ISBN 10: 0-7844-0814-9

Manufactured in the United States of America.

**About the cover:** River dunes in the Rio Paraná near Paso de la Patria, Argentina. Bed morphology measurements were made with a multibeam echo sounder in May 2004. Note the ubiquitous superimposition of smaller bedforms on the stoss side of the larger dunes. Image courtesy of Dan Parsons and Jim Best, University of Leeds, U.K.

## **MANUALS AND REPORTS ON ENGINEERING PRACTICE**

(As developed by the ASCE Technical Procedures Committee, July 1930, and revised March 1935, February 1962, and April 1982)

A manual or report in this series consists of an orderly presentation of facts on a particular subject, supplemented by an analysis of limitations and applications of these facts. It contains information useful to the average engineer in his everyday work, rather than the findings that may be useful only occasionally or rarely. It is not in any sense a “standard,” however; nor is it so elementary or so conclusive as to provide a “rule of thumb” for nonengineers.

Furthermore, material in this series, in distinction from a paper (which expressed only one person’s observations or opinions), is the work of a committee or group selected to assemble and express information on a specific topic. As often as practicable the committee is under the direction of one or more of the Technical Divisions and Councils, and the product evolved has been subjected to review by the Executive Committee of the Division or Council. As a step in the process of this review, proposed manuscripts are often brought before the members of the Technical Divisions and Councils for comment, which may serve as the basis for improvement. When published, each work shows the names of the committees by which it was compiled and indicates clearly the several processes through which it has passed in review, in order that its merit may be definitely understood.

In February 1962 (and revised in April 1982) the Board of Direction voted to establish:

A series entitled “Manuals and Reports on Engineering Practice,” to include the Manuals published and authorized to date, future Manuals of Professional Practice, and Reports on Engineering Practice. All such Manual or Report material of the Society would have been refereed in a manner approved by the Board Committee on Publications and would be bound, with applicable discussion, in books similar to past Manuals. Numbering would be consecutive and would be a continuation of present Manual numbers. In some cases of reports of joint committees, bypassing of Journal publications may be authorized.

## MANUALS AND REPORTS ON ENGINEERING PRACTICE

No.	Title	No.	Title
13	Filtering Materials for Sewage Treatment Plants	80	Ship Channel Design
14	Accommodation of Utility Plant Within the Rights-of-Way of Urban Streets and Highways	81	Guidelines for Cloud Seeding to Augment Precipitation
35	A List of Translations of Foreign Literature on Hydraulics	82	Odor Control in Wastewater Treatment Plants
40	Ground Water Management	83	Environmental Site Investigation
41	Plastic Design in Steel: A Guide and Commentary	84	Mechanical Connections in Wood Structures
45	How to Work Effectively with Consulting Engineers	85	Quality of Ground Water
46	Pipeline Route Selection for Rural and Cross-Country Pipelines	86	Operation and Maintenance of Ground Water Facilities
47	Selected Abstracts on Structural Applications of Plastics	87	Urban Runoff Quality Manual
49	Urban Planning Guide	88	Management of Water Treatment Plant Residuals
50	Planning and Design Guidelines for Small Craft Harbors	89	Pipeline Crossings
51	Survey of Current Structural Research	90	Guide to Structural Optimization
52	Guide for the Design of Steel Transmission Towers	91	Design of Guyed Electrical Transmission Structures
53	Criteria for Maintenance of Multilane Highways	92	Manhole Inspection and Rehabilitation
54	Sedimentation Engineering	93	Crane Safety on Construction Sites
55	Guide to Employment Conditions for Civil Engineers	94	Inland Navigation: Locks, Dams, and Channels
57	Management, Operation and Maintenance of Irrigation and Drainage Systems	95	Urban Subsurface Drainage
59	Computer Pricing Practices	96	Guide to Improved Earthquake Performance of Electric Power Systems
60	Gravity Sanitary Sewer Design and Construction (Second Edition)	97	Hydraulic Modeling: Concepts and Practice
62	Existing Sewer Evaluation and Rehabilitation	98	Conveyance of Residuals from Water and Wastewater Treatment
63	Structural Plastics Design Manual	99	Environmental Site Characterization and Remediation Design Guidance
64	Manual on Engineering Surveying	100	Groundwater Contamination by Organic Pollutants: Analysis and Remediation
65	Construction Cost Control	101	Underwater Investigations
66	Structural Plastics Selection Manual	102	Design Guide for FRP Composite Connections
67	Wind Tunnel Studies of Buildings and Structures	103	Guide to Hiring and Retaining Great Civil Engineers
68	Aeration: A Wastewater Treatment Process	104	Recommended Practice for Fiber-Reinforced Polymer Products for Overhead Utility Line Structures
69	Sulfide in Wastewater Collection and Treatment Systems	105	Animal Waste Containment in Lagoons
70	Evapotranspiration and Irrigation Water Requirements	106	Horizontal Auger Boring Projects
71	Agricultural Salinity Assessment and Management	107	Ship Channel Design
72	Design of Steel Transmission Pole Structures	108	Pipeline Design for Installation by Horizontal Directional Drilling
73	Quality in the Constructed Project: A Guide for Owners, Designers, and Constructors	109	Biological Nutrient Removal (BNR) Operation in Wastewater Treatment Plants
74	Duidelines for Electrical Transmission Line Structural Loading	110	Sedimentation Engineering: Processes, Measurements, Modeling, and Practice
76	Design of Municipal Wastewater Treatment Plants	111	Reliability-Based Design of Utility Pole Structures
77	Design and Construction of Urban Stormwater Management Systems	112	Pipe Bursting Projects
78	Structural Fire Protection	113	Substation Structure Design Guide
79	Steel Penstocks	114	Performance-Based Design of Structural Steel for Fire Conditions

