by weighing and compacting each lift in the model. The gradation and compaction of the graded material are important in properly simulating the erosion rate.

**Fig. C-9.** Fuse plug model test at Reclamation's hydraulic laboratory; pilot channel breach.

Figure C-9 shows the initial breach process in the pilot channel section. This process is controlled by the structural strength of the cantilevered core, as described above. The erosion of the shell material beneath the core controls the initial breach rate of the pilot channel, as well as the lateral erosion process after the initial breach. During the initial breach and the lateral erosion, the upstream water surface was maintained constant to approximate a prototype condition with much more reservoir storage. This also eliminates the variable water surface as a complicating variable in the tests.

A field test was performed in 1959 (Albrook 1959) on a 1:2 scale model of the 8.2-m-high fuse plug used for the Oxbow Project on the Snake River in Idaho. The gradation curve for the 4.1-m-high test embankment was very close to the prototype gradation simulated in the fuse plug model study conducted at the Bureau of Reclamation's hydraulic laboratory in 1985.

The geometrically scaled sand grain diameters in the model were adjusted in size with the settling velocity adjustment correcting for the Reynolds number offset (Pugh 1985).

The lateral erosion rate predicted by Reclamation's 1:10 scale model for the Oxbow field test was 1.66 m/min as compared to 1.71 m/min measured during the Oxbow test (Fig. C-10). The difference of 2% is well within experimental accuracy and seems to substantiate the scaling technique.

### C.3 Nomenclature

Subscripts  $_m$  and  $_p$  refer to the model and prototype, and  $_r$  refers to the ratio between the model and prototype.

$D$  = water depth; pipe diameter in Fig. C-2

$d$  = sand grain diameter

$d_{90}$  = grain diameter at which 90% of the grains are smaller

$E$  = modulus of elasticity of the cohesive sediment material

$F = V/\sqrt{gD}$  = Froude number

$F_c$  = critical tractive force

$F_w$  = weight force

$f_w$  = the Darcy-Weisbach friction factor

$g$  = acceleration due to gravity

$K_s = 2 \cdot d_{90}$  (rugosity)

$L$  = a characteristic length

$L_r$  = length ratio between model and prototype

$M$  = the structural merit number

$Q_s$  = sediment discharge rate

$q$  = unit discharge

$q_s$  = unit sediment discharge

$q_s^*$  = dimensionless unit sediment discharge

$R$  = the hydraulic radius

$R = Vd/\nu$  = Reynolds number

$R^* = u^* \cdot d/\nu$  = boundary or grain Reynolds number

$R_r = L_r^{3/2}$  = Reynolds number offset ratio for a Froude-scaled model

$S$  = water surface slope

$u^*$  = shear velocity

$V$  = average water velocity at any point

$w$  = settling velocity of sand and silt in water

$\gamma$  = specific weight of water

$\gamma_s$  = specific weight of sediment

$\rho$  = water density

$\rho_s$  = sediment density

$\sigma$  = surface tension

$\sigma$  = standard deviation of grain sizes

$\tau^{*g}$  = dimensionless shear stress

$\tau_o$  = the tractive stress

$\tau_c$  = critical shear stress, where sediment starts to move

$\nu$  = the kinematic viscosity

$\phi$  = sediment friction angle

Fig. C-10. U. S. Bureau of Reclamation fuse plug model test results (Oxbow field test included).

## APPENDIX D

### *Estimating Sediment Discharge*

*John R. Gray and Francisco J. M. Simões*

#### D.1 INTRODUCTION

Sediment-discharge measurements usually are available on a discrete or periodic basis. However, estimates of sediment transport often are needed for unmeasured periods, such as when daily or annual sediment-discharge values are sought, or when estimates of transport rates for unmeasured or hypothetical flows are required. Selected methods for estimating suspended-sediment, bed-load, bed-material-load, and total-load discharges have been presented in some detail elsewhere in this volume. The purposes of this contribution are to present some limitations and potential pitfalls associated with obtaining and using the requisite data and equations to estimate sediment discharges and to provide guidance for selecting appropriate estimating equations.

Records of sediment discharge are derived from data collected with sufficient frequency to obtain reliable estimates for the computational interval and period. Most sediment-discharge records are computed at daily or annual intervals based on periodically collected data, although some partial records represent discrete or seasonal intervals such as those for flood periods. The method used to calculate sediment-discharge records is dependent on the types and frequency of available data. Records for suspended-sediment discharge computed by methods described by Porterfield (1972) are most prevalent, in part because measurement protocols and computational techniques are well established and because suspended sediment composes the bulk of sediment discharges for many rivers. Discharge records for bed load, total load, or in some cases bed-material load plus wash load are less common.

Reliable estimation of sediment discharges presupposes that the data on which the estimates are based are comparable and reliable. Unfortunately, data describing a selected characteristic of sediment were not necessarily derived—collected, processed, analyzed, or interpreted—in a consistent manner. For example, bed-load data collected with different types of bed-load samplers may not be comparable (Gray et al. 1991;

Childers 1999; Edwards and Glysson 1999). The total suspended solids (TSS) analytical method tends to produce concentration data from open-channel flows that are biased low with respect to their paired suspended-sediment concentration values, particularly when sand-size material composes more than about a quarter of the material in suspension. Instantaneous sediment-discharge values based on TSS data may differ from the more reliable product of suspended-sediment concentration values and the same water-discharge data by an order of magnitude (Gray et al. 2000; Bent et al. 2001; Glysson et al. 2000; 2001). An assessment of data comparability and reliability is an important first step in the estimation of sediment discharges.

There are two approaches to obtaining values describing sediment loads in streams. One is based on direct measurement of the quantities of interest, and the other on relations developed between hydraulic parameters and sediment-transport potential. In the next sections, the most common techniques for both approaches are briefly addressed.

#### D.2 SUSPENDED-SEDIMENT CONCENTRATION INTERPOLATION METHOD

Suspended-sediment-discharge records are derived from analytical results of sediment samples and water discharge. Most are computed as daily time-series records. Some are computed on an annual basis, and some are computed for fractions of a day that can be summed to derive daily-value data.

The fundamental methods used by the U.S. Geological Survey (USGS) for collecting and computing daily suspended-sediment-discharge records have not changed since the 1940s. The most commonly used method is based on the derivation of a temporal relation by interpolating between measured suspended-sediment concentration values and using measured and estimated concentration values with

time-weighted water-discharge values to calculate suspended-sediment discharges (Porterfield 1972). A temporal plot of suspended-sediment concentration values representative of the mean cross-sectional value at the time of collection is developed. A smooth curve, or in some cases a linear interpolation based on these values and other hydrologic information, is developed. Concentration values are merged with discharge values representing a selected time interval and summed to derive daily suspended-sediment discharges using the equation

$$Q_s = Q_w C_s k \quad (\text{D-1})$$

where

$Q_s$  = suspended-sediment discharge, in tons per day or metric tonnes per day;

$Q_w$  = water discharge, in cubic feet per second or cubic meters per second;

$C_s$  = mean concentration of suspended sediment in the cross-section in milligrams/liter; and

$k$  = a coefficient based on the unit of measurement of water discharge that assumes a specific weight of 2.65 for sediment, and equals 0.0027 in inch-pound units, or 0.0864 in SI units.

The suspended-sediment concentration relations based on linear interpolation and associated water discharges for two floods on the Mississippi River at Thebes, Illinois, are shown in Fig. D-1 (Holmes 1993).

Reliable suspended-sediment records cannot be obtained unless all concentration values used in the computation are representative of the mean cross-sectional value. Most suspended-sediment data in the United States are collected from only part of the stream cross-section, either manually as a surface dip or a single vertical, or automatically from a point in the stream. Because the derived concentration values may not represent the mean cross-sectional sediment concentration, they must be adjusted by empirically developed

coefficients computed for the period of interest from concentrations obtained from partial-section samples and concurrently collected velocity- and depth-integrated, cross-sectional samples. It is seldom possible to collect a single cross-sectional sample in the length of time that it takes to obtain a sample with a pumping sampler, or to collect a single-vertical sample. Consequently, it is recommended that partial-section samples be collected immediately before and after one or more cross-sectional samples are collected. This procedure will serve to better define any changes in concentration that might occur during the time period necessary to collect the cross-sectional samples. If it is suspected that the concentration is changing rapidly during the collection of the cross-sectional samples, additional interim partial-section samples should be collected during the time that the cross-sectional samples are collected. Collection and comparison of these interim samples should be repeated during routine site visits, as well as during rising and falling stages, and during high flows for all seasons.

Cross-sectional coefficients usually are applied on a discharge-weighted or time-weighted basis. Increasing flow rates tend to be correlated with higher turbulence, more efficient mixing of sediment particles, and changes in the percentage of sand-size material in transport. Concentration values adjusted by discharge-weighted cross-sectional coefficients generally have been found to be more reliable and accurate than those adjusted by time-weighted coefficients. Regardless of the application method used, insufficient definition of these coefficients, or their subsequent misapplication, can result in substantial errors in the derivation of daily suspended-sediment-discharge records. A more detailed discussion of the development and application of cross-sectional coefficients is provided by Guy (1970) and Porterfield (1972) (also see Chapter 5 in this volume).

Computer software developed since the 1980s facilitates computational procedures and improves the accuracy of suspended-sediment-discharge records (Koltun et al. 1994; McKallip et al. 2001). The method of McKallip et al. (2001)

**Fig. D-1.** Water-discharge and suspended-sediment concentration graphs for two floods on the Mississippi River at Thebes, Illinois (USGS Streamgauging Station 07022000; Holmes 1993, p. 17).

provides advanced options for manipulating and portraying the sediment and flow data and for reliable development and application of cross-sectional coefficients.

### D.3 TRANSPORT-CURVE METHOD FOR SUSPENDED SEDIMENT LOAD, BED LOAD, AND TOTAL LOAD

The empirical relation between water discharge and sediment concentration (or sediment discharge) at a site can be expressed graphically as a single average relation (Fig. D-2), and as a temporal relation (Fig. D-3). Such relations, referred to collectively as sediment-transport curves, are widely used to estimate sediment concentrations or sediment discharges for periods when water-discharge data are available but sediment data are not (Colby 1956). Sediment-transport curves can be classified according to either the period of the basic data that define the curve—instantaneous, daily, monthly, annual, or flood-period—or the kind of sediment discharge that the curve represents—suspended-sediment load, bed load, or total load (Glysson 1987).

Transport curves such as those in Figs. D-2 and D-3 are usually developed from logarithmically transformed data with water discharge as the independent variable and either sediment concentration or sediment discharge as the dependent variable. Bean and Al-Nassri (1988) consider use of sediment discharge as the dependent variable to be misleading because the goodness of fit implied by the relation is spurious.

Transport-curve relations are usually defined as a power function (Glysson 1987),

$$Q_s = aQ_w^b \quad (\text{D-2})$$

where

$Q_s$  = suspended-sediment discharge, in tons per day or tonnes per day;

$Q_w$  = water discharge, in cubic feet per second or cubic meters per second;

$a$  = the intercept; and

$b$  = the slope.

The function can be formulated as either a linear or non-linear model to find the solution for transport-curve parameters  $a$  and  $b$ . Formulation of the power function as a linear model requires a logarithmic transformation to linearize the function and subsequently correct for subunity bias in the retransformation of sediment-discharge or -concentration estimates (Crawford 1991). The degree to which constituent discharges are underestimated as a result of retransformation is a function of the goodness-of-fit of the regression line. Generally, increasing the data scatter around the regression line results in decreasing estimates of the value of the dependent variable.

Various methods are available for developing bias correction factors. Ferguson (1986) proposed a bias correction factor based on the standard error of the regression equation. Although satisfactory in many practical situations, Ferguson's (1986) method not only fails to eliminate bias but also can lead to severe overestimation of constituent loads (Cohn et al. 1989). Duan (1983) developed the "smearing estimator," which is insensitive to nonnormality in the distribution of regression residuals about the logarithmic model and avoids the overcompensation of Ferguson's (1986)

**Fig. D-2.** Relation between water discharge and suspended-sediment concentration for the Missouri River at Hermann, Missouri (USGS Streamgauging Station 06934500; Holmes 1993, p. 5).

Fig. D-3. Relation between water discharge and suspended-sediment concentration for the Mississippi River below Grafton, Illinois (USGS Streamgauging Station 05587455; Holmes 1993, p. 4).

approach. A method proposed by Cohn et al. (1989) assumes normally distributed residuals about the logarithmic model and results in an exact minimum variance unbiased estimator and its variance.

A direct relation between  $Q_w$  and  $Q_s$  in streams is rarely present. A lack of synchronization between the peaks of water discharge and sediment concentration over a flood hydrograph is more the rule than the exception. That means that in parts of the hydrograph where sediment discharge is increasing, sediment concentration may be decreasing, and vice versa. That effect is clearly present in the 1993 Mississippi River flood at Thebes, Illinois (Fig. D-1), where in parts of the hydrograph not only are changes in the magnitude of water discharge not accompanied by associated changes in sediment concentration, but at times they show opposite trends.

A more complicated example of transport relations is demonstrated by a graph of instantaneous flow versus suspended-sand (0.062–2.0 mm) concentration data for the Colorado River near Grand Canyon, Arizona (USGS streamgauging station 09402500, Fig. D-4) (David Topping, U.S. Geological Survey, written communication, 2003), located 164 river km downstream from Glen Canyon Dam. General transport relations are depicted within three regions, or envelopes, on the graph. The left-most envelope encompasses the bulk of sand data for the period collected before closure of the dam in 1962. The right-most envelope encompasses most of the sand-concentration data collected after the upper river main channel sediment supply was essentially cut off following dam closure, through 1986. The central envelope encompasses most of the data for the period from 1991 to 2001. These general relations reflect

a combination of dynamics in this river system, including natural variability in sand transport as a function of short-term (hours-to-days) flow fluctuations; cut-off of the main stem sediment supply 164 km upstream from the gauge; variability in the timing and rates of flow and sand transport from tributaries to the Colorado River in the reach between the dam and the gauge; and sand storage and redistribution patterns that occur over short- and long time-scales in that river reach.

The sediment-transport curve flow-duration method (Livesey 1975) was developed for sites where the duration of discharge record greatly exceeds the period for which sediment data are available. This method combines the transport-curve principle with streamflow records to develop a probability correlation between the sediment concentration and water discharge of a stream. It consists of determination of suspended-sediment-discharge values from the transport curve for corresponding increments of discharge from a flow-duration curve. Multiplication of the suspended-sediment load and discharge increments by the time-percentage interval results in a daily occurrence value. These daily average values can be summed to produce an estimate of annual suspended-sediment discharge.

Most sediment data obtained as part of monitoring programs tend to be associated with nonflood flows. The slope and intercept from linear regression analysis under these circumstances tend to be unduly affected by the large number of concentration values at low flows (Porterfield et al. 1978). Glysson (1987) describes a group-averaging method that determines the average—usually the arithmetic mean—of all values of the dependent variable (sediment discharge) for a small range of the independent variable (water discharge).

**Fig. D-4.** Relations between water discharge and suspended-sand (0.062–2.0 mm) concentrations for the Colorado River near Grand Canyon, Arizona (USGS Streamgauging Station 09402500; adapted from David Topping, USGS, written communication, 2003).

The average sediment discharge within each small range of water discharge then can be plotted against the average observed water discharge for that range. A transport curve then is fitted to these points in logarithmic space, such as that shown in Fig. D-5 for the Eel River at Scotia, California.

A combination of the suspended-sediment interpolation and suspended-sediment transport curve methods is referred to as the “hydrograph-shifting method” (Colby 1956). This empirical method requires daily water-discharge data and a sediment-transport curve for the same period and site. Daily suspended-sediment discharges (control points) estimated from the transport curve and daily mean water discharges are plotted on semilogarithmic coordinates. By viewing the curves on a light table or computer screen, the sediment-discharge hydrograph is moved vertically (shifted) to pass through or near the control points. After the base hydro-

graph is shifted to the control points, daily values are determined from the graph and are summed to give monthly and annual suspended-sediment discharges. Frost and Mansue (1984) estimated suspended-sediment discharges for 12 streams in Illinois using the hydrograph-shifting method with 2 yr of daily-flow and suspended-sediment record. Estimates of monthly and annual suspended-sediment discharges ranged from 16 to 326% and 41 to 136%, respectively, of measured values. This method is known to work well at sites with stable transport relations and where the transport curves indicate little or no hysteresis looping (G. Douglas Glysson, U.S. Geological Survey, written communication, 2000).

The reliability of sediment discharges computed from transport curves depends on a number of factors, including the range of discharges over which the data were collected to

**Fig. D-5.** Sediment-transport curves based on the group averages method for Eel River at Scotia, California (USGS Streamgauging Station 11477000), 1958–1960 water years (Glysson 1987, p. 34).

define the curve, the number and reliability of the concentration-discharge relations used to define the curve, and whether the data are representative of water and sediment discharges for the computational period. The National Council for Air and Stream Improvement (NCASI 1999) considers “relatively good” suspended-sediment-discharge estimates from transport curves to be within 30% of the actual value. Meade et al. (1990) proffered that an average error of 50% for annual sediment-discharge estimates derived from sediment-transport curves.

Specification of a reference time interval has a direct bearing on the magnitude of errors in load estimates from transport curves. Walling (1977), using transport curves for the River Creedy, found that annual loads could be overestimated by as much as 30% even when the relations were refined for seasonal and stage effects, and monthly errors could vary from –80 to 900% of actual loads.

Glysson et al. (2001) compared transport-curve-generated suspended-sediment loads on daily, annual, and period-of-record intervals for 10 USGS streamgauging stations to loads computed by traditional techniques (Porterfield 1972) for the same stations and periods. Table D-1 shows the annual and total errors in the estimate of the suspended-sediment loads for the 10 stations used in this analysis. The magnitude of variations resulting from the use of regression analysis to estimate sediment loads decreased substantially with respect to those computed by traditional USGS techniques as the time frame associated with the estimated value

increased. For example, errors between daily-sediment loads computed by regression versus traditional USGS techniques at the Rio Grande at Otowi Bridge station were as large as 4000%. However, the maximum error in the estimation of an annual load was 526%, and the error in the estimate of the total suspended-sediment load for 34 years of record at this station was within 38% of the traditionally derived value.