# CONTENTS

	Foreword	xvii
	Dedication	xxi
CHAPTER 1	OVERVIEW OF SEDIMENTATION ENGINEERING	1
	<i>Robert C. MacArthur, Charles R. Neill, Brad R. Hall, Vic J. Galay, and Andrey B. Shvidchenko</i>	
	1.1 Introduction	1
	1.2 Overview of Erosion	4
	1.3 Overview of Sediment Transport	8
	1.4 Overview of Sediment Deposition	11
	1.5 Management and Treatment of Sedimentation Problems	14
	References	17
CHAPTER 2	SEDIMENT TRANSPORT AND MORPHODYNAMICS	21
	<i>Marcelo H. García</i>	
	2.1 Sediment Transport Mechanics and Related Phenomena	21
	2.2 Fluid Mechanics and Hydraulics for Sediment Transport	24
	2.3 Sediment Properties	34
	2.4 Threshold Condition for Sediment Movement	44
	2.5 Sediment Transport	60
	2.6 Bed Load Transport	66
	2.7 Bed Forms	77
	2.8 Bed Forms, Flow Resistance, and Sediment Transport	99
	2.9 Suspended Load	107
	2.10 Dimensionless Relations for Total Bed-Material Load in Sand-Bed Streams	123
	2.11 Morphodynamics of Rivers and Turbidity Currents	129
	2.12 Morphodynamics of Lake and Reservoir Sedimentation	133
	References	146
CHAPTER 3	TRANSPORT OF GRAVEL AND SEDIMENT MIXTURES	165
	<i>Gary Parker</i>	
	3.1 Fluvial Phenomena Associated with Sediment Mixtures	165
	3.2 Engineering Relevance	171
	3.3 Grain-Size Distributions	175

	3.4	Dimensionless Bank-Full Relations for Gravel-Bed and Sand-Bed Streams	178
	3.5	The Active Layer Concept	183
	3.6	General Formulation for Bed-Load Transport of Mixtures	186
	3.7	Relations for Hiding and Bed-Load Transport in Mixtures	191
	3.8	Field Data	209
	3.9	Abrasion	210
	3.10	Numerical Modeling of Bed Level Variation with Sorting	213
	3.11	Static and Mobile Armoring: Observations, Experiments, and Modeling	216
	3.12	Downstream Fining: Observations, Experiments, and Modeling	223
	3.13	Morphodynamics of Local Planform Sorting	227
	3.14	The Case of Suspension-Dominated Sand-Bed Rivers	229
	3.15	Tracers and Vertical Sorting	237
		Notation	239
		References	243
CHAPTER 4		FINE-GRAINED SEDIMENT TRANSPORT	253
		<i>Ashish J. Mehta and William H. McAnally</i>	
	4.1	Introduction	253
	4.2	Sediment Characterization	254
	4.3	Sediment Transport Processes	259
	4.4	Aggregation	261
	4.5	Settling Velocity	266
	4.6	Deposition Under Flow	270
	4.7	Consolidation and Gelling	272
	4.8	Erosion	275
	4.9	Wave-Induced Erosion	283
	4.10	Diffusion	291
	4.11	Applications	293
		References	297
CHAPTER 5		SEDIMENT TRANSPORT MEASUREMENTS	307
	5.1	General	307
		<i>P. Diplas, R. Kuhnle, J. Gray, and D. Glysson</i>	
	5.2	Bed-Material Measurement Techniques	309
		<i>P. Diplas</i>	
	5.3	Suspended-Sediment Samplers and Sampling Methods	320
		<i>J. Gray, D. Glysson, and T. Edwards</i>	
	5.4	Bed Load Samplers	339
		<i>R. Kuhnle</i>	
		References	346
CHAPTER 6		FUNDAMENTALS OF FLUVIAL GEOMORPHOLOGY	355
		<i>D. S. Biedenharn, C. C. Watson, and C. R. Thorne</i>	
	6.1	Basic Concepts	355
	6.2	Channel Morphology	359

	6.3 Sediment Transport	363
	6.4 Channel-Forming Discharge	364
	6.5 Relationships in Rivers	367
	6.6 Channel Stability and Instability	371
	6.7 Channel Classification	375
	6.8 Channel Evolution Models	379
	6.9 Geomorphic Assessment	381
	6.10 Closure	382
	Notation	382
	References	383
CHAPTER 7	STREAMBANK EROSION AND RIVER WIDTH ADJUSTMENT	387
	<i>James E. Pizzuto and the ASCE Task Committee on Hydraulics, Bank Mechanics, and Modeling of River Width Adjustment</i>	
	7.1 Introduction	387
	7.2 Geomorphic Context of River Width Adjustment	387
	7.3 Factors Influencing Bank Erosion and Width Adjustment	391
	7.4 Methods for Evaluating Bank Erosion and Width Adjustment	408
	7.5 Procedure for Approaching Width-Adjustment Problems	426
	7.6 Conclusions	428
	Appendix. Data Sources	429
	Acknowledgments	430
	References	430
CHAPTER 8	RIVER MEANDERING AND CHANNEL STABILITY	439
	<i>A. Jacob Odgaard and Jorge D. Abad</i>	
	8.1 Introduction	439
	8.2 Meandering Process	439
	8.3 Flow and Bed Topography in Meanders	443
	8.4 Channel Stability	445
	8.5 Applications of Flow and Stability Relations	449
	8.6 Simulation of Meander Evolution	450
	8.7 Channel Stabilization	451
	References	454
CHAPTER 9	STREAM RESTORATION	461
	<i>F. Douglas Shields, Jr., Ronald R. Copeland, Peter C. Klingeman, Martin W. Doyle, and Andrew Simon</i>	
	9.1 Introduction	461
	9.2 Preparation of Sediment Studies Plan	466
	9.3 Selecting Values for Design Discharge and Bed Material Size	469
	9.4 Stability Assessment	474