Glysson et al. (2001) concluded that estimates of suspended-sediment loads based on regression analyses are subject to significant errors. Because of the nature of sediment transport in open channels, there can be a large range in sediment concentrations at any given discharge. The fewer the number of concentration values available to define this range, the larger the potential errors can be. Although a well-defined, carefully constructed, and judiciously applied sediment-transport curve can be a useful tool for estimating sediment loads, load estimates derived from transport curves should not be considered a substitute for daily-sediment records computed by methods described by Porterfield (1972).

Because time-series data for bed load and total load are rare, the transport-curve method is more widely applied to estimate bed-load and total-load transport. Furthermore, for alluvial rivers, transport curves constructed for sediments that are characteristic of the bed will tend to be more accurate than those that include the wash-load component. Wash load is affected by watershed-wide processes that can vary with season, land use, rainfall, and other factors, whereas the bed-material load is primarily a function of the relation between river power and the availability of transportable bed sediments.

The empirical methods described in this and the previous section necessarily are based on direct measurements of sediment-transport rates using techniques described by Edwards and Glysson (1999) and samplers described by Davis and the Federal Interagency Sedimentation Project (2005), Childers (1999) and Edwards and Glysson (1999) and in other chapters of this volume. Depending on the phase of transport, the transport rate is either directly or indirectly dependent on water discharge, a quantity that can be measured with relative accuracy using conventional techniques (Buchanon and Somers 1969; Rantz 1982; USGS 2001). However, one or more factors can render these empirical methods difficult, impractical, or inappropriate to use and thus restrict their utility. On one hand, the sediment-transport curves thus obtained are valid only for the cross section or reach at which the data were collected, and for the watershed and channel conditions characteristic of those existing when the data were collected. On the other hand, information requirements for these empirical techniques, typically involving large amounts of data describing sediment and flow characteristics over a wide range of discharges and/or seasons, can be overwhelming to obtain with respect to available resources. Additionally, transport-rate estimates obtained from empirical techniques reflect a combination of errors

**Table D-1 Summary Errors<sup>a</sup> in the Estimations of Annual Suspended-Sediment Loads<sup>b</sup> for the Period of Record for 10 USGS Streamgauging Stations**

Site ID	Name	Years of record	Maximum annual error	Minimum annual error	Median annual error	Mean annual error	Error in total estimated load for period of record <sup>c</sup>

<sup>a</sup>Error = 100 (estimated load – measured load)/measured load; all errors are expressed in percent.

<sup>b</sup>Suspended-sediment data (ASTM International 1997) were used in load calculations.

<sup>c</sup>The sum for the period of record of the measured load and the estimated load were used in this calculation.

inherent in the sampling and load-estimation techniques used. The magnitudes of these errors remain largely undefined and indefinable. Therefore, there is a need for sediment-transport estimation methods that can be used where field data are few or nonexistent and/or where exigency favors their application.

#### D.4 EQUATIONS FOR ESTIMATING BED LOAD AND BED-MATERIAL LOAD

Bed-load and bed-material transport have been studied systematically since the pioneering work of DuBoys in 1879. Since then, many empirical equations have been developed

to estimate bed load and bed-material load and, at least in theory, they are straightforward to apply. These equations are predicated on the presence of specific relations among hydraulic variables, sedimentological parameters, and the rate at which bed load or bed-material load is transported.

Quantifying these relations has been problematic. On one hand, the theory supporting their derivations is incomplete, oversimplified, or nonexistent, with some empirical relations based entirely on data fitting. On the other hand, even the theoretically most complete equations rely on experimental data to determine the values of some of their coefficients, and their accuracy is often further undermined by the lack of reliable environmental data. Factors that may affect the usefulness of these equations are described in the following paragraphs.

#### D.4.1 Data Issues

The availability, reliability, and comparability of data to quantify coefficients for bed-load and bed-material-discharge equations cannot be taken for granted. Most estimating equations require data describing characteristics of the coarser sediment fractions in the channel. However, the preponderance of sediment data available from the USGS are for sand-size and finer material in suspension (Turcios et al. 2000;

Turcios and Gray 2001). Data-collection techniques for coarser size fractions, such as those described by Bunte and Abt (2001), tend to be relatively costly and time-consuming. According to Wilcock (2001), estimates of sediment transport based on reliable local information require up to several days of nontrivial field work, and at least several return visits to collect the requisite data.

Bravo-Espinosa (1999) observed that many of the measured bed-load-transport rates used in his research were not particularly accurate. Leopold and Emmett (1997) state that “it would be highly desirable to have direct measurements of the bed-load transport in a natural river and of the concomitant hydraulic characteristics of the flow. The problem has been particularly intractable, because no sampling device has been available that would provide reliable and repeatable measurements of the debris load moving along the bed of the river.” Gray et al. (1991) demonstrated that two types of pressure-difference-type bed-load samplers deployed simultaneously 2 m apart in the middle of the sand-bedded Colorado River under steady low-flow conditions (mean discharge 167 m<sup>3</sup>/s) exhibited divergent sampling efficiencies (Fig. D-6). At-a-point bed-load-transport rates measured by the experimental BL-86-3 sampler with a nozzle outlet-to-inlet ratio of 1.40 were compared to those from a Helley-Smith sampler with a 3.22 ratio. Although short-

**Fig. D-6.** Differences in bed-load-transport rates concurrently measured with the Helley-Smith bed-load sampler (3.22 outlet-to-intake-nozzle ratio) and the experimental BL-86-3 bed-load sampler (1.40 outlet-to-intake-nozzle ratio) to those measured with the Helley-Smith sampler at the Colorado River above National Canyon, near Supai, Arizona (USGS Streamgauging Station 09404120; Gray et al. 1991, pp. 4–76).

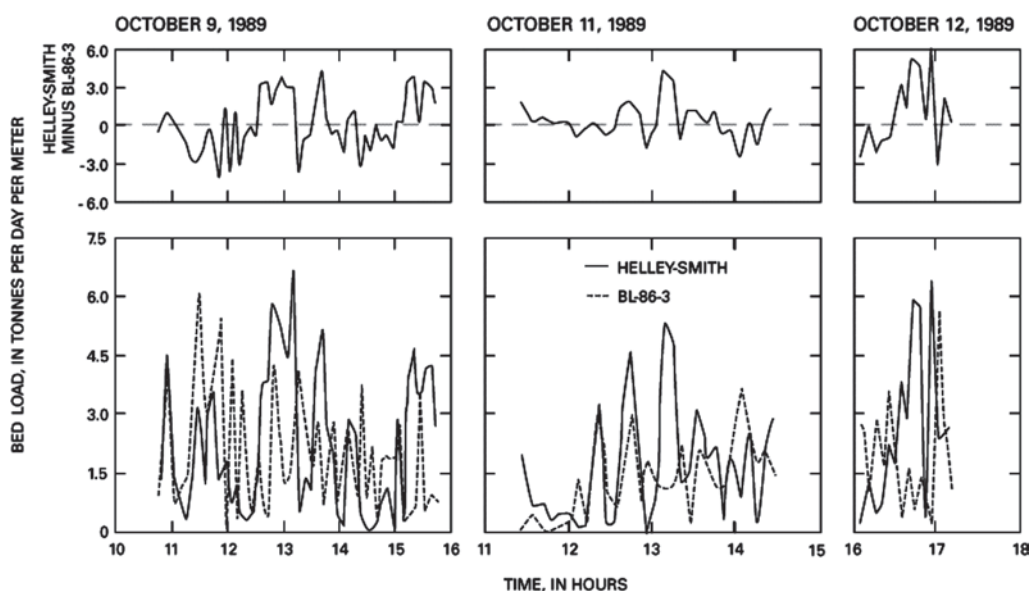

term transport rates—minutes to hours—measured by both samplers were highly variable (Fig. D-7), the cross-sectional bed-load-transport relation based on results from all 390 bed-load samples collected over a 5-day period showed that the bulk of the bed-load transport occurred in the middle 15 m of the 76-m-wide river at a more or less uniform mean transport rate of 2.8 tn/day per meter of width (Fig. D-8). This study demonstrated potential inconsistencies in sampler performance and the need for large amounts of data to adequately describe spatial and temporal characteristics of bed-load transport even under steady-flow conditions.

Another indication of bed-load-sampler performance was provided by Childers (1999), who compared the relative sampling characteristics of six pressure-difference bed-load samplers in high-energy flows of the Toutle River at the Coal Bank bridge near Silver Lake, Washington (USGS Streamgauging Station 14242450). The sampling ratio of each pair of samplers tested was computed by dividing the mean bed-load-transport rate determined for one sampler by the mean rate for a second sampler. Ratios of bed-load rates between measured bed-load pairs ranged from 0.40 to 5.73, or more than an order of magnitude in differences of sampling efficiencies. Based on these tests, Childers (1999) concluded that the Toutle River-2 bed-load sampler appears to be capable of providing representative bed-load samples for material ranging from 1.0 to 128 mm median diameter.

Bunte (1996) attributes deficiencies in the understanding of coarse bed-load-transport processes to a “dearth of appropriate measuring techniques and data from natural streams.”

Emmett’s (1980) solution to this problem was to construct a conveyor-belt bed-load trap in a concrete trough across the bed of the East Fork River of Wyoming. The trap caught all the bed load that dropped into the trough, conveyed it to the streambank for weighing and sampling, and returned it to the river downstream from the trough. The bed-load trap was used to collect bed-load data for 7 yr and to field-calibrate the Helley-Smith bed-load sampler. This work is as notable for its considerable success in quantifying the bed-load characteristics of the East Fork River and calibrating the Helley-Smith bed-load sampler as it is in highlighting difficulties and the considerable expense of obtaining reliable bed-load data.

Because of the difficulty of obtaining accurate field sediment-transport data, many researchers rely on laboratory flume data. The measurements of sediment-transport rates in the laboratory can be quite accurate, but do not represent natural river conditions well. Leopold and Emmett (1997) observed that a river’s ability to adjust its cross section to a variety of flows is a characteristic not shared by a fixed-wall flume. The sediment in transport is determined by the geological and physiographic setting of the river and river basin; thus, sediment is not a controllable variable. The variety of conditions controlled in a laboratory experiment cannot be established in a natural river. Furthermore, bed-material transport in a flume is tantamount to total load, in that fine material typically is excluded from flume bed-load or bed-material-load experiments. In a river, total load is equal to bed-material load plus wash load. Bed-material equations

**Fig. D-7.** Temporal variability in bed-load-transport rates between the Helley-Smith bed-load sampler (3.22 outlet-to-intake-nozzle ratio) and the experimental BL-86-3 bed-load sampler (1.40 outlet-to-intake-nozzle ratio) at the Colorado River above National Canyon, near Supai, Arizona (USGS Streamgauging Station 09404120; Gray et al. 1991, pp. 4–68).

**Fig. D-8.** Box-and-whisker plots showing the cross-sectional distribution of bed load during steady flow of 165 m<sup>3</sup>/s at the Colorado River above National Canyon, near Supai, Arizona (USGS Streamgauging Station 09404120; Gray et al. 1991, pp. 4–70).

calibrated on coarse-sediment flume data may substantially underestimate the total load when the wash-load component is comparatively large.

Based on the preceding information, it is not surprising that most bed-load and bed-material-load equations are derived from a comparatively restricted database, and their utility has been established on the basis of relatively few field data (Gomez and Church 1989). The disparate nature of much of the experimental data that are available, coupled with a dearth of reliable field data, seem to have encouraged the proliferation rather than the consolidation of transport equations. Ashworth and Ferguson (1986) point out that more data sets of integrated and intensive field measurements are needed if a better understanding of the functioning of active gravel-bed rivers is to be gained.

#### D.4.2 Sediment-Supply Issues

A key question in investigating sediment transport in natural flows is whether transport is limited by flow strength or sediment supply. The answer to this question determines whether research should focus on the relation between flow strength and sediment transport, the rate at which sediment of different grain sizes is supplied to the flow, or both (Rubin and Topping 2001).

Characteristics of sediment supply and transport affect the reliability of equations for estimating sediment discharge. Bed-load and bed-material-load equations are designed to estimate the actual transport of the watercourse. The transport capacity is the maximum tractive sediment

load that the watercourse can convey for the given hydraulic and sedimentary conditions. However, the transport capacity calculated for a given stream and flow condition may differ substantially from the actual transport rate. For example, the natural processes of imbrication (longitudinal orientation of coarse surficial material in a fish-scale pattern) and/or armoring (coarse surficial material, such as boulders and cobbles, overlying finer material) can result in a calculated transport capacity substantially larger than the true capacity, because the flows may lack sufficient energy to move the bed material. Additionally, many streams are naturally or unnaturally in disequilibrium and are aggrading or degrading on time scales of years and decades—factors that may not be consistent with the estimating-equation requirements.

Besides the hydraulic factors, hydrological, geological, geographical, biological and other factors affect the sediment load of a stream. Some of a stream's sediment supply is derived from runoff from upland areas. Factors including season, snowmelt, rainstorm duration and intensity, watershed use, vegetation cover, watershed field slope, soil types, and human and animal activities determine the amount of sediment entering the stream and ultimately affect the sediment transported by the watercourse. Therefore, all of the assumptions on which most of the bed-load and bed-material-load equations are based may not be valid, or at least verifiable in a riverine setting. These include steady and uniform flow conditions and, as previously noted, an unlimited supply of sediment. Regarding the latter assumption, Bravo-Espinosa (1999) notes a need for a clear identification of sediment-supply conditions before a bed-load equation is applied. In summary, using equations to estimate

sediment transport, particularly in gravel-bed rivers, remains problematic and is the focus of ongoing research.

### D.4.3 Other Technical Issues

Difficulties in quantifying incipient motion—the initiation of bed-particle movement—pose another obstacle for the accurate estimation of sediment discharge. Determination of incipient motion in gravel-bed systems is complicated by a number of factors, including imbrication, armoring, and other nonhomogeneous distributions of bed material; determination of turbulent shear stress; and surface-packing density. Many sediment-transport equations, especially those for gravel-bed rivers, have a term that includes the critical shear stress,  $\tau_c$ , which is the value of the bed shear stress for which initiation of bed motion occurs. This term is present as a coefficient in the form  $\tau/\tau_c$ , the associated uncertainty of which is the single largest source of error in the transport estimates. Wilcock (1997; 1998) presents a method, based on a calibrated approach, that is a compromise between the estimation methods of this section and empirical approaches for quantifying sediment transport presented previous to this chapter. This method emphasizes the measurement of the bed-material-transport rates under flow conditions close to incipient motion. A small number of accurate observations are used to identify the value of  $\tau_c$ , thus reducing the error in  $\tau/\tau_c$  and resulting in transport estimates with higher accuracy.

Verifiably accurate estimation of wash-load transport rates remains an illusive goal. Most wash load other than that from bank caving originates in nonchannel parts of the watershed and is transported to the channel primarily by overland flow. It consists of fine material that flows through a reach without appreciable interaction with the bed, and represents the bulk of deposits in many lakes and reservoirs. Wash load tends not to be directly related to streamflow—except through rainfall, which is an important factor in detaching the sediment and producing the overland flow that delivers the wash load to the watercourse and adds to streamflow. This general lack of a direct relation between streamflow and wash load has complicated development of an analytic method to estimate wash-load-transport rates. Various watershed models have been developed to simulate runoff and wash load from the land surface. Although it is recognized that the sediment load of rivers and streams is composed of wash load and bed-material load, the equations described in this section are applicable only to the estimation of bed load or bed-material load, necessarily neglecting wash-load transport and its effects.

In spite of the problems associated with the derivation and application of bed-load and bed-material-load equations, they are necessary, because it is neither practical nor feasible to measure bed load or bed-material load at all desired sites and under all desired conditions. Numerous equations for estimating bed-load and bed-material-load transport

have been developed based on four principal approaches:<sup>1</sup> shear stress or tractive force; energy; discharge or velocity; and probabilistic (Chang 1988; Yang 1996). These are described in the following paragraphs.

*Shear Stress or Tractive Force:* This approach assumes that the capacity of a stream to transport sediment varies directly with the shear stress acting on the bed, or with the difference between the shear stress acting on the bed particles and the critical shear stress for initiation of particle motion. The major difficulty of this approach is in determining the effective bed shear stress, which must be equal to the bed-form drag, a quantity that differs from the grain roughness and from the total bed shear stress. The determination of the initiation of motion poses another difficulty for this method (usually, the Shields  $\tau_c$  is used, but the issue has not been satisfactorily resolved). The lift forces acting on the sediment particles also are ignored, which may constitute another source of error.

*Energy:* The energy approach is based on considerations of the energy carried by the flow and the energy necessary to carry the sediment particles. This approach may include considerations based on equating the work done by the flowing water and the rate of sediment transport or based on a balance of forces acting on the sediment particle. It includes equations based on unit stream power (power per unit of weight of water), which is expressed as the product of average velocity and channel gradient, and equations based on the stream power, which is the product of bed shear stress and average flow velocity, expressed as stream power per unit bed area.

*Discharge or Velocity:* This method uses the critical unit water discharge as a criterion for initiation of bed-load transport. It is the only approach that does not explicitly involve flow depth. Equations using the discharge or velocity approach have been criticized because sediment transport should depend on the velocity near the bed, rather than on the mean flow velocity.

*Probabilistic:* The probabilistic approach relates bed-load transport to the turbulent-flow fluctuations acting on the sediment particle, which vary in time and space. The movement of each particle depends on the probability that, for a particular time and location, the applied forces are greater than the resisting forces applied to the particle.

<sup>1</sup>This classification is not the only one possible. For example, some authors classify the equations into the following four categories: empirical equations (based almost exclusively on fitting equations to large amounts of data); semitheoretical equations (based on physical concepts and reasoning); probability-based equations; and dimensional analysis equations (using dimensional analysis and some physical reasoning, also using large amounts of data for calibration of parameters). In some respects, this type of classification may be more useful to the practicing engineer.

Although listing and describing all bed-load and bed-material-load equations is beyond the scope of this chapter, some of the more common equations found in the literature are presented in Table D-2. It is of concern that there appear to be more bed-load equations than there are reliable data sets by which to test them. Consequently, few of the equations have been universally accepted or generally recognized as especially appropriate for practical application.