	9.5 River Restoration Design	485
	9.6 Stability Checks	494
	9.7 Implementation and Construction	496
	9.8 Monitoring and Postconstruction Adjustment	496
	9.9 Conclusions	497
	Acknowledgments	497
	References	497
CHAPTER 10	BRIDGE SCOUR EVALUATION	505
	<i>J. R. Richardson and E. V. Richardson</i>	
	10.1 Introduction	505
	10.2 Total Scour	506
	10.3 Clear-Water and Live-Bed Scour	507
	10.4 Long-Term Bed Elevation Changes	507
	10.5 General Scour	508
	10.6 Critical Velocity for Movement of Bed Material	510
	10.7 Local Scour	511
	10.8 Local Scour at Piers	512
	10.9 HEC 18 Pier Scour Equation	513
	10.10 Scour Depths with Debris on Piers	523
	10.11 Jain and Fisher's Equation	523
	10.12 Melville's Equation	524
	10.13 Other Pier Scour Equations	525
	10.14 Top Width of Pier Scour Holes	525
	10.15 Local Scour at Abutments	525
	10.16 Chang and Davis Abutment Scour Equation	527
	10.17 Sturm Abutment Scour Equation	528
	10.18 Richardson and Trivino Abutment Scour Equation	529
	10.19 Richardson et al. Equation for $L/y > 25$	530
	10.20 Computer Models	530
	10.21 Stream Instability	530
	10.22 Scour in Tide-Affected Waterways	531
	10.23 Scour Calculations for Tidal Waterways	532
	10.24 Overview of Tidal Processes	533
	10.25 Preliminary Analysis	534
	10.26 Determination of Hydraulic Variables	536
	References	539
CHAPTER 11	BRIDGE-SCOUR PREVENTION AND COUNTERMEASURES	543
	<i>Bruce W. Melville, Arthur C. Parola, and Stephen E. Coleman</i>	
	11.1 Introduction	543
	11.2 Scour Processes	543
	11.3 Protection against General Scour and Contraction Scour	549
	11.4 Countermeasures for Local Scour at Bridge Piers	557
	11.5 Abutment Protection	568
	11.6 Environmental Considerations	574
	References	574

CHAPTER 12	RESERVOIR SEDIMENTATION	579
	<i>Gregory L. Morris, George Annandale, and Rollin Hotchkiss</i>	
	12.1 Introduction	579
	12.2 Sedimentation Rates	580
	12.3 Sustainability	582
	12.4 Sedimentation Impacts	585
	12.5 Sediment Delivery to Reservoirs	587
	12.6 Quantifying Sediment Yield	590
	12.7 Sediment Deposition in Reservoirs	595
	12.8 Sediment Management in Reservoirs	598
	12.9 Dam Removal	607
	12.10 Concluding Remarks	608
	References	609
CHAPTER 13	ICE EFFECTS ON SEDIMENT TRANSPORT IN RIVERS	613
	<i>Robert Ettema</i>	
	13.1 Introduction	613
	13.2 Ice Formation	615
	13.3 Ice-Cover Effects on Flow Distribution	619
	13.4 Ice-Cover Breakup	623
	13.5 Sediment Transport by Ice	625
	13.6 Ice-Cover Effects on Sediment Transport by Flow	627
	13.7 River-Ice Effects on Alluvial-Channel Morphology	635
	Acknowledgments	645

# FOREWORD

*Robert C. MacArthur, Charles R. Neill and Marcelo H. Garcia*

It is increasingly evident that global water and soil resources require significantly increasing efforts in management and preservation in order to meet present and future needs for human consumption and ecological balance. In many regions of the world, these resources are adversely affected by water or wind erosion of rocks and soils, by the consequent transport of sediment by streams and rivers, by the deposition of riverborne sediment in lakes, reservoirs, estuaries and seas, and by the incorporation or concentration of contaminants and toxic substances in sediments. This series of processes is often referred to briefly as *sedimentation*. Their investigation, evaluation and treatment in the context of civil engineering and public works facilities is commonly referred to as *sedimentation engineering*.

As distinct from articles and reports on specific aspects of sedimentation, one of the first English-language books to attempt a comprehensive treatment in a civil engineering context was ASCE's Manual 54, *Sedimentation Engineering*, edited by the late Professor Vito Vanoni with a long list of contributors, and published in 1975 after more than a decade of preparatory work. The 1975 manual describes and analyzes soil erosion and sediment yields, properties of sediment, sediment transport under the action of water and wind, techniques of sediment measurement, methods of sediment control in engineering works, and economic and legal aspects of sedimentation engineering. Manual 54 remains an important and reliable reference on many aspects of sedimentation engineering, but in other aspects it has become out-dated by advances in knowledge and by the emergence of new problems, issues and methods for assessing them. In terms of key issues at the beginning of the twenty-first century, perhaps the most notable missing material in the 1975 Sedimentation Engineering Manual relates to environmental and ecological problems associated with sedimentation and other significant topics such as river restoration and reservoir sedimentation. This is not surprising since most sediment-related environmental concerns were in their early stages at the time the original manual was being prepared.

Since the publication of Manual 54, extensive advances have been made in methods of investigation, measurement and analysis, including the extensive use of computer modeling procedures that are becoming increasingly more reliable to simulate sediment transport dynamics. Today more is known about fluvial transport of coarse sediment mixtures, erosion of cohesive and semi-cohesive materials, bridge-pier scour, reservoir sedimentation, river morphodynamics and about sedimentation hazards including debris torrents, mudflows and hyper-concentrated flows. Multidisciplinary research has expanded the understanding of linkages between fluvial processes and ecological responses, while sediment engineering studies are increasingly accepted and relied upon as necessary input to schemes for water resource development and for environmental restoration or enhancement. Perhaps most significant of all, the ecology and morphology of streams and the transport of contaminants has emerged as a major rationale for many sediment studies and are now essential considerations in project planning, design and permit consideration.

Moves towards the present publication began with the formation in 1991 of a *Task Committee to Expand and Update ASCE Manual 54* under the formulation and leadership of Dr. Robert MacArthur, then with the Corps of Engineers' Hydrologic Engineering Center in Davis, CA. In 1999, by which time initial drafts had been prepared for ten chapters, Professor Marcelo Garcia of the University of Illinois at Urbana-Champaign was appointed as Chief Editor, with the vision of a new volume of the Manual that would utilize state-of-the-art information published in ASCE's *Journal of Hydraulic Engineering* and other internationally recognized sources such as the IAHR Journal of Hydraulic Research. Realizing the monumental effort required to prepare a complete revision of the original Manual 54, it was decided that the new publication should be treated as a companion to its progenitor, which would be made available again through a new printing to be known as the Classic Edition (Vanoni, 2006).

This companion volume, designated Manual of Practice 110, *Sedimentation Engineering: Processes, Measurements, Modeling, and Practice*, consists of 23 chapters and 6 appendices covering selected topics — generally, those where important advances have been made since 1975, or topics that were not addressed at that time. The list of topics covered is not necessarily comprehensive, having been limited by constraints on the availability and time of writers. Significant matters that are not addressed include wind-induced erosion and transport and sediment transport in pipes (treated in Manual 54) and the field of coastal erosion and sedimentation (not addressed in Manual 54 or Manual 110).

This Manual 110 includes contributions from internationally recognized experts in various fields of sedimentation science and engineering. Lists of persons involved in preparing and writing this Manual are provided below. All parts of the manual have been subjected to extensive review and technical editing, and all writers and reviewers have operated either on a voluntary basis or with the support of their employing organizations.

## ACKNOWLEDGMENTS

The preparation and writing of MOP 110 required a substantial effort by many authors and reviewers. Contributors to the writing of MOP 110 include the following: Norman Brooks, Robert MacArthur, Brad Hall, Charles Neill, Vic Galay, Andrey Shvidchenko, Marcelo Garcia, Gary Parker, Ashish Mehta, William McAnally, Jr., Panos Diplas, Roger Kuhnle, John Gray, Douglas Glysson, Thomas Edwards, Dallas Childers\*, David Biedenharn, Chester Watson, Colin Thorne, Jim Pizzuto & ASCE Task Committee on River Width Adjustment, Jacob Odgaard, Jorge Abad, Douglas Shields, Jr., Ronald R. Copeland, Peter Klingeman, Martin Doyle, Andrew Simon, J. R. Richardson, E.V. Richardson, Bruce Melville, Arthur Parola, Stephen Coleman, Greg Morris, George Annandale, Rollin Hotchkiss, Robert Ettema, W. Anthony “Tony” Thomas, Howard Chang, Miodrag Spasojevic, Forrest Holly, Jr., Dennis Lyn, Deva Borah, Edward Krug, Daniel Yoder, Stanley Schumm, Michael Harvey, Richard French, Jeffrey Bradley, Julianne Miller, Thomas Grindeland, Hans Hadley, James Slosson, Douglas Hamilton, Gerard Shurman, Danny Reible, Miki Hondzo, Nancy Steinberger, Yantao Cui, Andrew Wilcox, Erik Bollaert, Steve Maynard, Cliff Pugh, Francisco Simoes, and Lawson Smith\*.

*\*Deceased*

Reviewers that contributed with their effort include: Gary Parker, Peter Wilcock, Jose Rodriguez, Robert MacArthur, Charles Neill, Ray Krone, Han Winterwerp, Robert Holmes, Jr., Bruce Rhoads, Steve Darby, Jorge Abad, Peter Downs, Meg Jones, David Mueller, Peggy Johnson, Juan Pedro Martin-Vide, Brian Barkdoll, David Admiraal, S. Beltaos, H. T. Shen, Sam Wang, Forrest Holly, Octavio Sequeiros, Wolfgang Rodi, Cesar Mendoza, Arthur Schmidt, Julianne Miller, Steve McCutcheon, Aaron Packman, William Dietrich, Jim Pizzuto, Tom Lisle, Steve Wiele, Gary Freeman, Thanos Papanicolau, Yovani Cataño, and Francisco Pedocchi.

A Review Panel revised and approved the publication of MOP 110. Members of the review panel included: Pierre Julien, Jeffrey Bradley, Richard French, and Rollin Hotchkiss.