Fuller descriptions of these and many other equations can be found in Shulits and Hill, Jr. (1968), Garde and Ranga Raju (1977), Stelczer (1981), Graf (1984), Bathurst et al. (1987), Yang (1996), and Yang and Huang (2001), among others. Computer programs are available that implement some of these equations. A computer program developed by Stevens (1985), based on the computational sequence of Hubbell and Matejka (1959), facilitates computations by the Modified Einstein Procedure (Colby and Hembree 1955; USGS 2000a). The Bureau of Reclamation Automated Modified Einstein Procedure (BORAMEP) is described by Holmquist-Johnson (2004). O'Brien and McCorquodale (2001) describe a technique for applying the Modified Einstein Procedure in multiple subsections of a river cross section. Stevens and Yang (1989) provide a computer program for computing bed-load discharge using any of five equations and bed-material discharge with any of eight equations (USGS 2000b). All of these equations are included in Table D-2.

Williams and Rosgen (1989) provide a compilation of measured suspended-sediment loads and approximately concurrently measured bed-load transport rates with associated hydraulic variables for 93 U.S. streams, which the authors consider to be the first comprehensive collection of field-measured total sediment load—bed loads plus suspended loads—in a variety of streams. These data sets might be useful to those who wish to test selected equations with data collected by the best sampling techniques available before 1987.

Because of the number of available equations, the ultimate question is which equation(s) should be selected for a given application. There is no simple answer to this question. Because of the semiempirical character of most equations and the extensive use of data calibration in deriving the transport-equation coefficients, each equation has a range of validity determined by the range of experimental data used in those calibrations (see Table D-2). Therefore, application of an equation for a range of hydraulic and sedimentary parameters, such as water depth, channel width, and sediment particle size, should be similar to those for which the equation was validated. Unfortunately, authors of transport equations do not always indicate the range of validity for their equations. Additionally, application of equations beyond their verified range is all too common, often resulting in substantial discrepancies between observed and estimated transport rates, or in production of unverified transport estimates.

Various comparative analyses of sediment-transport equations have been formulated with the purpose of assessing their quality. This is a subjective task that depends on the data and

methods of comparison. Some of the most complete and/or useful assessments can be found in White et al. (1975); Alonso (1980); Alonso et al. (1982); ASCE (1982); Vetter (1987; 1988); Gomez and Church (1989); Yang and Wan (1991); Lopes et al. (2001); and Yang and Huang (2001). Some of these analyses rank the equations by reliability and applicability. Not surprisingly, the rankings are quite different. A summary of the results obtained by ASCE (1982) is shown in Table D-3.

Yang and Huang (2001) performed a comprehensive and systematic analysis of 3,391 sets of laboratory and river sediment-transport data to aid in selecting from 13 sediment-transport formulas under different flow and sediment conditions. Among their conclusions are the following:

- Sediment-transport formulas based on energy dissipation rates or power concepts are superior to those based on other concepts.
- Yang's 1973, 1979, and 1984 formulas are the most robust and least sensitive to the variation of relative depth, Froude number, dimensionless shear velocity, dimensionless unit stream power, and sediment concentration.
- All but the formulas of Engelund and Hansen (1967) and Yang (1973; 1979; 1984) should be limited to subcritical flows.
- The Einstein bed-material-load and bed-load (1950) formulas and those by Meyer-Peter and Müller (1948) and Toffaleti (1968) are not as accurate as those formulas based on the power approach.

Lopes et al. (2001) categorized stream reaches into three bed-load-transport categories based on supply: those without bed-load supply limits (transport limited); those with supply limits for some particle sizes; and those supply-limited for all particle sizes. The applicability of seven bed-load equations—those of Kalinske (1947), Meyer-Peter and Müller (1948), Einstein (1950), Schoklitsch (1962), Yalin (1963), Bagnold (1980), and Parker et al. (1982)—in 22 stream reaches for which comparative bed-load data were available was tested. They found that equations of Parker et al. (1982) and Meyer-Peter and Müller (1948) adequately estimated bed-load transport in transport-limited reaches. The equations of Bagnold (1980) and Schoklitsch (1962) performed well in supply-limited channels, including those limited in some particle-size classes. The equations considered most robust were the Schoklitsch (1962) equation, which is capable of estimating the trend of measured bed load for 8 of the 22 streams; and the Bagnold equation (1980), which duplicated the trend of measured data in 7 streams.

Yang (1996) presented the following steps for the selection of a sediment-transport-rate equation:

1. Use as many field data as permissible within the resource limits of the study.
2. Examine as many equations as possible, based on assumptions used in their derivation and the range of data used to determine their coefficients, and select

**Table D-2 Some Common Bed-Load and Bed-Material-Load Equations and Associated Information Presented in Chronological Order of Development**

Formula	Foundation	Type <sup>a</sup>	Range of validity <sup>b</sup>	Comments
Du Buoy (1879)	Theoretical, based on excess of shear stress	B	—	First known model of sediment transport, it is based on the concept that the bed load moves in sliding layers. Includes parameters that can be determined only by experimentation and that have limited range of validity; has to be calibrated for each application.
Schoklitsch (1934) <sup>c</sup>	Theoretical, based on excess of shear stress	B	$0.305 \leq d \leq 7.02$	Can be applied to sediment mixtures divided into size fractions. Bed load is a function of water discharge.
Shields (1936)	Semiempirical, based on excess of shear stress	B	$1.56 < d < 2.47$ $1.06 < s < 4.25$	Derived to show the many factors influencing sediment transport, rather than to establish a universal equation.
Einstein (1942, 1950) <sup>c</sup>	Theoretical, probabilistic	B, BM	$0.785 \leq d \leq 28.65$	Originally derived for single-size sediments, it was later extended to sediment mixtures by the introduction of hiding factors. Hiding factors account for the sheltering of the smaller particles by the larger particles present in the mixture. Bed-material-load formula is the sum of bed load and suspended load formulae. Einstein's formula has been corrected and expanded by many authors, such as Brown (1950), Colby (1964), Pemberton (1972), and Yalin (1972).
Kalinske (1947) <sup>c</sup>	Theoretical, probabilistic	B	—	This equation is based on a discharge relation. It can be applied to sediment mixtures.
Meyer-Peter and Müller (1948) <sup>c</sup>	Theoretical, based on shear stress	B	$0.15 \leq W \leq 2$ $0.01 \leq D \leq 1.2$ $0.04 \leq S_f \leq 2$ $1.25 \leq \rho \leq 4$ $0.40 \leq d \leq 30$	Expansion of earlier work by Meyer-Peter et al. (1934). It is widely used in mountain streams with gravel beds. Should not be used for grain sizes $d$ smaller than ~1 mm.
Frijlink (1952)	Empirical, based on shear stress	B	—	This method is simply an approximation to the formula of Meyer-Peter and Müller (1948) and Einstein (1950).
Velikanov (1954)	Theoretical, based on energy concepts	BM	—	Equation derived from gravitational power theory. Led to a number of other similarly derived sediment-transport equations by Chinese engineers, such as those by Zhang (1959) and Dou (1974).
Bagnold (1956,1966)	Theoretical, based on energy concepts	B, BM	$d > 0.015$	Bagnold's bed-material-load formula is the sum of his bed-load and suspended-load formulae.
Laursen (1958) <sup>c</sup>	Empirical	BM	—	Can be applied to sediment mixtures divided in size fractions. It is based on a graphical relation representing experimental data collected in sand-bed flumes, without direct physical interpretation. Originally based on laboratory data, it has been modified and expanded by others to increase its scope of validity (e.g., Madden 1993).
Rottner (1959) <sup>c</sup>	Empirical, based on dimensional considerations	B	—	Related bed-load transport per unit width to dimensionless depth, velocity, and slope parameters. A regression analysis was performed to determine the effect of a relative roughness parameter $d_{50}/d$ . The equation may not be applicable at low bed-load-transport rates.

(Continued)

**Table D-2 Some Common Bed-Load and Bed-Material-Load Equations and Associated Information Presented in Chronological Order of Development (*Continued*)**

Formula	Foundation	Type <sup>a</sup>	Range of validity <sup>b</sup>	Comments
WIHEE (1961) <sup>d</sup>	Empirical	BM	—	Originally a suspended-load equation, it applies to rivers flowing over alluvial plains, where bed load is generally negligible and suspended load predominates. It is one of the equations most widely used in China.
Yalin (1963, 1972)	Theoretical, based on probabilistic concepts	B	$0.315 \leq d \leq 28.65$	This equation incorporates both probabilistic and energy concepts, such as Bagnold's rate-of-work approach. It considers particle saltation to be the mode of sediment transport.
Colby (1964) <sup>c</sup>	Empirical	BM	—	Formula is presented in graphical relations. It includes a correction factor for flows with high concentrations of fine silt and clay. Applicable to rivers with medium to fine sand beds. Available on line at <a href="http://water.usgs.gov/cgi-bin/man_wrdapp?mode=in">http://water.usgs.gov/cgi-bin/man_wrdapp?mode=in</a> .
Engelund and Hansen (1967) <sup>c</sup>	Semiempirical, based on energy concepts	BM	—	Derived for sand-dune beds; has been widely used for sandy streams. Not accurate close to the initiation of sediment motion. Yang (2005) provide a step-by-step deviation of this transport function.
Graf and Acaroglu (1968)	Semiempirical, based on shear stress	BM	—	This equation was developed for open channels and closed conduits. Somewhat similar to Einstein's (1950) equation for open channels.
Toffaletti (1968, 1969) <sup>c</sup>	Theoretical, probabilistic	BM	—	Makes the following departures from Einstein's method: collapses several correction factors into one; sediment transport is related to stream properties using more parameters; and a vertical velocity distribution is used.
Paintal (1971)	Empirical, based on shear stress	B	$0 < 0.06$ $1 < d \leq 25$	For bed-load transport at low shear stress.
Shen and Hung (1972)	Empirical	BM	—	A regression equation based on laboratory data with sand bed.
Ackers and White (1973) <sup>c</sup>	Semiempirical, based on energy concepts	BM	$0.04 \leq d \leq 4.94$	Updated by Ackers (1993) to correct transport rates for fine and coarse material. The 1973 equation was expanded by White and Day (1982) to allow the computation of the transport rate by particle size fraction. Yang (2005) provide a step-by-step deviation of this transport function.
Yang (1973, 1979)	Theoretical, based on energy concepts	BM	$0.063 \leq d \leq 2.0$	Unit stream power formula. Coefficients found by computer calibration. Has been used successfully for sediments with particle sizes in the silt range. The 1979 equation should be used for concentrations higher than 100 mg/L.

Engelund and Fredsoe (1976)	Theoretical, probabilistic	B	—	—
Bagnold (1980)	Theoretical, based on energy concepts	BM	—	Stream power formula. Included bimodal gravel-bed rivers in the analysis.
Brownlie (1981)	Semiempirical, based on energy concepts	BM	—	Based on regression analysis of laboratory and field data with mainly sand beds.
Parker et al. (1982)	Semiempirical, probabilistic	B	$0.60 \leq d \leq 102.0$	Uses the concept of equal mobility. It has been corrected and expanded by others, such as Diplas (1987) and Bakke et al. (1999). Applies to gravel-bed rivers with pavement and subpavement layers, and is used by particle size fraction.
Smart (1984)	Empirical, based on shear stress	B	Plane bed $d \geq 0.4$ $0.4 \leq S \leq 20$	Equation for steep slopes. Based on the old data of Meyer-Peter and Müller (1948) and on new data collected on a steep flume. Not applicable to negative slopes.
van Rijn (1984a, 1984b)	Semiempirical, based on energy concepts	B, BM	$0.2 \leq d \leq 2.0$	Different semiempirical methods were used to derive bed-load transport rate equations. Experimental data and other simplifications were used to fine-tune the equations. The bed-material-load formula is the sum of the bed-load and suspended-load equations.
Yang (1984) <sup>c</sup>	Theoretical, based on energy concepts	BM	$2.0 \leq d \leq 10$	Unit stream power formula for gravel.
van Rijn (1987)	Empirical, probabilistic	B	—	—
Karim and Kennedy (1990)	Empirical	BM	—	This is a set of equations based upon nonlinear multiple regression analysis, 339 sets of river data, and 608 sets of laboratory data. They have no physical meaning. Equations require iterative solution schemes.
Suszka (1991)	Empirical, probabilistic	B	$3.3 \leq d \leq 43.5$ $0.9 \leq D/d \leq 73.3$ $0.17 \leq S \leq 9$ $147 \leq R_e \leq 14000$	Modification of an earlier formula by Graf and Suszka (1987). Developed for stream mountains, with high slopes and low submergence (i.e., low values of $D/d$ ).
Yang et al. (1996)	Theoretical, based on energy concepts	BM	—	Unit stream power formula for sediment-laden flows. Has been applied with success to the Yellow River in China.
Damgaard et al. (1997)	Empirical, based on shear stress	BM	$2 \leq \theta/\theta_{cr} \leq 6$	Valid for horizontal, mild, and steep slopes. Authors also present a method for including the effects of steep beds in the equation of Meyer-Peter and Müller (1948). Equation is based on limited laboratory data with well-sorted sand with mean size $d = 0.208$ mm.

(Continued)

**Table D-2 Some Common Bed-Load and Bed-Material-Load Equations and Associated Information Presented in Chronological Order of Development (Continued)**

Formula	Foundation	Type <sup>a</sup>	Range of validity <sup>b</sup>	Comments
Karim (1998)	Empirical	BM	$0.137 \leq d \leq 28.65$ 20 $\leq C \leq 49,300$ 0.03 $\leq D$ $\leq 5.29$ 0.32 $\leq U \leq 2.88$ $0.015 \leq S \leq 2.4$ 0.09 $\leq$ $F_r \leq 2.08$	The transport relation results from fitting a power-form relationship to experimental data from natural rivers and laboratory flumes. It takes into account sediment mixtures, including particle sheltering and exposure. Not accurate for partially armored beds.

Nomenclature:

$C$  = sediment concentration, ppm;  
 $d$  = particle diameter, mm;  
 $d_{50}$  = particle size for which 50% of the material by weight is finer;  
 $D$  = water depth, m;  
 $F_r$  = Froude number;  
 $g$  = acceleration due to gravity;  
 $R_e$  = Reynolds number,  $= u^* d / \nu$ ;  
 $s$  = specific gravity of sediment;  
 $S$  = bed slope, %;  
 $S_f$  = energy slope, %;  
 $U$  = flow velocity, m/s;  
 $u^*$  = shear velocity;  
 $W$  = width, m;  
 $\theta$  = bed shear stress parameter,  $= u^{*2} / [(s-1)gd]$ ;  
 $\theta_{cr}$  = critical bed shear stress parameter;  
 $\rho$  = density, g/cm<sup>3</sup>;  
 $\nu$  = kinematic viscosity of water.

<sup>a</sup>B, bed load; BM, bed-material load.

<sup>b</sup>Representative of the range of the data that were used in the derivation of the equations.

<sup>c</sup>Described by Stevens and Yang (1989) and available from the U.S. Geological Survey on the World Wide Web at <http://water.usgs.gov/software/seddisch.html>.

**Table D-3 Summary of the Sediment-Transport Equations Ranking by ASCE (1982), Based on 40 Sets of Field Data and 165 Sets of Flume Data**

Rank	Equation	Type
1	Yang (1973)	Bed-material load
2	Laursen (1958)	Bed-material load
3	Ackers and White (1973)	Bed-material load
4	Engelund and Hansen (1967)	Bed-material load
5	Bagnold (1956)	Bed load
6	Meyer-Peter and Müller (1948) and Einstein (1950)	Bed-material load
7	Meyer-Peter and Müller (1948)	Bed load
8	Yalin (1963)	Bed load

those consistent with the data and field conditions from step 1.

3. If more than one equation is acceptable after step 2, compute sediment-transport rates with these equations and select those that best agree with any field measurements taken in step 1.
4. In the absence of measured sediment loads for comparison, the following guidelines could be considered:
  - a. Use Meyer-Peter and Müller's (1948) equation when the bed material is coarser than 5 mm.
  - b. Use Einstein's (1950) method if the bed load constitutes a substantial part of the total load.
  - c. Use Toffaleti's (1968; 1969) equation for large sand-bed rivers.
  - d. Use Colby's (1964) equation for rivers with a depth of less than 10 ft.
  - e. Use Shen and Hung's (1972) regression equation for laboratory flumes and small streams.
  - f. Use Karim and Kennedy's (1990) equation for natural rivers with a wide range of variation in the flow and sediment conditions.
  - g. Use Yang's (1973) equation for sand transport in laboratory flumes and natural rivers; use Yang's (1979) equation for sand transport when the critical unit stream power at incipient motion can be neglected.
  - h. Use Parker's (1990) or Yang's (1984) gravel equation for bed-load or gravel transport.
  - i. Use Yang's (1996) modified equation for high-concentration flows when the wash load or concentration of fine material is high.
  - j. Use Ackers and White's (1973) or Engelund and Hansen's (1967) equation for subcritical flow in the lower flow regime.
  - k. Use Laursen's (1958) equation for laboratory flumes and shallow rivers with fine sand or coarse silt.

- l. Use Meyer-Peter and Müller's (1948) equation for bed load and the Modified Einstein equation (Colby 1964) for suspended load to obtain total bed-material load.
- m. Apply a regime or regression equation only if the flow and sediment conditions of interest are similar to those used in the equation's derivation.
- n. Select an equation according to the ranking in Table D-3.
- o. Select an equation based on the analysis of Yang and Wan (1991).
5. If none of the available sediment-transport equations is adequate, use available data and plot them against water discharge, velocity, slope, depth, shear stress, stream power, unit stream power (or dimensionless unit stream power), and Velikanov's parameter.<sup>2</sup> Select the curve with the least scatter in the data.

## D.5 TOWARD COLLECTION OF CONSISTENT, RELIABLE FLUVIAL-SEDIMENT DATA

The preceding sections presented a synopsis of the methods commonly used to calculate sediment transport loads in rivers and streams, and the problems associated with them. Those problems—which range from data collection procedures, interpretation, and manipulation to the principles (or absence thereof) behind the equations employed—burden these methods with uncertainty, inconsistency, and inaccuracies of unknown magnitudes. They also contribute to considerable difficulty in the error analysis of the methods' results, therefore severely compromising their reliability.