Many others contributed to this work by reviewing and discussing various topics and manuscripts with the authors and committee members. ASCE/EWRI contributed guidance, support and patience for the project and arranged the final editing and publication. The support of the Department of Civil and Environmental Engineering at the University of Illinois at Urbana-Champaign is gratefully acknowledged.

# DEDICATION

*Vito A. Vanoni (1904–1999)*

**Fig. 1.** Prof. Vito A. Vanoni in his office, 1974. (Photo credit: Caltech)

This updated edition of *Sedimentation Engineering* (ASCE Manuals and Reports on Engineering Practice No. 110) is dedicated to Professor Vito A. Vanoni, an internationally recognized professor of Civil, Hydraulic, and Sedimentation Engineering at the California Institute of Technology from 1942 to 1999. Professor Vanoni was an insightful researcher, an energetic and inspirational teacher, and the visionary editor and a contributing author of the original volume of *Sedimentation Engineering* (ASCE Manuals and Reports on Engineering Practice No. 54) published in 1975. Manual 54 is a classic reference used by professionals and academics around the world. Professor Vanoni was the recipient of numerous professional honors and awards; however, he always displayed a humble and sincere interest in all of his students, his family, his profession, and his colleagues at Caltech. He encouraged fundamental research on sediment transport using modern fluid mechanics, and recognized the need for much more graduate level education to support the advances in research and applications of sedimentation engineering. The profession and science of sedimentation engineering was greatly advanced by the research, teachings and publications produced by Professor Vanoni during his career.<sup>1</sup> Therefore, the ASCE Task Committee to Expand and Update ASCE Manual 54 dedicates this edition of *Sedimentation Engineering* to Vito A. Vanoni for the significant contributions he made to the profession of sedimentation engineering and mobile boundary hydraulics during his career. We miss his charm, intellect, enthusiasm, insightfulness, and friendship.

# CHAPTER 1

## *Overview of Sedimentation Engineering*

*Robert C. MacArthur, Charles R. Neill, Brad R. Hall, Vic J. Galay,  
and Andrey B. Shvidchenko*

### 1.1 INTRODUCTION

#### 1.1.1 General

Sedimentation engineering embraces the identification, planning, analysis, and remediation, principally in the context of civil and hydraulic engineering practice, of projects or technical investigations to avoid and/or mitigate problems caused by sedimentation processes. These processes include erosion, entrainment, transport, deposition, and compaction of sediment. External agents and forces driving these processes may include water, wind, gravity, and ice. Human activities also affect sedimentation processes. This volume of *Sedimentation Engineering*, referred to herein as Manual 110, focuses primarily on physical processes, measurements, modeling, and the practice of sedimentation engineering, mainly in the context of rivers and inland water bodies. (Chapter 4, however, addresses fine sediments topics, including those found in coastal and estuarine environments.)

The original ASCE Manual 54 *Sedimentation Engineering*, edited by Vito A. Vanoni (1975), represents a 10-year effort by the Task Committee for the Preparation of a Manual on Sedimentation under the coordination of the Sedimentation Committee of the Hydraulics Division of ASCE. Professor Vanoni and the Task Committee assembled and organized state-of-the-art information on sediment mechanics and sedimentation engineering available at the time. Since then, awareness of the importance, scope, and potential consequences of sedimentation processes in relation to civil engineering works, human activities, and the environment has greatly increased. Also greatly expanded are the scientific and engineering understanding and knowledge of underlying processes related to sedimentation engineering. Manual 110 is designed to update selected topics in the original manual and to present recent advances and new topics in sedimentation engineering as a complement to the

original Manual 54. Manual 110 is intended to supplement rather than replace the original manual, which contains a wealth of fundamental information that has not lost its validity. Together, both manuals document the evolution of the specialized field of sedimentation engineering over a 50-year period.

#### 1.1.2 Global Aspects and Changing Roles

As awareness of sedimentation processes and the consequences of poor sediment-management practices has increased among civil engineers and other water resources professionals, it has increasingly been realized that a multidisciplinary approach to problem identification, quantification, and management is often required to deal with the interrelated effects of geomorphologic, environmental, and engineering issues. This type of comprehensive systems approach is also demanded by more stringent legal and regulatory requirements regarding sediment and hydraulic processes in water bodies.

Factors that have resulted in increased public awareness and greater potential impacts to water resources and the environment include the following:

- Growing global populations place increasing pressures on land and water resources. As forest and farmlands become subject to increased soil erosion (Fig. 1-1), reservoirs designed for centuries of useful life may fill with sediment in a few decades, and water supply, irrigation systems, and critical aquatic habitat areas may become clogged with sediment deposits, while poorly managed forests and farmlands decline in function and productivity.
- Human settlements have increasingly occupied areas more vulnerable to erosion and sedimentation, thus aggravating runoff, soil erosion, and gullyng (Fig. 1-2). Poor land use planning, management, and maintenance

**Fig. 1-1.** Severe soil erosion resulting from annual burning of underbrush in teak forests on hillsides in Java, Indonesia. *Photograph by B. J. Evans.*

**Fig. 1-2.** Accelerated land erosion and gullyng: active gullyng resulting in severe soil loss and high sediment yields on the upper plateau of Rio Calicanto, Bolivia. This fertile cropland was abandoned by local farmers because of their migration to coca producing areas. Because of neglect and lack of annual maintenance, the altered lands are no longer managed or stabilized, resulting in rapid erosion and headcutting of gullies during rainstorms. Irrigation reservoirs downstream are now filled with sediment eroded from this area, resulting in significant impacts to water supply and flood control. *Photograph by V. J. Galay.*

practices often lead to dramatic consequences. Severe natural events such as floods, hurricanes, earthquakes, landslides, and volcanic eruptions can produce more dramatic geomorphic changes and sedimentation effects in highly altered settings that can last for decades.

- One of the most significant factors affecting global management and delivery of sediment has been the construction of dams on rivers. Approximately 80,000 dams have been built in the United States of America during the past century (Graf 2001). Morris and Fan (1997) summarize how construction of dams provides many benefits but may alter a river's natural balance of sediment inflow and outflow. They emphasize the urgent need to improve global planning, operation, maintenance, and management of dams and reservoirs with respect to sediment-related problems. An example is the Davis Dam on the Colorado River near Las Vegas (Fig. 1-3), which, along with the Hoover, the Glen Canyon, the Parker, the Headgate Rock, the Palo Verde, the Imperial, and the Laguna dams, have fragmented the river into a series of pools and sediment sinks that alter the nature and movement of sediment along the Colorado River.
- Scientific experts and governments worldwide acknowledge strong scientific evidence demonstrating that human activities are changing the Earth's climate and that further change is inevitable. Expected results include an increasing likelihood worldwide for more frequent occurrences of extreme storms and flood events (National Research Council 1989; Hasselmann et al. 2003; Watson 2003). Such events are often responsible for a major part of long-term morphologic changes and sedimentation activity, while the occurrence of severe hydrologic events on highly altered, destabilized landscapes may result in more dramatic consequences than previously anticipated. This may become one of the most important engineering and environmental issues facing societies worldwide.

**Fig. 1-3.** Photo of Davis Dam on the Colorado River. Watershed sediments are trapped behind a series of eight dams and reservoirs resulting in approximately 20 feet of riverbed lowering in places along the Colorado River. *Photograph by V. J. Galay.*

The following excerpts from a volume devoted to reservoir sedimentation by Morris and Fan (1997) raise difficult issues related to water resources and sedimentation engineering:

In a number of countries population growth seems to be rapidly outstripping the available water resources base. . . . Water resource engineers and development planners have a responsibility to study, understand and communicate the capacity and limits of the earth's resources. . . . Is it a legitimate or ethical function of the engineering profession to destroy entire ecosystems to feed a runaway human population?

With increasing awareness of the importance, scope, and potential consequences of sedimentation processes in relation to civil engineering works, human activities, and the environment, sedimentation engineering studies require consideration of basinwide processes associated with sediment sources, transport routes, and depositional sinks, as well as the potential future effects on the environment and on upstream and downstream interests. Forecasting may be required of incremental and cumulative impacts from a sequence of past and future projects—for example, possible impacts of a series of road and bridge crossings on the hydraulics and morphology of a river floodplain should be assessed prior to project construction. Sedimentation issues often embrace water quality, contaminant transport (e.g., heavy metals, pesticides, and petroleum by-products that attach to sediments), and impacts on natural habitat, health, and amenities, requiring that sedimentation engineers participate in multidisciplinary teams to plan and design effective projects. In the United States and other countries, legislation increasingly calls for detailed quantification of sedimentation processes as well as other impacts from water resources projects.

### 1.1.3 Additional Comments

Some general observations on the state of sedimentation engineering in the early years of the twenty-first century are as follows:

- Sedimentation processes are not always adverse or undesirable as some writings suggest. To the contrary, sedimentation processes are essential for the maintenance of morphologic balance and are critical components of aquatic ecosystems. For example, fertile agricultural lands and wildlife areas may benefit from periodic flooding and silt deposition, and fish may rely on continual renewal of bed sediment (gravels) in spawning areas. Sedimentation processes are key components of most fluvial systems.
- Project planners and designers are presented with so much information on environmental and biological issues that the importance of hydraulic and sedimentation processes are sometimes overlooked or underestimated. Given the need for reliable field data, however, it is important to address sedimentation issues at an early

stage. Where there are clearly significant problems or impacts, sediment data collection should receive as much attention as hydrometeorologic and environmental data. It is as important to develop uninterrupted long-term sedimentation data sets as it is to monitor hydrologic and biologic changes and trends.

- Field studies providing full-scale confirmation of theoretical and laboratory results are relatively scarce, compared to the large number of theoretical and small-scale experimental studies proposing methods for the computation of sediment transport rates, scour depths at bridge foundations, and so on. This is not surprising given their difficulty and cost, but the limitations of theoretical formulations and scaled-up laboratory results are sometimes overlooked.
- Sediment management issues and morphological changes may arise from reduction of sediment inputs as well as from increases in sediment production. Poor project planning, poor land use management, or the occurrence of significant natural hazards (fires, earthquakes, and floods) may result in short- or long-term sediment imbalances. For example, construction of storage reservoirs that trap fluvial sediment or excessive mining (extraction) of fluvial sediments may have adverse effects on channel morphology and the biological habitat in downstream river reaches and cause undermining of structure foundations and alter coastal morphology and stability.
- Addressing real-world problems in water resources and sedimentation engineering is often challenging because of the extreme complexities related to large spatiotemporal heterogeneities, sparsity of reliable data, and knowledge gaps that limit our ability to predict morphologic changes during individual storm events or during longer, decadal periods of time. Perhaps even more challenging to hydraulic and sediment engineering scientists is understanding and quantifying the interaction between flow and sediment dynamics, and the short- and long-term effects of these processes on aquatic ecosystems (modified from Lyn, 2006). Solutions to this class of challenging issues will require a multidisciplinary approach from engineers and scientists. This need is “driving the development of a predictive science of Earth surface dynamics that integrates many disciplines and approaches, including hydrology, geomorphology, ocean and atmospheric science, sedimentary and structural geology, geochemistry, and ecology” (Paola et al. 2006).