<sup>2</sup>The Velikanov parameter is defined as  $U^3/(gR\omega)$ , where  $U$  is the mean velocity,  $g$  is the acceleration due to gravity,  $R$  is the hydraulic radius, and  $\omega$  is the sediment particle's fall velocity.

In an attempt to overcome some of the limiting difficulties described above, Gray (2002) presents a vision of a national sediment monitoring and research network that would provide a national sediment dataset collected with uniform protocols and methods. It is predicated on development and adoption of surrogate technologies (Bogen et al. 2003; Wren and Kuhnle 2003; Gray 2005) providing fluvial-sediment data characteristics at a site continuously with only periodic calibration. The components of a national sediment monitoring and research network are

- A core streamgauging station network that is equipped to continuously monitor a basic set of flow, sediment, and ancillary characteristics based on a consistent set of protocols and equipment at perhaps hundreds of sites representing a broad range of drainage basins in terms of geography, areal extent, hydrology, and geomorphology. The focus of these sites would be measurement of fluvial-sediment yields.
- A subset of the core streamgauging station network at which testing on emerging sediment-surrogate technologies and new methodologies can take place at a minimum of additional expense. A major focus of this effort would be to identify technologies that provide a reliable sediment-concentration time series that can be used as the basis for computing daily suspended-sediment discharges with known accuracies (Bogen et al. 2003; Gray and Glysson 2003; Gray 2005; Kuhnle and Wren 2005). A secondary focus would be to identify surrogate technologies for measuring characteristics of bed load (Bogen et al. 2003; Gray 2005; Ryan et al. 2005), bed material, and bed topography (Gray 2005; Young and Tidwell 2005).
- An equipment and techniques research component that addresses development of new, less expensive, safer, and quantifiably accurate means for collection, processing, and laboratory analysis of sediment samples (Bogen et al. 2003; Gray 2005).
- A data-synthesis component that focuses on identifying or developing more efficient methods of measuring and estimating selected fluvial-sediment characteristics; developing a means to estimate the uncertainty associated with these measurements and estimates; and performing syntheses on historical and new sediment and ancillary data to learn more about the sedimentary characteristics of the nation's rivers (Gray 2005; Landers and Freeman 2005).
- A common database that can accept all types of instantaneous and time series sediment and ancillary data collected by approved protocols (see Chapter 5 in this volume), including specific information on the instruments and methods used to acquire the data, available online via a map interface (Gray 2005; USGS 2005).

The principal benefits of a national sediment monitoring and research network would be production of quality-

assured data that in some cases would preclude the need for the sediment-discharge estimating tools described in this section.

## APPENDIX E

### *Limited Glossary of Selected Terms*

*Robert C. MacArthur and Brad R. Hall*

**Accuracy**

Degree of conformity of a measure to a standard or true value.

**Active bed (layer)**

The active bed is a simplifying concept used in mobile boundary models. The layer of material between the bed surface and a hypothetical depth at which no transport will occur for the given gradation of bed material and flow conditions. See Fig. E-1.

**Adjustment**

Variation of the parameters in a model to ensure close reproduction of a set of prototype conditions by the model.

**Aggradation**

The process by which stream beds, floodplains, and the bottoms of other water bodies are raised in elevation by the deposition of material eroded and transported from other areas. It is the opposite of degradation.

**Algorithm**

A procedure for solving a mathematical problem in a finite number of steps that frequently involves repetition of an operation. A step-by-step procedure for solving a problem or accomplishing an end. A set of numerical steps or routines to obtain a numerical output from a numerical input.

**Alluvial**

Pertains to alluvium deposited by a stream or flowing water.

**Alluvial fan**

A conical or fan-shaped deposit at the base of a mountain range where the mountain stream encounters the lesser slope of the valley floor. The deposits are generally coarse, alluvial fans most often occur in arid and semiarid regions where streamflow is ephemeral and vegetation cover is sparse.

**Alluvial reach**

A reach of river with a sediment bed composed of the same type of sediment material as that moving in the stream.

**Alluvial stream**

A stream whose channel boundary is composed of alluvium, and which generally changes its cross section and bed form due to the interaction of the flow and mobile boundary adjustment.

**Alluvium**

A general term for detrital deposits made by (modern) streams on riverbeds, floodplains, and alluvial fans.

**Alternate bars**

Bars formed in a staggered pattern near the banks of channels. See Fig. E-2.

**Analytical model**

Mathematical model in which the solution of the governing equations is obtained by algebraic analysis.

**Anomaly**

(1) A departure from the expected or normal. (2) A geological feature, esp. in the subsurface, distinguished by geological, geophysical, or geochemical means, which is different from the general surroundings and is often of potential value.

**Armor layer**

See **Armoring**.

**Armoring**

The process of progressive coarsening of the bed layer by removal of fine particles until it becomes resistant to scour. The coarse layer that remains on the surface is termed the "armor layer." Armoring is a temporary condition; higher flows may destroy an armor layer and it may reform as flows decrease. Or, simply, the formation of a resistant layer of relatively large particles resulting from removal of finer particles by erosion.

**Fig. E-1.** Composition of the active layer.

### Average end method

The averaging of the two end cross sections of a reach in order to smooth the numerical results.

### Avulsion

A rapid change in channel location and form that occurs during severe floods.

### Backwater curve

Concave-upward longitudinal profile of the water surface in a stream where the water surface is raised above its normal level by a natural or artificial obstruction.

### Bank migration

Lateral shifting of the banks of a streamcourse.

### Bank sediment reservoir

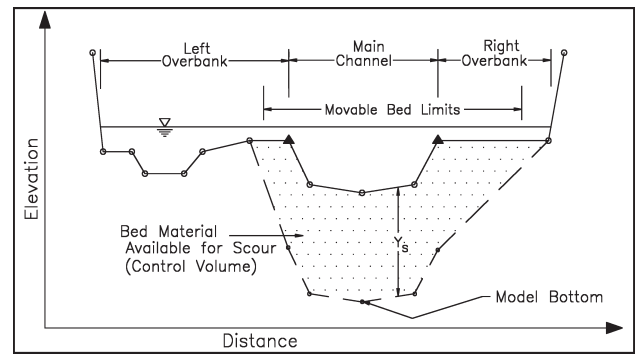

A hypothetical reservoir of sediment specified in some mobile boundary models to accommodate vertical bed adjustment due to scour and deposition. See Fig. E-3.

### Bed forms

Wave-like irregularities found on the bottom (bed) of a stream that are related to flow characteristics. They are given names such as “dunes,” “ripples,” and “antidunes.” They are related to the transport of sediment and they interact with the flow because they change the roughness of the stream bed. An analog to stream bed forms is desert sand dunes.

**Fig. E-2.** Alternate bars.

**Fig. E-3.** Components of the streambed as depicted in some mobile boundary models.

### Bed layer

An arbitrary term used in various procedures for computation of sediment transport. From observation of slow-motion movies of laboratory flume experiments, H. Einstein defined the “bed layer” as “A flow layer, 2 grain diameters thick, immediately above the bed. The thickness of the bed layer varies with the particle size.”

### Bed load

Material moving on or near the stream bed by rolling, sliding, and sometimes making brief excursions into the flow a few diameters above the bed, i.e., jumping. The term “saltation” is sometimes used in place of “jumping.” Bed load is bed material that moves in continuous contact with the bed; contrast with **Suspended load**.

### Bed-load discharge

The quantity of bed load passing a cross section in a unit of time. Usually presented in units of tons per day. May be measured or computed. See **Bed load**.

### Bed material

The sediment mixture of which the bed is composed. In alluvial streams, bed-material particles are liable to be moved at any moment or during some future flow condition. Bed material may include grain sizes that travel both as bed load and suspended load. Contrast with **Wash load**.

### Bed material load

The total rate at which bed material is transported by a given flow at a given location on a stream. It consists of bed material moving both as bed load and suspended load. Contrast with **Wash load**.

### Bed or hydraulic sorting

See **Sorting**.

### Bedrock

A general term for erosion resistant, consolidated material that underlies soil or other unconsolidated superficial material.

**Bias**

A systematic error introduced into sampling or testing by selecting or encouraging one outcome or answer over others. Bias can be introduced by setting variables or factors which would result in one outcome.

**Boundary conditions**

Definitions or statements of conditions or phenomena at spatial or temporal boundaries of a model. Water levels, flows, sediment concentrations, etc., that are specified at the boundaries of the area being modeled. A specified tailwater elevation and incoming upstream discharge are typical boundary conditions.

**Boundary effect**

Consequence of dissimilarities between the model boundary conditions and the conditions occurring in the prototype at the location of the model boundaries.

**Boundary roughness**

A measure of hydraulic resistance in a stream or river or floodplain. The greater the roughness, the greater the frictional resistance to flows; and, hence, the higher the water-surface elevation for any given discharge.

**Braided channel**

A stream that is characterized by random interconnected channels divided by islands or bars. Bars that divide the stream into separate channels at low flow are often submerged at high flow.

**Calibration**

Adjustment of a model's parameters such as roughness or dispersion coefficients so that it reproduces observed prototype data to acceptable accuracy.

**Channel**

A natural or artificial waterway that periodically or continuously contains moving water.

**Channel invert**

The lowest point in the channel at a given cross section.

**Characteristics method**

Numerical method in which the governing partial differential equations of a mathematical model are transformed into characteristic (ordinary differential) equations.

**Clay**

See Table E-1.

**Table E-1 Scale for Size Classification of Sediment Particles<sup>a</sup>**

Class name	Millimeters	Feet	PHI value
Boulders	>256	—	< -8
Cobbles	256–64	—	-8 to -6
Very coarse gravel	64–32	0.148596	-6 to -5
Coarse gravel	32–16	0.074216	-5 to -4
Medium gravel	16–8	0.037120	-4 to -3
Fine gravel	8–4	0.018560	-3 to -2
Very fine gravel	4–2	0.009279	-2 to -1
Very coarse sand	2.0–1.0	0.004639	-1 to 0
Coarse sand	1.0–0.50	0.002319	0 to +1
Medium sand	0.50–0.25	0.001160	+1 to +2
Fine sand	0.25–0.125	0.000580	+2 to +3
Very fine sand	0.125–0.0625	0.000288	+3 to +4
Coarse silt	0.0625–0.031	0.000144	+4 to +5
Medium silt	0.031–0.016	0.000072	+5 to +6
Fine silt	0.016–0.008	0.000036	+6 to +7
Very fine silt	0.008–0.004	0.000018	+7 to +8
Coarse clay	0.004–0.0020	0.000009	+8 to +9
Medium clay	0.0020–0.0010	—	+9 to +10
Fine clay	0.0010–0.0005	—	+10 to +11
Very fine clay	0.0005–0.00024	—	+11 to +12
Colloids	<0.00024	—	> +12

<sup>a</sup>Portions of Table E-1 are taken from Corps of Engineers *EM 1110-2-4000*, March 1988.

**Cobbles**

See Table E-1.

**Cohesive sediments**

Sediments whose resistance to initial movement or erosion is caused mostly by cohesive bonds between particles.

**Computational hydrograph**

A sequence of discrete steady flows, each having a specified duration in days, used to represent a continuous discharge hydrograph. See Fig. E-4.

**Concentration of sediment**

The dry weight of sediment per unit volume of water-sediment mixture.

**Conceptual model**

A simplification of prototype behavior used to illustrate functional relationships.

**Confirmation**

Process in which a model of a specific study area is built and tested to prove that the model design and implementation are adequate and no major phenomenon has been overlooked.

**Consistency**

The property of a numerical solution to a set of partial differential equations that, as time and distance steps are decreased, the difference equations approach the differential equations.

**Consolidation**

The compaction of deposited sediments caused by grain reorientation and by the squeezing water out of the pores.

**Control point**

Term used in river modeling to describe the downstream boundary of the main river segment and the junction point of

**Fig. E-4.** Computational hydrograph.

each tributary. In Fig. E-5, each control point is designated by a circled number.

**Convergence**

The state of tending to a unique solution. A given scheme is convergent if an increasingly finer computational grid leads to a more accurate solution.

**Conveyance**

A measure of the flow capacity of a channel section. Flow is directly proportional to conveyance for steady uniform flow. From Manning's equation, the proportionality factor is the square root of the energy slope.

**Cover layer**

One of the two sublayers of the active layer. It lies above the subsurface layer (the second sublayer in the active layer). See Fig. E-1.

**Critical depth**

If discharge is held constant and the water depth allowed to decrease, as in the case of water approaching a free overfall, velocity head will increase, pressure head will decrease, and total energy will decrease toward a minimum value where the rate of decrease in the pressure head is just balanced by the rate of increase in velocity head. This is the critical depth. More generally, the critical depth is the depth of flow that would produce the minimum total energy head and a Froude number equal to one (1).

**Critical flow**

The state of flow where the water depth is at the critical depth.

**Fig. E-5.** Example of segment and control point numbering for a river system.

**Critical shear stress**

The minimum amount of shear stress exerted by passing stream currents required to initiate soil particle motion.

**Cross section**

The shape of the channel in which a stream flows on a line perpendicular to the flow or banks.

**Cross-sectional area**

The wetted area of a cross section perpendicular to the direction of flow.

**Degradation**

The process by which stream beds, floodplains, and the bottoms of other water bodies are lowered in elevation by erosion of material. It is the opposite of aggradation.

**Delta**

A fan-shaped deposit of sediment formed where moving water (as from a stream at its mouth) enters a body of standing water and deposits a portion of its sediment load.

**Density**

The mass of a substance per unit volume. The Greek letter  $\rho$  is the common symbol.

**Density (turbidity) current**

A mixture of water and fine-grained sediment that flows into and along the bottom of a reservoir or other static body of water because its density is greater than that of the standing water in the reservoir.

**Deposition**

The mechanical or chemical processes through which sediments accumulate in a (temporary) resting place.

**Depth of flow**

The vertical distance from the bed of a stream to the water surface.

**Deterministic model**

Mathematical model in which the behavior of every variable is completely determined by the governing equations and the initial states of the variables.

**Digitize**

To convert data from maps or graphical form to digital form for use by computer programs.

**Dimensionless number**

A physically meaningful relationship of parameters that is dimensionless. These dimensionless relationships are useful in determining scaling laws because a particular dimensionless number should be the same in both model and prototype

to achieve complete similarity. Examples are the common force ratios, such as the Froude and Reynolds numbers.

**Discharge**

The discharge ( $Q$ ) is the volume of a fluid or solid passing a cross section of a stream per unit time.

**Discretization**

The procedure of representing a continuous variable by discrete values at specified points in space and/or time.

**Discretization error**

Error introduced by the discrete representation of a continuous variable.

**Distorted model**

Physical hydraulic model in which horizontal and vertical scales are different.

**Distortion**

Intentional departure from a scaling law often necessitated by a complex set of prototype and laboratory conditions. The term is most commonly used for geometric distortion in physical models where the vertical and horizontal scales of the model are different.

**Distributaries**

Diverging channels that do not return to the main stream, but discharge into another stream system or the ocean.

**Dominant discharge**

The “dominant or effective discharge” is associated with the peak of cumulative sediment transport for a given stream-flow magnitude and frequency of occurrence. It is the discharge that is generally doing the work (sediment transport) that results in the average morphologic characteristics of alluvial channels.

**Draft (depth)**

The depth measured perpendicularly from the water surface to the bottom of a boat or ship. Clearance depth.

**Drainage basin**

The area tributary to or draining into a lake, stream, or measuring site. See **Watershed**.

**Drop**

A structure in an open conduit or canal installed for the purpose of dropping the water to a lower level and dissipating its energy. It may be vertical or inclined; in the latter case it is usually called a chute.

**Dunes**

Bed forms with triangular profile that advance downstream due to net deposition of particles on the steep downstream

slope. Dunes move downstream at velocities that are small relative to the streamflow velocity.

### **Dynamic model**

A mathematical model of flow in an open channel that solves the complete unsteady-flow equations (Saint-Venant equations for one-dimensional problems).

### **Effective (grain) size**

The effective grain size is that single particle diameter that best depicts the bed-material properties. The D50 grain size is often used as the effective grain size.

### **Empirical model**

Representation of a real system by a mathematical description based on experimental or observed data rather than on general physical laws.

### **Entrainment**

The process of picking up and carrying into the flow of bed material produced by erosive action and turbulence of moving water.

### **Equilibrium load**

The amount of sediment that a river channel system can carry for a given discharge without overall accumulation (deposition) or scour (degradation).

### **Erosion**

The wearing away of the land surface or stream boundaries by detachment and movement of soil and rock fragments through the action of moving water or other geological agents.

### **Explicit scheme**

A numerical approximation scheme in which the governing equations of a numerical model are arranged to update the dependent variables in terms of previously known values only. Compare with **Implicit scheme**.

### **Fall velocity**

The falling or settling rate of a particle in a given fluid or gaseous medium.

### **Finite element method**

Method of solving the governing equations of a numerical model by dividing the spatial domain into elements in each of which the solution of the governing equations is approximated by some continuous function.

### **Fixed-bed model**

Type of model (a simplification) in which the bed and bank materials are nonerodible and deposition does not occur either.

### **Floodplain**

Normally dry land adjacent to a body of water which is susceptible to periodic inundation by floodwaters.

### **Flood routing**

The process of tracing, by calculation, the height and discharge of a flood as it progresses through a river reach or a reservoir.

### **Flow duration curve**

A measure of the range and variability of a stream's flow. The flow duration curve represents the percent of time during which specified flow rates are exceeded at a given location. This is usually presented as a graph of flow rate (discharge) versus percent of time that flows are greater than, or equal to, that flow.

### **Fluvial**

(1) Pertaining to streams. (2) Growing or living in streams or ponds. (3) Produced by river action, as a fluvial plain.

### **Fluvial sediment**

Particles derived from rocks or biological materials that are transported by, suspended in, or deposited by streams.

### **Frequency**

The number of repetitions of a periodic process in a certain time period.