### 1.1.4 Scope of Subsequent Chapters and Appendices

Chapters 2 through 23 and Appendices A through D address a wide range of sedimentation topics. To a considerable extent, the topics covered reflect the expertise and interests of individual authors and are intended to present recent

advances and new topics in sedimentation engineering. Primary topics include:

- Sediment sources, erosion, and hazards: Chapters 6, 17–19.
- Sediment transport mechanics and measurement: Chapters 2–5.
- Computational modeling of sediment transport: Chapters 14, 15, 19, and 23.
- Lateral stability of river channels: Chapters 7 and 8.
- Assessment and remediation of selected sedimentation problems: Chapters 9–12 and 23.
- Environmental issues: Chapters 9, 21, and 22.
- Ice effects on sediment transport: Chapter 13.
- Turbulence modeling: Chapter 16.
- Sedimentation law: Chapter 20.

Appendices A through D provide summaries on additional topics including rock erosion, riprap design, the use of physical models for assessing sediment engineering problems, and methods for estimating sediment discharge. Appendices E and F provide a glossary of terms and unit conversions.

## 1.2 OVERVIEW OF EROSION

### 1.2.1 General

ASCE's original Manual 54 (Vanoni 1975) distinguished between geological (or natural) erosion and accelerated (or human-induced) erosion, viewing the latter as a mainly local phenomenon. In the twenty-first century, such a view is outdated. Hooke (1994) estimated annual global volumes of erosion due to various agents and concluded that "humans are arguably the most important geomorphic agent currently shaping the surface of the Earth." However, others (Valdiya 1998) have shown that geological erosion through mountain ranges, such as the Himalayas, continues to produce immense volumes of sediment.

It is often difficult to determine whether an observed erosional process is natural or whether it results wholly or partly from human influences. For example, gullying and landslides that appear natural may have been triggered or aggravated by overgrazing, significant land use modifications such as urbanization, infiltration of irrigation water, or deforestation. Overviews of erosion, sediment transport, and deposition are presented in Sections 1.2, 1.3, and 1.4, respectively.

### 1.2.2 Geologic or Natural Erosion

Geological erosion results from tectonic uplift, earthquakes, weathering, and chemical decomposition and the long-term action of water, wind, gravity, and ice (see Chapters 6, 17, and 18). Over long periods, such processes have produced some enormous erosional scars—for example, the Grand Canyon in Arizona (Fig. 1-4). In some regions, the bulk of natural erosion may result from severe episodic events like

**Fig. 1-4.** Grand Canyon, Arizona: spectacular example of geologic erosion by flowing water through layers of sedimentary deposits. Note sites where active erosion provides sediment directly into the river from small, steep drainages. *Photograph by V. J. Galay.*

earthquakes, landslides, volcanic eruptions, and extreme floods.

Rates of geologic erosion vary widely both among and within regions. Summerfield and Hutton (1994) list average rates of natural erosion estimated for major world drainage basins. Rates tend to be slow in terms of a human lifetime but may be significant enough to require consideration in some projects. Control is often difficult or impractical because the erosion is distributed over large areas divided among multiple owners and resource management jurisdictions. Poorly designed and implemented land or water use projects can dramatically accelerate prior erosion rates.

Geologic erosion rates have varied widely over time, primarily as a result of climatic variations. Rapid climate change in the form of global warming has led to unprecedented erosion in sensitive areas like the Arctic coast of North America (McCarthy et al. 2001).

### 1.2.3 Accelerated or Human-Induced Erosion

Accelerated erosion may be wholly or partly caused by human activities. The impacts of individual or cumulative human activities may be subtle and may commence slowly but can result in dramatic rapid changes in morphology, sediment production, and deposition with time once critical geomorphic stability thresholds are exceeded. Hatheway (2005) explains that prior to the nineteenth century, humans possessed a relatively limited ability to alter the geologic landscape. However, anthropogenic effects on global landscapes and the environment dramatically accelerated during the nineteenth and twentieth centuries. Besides causing sedimentation problems and impacting constructed facilities, poorly planned human activities often lead to environmental degradation and damage to habitat. Simply to address accelerated erosion as a local engineering problem without regard to basinwide sources and responses is generally inadvisable. The potential for erosion should be considered in the context of a multidisciplinary and participatory approach to a range of associated problems. In the face of growing populations and associated pressures placed on land and natural resources, the basic problems associated with sedimentation processes may not be fully solvable, but at least they should be recognized and faced by authorities and the public.

### 1.2.4 Sources of Accelerated Erosion

Extensive discussions on a number of sources of accelerated erosion are contained in the original Manual 54. Some important sources are discussed briefly below and in Chapters 6 and 17 through 19.

**1.2.4.1 Agricultural Activities** Manual 54 cited an estimated annual soil loss from croplands in the United States of  $4 \times 10^9$  tons/year, of which about 25% was estimated to reach the oceans. In the United States, severe soil erosion in the 1930s was followed by intensive conservation efforts, which substantially reduced rates of soil loss by about 40% in vulnerable regions, between 1982 and 1997 (Uri and Lewis 1998).