### **Froude number**

$U/(g \cdot L)^{1/2}$  ( $U$  = velocity,  $g$  = gravity,  $L$  = length). A dimensionless number expressing the ratio between the influences of inertia and gravity in a fluid. The Froude number is primarily related to surface phenomena in flowing water.

### **Froude number model (or Gravitational model)**

Model designed to emphasize similarity of gravitational and inertial forces (Froude number). Other forces, such as viscous (Reynolds number) forces, may not be reproduced correctly.

### **Gauging station**

Location in a stream channel where discharge and other parameters are measured continuously or periodically.

### **Geologic control**

A local rock formation or scour-resistant layer that limits (within the engineering time frame) the vertical and/or lateral movement of a stream at a particular point. Man-made controls such as drop structures also exist.

### **Geology**

The science that deals with the physical history and state of the earth, especially as recorded in rocks and landforms.

### **Geomorphology**

The science that considers the processes that contribute to the changing configuration of the earth's surface.

### **Gradation**

The proportion of material of each particle size, or the frequency distribution of various sizes, constituting a particulate material such as a soil, sediment, or sedimentary rock.

**Grain shape factor**

See **Particle shape factor**.

**Grain size**

See **Particle size**.

**Grain size distribution (gradation)**

A measure of the variation in grain (particle) sizes within a mixture. Usually presented as a graph (gradation curve) of grain diameter versus percentage of the mixture that is finer than that diameter. See Fig. E-6.

**Gravel**

See Table E-1.

**Grid**

Network of points covering the space or time-space domain of a numerical model. The points may be regularly or irregularly spaced.

**Heuristic model**

Representation of a real system by a mathematical description based on reasoned, but unproven, argument.

**Historic flows**

The collection of recorded flow data for a stream during the period of time in which stream gauges were in operation.

**Hybrid model**

Model combining at least two modeling techniques (e.g., physical and numerical) in a closely coupled fashion.

**Hydraulic depth**

The ratio of cross-sectional area.  $A$  divided by the width of the free surface  $T$  at a specific cross-section along the channel.

**Fig. E-6.** Example of a sediment gradation curve.

**Hydraulic model**

A physical scale model of a river, hydraulic structure, etc. used for engineering studies.

**Hydraulic radius**

The ratio of cross-sectional area to wetted perimeter at any given elevation.

**Hydrograph**

The graph of stage or discharge versus time at a specified location along a stream or river.

**Implicit scheme**

Scheme in which the governing equations of a numerical model are arranged to obtain solutions for the dependent variables simultaneously at all grid points corresponding to any one time. The computed values depend not only on known values at a previous time but also on the other unknown neighboring values at the surrounding grid points at the time being calculated. Compare with **Explicit scheme**.

**Impoundment**

Body of water formed by blocking flowing water, as at a dam.

**Inactive layer**

The depth of material beneath the active layer. See Fig. E-1.

**Incipient motion**

The flow condition at which a given size bed particle just begins to move. Usually related to a “threshold” shear stress.

**Initial conditions**

The values of water levels, velocities, concentrations, etc., that are specified everywhere in the computational mesh at the beginning of a model run. For an iterative solution, the initial conditions represent the first estimates of the variables the model is trying to solve.

**In situ**

In (its original) place.

**Linear model**

Mathematical model based entirely on linear equations.

**Local inflow/outflow point**

Points along any river segment at which water and sediment enter or exit as specified for modeling purposes. Fig. E-7.

**Local scour**

Erosion caused by an abrupt change in flow direction or velocity. Examples include erosion around bridge piers, downstream of stilling basins, at the ends of dikes, and near snags.

Fig. E-7. Local inflow/outflow points.

### Main stem

The primary river segment in the schematization of a river system.

### Manning's equation

Empirical equation commonly applied in water-surface profile calculations to define relationships between surface roughness, discharge, flow geometry, and rate of friction loss.

### Manning $n$ Value

$n$  is the coefficient of roughness with the dimensions of  $T \times L^{-1/3}$ .  $n$  accounts for energy loss due to friction. In movable boundary hydraulics, the Manning  $n$  value includes the effects of all losses, such as grain roughness of the movable bed, form roughness, bank irregularities, vegetation, bend losses, and junction losses. Contraction and expansion losses are usually not included in Manning's  $n$ , but are typically accounted for separately.

### Mathematical model

A model that uses mathematical expressions (i.e., a set of equations, usually based upon fundamental physical principles) to represent a physical process.

### Meandering stream

An alluvial stream characterized in planform by a sequence of alternating bends. The bends are usually a result of alluvial processes rather than the nature of the terrain.

### Mean velocity

The discharge divided by the wetted area of a cross section.

### Movable bed

That portion of a river channel cross section specified in a mobile boundary model that is considered to be subject to erosion or deposition.

### Movable bed limits

The lateral limits of a channel used to define where scour or deposition may occur. See Fig. E-3.

### Movable bed model

Model in which the bed material is erodible and transported in a manner similar to the prototype; can be a hydraulic or numerical model.

### Navigation model

Model used to study maneuverability of vessels under currents, waves, wind, etc., for design of navigable waterways.

### Network model

A network model is an arrangement of main stem, tributary, and local inflow/outflow points that can be simulated simultaneously and in which flow and sediment transport can be calculated.

### NGVD

National Geodetic Vertical Datum; vertical datum plane of reference.

### Node

Location in a numerical network where computations are performed and/or output is requested.

### Nonlinear model

Mathematical model based on one or more nonlinear equations.

### Normal depth

The depth that would exist or be approached if the flow were uniform.

### Numerical experiments

Varying the input data or internal parameters of a numerical model to ascertain the impact on the output.

### Numerical model

A numerical model is a representation of a mathematical model as a sequence of instructions (program) for a computer. Given approximate data, the execution of this sequence of instructions yields an approximate solution to the set of equations that compose the mathematical model.

### One-dimensional model

Model defined with one space coordinate; usually distance. Variables are averaged over the other two directions (e.g., wave propagation in a narrow channel).

**Operating rule**

A rule that specifies how water is managed throughout a water resource system. Often defined to include target system states, such as storage, above which one course of action is implemented and below which another course is taken.

**Overbank area**

In a river reach, the surface area between the bank on the main channel and the outer limits of the floodplain. See Fig. E-8.

**Overdredging**

Additional depth dredged beyond the minimum dredging depth used to provide sufficient navigational depth, to minimize redredging, and to help compensate for the sloughing off and resettling of sediment after dredging occurs.

**Parameter**

A constant or variable in a mathematical expression.

**Particle shape factor**

The particle shape factor of a perfect sphere is 1.0 and can be as low as 0.1 for very irregular shapes. It is defined by

$$SF = \frac{c}{(a \cdot b)^{1/2}} \quad (E-1)$$

where

$a, b, c$  = the lengths of the longest, intermediate, and shortest, respectively, mutually perpendicular axes on a sediment particle.

**Particle size**

A linear dimension, usually designated as “diameter,” used to characterize the size of a particle.

**Permeability**

The property of a soil or rock materials that permits the passage of water under a hydraulic gradient.

**Phasing**

Phasing refers to the timing of flows between the main stem of a river and its tributaries. The arrival of flows into the main stem from the upper watersheds is a function of the size and characteristics of the watersheds, tributary channels, and characteristics of the storm event.

**Physical model**

Model using the physical properties and behavior of modeling materials to represent the prototype; a three-dimensional scale model of the prototype.

**Planform**

The shape and size of channel and overbank features as viewed from directly above.

**Point bar**

Deposits of sediment that occur on the convex side or inside of channel bends. Their shape may vary with changing flow conditions, but they do not move significantly relative to the bends. However, the general magnitude and location of the bars vary with discharge and sediment load. See Fig. E-9.

**Probabilistic model**

Mathematical model in which the behavior of one or more of the variables is either completely or partially subject to probability laws.

**Prototype**

The full-sized structure, river system process, or phenomenon being modeled.

**Quasi-steady-state model**

Model in which time-dependent variables are simulated by a sequence of steady states.

**Quasi-three-dimensional model**

A combination of two-dimensional models used to simulate variations in three dimensions.

**Fig. E-8.** Examples of overbanks.

Fig. E-9. View of three-point bars.

### Rating curve

See **Stage-discharge curve**.

### Reach

(1) A length of a channel that is approximately uniform with respect to discharge, depth, area, and slope; (2) A length of a stream between two specified points.

### Reservoir

An impounded body of water or controlled lake.

### Reynolds number

$(U \cdot L)/\nu$  Dimensionless ratio of inertial force to viscous force; the length may represent grain size, depth of flow, or pipe diameter, resulting in different Reynolds numbers for different purposes. The critical Reynolds number describes the onset of turbulence. The Reynolds number is defined as velocity multiplied by length divided by kinematic viscosity. It is usually involved wherever viscosity is important, such as in slow movement of fluid in small passages or around small objects.

### Roundoff error

Cumulative error introduced by rounding of the results from individual arithmetic operations because only a finite number of digits can be retained after each operation on a digital computer.

### Routing

Technique used to compute the effect of channel storage and conveyance on the characteristics of a flood wave moving through a river reach. Also used when describing the movement of sediment volumes through a river system.

### Runoff

Surface flow resulting from rainfall that is discharged from a specified area of land sometimes subdivided into direct surface runoff, ground-water runoff, and seepage.

### Sand

See Table E-1.

### Saturation

The degree to which voids in soil are filled with water.

### Scale (or scale ratio)

Ratio of a parameter in a model to the corresponding parameter in the prototype.

### Scale effect

Consequence of nonsimilarity between model and prototype resulting from the fact that not all pertinent dimensionless numbers are the same in the model and prototype.

### Scaling laws

Conditions that must be satisfied to achieve desired similarity between model and prototype.

### Schematization

Representation of a continuum by discrete elements; e.g., dividing a real river into reaches with constant parameters.

### Scheme (numerical or computational)

Systematic program of action for solving the governing equations of a mathematical model.

### Scour

Concentrated erosive action by water. The enlargement of a flow section or creation of a depression by the removal of bed material through the action of moving water.

### Secondary currents (or flow)

The movement of water particles on a cross section normal to the principal direction of flow.

### Sediment

Solid fragmental material transported and deposited by the actions of water, wind or ice. A collective term meaning an accumulation of soil, rock, and mineral particles transported or deposited by flowing water.

### Sedimentation

Consists of five fundamental processes: (1) erosion or detachment, (2) entrainment, (3) transportation, (4) deposition, and (5) diagenesis, or consolidation. Also refers to the gravitational settling of suspended particles that are heavier than water.

### Sedimentation diameter

The diameter of a sphere of the same specific weight and the same terminal settling velocity as a given particle in the same fluid.

### Sediment discharge

The mass or volume of sediment (usually mass) passing a stream cross section in a unit of time. The term may be qualified, for example; as suspended-sediment discharge, bed-load discharge, or total-sediment discharge. See **Sediment load**.

**Sediment-discharge relationship**

A relationship required by mobile boundary models. Tables that relate inflowing sediment loads to water discharge for the upstream ends of the main stem, tributaries, and local inflows.

**Sediment load**

A general term that refers to material in suspension and/or in transport. It is not necessarily synonymous with either discharge or concentration. It may also refer to a particular type of load; e.g., total, suspended, wash, bed, or bed material.

**Sediment particle**

Solid fragments of mineral material in either a singular or aggregate state.

**Sediment sample**

A quantity of water-sediment mixture or deposited sediment that is collected to characterize some property or properties of the sampled medium.

**Sediment transport (rate)**

See **Sediment discharge**.

**Sediment-transport function**

A formula or algorithm for calculating sediment transport rate given the hydraulics and bed material characteristics at a cross section. Most sediment transport functions compute the bed-material load capacity. The actual transport may be less than the computed capacity due to armoring, geologic controls, etc., or greater due to fine material (wash load) that originates upstream rather than from the bed.

**Sediment-transport routing**

The computation of sediment movement for a selected length of stream (reach) for a period of time with varying flows. Application of sediment continuity relations allows the computation of aggradation and deposition as functions of time.

**Sediment trap efficiency**

See **Trap efficiency**.

**Sediment yield**

The total sediment outflow from a drainage basin at a specified location for a specific period of time. It includes bed load as well as suspended load and is usually expressed in terms of mass, or volume per unit of time.

**Settling velocity**

See **Fall velocity**.

**Shape factor**

See **Particle shape factor**.

**Shear stress (boundary shear stress)**

Frictional force per unit of area exerted on a channel boundary by the flowing water. An important factor in the movement of bed material.

$$\tau_0 = \gamma RS \quad (\text{E-2})$$

where

$\tau_0$  = unit tractive force;

$\gamma$  = unit weight of water;

$R$  = hydraulic radius;

$S$  = slope of the channel.

**Shear velocity**

The shear velocity is defined as the square root of the quantity of shear stress divided by fluid density.

**Shield's curve**

A curve of the dimensionless tractive force plotted against the grain Reynolds number (i.e.,  $U^* \cdot D_s / \nu$ , where,  $U^*$  = turbulent shear velocity,  $D_s$  = characteristic or effective size of the grains or roughness elements, and  $\nu$  = kinematic viscosity).

**Shield's parameter**

A number also referred to as a dimensionless shear stress. The beginning of motion of bed material is a function of this dimensionless number:

$$\frac{\tau_c}{(\gamma_s - \gamma)D_s} \quad (\text{E-3})$$

where

$\tau_c$  = critical tractive force;

$\gamma_s$  = specific weight of the particle;

$\gamma$  = specific weight of water;

$D_s$  = characteristic or effective size of the grains or roughness elements.

**Sieve diameter**

The smallest standard sieve opening size through which a given particle of sediment will pass.

**Silt**

See Table E-1.

**Similarity (or similitude)**

Correspondence between the behavior of a model and its prototype.

**Simulation**

Reproduction of prototype behavior using a model.

**Sinuosity**

The ratio of the length of a stream measured along its centerline to the length of the valley through which the stream flows.

**Sorting**

The dynamic process by which sedimentary particles having some particular characteristic (such as similarity of size, shape, or specific gravity) are naturally selected and separated from associated but dissimilar particles by the agents of transportation. Also, see **Gradation**.

**Split flow**

Flow that leaves the main river flow and takes a completely different path from the main river (Case (a)). Split flow can also occur in the case of flow bifurcation around an island (Case (b)). See Fig. E-10.

**Stability (numerical or computational)**

The ability of a scheme to control the propagation or growth of small perturbations introduced during numerical calculations. A scheme is unstable if it allows the growth of error to eventually obliterate the true solution.

**Stable channel**

A stream channel that does not change in planform, cross section or bed profile during a particular period of time. For purposes of this glossary the time period is years to tens of years.

**Fig. E-10.** Split flow.

**Stage**

The stage is the vertical distance from any selected and defined datum to the water surface.

**Stage-discharge (rating) curve**

Defines a relationship between discharge and stage at a given location.

**Standard step method**

An iterative procedure for calculating water surface profiles for steady gradually varied, one-dimensional flow.

**Steady state model**

Model in which the variables being investigated do not change with time.

**Stochastic model**

See **Probabilistic model**.

**Stream bank erosion**

The removal of bank material primarily by hydraulic action.

**Stream discharge**

The volume of flow passing a stream cross section in a unit of time.

**Stream gauge**

A device that measures and records temporal flow characteristics such as water discharge and water surface elevation at a specific location on a stream. Sediment transport measurements are usually made at stream gauge sites.

**Stream profile**

A plot of the elevation of a stream bed and/or water surface versus distance along the stream.

**Stream segment**

A term often used in modeling. A stream segment is a specified portion of a river with an upstream inflow point and with a downstream termination at a control point. Primary Inflow points are designated by  $\ell_n$ , where  $n$  is the segment number. Primary inflow points are always at the upstreammost end of a tributary or main stem segment. See Fig. E-7.

**Subcritical (tranquil) flow**

The state of flow where the water depth exceeds the critical depth. Here, the influence of gravity forces dominates the influence of inertial forces.

**Supercritical flow**

The state of flow where the water depth is below the critical depth, inertial forces dominate the gravitational forces, and the flow is described as rapid or shooting.

**Suspended bed-material load**

That portion of the suspended load that is composed of particle sizes found in the bed material.

**Suspended load**

Includes both suspended bed-material load and wash load. Sediment that moves in suspension is continuously supported in the water column by fluid turbulence. Contrast with **Bed load**.

**Suspended-sediment discharge**

The quantity of suspended sediment passing a cross section in a unit of time. See **Suspended load**.

**Thalweg**

The line following the lowest part of a valley, whether under water or not. Usually the line following the deepest points along the bed of a river.

**Top width**

The width of a stream section at the water surface; it varies with stage in most natural channels.

**Total sediment discharge**

The total rate at which sediment passes a given point on the stream. See **Total sediment load**.

**Total sediment load (Total load)**

Includes the sum of bed load and suspended load, or the sum of bed-material load and wash load.

**Transect**

A sample area, cross section, or line chosen as the basis for studying one or more characteristics of a particular assemblage.

**Transportation (sediment)**

The process of moving sediment particles from place to place once they are entrained into the flow. The principal transporting agents are flowing water and wind.

**Transport capacity**

The ability of a stream to transport a given volume or weight of sediment material of specific size per time for a given flow condition.

**Trap efficiency**

Proportion of sediment inflow to a stream reach (or reservoir) that is retained within that reach (or reservoir). Computed as inflowing sediment volume minus outflowing sediment volume divided by inflowing sediment volume. Positive values indicate aggradation; negative values, degradation.

**Tributary**

A stream or channel that contributes its flow (water and sediment load) to another stream.

**Truncation error**

The error introduced by replacing the derivative terms of a differential equation by finite differences using a Taylor series and then truncating after a certain number of terms.

**Turbulence**

In general terms, the irregular motion of a flowing fluid.

**Two-dimensional model**

Model defined with two space coordinates (i.e., variables are averaged over the third direction).

**Unsteady-state model**

Model in which the variables being investigated are time-dependent.

**Verification**

Check of the behavior of a calibrated model against a set of prototype conditions that was not used for calibration.

**Wash load**

The part of the suspended load that is finer than the bed material. Wash load is limited by supply rather than hydraulics. What grain sizes constitute wash load varies with flow and location in a stream. Sampling procedures that measure suspended load will include both wash load and suspended bed-material load. Normally, it consists of sediment particles smaller than 0.062 mm.

**Water column**

An imaginary vertical column of water used as a control volume for computational purposes. Usually of unit area and the depth of water at that location.

**Water discharge**

See **Stream discharge**.

**Watershed**

A topographically defined area drained by a river/stream or system of connecting rivers/streams such that all outflow is discharged through a single downstream outlet. Also called a drainage area.

**Weir**

A small dam in a stream, designed to raise the water level or to divert its flow through a desired channel.

**Wetted perimeter**

The wetted perimeter at a cross-section is the length of the wetted contact between a stream of flowing water and its containing channel, measured in a direction normal to the flow.

# VITO A. VANONI (1904–1999): LEADER IN SEDIMENTATION ENGINEERING

*Norman H. Brooks, Honorary Member ASCE<sup>1</sup>*

## A LONG CAREER

Vito Vanoni, born on August 30, 1904 in Somis, Ventura County, California, attended Caltech, earning a B.S., M.S., and PhD in civil engineering. After ten years in a research position in hydraulics at Caltech, Dr. Vanoni was appointed assistant professor of hydraulics at the California Institute of Technology in 1942, promoted to associate professor in 1949, and served as professor from 1955 until becoming professor emeritus in 1974 (Fig. 1). He remained professionally active almost until age 90, and died at age 95 on December 27, 1999.

Professor Vanoni was a world-renowned authority on the mechanics of transport of sediments by streams and rivers. His teaching and research were not only in the area of mechanics of sediment transport, but also included advanced hydraulics, hydraulic structures, and coastal engineering. In his quiet determined way, he contributed greatly to the robust development of the field of sedimentation engineering, especially through his pioneering flume experiments of suspended sediment transport of fine sands in the late 1930s (Vanoni 1940, 1946), and the publication of the famous book *Sedimentation Engineering*, ASCE Manual No. 54, edited and written in part by Vanoni (1975).

He encouraged fundamental research on sediment transport using modern fluid mechanics, and recognized the need for much more graduate-level education to support the advances in research and applications of sedimentation engineering. In his later years he was the recognized distinguished patriarch of his field in the United States.

## Youth on the Vanoni Farm

Vanoni was raised on the family farm developed by his unusually enterprising father, Battista Vanoni, an immigrant from Italy. They grew lima beans, then walnuts and citrus fruits. Early problems on the ranch included drainage of flood waters, erosion control, and sediment management. His father was the first in the area to bring the industrial revolution to the farm—during Vanoni's boyhood—first various horse-drawn machines, then trucks, tractors, and other motorized machines.

His father believed strongly in getting his many children the best education possible. After high school Vanoni enrolled in 1922 in the newly established California Institute of Technology, majoring in civil engineering, and graduated with a Bachelor of Science degree in 1926. His early experiences on the farm profoundly affected his attitudes and interests throughout his life. He loved the soil and had an active half-acre farm behind his large home lot in Pasadena for 50 years, right up to his final year. His future professional work in sedimentation must have had its common-sense intuitive roots in his early years on the family farm.

### **The Structural Engineer**

As a new civil engineering graduate from Caltech, Vanoni worked five years for a consulting engineering firm doing structural steel design in Ohio, then returned to Caltech in 1931 to obtain a Master of Science degree in civil engineering in 1932, specializing in structural engineering. When he looked for a job in that depression year he got an offer from Professor Robert Knapp to work at the Hydraulic Structures Laboratory, then mostly outdoors. This was the starting point for his hydraulics career, first in hydraulic model studies of various proposed structures, often with sediment problems, and then into sedimentation research. At the same time he continued his graduate study toward his PhD.

### **The Hydraulic Researcher**

From 1935 to 1947 Vanoni supervised the cooperative Sedimentation Laboratory of the Soil Conservation Service (SCS) and Caltech in a large one-story wooden building on the Caltech campus. The SCS sponsorship stopped in 1947, but research on sediment transport in open channel flumes and

turbulent diffusion in a low-speed water tunnel continued. In 1961 the new W. M. Keck Laboratories became the home for this program.

His meticulous experimental PhD research on transportation of suspended sediment in a 60-foot recirculating flume is still regarded as one of the classic contributions in his field, and was recognized by the American Society of Civil Engineers (ASCE) with the Hilgard Hydraulics Prize for the most outstanding paper in hydraulic engineering published by the ASCE in 1946.

During the war years, Vanoni did defense-related research for the National Defense Research Committee and the U.S. Navy, primarily related to the investigation and control of wave action in harbors using hydraulic models on the campus and later in a large off-campus facility in Azusa. He was also active in the design and testing of hydraulic structures such as drop structures for energy dissipation. When Lake Mead was being filled after the closure of Hoover Dam, he and his colleagues demonstrated qualitatively in the laboratory the newly recognized phenomena of inflowing density currents and selective withdrawal in density-stratified reservoirs.

Sediment research continued after the SCS sponsorship stopped in 1947, but at a reduced level. Five more doctoral students completed PhD research on sedimentation topics in the Sedimentation Laboratory up until 1960 (in chronological order): Hassan Ismail, myself, George Nomicos, Ronald McLaughlin, and John Kennedy. Vanoni was the thesis adviser for the first three of these.

In the late 1950s Vanoni and I planned the new Keck Hydraulics Laboratory, which opened in 1961. (Professors Fredric Raichlen and John List joined the laboratory group in 1962 and 1969 respectively.)

**Fig. 2.** Vanoni with Ph.D. student Richard Brock at the downstream end of the 40-meter tilting flume in the Keck Hydraulics Laboratory, approximately 1965. (Photo credit: Caltech)

**Fig. 3.** Members of the Missouri River Division Sediment Advisory Board (July 26, 1950). From left to right: H. A. Einstein, Univ. of California, Berkeley; T. H. Means, consulting engineer, San Francisco; E. W. Lane, Bureau of Reclamation, Denver; L. G. Straub, University of Minnesota, Minneapolis; G. A. Hathaway, Corps of Engineers, Washington, D.C.; and V. A. Vanoni, California Institute of Technology, Pasadena. Picture taken while on inspection trip of Missouri River below Fort Peck Dam. (Credit for photo and legend: Corps of Engineers, Fort Peck District, Photo No. 17920)

Under Vanoni's leadership, the program of the new Keck Hydraulics Lab focused on sediment transport, coastal engineering, and the emerging area of environmental hydraulics. Basic hydraulic structures and model studies became secondary. In the Keck Lab years, the PhD students he supervised were Alexander Sutherland, Li-San Hwang, Richard Brock (Fig. 2), and Brent Taylor.

One of Vanoni's fine attributes, starting from his earliest research work, was his extreme care in crediting other people's ideas and work, while claiming the minimum for himself.

### **The Sedimentation Engineering Manual**

As a major contribution to the profession, he organized, partially wrote, and edited the 730-page definitive ASCE Manual 54, *Sedimentation Engineering* (Vanoni 1975). As chairman of the special Task Committee, established in 1954, charged with writing the manual, Vanoni worked very hard for two decades and set a high standard, persuading many contributors to do major rewrites as needed or doing them himself. In an unusual publication procedure, many of the sections of the original manuscript for the book were first published in the *Journal of the Hydraulics Division, ASCE*; they received consider-

able discussion, which was taken into account in the final manuscript. His effort was an example of strong multi-year persistence and unlimited patience with slow contributors.

The book has received worldwide recognition and widespread use in academia and practice, and was awarded the ASCE Hilgard Award for the best publication in hydraulics in 1976. The success of that book has inspired the current ASCE Sedimentation Committee, under the leadership of Professor Marcelo Garcia (University of Illinois), to write this second volume to document the progress of the past three decades.

### **The River Hydraulics Consultant**

Dr. Vanoni served as an expert individual consultant on river channel and sedimentation problems for many government agencies and consulting firms, extending for almost twenty years into his retirement. Most notable were the several consulting boards he served on for the U.S. Army Corps of Engineers, dealing extensively with sediment problems on the Missouri, Mississippi, and Sacramento Rivers (Fig. 3). After the eruption of Mount Saint Helens in 1980, he served the Corps for several more years to advise on coping with the huge sediment inputs to the Toutle, Cowlitz, and Columbia Rivers.

### **More Honors in Retirement**

In recognition of his outstanding lifetime work, Dr. Vanoni was elected to the National Academy of Engineering in 1977, and became an Honorary Member of the American Society of Civil Engineers in 1980.

In 1983 he was honored by his selection by ASCE to be the distinguished Hunter Rouse Hydraulic Engineering Lecturer (Vanoni 1984). In 1989 he was named the first recipient of the ASCE's Hans Albert Einstein Award. This prize is awarded annually for a "significant contribution to the engineering profession in the areas of erosion control, sedimentation and/or waterway development." It is interesting to note that both Rouse and Einstein had been Vanoni's colleagues at the Sedimentation Laboratory about 60 years ago. (Also Arthur Ippen and James Daily were among Vanoni's contemporaries at Caltech in the late 1930s.)

### **Personal Life**

Vanoni and his wife, Edith, enjoyed many activities together, especially foreign travel to all the continents, and camping in the Sierra Nevada mountains in California. They often opened their home and wonderful patio and "farm" to colleagues, students, and visitors. They are remembered by many for their friendship and warm hospitality. After 61 years of marriage, Edith died in 1995. Although they had no children, Vanoni (or Uncle Vito) is survived by many relatives in his extended family in his native Ventura County and in Santa Barbara.

## **VANONI'S RESEARCH ON SUSPENDED SEDIMENT TRANSPORT IN FLOWING WATER**

In the 1930s basic fluid mechanics was rapidly being infused into civil engineering hydraulics as well as all the other fields of engineering dealing with fluids. For his PhD research, Vanoni was the first to make definitive experiments to measure the transport of fine sand in suspension in turbulent flows of water in an open channel flume. He made his meticulous experiments using the new 60-foot-long steel recirculating laboratory flume, which he designed and built in the Sedimentation Laboratory. (He also designed the building.) His previous experience in structural steel design had proved to be very useful.

In his flume experiments Vanoni (1940, 1946) measured the vertical distribution of suspended sediment concentration along with velocity profiles for a number of experiments using fine, well-sorted sand. The flume bottom was artificially roughened to reduce the effect of the smooth sidewalls with a single layer of 0.88 mm-sand grains stuck to the steel bottom. He compared his measurements with the now well-known equation for the variation of the concentration of suspended sediment over the depth in an open-channel flow, first presented by Rouse (1937), who was also at the SCS Sedimentation Laboratory at Caltech at that time. The results confirmed this new equation derived from von Karman's logarithmic velocity distribution leading to a parabolic distribution of the diffusion coefficient—that is, for the upward diffusion of the sand grains to balance the gravitational

settling. In his PhD thesis he acknowledges both Professors Theodore von Karman and Robert Knapp for guidance in his research.

From the velocity distributions, Vanoni determined that the von Karman constant  $\kappa$  was decreased from its normal value of 0.40 by the presence of suspended sediment; the greater the concentration, the greater was the reduction in  $\kappa$ . This result has attracted the attention of numerous subsequent investigators.

To fit experimental results to theory, Vanoni had to determine the fall velocity of his carefully sorted sands by dropping hundreds of grains in water. Previous investigators had paid little attention to fall velocity of sands. He found that the sedimentation diameters are slightly larger than the sieve diameters for his sands (ranging from 0.10 to 0.16 mm mean diameter). He also observed longitudinal streaks of small sand deposits on the bed of the flume, indicating definite secondary circulations. This was probably one of the first observations of streaks in flumes and prompted much discussion of his ASCE paper (Vanoni 1946).

Another by-product of Vanoni's work was the acceptance of recirculating flumes for sediment transport experiments. Previous to his work the prevailing approach was to feed sediment at the upstream end of the flume and remove it at the downstream end. In Vanoni's experiments the water and sediment were collected at the downstream end in a hopper and pumped together through a return pipe to a well-designed diffuser and inlet section. The recirculation in a closed circuit allows control of the total volume of water in the system, thereby fixing the mean depth, while the flume slope remains adjustable (by a flume jacking system). With a discharge regulated by the speed of the pump, the velocity is also then predetermined in such experiments. This has interesting implications for transfer of results to the field in terms of which variables are independent or dependent.

It should be noted that in Vanoni's experiments the stream was really starved for sediment, namely there was not a sediment bed in the flume. This meant that no bedforms (ripples or dunes) were allowed to develop and there was no question about separating the resistance into skin friction and form drag.

With his students in the subsequent years, he continued to work on the effects of suspended sediment and bedforms on the flow resistance (friction factor) and the velocity profiles. In the 1950s the Sedimentation Laboratory had support from the Corps of Engineers and the Agriculture Research Service to continue flume studies of roughness and suspended load in alluvial channels. For example, in Vanoni and Brooks (1957), we showed clearly how greatly the friction factor changes in an alluvial stream as the bedforms change. Added form drag on the bed completely overwhelms any of the damping effects of sediment in suspension.

In the 1950s Vanoni was a collaborator with the Corps of Engineers in a large field study on the Missouri River, which again confirmed the basic equations for suspended sediment distribution at a much larger scale.

## **VANONI'S OVERVIEW OF PROGRESS IN SEDIMENTATION RESEARCH IN 1963**

With the passage of so much time it is hard to get a good perspective on the developments that occurred during Vito Vanoni's prime years. This is also confounded by the burst of computer programs for solving lots of problems in alluvial channels in the last two decades. Vanoni had a time mismatch with the computer age because he was well into his 80s before the first user-friendly PC's came along. Nonetheless, he was a fan of the pocket calculators from Hewlett Packard and always bought the latest version as soon as it came out.

It is interesting to go back to see what the research progress in this field looked like before modern instrumentation and computers became available to process the data and run model simulations. An important conference held in 1963 in Jackson, Mississippi—the Federal Interagency Sedimentation Conference—provides this historical perspective. The 933-page proceedings volume is a very good summary of all the facets of U.S. sedimentation engineering work in progress at that time. Vanoni presented a paper titled “Review of Research Activities in Sedimentation” (Vanoni 1965) in which he summarized in six pages what he considered the significant advances in the previous 15 to 20 years. His paper is also a valuable source of 46 key references from the mid-1930s to the early 1960s. These will not appear in typical computer searches today.

Vanoni's remarks have relevance today. The following paragraph from the summary of his paper gives an example of his thinking in the early 1960s:

I have pointed out three developments which in my opinion have keynoted the work of recent years. These are (1) the theory of turbulent suspension, (2) the clarification of the role of bed forms, and (3) the discovery of the great difference between flow in curved and straight channels. The first of these differs from the other two in that it is expressible theoretically in equations in concise and quantitative form. As such, it is readily understandable, and can be assimilated into textbooks and preserved permanently. The other two items are qualitative ideas, expressible only in words, and hence their true significance is appreciated only by those with some familiarity with sedimentation. Because of this they are more difficult to incorporate into textbooks and are in danger of being lost and then rediscovered, as was the work of river engineers of several generations ago.

Vanoni urged that information about peculiar behavior of streams be documented in the literature even if the investigator can't yet explain it. He was also a great promoter of more interaction between laboratory and field research, and believed that one of the reasons for good progress in the 1950s was increased collaboration on a personal level. He also encouraged university research as a way to increase the number of highly-qualified researchers and practitioners to handle the ongoing sedimentation problems, which he thought would be with us for many years.

His last significant research paper showed how to predict what type of bedforms occur (ripples, dunes, flat, antidunes) from dimensionless hydraulic parameters describing the characteristics of the flow and the bed sediment (Vanoni 1974). The paper presented graphs showing large quantities of sediment data which had been hand-calculated and hand-plotted, just before the advent of good computer-driven plotters.

In his retirement, Vanoni continued to publish excellent comprehensive review papers, most notably the monograph "River Dynamics" in *Advances in Applied Mechanics* (1975), and the ASCE Rouse Hydraulic Engineering Lecture, "Fifty Years of Sedimentation" (1984).

## CLOSING REMARKS

It was a great privilege to have had Vito Vanoni as a mentor, faculty colleague, and friend—he had a tremendous impact on my career and life over 49 years. When I first came to Caltech in 1950, I was immediately attracted to work with him because of his knowledge and inspiring approach to hydraulics—and life in general. I was fascinated to learn the mechanics of rivers and how they were being disturbed by the works of man. He seemed especially enthusiastic when he took me out in the field to inspect local flood events and damage, which is a tradition I kept up with my students.

As a thesis adviser he showed me that careful observations trumped theories if they disagree. He turned me from being a young, idealistic theorist into a careful observer and pragmatist. I was trying to solve the problem of how to predict  $C_a$ , the sediment concentration at a small height "a" above the bed, which was needed to make the suspended load equation useful for applications. I worked out what I thought was a good theory first, then set out to "confirm" it with experiments. But when I started making flume experiments with a sand-covered bed, small sand dunes appeared, and I was distressed because they had no place at all in my theory. I consulted with him as to how I could get rid of the pesky dunes, so I could check my theory. Vanoni said, "Young man, that's the way it is, so that's what you should study." So right then and there my focus shifted to studying these bedforms and their impact on sediment transport and stream roughness.

After I became a faculty member in 1954, Vanoni never made me feel like a junior colleague. He shared many responsibilities of the lab with me and encouraged my initiatives. I had fun planning the new Keck Hydraulics Laboratory with him in the late 1950s. He sent me on a tour to visit other prominent hydraulics labs in the United States to pick up ideas of what to do or not do in designing a hydraulics lab. The visits also allowed me to meet numerous other hydraulics researchers around the country and find out what they were doing.

As Vanoni approached his mandatory retirement date at age 70, he was still impressing the students with his energy and enthusiasm. Vanoni was in a stage of life that I call "young old age," which lasts until you transition to "old old age." Vanoni made "young old age" last for about 20 more years, going

to the lab almost daily, writing papers, doing consulting work well into his 80s. He greatly enjoyed consulting with the Corps of Engineers after the Mount St. Helens eruption in the early 1980s about what to do with all that extra sediment.

Throughout his career and well into his retirement, he was always interested in visiting all the hydraulics research students in the lab (not just his own students); he wanted to hear and see what they were doing, make suggestions, and almost always offer words of encouragement. His comments were always quick and to the point. We miss his cheerful visits, as he seemed to represent the heart and soul of the Keck Hydraulics Laboratory at Caltech.

 equilibrium: bank erosion, 408–411; bed forms, 94–97; depth, 1085, 1090; Eddy-viscosity model, 780; load, 1090; near-bed sediment concentration, 116–119; nonequilibrium channels, 429–430; passive sediment fate and transport processes, 969–971; river width adjustment, 428; in wide channel, 109–110  
 Erodibility Index Method (EIM): erodibility index, 1025–1026, 1026(t); scour assessment, 1026, 1027(t), 1028(t); stream power, 1024–1025  
 erosion. *see also* accelerated erosion; wave-induced erosion: defined, 1094; engineering works, 8; fluid mud entrainment, 283; geologic or natural, 4; mass, 282–283; modes, 275; overview, 4; rate constant, 281–282; rates and quantities, 7–8; sedimentation delivery, 587; shear strength, 276–280; streambank, 387 (*see also* river width adjustment); surface, 275–278  
 EROSION model, 840  
 erosion rate: *vs.* bed shear stress for mixtures, 276(f); constant *vs.* bed shear strength, 281(f); *vs.* excess shear stress, 276(f); *vs.* meander bends, 363(f); surf zone functions, 288(f)  
 estuary, 533  
 Exner equation, 10, 69–70  
 explicit scheme, 1094, 1095  
 extension, 875

## F

falling jet module, 1028–1030  
 fall velocity, 41–43, 42(f), 1094  
 fan-delta, 143(f)  
 FAST2D, 700, 701  
 FAST3D, 700, 701  
 Federal Emergency Management Agency (FEMA), 889, 900–902, 905, 954–955  
 Federal Highway Administration, 512  
 Federal Interagency Sedimentation Project BL-84, 341(f)  
 feldspar, 34  
 Fernandez-Luque-van Beek formula, 73  
 FHWA manual design of riprap revetment, 1051  
 final conditions, survey data for, 655  
 fine-grained sediment transport, 253. *see also* erosion; aggregation, 261–266; applications, 293; deposition under flow, 270–272; diffusion, 291–292; gelling, 274–275; sediment characterization, 254–259; sediment transport processes, 259–261; settling and consolidation, 272–275; settling velocity, 266–270  
 finite-difference methods, 694–695  
 finite element method, defined, 1094  
 fixed-bed model, defined, 1094  
 FLESCOT, 700, 701  
 floating material, 61, 62

flocculation, 254(t), 272(f), 278(f)  
 floc strength, aggregation and, 263–264  
 floc transport, aggregation and, 261–262, 261(f)  
 flocs, 617  
 flood/flood tide, 533  
 floodplain, 232–234, 233(f), 234(f)  
 flood protection levees, 7  
 flood routing, defined, 1094  
 floods, 892  
 flow: aligned with piles, 518(f); around a circular bridge pier, 811(f), 812(t); in a bend, 806(t); in a channel reach and fixed ice cover, 636(f); competence, 51; discharge rating curve, 122–123(f); distribution, 669; duration curve, 473, 1094; field, around consecutive vanes, 453(f); measurements and predictions of, 809(f); open-water, 638(f); over bed forms, 797(t); retarding measures, 553; routing models, 416(t); in sedimentation tanks, 800(t); sediment modeling, 676–678(f); stability relations, 449–450, 449(f); structures at a rectangular pier, 547(f); through non-emergent vegetation, 802(f); between two parallel plates, 985(f)  
 flow and bed topography in meanders: governing equations and sample solution, 443–445; simulation of, 445  
 flow in mobile boundary channels, equations for: allocation of scour and fill, 652–653; bankline migration, 653–654; channel width, 653; continuity, 650; diffusion, 651–652; energy, 650; planform migration, 653–654; sediment transport, 650–651  
 flow resistance. *see also* shear stress partitions; stage-discharge relations: channel, 27–29; diagrams, 103–104(f); equivalent roughness of bed forms, 33–34; fixed-bed (skin or grain) roughness, 29–31; form drag and skin friction, 99–100; movable flat-bed roughness, 32  
 flow velocity: concentration profiles, 284(f); law of the wall, 24–25; velocity-defect and log-wake laws, 25–27  
 fluidization, 261  
 fluid mud generation experiments in flumes, 290(t)  
 FLUVIAL-12 model, 415, 422  
 fluvial data: sediment, 1083–1084; sediment rating curves, 593–594; turbidity measurements, 594  
 fluvial geomorphology: channel classification, 375–379; channel evolution models, 379–381; channel-forming discharge, 364–367; channel instability, 371, 372; channel morphology, 359–363; channel narrowing, 389(f); channel stability, 371; channel widening, 388(f); closure, 382; complexity of, 357; defined, 355; dynamic system, 356–357; fluvial system, 355–356; geomorphic assessment, 381–382; local instability, 372–373; relationships in rivers, 367–371; scale and, 358–359; sediment transport, 363–364; system stability and instability, 373–375; thresholds of, 357; time, 358  
 fluvial hydraulics in bank mechanics: cross-sectional shape, 392–398; hydrodynamics, 415–417; interactions, 422–423; longitudinal changes, 398–399; near-bank zones, 399–400  
 Food and Agricultural Organization (FAO), 5  
 foreset evolution, 133–134; linked-one dimensional model of, 139–141  
 forest activities, 5  
 fractal depression, 261  
 frazil ice, 616–618, 617(f), 618(f)  
 free overfall jet plunging, 1030(f)  
 free-surface elevations, 724(t), 738(t), 740(t)  
 freeze-up jam, 618(f)  
 frequency, defined, 1094

Froude number, 92, 182(f), 1094  
 full sediment balance, 581  
 fuse plug: core, 1059, 1059(f); lateral erosion process, 1060(f); prototype gradation curves, 1063(f); test, 1062–1064, 1063–1064(f), 1065(f)

## G

gabions, 551, 563, 565(t)  
 García-Parker sediment entrainment function, 118, 118(f)  
 gauging station, 334, 748, 862, 1094  
 gelling, 274–275  
 General Land Office (GLO), 861–862  
 general scour, 508–510, 549–557  
 geological control, defined, 1094  
 geological erosion, 3(f)  
 geologic (natural) deposition, 11  
 geology, defined, 1094  
 geometric data: cross-sectional layout and spacing, 656–657; hydraulic roughness, 657–658  
 geometric similarity, 1057  
 geomorphic hazards: drainage network, 875; identification of, 873, 874; piedmont and coastal plains, 878; river, 876–878; slope, 875–876; variables affecting, 874–875(t)  
 geomorphology. *see also* fluvial geomorphology: defined, 355  
 glacial till profile plot, 296(f)  
 GLEAMS, 841, 848  
 glossary, 1089–1101  
 gouging of banks, 643–645, 644(f)  
 Government Performance and Results Act (GPRA), 955  
 gradation: of bed sediment reservoir, 658–659; curves, 1040(f), 1063(f), 1095(f); defined, 1094; model calibration, 668; on point bar, 664, 664(f); of riprap, 559, 561(f), 1040, 1040(t); types, 1040(t)  
 grade scale, sediment, 36(t)  
 grain shape factor, defined, 1097  
 grain-size distributions: annual bed load, 222(f); bed samples, 177–178; definitions and continuous formulations, 175–176; densities, 45(f), 171(f), 176(f); discretization, 177; fifty-stone grid samples, 319(f); grain mobility number and grain size, 46, 94(f); numerical modeling, 213, 216; reaches plot, range and number of, 178(f); scale, 37–38(f), 37–39; sediment deposits, 1008(f); sediment load, 662(t); sediment transport sensitivity, 665(f)  
 granite, 34  
 granular flows, 895  
 graphical user interfaces (GUIs), 10–11  
 gravel, defined, 1091(t), 1095  
 gravel and sediment mixtures, transport of. *see also* active-layer concept; bed load transport of mixtures: abrasion, 210–213; in bed loads, fraction of, 203(f); distributions, 203(f); downstream fining, 223–227; engineering relevance, 171–175; equal mobility, hypothesis of, 221; field data, 209–210; fluvial phenomena associated with, 165–171; geometric mean size and, 203(f); gravel-bed and sand-bed streams, dimensionless bank-full relations, 178–183; mobile armor, 219–221; numerical modeling, 213–216; planform sorting, 227–228; static armor, 216–219; suspension-dominated sand-bed rivers, 229–237; tracers, 237; vertical sorting, 238–239  
 gravel-bed streams, 63  
 gravelometer, 310, 310(f), 311, 313

gravitational sediment flows, 892  
 gravity, 35(t)  
 grid, 714, 1095  
 groins/groin fields, 553, 553(f), 554(t)  
 gross erosion, 839  
 grout-filled bags, 550–551, 563, 566(t)  
 grout-filled mats, 551, 563  
 GSTARS model, 417, 419, 422  
 gauge stations, 588(t)  
 guide banks, 555–556, 569(f)  
 gullies: erosion, 2(f), 837–839; in floodplains, 374(f)

## H

habitat structures: design of, 491, 492(t); migratory barrier removal (fish passage), 491, 493; river restoration design, 491; spawning gravel, 491, 493  
 handheld and hand-line samplers, 323, 325, 326(f)  
 hardpoints, 553  
 Hawaii, isoerodent map of, 835(f)  
 headcutting: development, 997, 998(f); severe erosion, 7, 7(f)  
 headgate, 655  
 HEC-1 hydrologic model, 914, 915(f), 916–917  
 HEC-6, 294, 508, 602, 652, 680(t), 758, 996, 997  
 HEC-18 pier scour equation, 513. *see also* pier foundations (complex), scour for; correction factor for very large piers, 514; Mueller (1996)  $K_4$  correction coefficient, 514; multiple columns skewed to flow, 521–523; pressure flow scour, 523  
 Helley-Smith bed load samplers, 1074–1075(f)  
 heuristic model, 1095  
 hexachlorbenzene, 962  
 hiding function plot, 192(f), 202(f)  
 high sediment: concentration flows, 893(t); concentration turbidity currents, 13(f)  
 Hirano formulation, 183–184  
 historic flows, defined, 1095  
 horizontal collars, 568, 568(f)  
 hybrid model, 1095  
 hydraulic calibration: fixed bed steady and unsteady-state, 668–669; hydraulic and sediment calibration, 669–670; movable-bed, steady-state, 669–670; movable-boundary, unsteady-state, 669  
 hydraulic depth, 1095  
*Hydraulic Design of Flood Control Channels (Engineering Manual 1110-2-1601)*, 906–907, 1051–1052  
 hydraulic dredging, 604–605  
 hydraulic flushing, 605–607, 606(f)  
 hydraulic geometry formulas, 370(t)  
 hydraulic impacts and geomechanic impacts, 644(f)  
 hydraulic impacts of river ice, 635; avulsions, 636–637; channel anabranching, 636–637; channel confluences, 638; cover influence on thalweg alignment, 638–639, 638(f), 639(f); cutoffs, 636–637; ice-cover influence, 636; jam-collapse surges, 639  
 hydraulic loading: for bank protection, 1042–1043; below energy dissipators, 1043; classifications of, 1042(t); descriptors of channel type and bend severity, 1041; parameters, 1041, 1042(t); from propeller jets, 1043; for steep slopes and river closures, 1043; from waves, 1043–1044  
 hydraulic model, 722, 1095  
 hydraulic radius, 126, 1095  
 hydraulics, defined, 1095

hydraulic sorting, defined, 1100  
 hydraulic variables, determination of: computer programs for, 539; for constricted waterways, 538–539; design flows, 536–537; for unconstricted waterways, 537–538  
 hydrodynamic boundary conditions, 749(f)  
 hydrodynamic modeling, 488, 690, 756; coordinate transformations for finite-difference methods, 694–695; depth-averaged equations, 691–692; hydrostatic pressure assumption, 691, 693; introduction and scope, 690; Reynolds-averaged Navier-Stokes equations, 690–691; solution techniques and applicability, 693–694; turbulence closure models, 692–693, 695  
 hydrodynamic-process formulations: basic equations, 690; depth-averaged equations, 691–692; hydrostatic-pressure simplification, 691; Reynolds-averaged Navier-Stokes equations, 690–691; turbulence closure problem, 692–693  
 hydrograph: computational, 1092(f); defined, 1095; 1999 flood, estimated, 913–914; prediction, 602–603, 603(f)  
 hydrographic track lines, 592(f)  
 Hydrological Simulation Program—Fortran (HSPF), 848, 850  
 hydrologic data: boundary condition changes over time, 665; main stream water inflows, 664; trailwater elevation, 665; tributaries, 664–665; water temperature, 665  
 Hydrologic Engineering Center (HEC). *see also* HEC-18 pier scour equation: *Assessment of Structural Flood-Control Measures on Alluvial Fans*, 907; HEC-1 hydrologic model, 914, 915(f), 916–917; HEC-6 numerical model, 294, 508, 602, 652, 680(t), 758, 996, 997; numerical models, 495  
 Hydrologic Simulation Program (HSP), 848  
 hydrology, defined, 1095  
 hydrostatic pressure assumption: ch3d hydrodynamic module, 738, 740; role of, 693; streamline curvature, 700; three-dimensional models for reservoir sedimentation, 686–691, 755, 756–757  
 hyperconcentrated flow: defined, 885–887, 891–892; rheology of, 892–895; streamflows, 894, 895  
 hypothetical stability assessment, 484(t)

## I

ice-cover effects, 613–614, 614(f). *see also* hydraulic impacts of river ice; river-ice effects on alluvial channel morphology; effects on secondary currents, 623(f); flow distribution, 619–623; ice-cover breakup, 623–625; ice-cover effects on sediment transport by flow, 627–628; on a meandering channel, 640(f); open-water proportions, 621(f); sediment transport by ice, 627–635; sinuous-braided channel, 637(f); transverse bed slope, 624(f)  
 ice-cover effects on sediment transport by flow: bed-sediment transport, 632–633; constriction scour and local scour at bridge piers, 634–635; flow resistance, 630–631; local scour beneath ice jams, 634; overview, 627–628; parameters, 628–629; sediment movement and bed forms, 629–630; water-temperature effects, 629  
 ice formation: bankfast ice, 616, 616(f); frazil ice, 616–618(f), 617(f), 618(f); skim ice, 616  
 ice jams, 557, 625(f), 634  
 ice model, defined, 1095  
 Ikeda-Coleman-Iwagaki analysis, 46, 48, 48(f), 53  
 Illinois State Water Survey (ISWS), 844  
 impeded removal, 404

implicit scheme, 851, 1094  
 impoundment, 1001, 1095  
 inactive layer, 1095  
 in-bed flow pressure variations, 973(f)  
 in-channel and overbank flow diagram, 214(f)  
 in-channel habitat structures, 492(t)  
 incipient motion, 480–481, 483, 1052, 1095; stability checks, 481(t)  
 incised channel evolution model (ICEM), 380(f), 409(f), 864, 864(f)  
 ineffective flow, 1095  
 inflowing sediment, size and concentration of: bed gradation on point bar, 664; concentrations, 660; grain size classes, 660; transport theory, 661–664; from tributaries, 660–661, 664  
 initialization, model, 655, 715–717  
 in situ capping of contaminated sediment, 975–977  
 instantaneous samplers, 321–322  
 Institute of Hydrology (U.K.), 844  
 International Erosion Control Association, 600  
 Iowa vanes: installation of, 453(f); as a pier-scour countermeasure, 567–568, 567(f); submerged, 553  
 island and bar formation and shift, 877  
 isoerodent maps, 830–831; of California, 833(f); of Hawaii, 835(f); of Oregon, 834(f); of U.S. (western), 832(f); of Washington, 834(f)  
 isokinetic samplers, 322–323, 324(t)

## J

Jacalitos Creek, 6  
 Jain-Fisher's equation, 523–524  
 jam-collapse surges, 639  
 jet turbulence intensity: based on outlet structure, 1030(t); polynomial coefficients and, 1031(t)  
 joint alternate number, 1027(t)  
 jointed rock, 1033(f)  
 joint roughness number, 1027(t)  
 joint set number, 1022(t)  
 June 2000 event. *See* Leavenworth Bend, Missouri River

## K

Kankakee River, 43, 43(f), 44  
 kaolinite, 78, 254  
 Karim-Kennedy relation, 127–128  
 KINematic runoff, 840  
 kinematic similarity, 1057  
 kinematic-wave approach to debris-flow routing: depth-averaged equations of motion, 909; kinematic wave approximation, 910–911; model application, 911; rheological equations, 909–910  
 KINEROS model, 840, 844, 849–850  
 Knapp-Vlugter criterion, 62  
 knickpoints, 876, 876(f)  
 $k$ - $\omega$  model, 788–790

## L

Lagrangian models, 71, 769–770  
 Laguna Dam, 2  
 lake and reservoir sedimentation, morphodynamics of: delta formation, 133–134, 133–134(f); detrainment and sediment

trap efficiency, muddy pond formation in reservoir, 144–146, 144(f), 145(f), 146(f); linked one-dimensional model of topset, foreset, bottomset evolution, 139–141, 141–142(f); linked quasi-dimensional model of topset, foreset, bottomset evolution, 141, 143–144, 143(f), 144(f); numerical modeling of, parameters used in, 136(t); plunging of muddy turbidity current, 138–139, 138(f); topset and foreset, fluvial deposition of formation, 134–138, 135(f), 136(f), 136(t), 137(f)  
 Lake Erie, 288  
 Lake Francis Case, 582(f)  
 Lake Mead, 133, 133(f)  
 Lake Ontario, 288  
 landslides, 170(f), 887–888, 892–893, 893(f), 895  
 Lane's balance, 372(f)  
 Lara-Pemberton method, 598(t)  
 lateral turbulence intensity, 809(f)  
 lateral velocity, 807(f)  
 Leavenworth Bend, Missouri River: background, 735; boundary and initial conditions, October 1999 event, 736–737, 737(t); field data campaigns, 736; flow computations, 738(t), 740; layout of, 735(f); measured and computed free-surface elevations, June 2000 event, 740(t); measured and computed free-surface elevations, October 1999 event, 738(t); model calibration, June 2000 event, 740; model calibration, October 1999 event, 737–740, 738(t), 739(f); model construction, 736; model to study proposed habitat restoration measures, 743–746, 744(f), 745(f), 746(f); sediment computations, 740–743, 742(f), 743(f)  
 left overbank. *see* overbank  
 Leopold scour chains, 237(f)  
 limestone, 34  
 linear elastic fracture mechanics (LEFM), 1032  
 linear model, 1069, 1095  
 linear scale, 37–38(f)  
 linked-one dimensional model of topset, foreset, bottomset evolution, 139–141  
 liquefaction, 261  
 Lischtvan-Levediev diagram, 55–56, 56(f)  
 Little Salmon Creek, 17  
 littoral drift, 532  
 live-bed abutment scour, 527–528  
 local agencies, 667  
 local inflow and outflow point, 1095  
 local scour. *see also* piers, local scour at: bridge-scour evaluation, 511–512; ice jams, 634; sedimentation processes, computational modeling of, 646; tidal waterways, calculations for, 529; total scour and, 503  
 location-for-condition evaluation (LCE), 867–868  
 location for time substitution (LTS) technique, 863, 867  
 logarithmic law: critical stress for flow over a granular bed, 46–47; vs. power laws for velocity, 27(f); velocity distribution, 775  
 log scale, 37–38(f)  
 Loíza reservoir, 603(f)  
 longitudinal staggered discharges, 751(f), 753(f)  
 Loowit Creek channel profiles, 928(f)

## M

Mad River, 172  
 Madsen-Jimenez formula, 41–42, 73, 106  
 magnetite, 34  
 Mahatta River, 16(f)

- main stem: defined, 1096, 1096(f); downstream fining, 172; water inflows, 664
- Manning's  $n$ : with flow discharge, 98(f), 489(f), 1096;  
Manning-Strickler form of, 28, 29
- Manual 54, 937–939
- Maple Gulch Dam, 998(f)
- Mapocho River, 28
- Marmot Dam, removal of (simulation): background gravel and sand transport rates, 1009; channel gradient and width, 1005; discharge data and hydrologic scenarios, 1005–1006; discussion, 1018–1019; grain-size distribution of reservoir sediment, 1008, 1008(f); grain-size distribution of the channel-bed surface layer, 1006–1008, 1007(f); input data, 1005–1009; model results, 1009; project background, 1000–1002, 1000(f), 1001(f); reference runs of numerical models, 1010–1012, 1011–1012(f); Sandy River, effects on, 1001–1002, 1002(t); Sandy River channel slope, 1006; sediment-transport models developed for, 1002–1005; sensitivity tests, 1016–1018; single-season dam removal and minimal sediment excavation, 1012–1016, 1013–1016(f), 1017(f); water year series selected for use in, 1007(t); zero process, 1009

rock mass module, 1031–1035, 1032(f), 1033(f), 1034(f), 1034(t)

rock scour: combined application methods, 1024; Comprehensive Scour Model (CSM), 1026, 1028; Erodibility Index Method (EIM), 1024–1026; falling jet module, 1028–1030, 1030(f); mechanisms, 1023–1024, 1023(f); overview of, 1021–1022; plunge pool module, 1030–1031, 1031(t); rock mass module, 1031–1035, 1032(f), 1033(f), 1034(t); water, erosive capacity of, 1022–1023, 1022(f)

roundoff error, defined, 1098

Rouse-Vanoni-Ippen suspended sediment distribution, flow stratification effects, inclusion of, 111–112, 112(f)

routing, defined, 1098

runoff, defined, 1098

Russian River, 16(f)

## S

sacrificial riprap, 566–567, 567(f)

Saeltzer Dam, 998, 998(f)

St. Anthony Falls Laboratory (SAFL), 64, 71

St. Venant equations, 10, 213–214, 391, 650, 669

saltation, 66–67

sampling methods, automatic: activation, 336; installation and use criteria, 334–335; overview, 333–334, 334; placement and orientation, 335–336, 335–336, 336(f), 336(f)

sampling methods, manual: bag, 328; cable-and-reel, 325–328; EDI method, 330–331, 332; EWI method, 331–332; handheld and handline, 323, 325; instantaneous, 321–322; isokinetic, 322–323, 324(f); multivertical, 330; overview, 328; point-integrated, 333; rigid-bottle, 323; single-vertical, 328–330; transit rates, 332–333; transit rates for suspended-sediment, 332–333

sand: size classification scale, 1091(t); transport rates, 1009

sand-bed rivers, suspension-dominated: downstream fining, 233–234, 234(f); entrainment and near-bed concentration, grain-size specific relations, 231–232; fine sediment deposition, flushing from gravel, 236–237; floodplain deposition, grain-size-specific formulations, 234–236, 235(f); grain-size-specific bulk predictors, 232–233; Rouse-Vanoni approach for grain-size-specific suspended load, 229–231; sorting in, 229

sand-bed streams. *see also* bed-material load in sand-bed streams, dimensionless relations for: flow resistance, 99, 103–107; vs. gravel-bed streams, 65

Sandy River. *see* Marmot Dam, removal of (simulation)

San Francisco sediment, orders of, 261(t)

saturation: defined, 1098; landslides, 895

Saylorville Reservoir, 755, 756(f)

scale: defined, 1098; effect, 1096; fluvial geomorphology, 358–359; influence of, 391; laws, 1096; sediment grade, 36(t); size classification of sediment particles, 1091(f); time (in turbulent sediment transport), 765; watershed, 842–848(t)

scale effect, 1098

Schmidt number, 772–774

Schumm and Rosgen channel classifications, 376

scour. *see also* local scour, total scour, bridge-scour: bend, 556–557; confluence, 556–557; general, 508; local, 511–512(f), 5011–512 (*see also* pier foundations (complex), scour for: piers, local scour at); total, 506–507

scour at abutments: Chang-Davis abutment scour equation, 527–528; design for scour, 526–527; overview, 525–526, 526(f); Richardson et al. abutment scour equation, 530; Richardson-Trivino abutment scour equation, 529–530; shape, 526, 527(f); site conditions, 526; skew adjustment of, 526, 527(f); Sturm abutment scour equation, 528–529

scour equations: Colorado State University (CSU), 512, 513, 515; contraction, 508; Jain-Fisher's equation, 523–524; Melville's equation, 524–525; other, 525; Richardson et al. abutment scour equation, 530; Richardson-Trivino abutment scour equation, 529–530; Sturm abutment scour equation, 528–529

secondary currents (flow): defined, 1098; ice-cover influence on, 623

second-moment closure, 793–794

sediment, defined, 8, 1098

sedimentation, defined, 1098

Sedimentation Committee of the Hydraulics Division of ASCE, 1

sedimentation engineering: global aspects and changing roles in, 1–3; scope of, 3–4; state of, general observations on, 3

*Sedimentation Engineering Manuals*, 1, 21, 907, 1051–1052, 1110–1111

sedimentation hazards, 881–883. *see also* alluvial fan flooding; geomorphic hazards; mud flows and debris-flows, mathematical modeling of; bank protection works, 907; crib barriers, 907; debris barriers, 908; debris basins, 908; dikes, 908–909; diversions and bypasses, 908; flood control channels, 908; floodwalls, 908–909; general approach to, 906; guidance, 906–907; hazard assessment and mitigation design procedures, currently accepted, 905; hazard mapping and avoidance, 905; history and magnitude of, 887–889; levees, 908; overview, 885–887, 886(f); retention basins, 908; sediment control structures, 908; sediment retention structures, 908; sediment traps, 908; small dam operations, 908; state-of-the-science procedures, 905

*Sedimentation Investigations of Rivers and Reservoirs (Engineering Manual 1110-2-4000)*, 907

sedimentation problems, management and treatment of: engineering treatment and, 15–16; fish habitat and environmental issues, 17; identification and definition of, 15; nonengineering treatment and, 16–17

- sedimentation processes, computational modeling. *see also*  
 data types and resolution; flow in mobile boundary channels,  
 equations for: base test, 670–671; boundary conditions for, 655;  
 computational and physical model studies, similarity between,  
 654–656; example application, 672–679, 675(t), 676–678(f);  
 local scour and deposition, 650; model applicability, examples  
 to illustrate, 671–672; overview of, 649–650; *vs.* physical  
 model, 654–656; plan test, 671; results, interpretation of, 671
- sediment characterization tests, 254–255, 255(t). *see also* mud  
 definition and rheology
- sediment cycle, 22–23
- sediment data: bed gradation on a point bar, 664, 664(f); gradation  
 of bed sediment reservoir, 658–659, 659(f); grain size classes,  
 660, 662(t); inflowing sediment concentrations, 660, 660(f),  
 661(f); sampling concepts, 659–660; sediment data set, criteria  
 for, 320–321; sediment inflow from tributaries, 664; size and  
 properties of bed sediment reservoir, 658; test for sufficiency,  
 660; transport theory, calculating with, 661–664; variability of  
 samples, 660
- sediment delivery ratios, 839–840, 840(t)
- sediment deposition. *see also* reservoir sediment deposition:  
 accelerated (human-induced), 11; causes of, 11–14;  
 environmental and habitat effects of, 14; geologic (natural), 11;  
 rates and quantities, estimation of, 7–8, 14
- sediment deposits: debris flow, 11–12; intermediate and lowland  
 river deposits, 12, 12(f); in lakes and reservoirs, 12–14;  
 river, 11–12, 12(f); sand, for single season dam removal,  
 1012–1013(f); thickness over event horizons, 592–593
- sediment-discharge, defined, 1097. *see also* sediment load
- sediment discharge, estimating, 1063. *see also* bed load material  
 equations; fluvial-sediment data, collection of, 1083–1089;  
 suspended-sediment concentration interpolation method,  
 1067–1069, 1068(f); transport-curve method, 1069–1070(f),  
 1069–1073, 1071(f), 1072(f), 1073(t)
- sediment-exchange processes: introduction, 707; near-bed  
 concentration, imposition of, 707; near-bed sediment exchange,  
 imposition of, 707
- sediment finer, defined, 12

- stratification and sorting, 239(f)
- stratification correction, 291(t)
- stratum control volumes, 704–705, 704(f), 709–711
- streambank erosion, defined, 1098. *see also* river width adjustment
- stream discharge, 366, 593, 1100
- streamflows, 891
- stream gauge, 656, 1100
- stream gauge, defined, 1100
- stream power: sinuosity variations and, 868(f); stability criteria, 480(f)
- stream profile, defined, 1100
- stream reach classifications, 494(t)

stream restoration: definitions, 461–462; discharge, 469–474; implementation and construction, 496; monitoring and postconstruction adjustment, 496–497; projects, 17, 17(f), 467(f); river dynamism, 463; sediment studies plan, preparation of, 466–469; stability assessment, 474–485; stability checks, 494–496

stream restoration, role of sedimentation engineering in. *see also* river restoration design: bed material size distribution, 474; engineer and, as part of a team, 463–464; habitat assessment, setting objectives and, 464–465; habitat restoration objectives, specific, 465; large scale projects, opportunities offered by, 465; monitoring and postconstruction adjustment, 496–497; objectives, setting, 464; project scale and, effects of objectives on, 465; risk evaluation, 466; sedimentation analysis, scope of, 465–466

stream segment, defined, 1100

streamwise velocity profiles, 114(f)

structure channel, 732(t)

Sturm abutment scour equation, 528–529

sturzstroms, 892

subcritical flow, 1100

submerged Iowa vanes, 453, 553

submodel domain, 744(f)

subsampling equipment, 338

sub-surface layer, 1090

summation convention, 816–817

supercritical flow, 83, 140, 1100

supplies and interests, definitions, 938

support practice factor, 837, 837(t)

surface armorings, contrasts in, 165(f)

surface-based relation of Parker plot, 196–197, 197(f)

surface grain-size distribution: pebble counts by stillwater sciences and, 1007(f); in the Sandy River, 1006(f)

suspended bed-material load: depth-discharge and sediment load computation, example of, 119–122 (*see also* depth-discharge computation); eddy diffusivity (Prandtl analogy), form of, 110–111; equilibrium, in wide channel, 109–110; equilibrium near-bed sediment concentration, 116–119; mass conservation of, 107–108; Rouse-Vanoni-Ippen suspended sediment distribution, 111–114; sediment advection-diffusion equation, boundary conditions for, 108–109; sediment entrainment, functions for, 116–119; vertically averaged concentrations, 114–116

suspended-material processes: sediment mixtures, formulations for, 706; three-dimensional formulation, 705–706; two-dimensional (depth-averaged) formulation, 706

suspended medium sand, computed and measured, 728(f)

suspended-sediment samplers, 326(f), 327(f). *see also* suspended bed-material load; boundary conditions, 749(f); concentrations, 739(f), 742(f), 749(f), 751(f); concentrations following dam removal, simulated, 1015(f); distribution, 112(f); fluxes, 296(f); loads, estimations of annual, 1073(t)

suspended silt and clay concentration, 481(f)

suspended very fine sand, 728(f), 729(f)

suspension concentration during a neap tide, 269(f)

sustainability: economic analysis and, 582–584, 583(f); regulatory and legal aspects, 584–585; RESCON approach, 584

SUTRENCH-2D, 699, 700, 701

SUTRENCH-3D, 699, 700, 701

SWRRB, 848

system closure: active-layer and active-stratum approach, 709–711; auxiliary relations, considerations, 711–712; bed load-layer approach, 709; introduction, 708–709; total-load approach, 709; two-dimensional models, 711

system instability: basin-wide factors, 375; downstream factors, 373–374; upstream factors, 374–375

## T

TABS-2, 699

tactical dredging, 604–605

tailgate, 655

tailwater elevation, 665

Taiwanese River, 555(f)

Tanaguarena, 913

Tanaguarena (f), 886

Tanana River, 622(f)

Tarawera River, 78

TELEMAC-3D, 700

tensors, 815–816

thalweg: alignment, 639–640, 640(f), 641(f); defined, 1100; effects, 553, 555; sinuosity and channel variations, 640(f)

thalweg alignment, 638–639, 638(f), 639(f)

thalweg effects, 553, 555

thalweg sinuosity, 639(f)

theoretical model, 48

3D hydrodynamic model, 417

three-dimensional models: computer resources, limitations of, 684, 686; contaminant-sediment capability, 758; field data for model construction, 715; long-term bed evolution in response to changes, 688–689; river-bend dynamics and training works, 687; settling basins, 687; structured vs. unstructured grids., 755

Three Gorges Reservoir profile, 601(f)

three-point bars, 1098(f)

threshold channel, river restoration design of: example of, 487; refinements, 487; step-by-step approach, 487; velocity and tractive force, allowable, 487; when to use, 486–487

threshold conditions for sediment transport. *see also* bed-slope, incipient motion and: critical stress for flow over granular bed, 46–48; Lischtván-Lebediev diagram for sediments for maximum permissible flow velocity, 55; Shields diagram, 48–51; submerged angle of response, 45; Wiberg-Smith diagram for heterogeneous sediments, 52–55; Yalin-Karahan diagram, 51–52

tidal amplitude, 533

tidal cycle, 533

tidal inlets, 533, 536(f)

tidal model, 717

tidal passage, 533

tidal period, 533

tidal prism, 533

tidal processes: defined, 533

tidal range, 533

tidal terms, principle, 535(f)

tidal waterways: crossings, types of, 534(f); definition, 533

tidal waterways, scour calculations for: contraction scour, 532–533; design discharge, 532; local scour, 533; long-term degradation, 532

tides, 533

Tinau River, 11, 11(f)

topographic variability, 206(f)  
 topset evolution: fluvial deposition, 134–137; linked-one dimensional model of, 139–141; linked-quasi-two-dimensional model of, 141–143  
 top width, defined, 525, 1101  
 total-load approach, 709  
 total maximum daily load (TMDL), 840  
 total scour: aggradation and degradation, long-term, 506; general scour (bridge-scour evaluation), 506–507; lateral shifting of a stream, 507; local scour, 503, 507  
 total sediment load, 8, 61(f), 308(f)  
 Toutle River channel profiles, 926(f)  
 toxic sediments on a floodplain, 235(f)  
 tracers as function relative to grain size, 237(f)  
 tractive force, 413–414, 428  
 transect, defined, 1101  
 transient flow and dam site following dam removal, 997(f)  
 transport capacity, 651, 654, 1101  
 transport modes, aggregation and, 265–266  
 transverse bed slopes, 445(f)  
 trap efficiency, 595–596, 1101; of a reservoir, 144(f)  
 trapezoidal channels, 393(f), 394(f), 395(f)  
 tributaries: defined, 1100; hydrologic data, 664–665; sediment inflow from, 660–661, 664; uncontaminated, healthy, 235(f)  
 truncation error, defined, 1101  
 Tsujimoto relation, 197–198  
 tsunami, 533  
 turbid density currents (turbid currents): morphodynamics of, equations governing, 131–133; overview, 597; plunging of, 137–139; rivers and, 129; routing of, 603–604, 606(f)  
 turbulence, aggregation and, 264–265  
 turbulence models. *see also* Eddy-viscosity model: aim and scope of modeling, 766; applications of, 794–812; auxiliary, boundary conditions and, 770–771, 784–794; Cartesian tensor notation, 815–817; choice models, considerations in assessment of, 812–815; closure, 695; defined, 1101; erodible-bed modeling, bed load transport and, 786–788; free-surface conditions, 788; other types of, 815; particulate flows, turbulence in, 763–766; problems in sediment transport, length and time scales in, 765; Reynolds-averaged equations, 766–771; sediment equation, boundary conditions and, 785–786; spatially averaged models, 817–820; turbulent flows, qualitative features of, 764–766  
 turbulent kinetic energy, equation for, 780–781  
 two-dimensional bed load transport, 75(f)  
 two-dimensional fan-delta, 143(f)  
 two-dimensional model, 141–143, 711  
 two-equation model: equation for  $\epsilon$ , 782–783;  $k$ - $\epsilon$  model and closure constants, 783–784, 788–789  
 two-phase models, 790–791

## U

U.K. Institute of Hydrology, 844  
 uniform flow, general resistance diagram for, 1058(f)  
 unimpeded removal, 404–405  
 U.S. Army Corps of Engineers: Unsteady flow through a full NETwork of open channels (UNET) model, 849  
 U.S. Geological Survey (USGS), 665, 667, 848, 955  
 U.S. Water Resources Council (WRC), 887