Global population increases, on the order of 80 million people per year between 1975 and 2000, have placed severe pressures on agricultural and water resources on several continents. It has been estimated that toward the end of the twentieth century, from 5 to 7 million hectares of arable land worldwide were lost annually because of soil degradation and erosion (Hauck 1985; Jalees 1985; Brown 1991). Although improvements have occurred and continue to take place in the United States, Canada, and some other parts of the world, soil loss has substantially increased in other regions, leading to a net increase in worldwide annual soil loss (Barrow 1991; Food and Agricultural Organization of the United Nations [FAO] 2001).

**1.2.4.2 Forest Activities** World timber demand, extended agriculture, and use of wood for fuel in many

regions have caused extensive destruction of forest land by cutting or burning, especially in parts of Africa, Asia, and South America (Bryant et al. 1997). In a single decade between 1990 and 1999, the global forest area declined by nearly 20% (FAO 2001). It has been claimed that conversion of forestland to agriculture generally increases soil erosion by a factor ranging from several times to as much as 25 times (Golubev 1982).

Where forests are managed for sustainable timber yield, extraction activities are not necessarily erosional, but accelerated erosion often results from cutting on steep slopes or close to streambanks and from construction of access roads and skid trails. In steep terrain, alteration of streams and drainage patterns can trigger destructive debris flows containing boulders, gravel, fine sediment, and woody debris (Costa 1988; Slaymaker 1988). Poorly planned, irresponsible conversion of forestlands has led to dramatic long-term environmental impacts and loss of stable forest areas in Asia, Africa, and in the Amazon River basin in South America. Stabilization and rehabilitation of such channels and river systems may require large-scale and expensive engineering measures (Wieczorek and Naeser 2000).

**1.2.4.3 Urbanization** Rapid growth of cities and suburban areas in the later twentieth century, especially in less developed countries, contributed to increases in erosion due to accelerated runoff from developed areas, especially where steep hillsides are used for unregulated low-cost shelter (Ismail 1997). In some cases, disastrous landslides and mud flows following severe rainfall have caused large-scale property destruction and loss of life (Quinones and Johnson 1987).

In well-planned urban developments, on the other hand, local erosion tends to be important only during construction. Accelerated runoff from developed areas has customarily been directed into storm drains or hard-lined flood-control channels, but this may cause adverse changes in downstream rivers and water bodies. In some jurisdictions, there is pressure to replace hard-lined channels with restored natural stream systems (see Chapter 9). Restoring natural streams to a semistable condition where they receive substantial urban runoff requires multidisciplinary planning and careful engineering design, generally involving storage facilities or the maintenance of large undeveloped floodplain areas to reduce flow peaks and trap sediment. Once confined, realigned, and affected by increased urban runoff, former natural channel processes are forever altered. This often results in regular, long-term management and maintenance requirements (including annual monitoring, permitting, and funding to support these activities) that may have been unanticipated by project proponents.

**1.2.4.4 Roads, Railways, Bridges, and Levees** The main sedimentation impacts of these facilities, apart from temporary construction effects, are (1) alteration of natural drainage patterns by redirecting and concentrating dispersed

cross-flows into bridge and culvert openings (which may have serious effects in steep terrain) and (2) interference with natural river migration and overbank flow patterns by construction of permanent bridge crossings, approach embankments, and levees running alongside rivers (Figs. 1-5 and 1-6). Chapters 8, 10, and 11 present materials relevant to these topics.

**1.2.4.5 Mining Activities** Attention is given in technically advanced countries to controlling erosion from open-pit mining operations, but operations in less developed countries have often proceeded with insufficient planning

**Fig. 1-5.** Jacalitos Creek, California: the creek is attempting to outflank a highway bridge because the narrow bridge constriction and approach embankment prevent natural down-valley migration of meanders. Flow is from right to left. *Photograph by V. J. Galay.*

**Fig. 1-6.** Lower Guadalupe River below the City of San Jose, California: an example of a channelized urban river. The formerly meandering river was significantly straightened and leveed, restricting floodwaters to the main river channel. Formerly an agricultural area, the floodplain is now mainly occupied by urban and industrial development. View downstream. *Photograph by R. C. MacArthur.*

and oversight. Uncontrolled excessive in-channel and floodplain mining can result in geomorphic alteration of river form and processes (Collins and Dunne 1990; Kondolf 1994, 1998a, 1998b; Brown et al. 1998; Church 2001). Poorly managed mining can lower water surface elevations and disrupt the balance between sediment supply and a stream's transporting capacity, which can result in channel incision, bed degradation, diversion of flow through disturbed sediment removal sites, increase of channel instability, and changes in overall channel morphology and sediment transport processes (Fig. 1-7).

**1.2.4.6 Dams and River Regulation** The primary sedimentation effect of a dam is usually to trap riverborne sediment in the reservoir and thereby reduce the availability of sediment load for downstream sediment transport, often leading to local "sediment starvation" and channel incision downstream of the reservoir. Sediment deposition

**Fig. 1-7.** Natural (top photo) and mined (bottom photo) reaches of Cache Creek, California, in 1986. Historically, excessive aggregate mining significantly altered the channel's morphology, causing channel degradation and thalweg lowering (incision). Implementation of comprehensive mining regulations in 1996 has improved conditions. *Photographs by R. C. MacArthur.*

in reservoirs is addressed in Chapters 2 and 12. Chapters 6 and 18 discuss other beneficial aspects of reservoirs as well as their potential impacts on river systems.

Erosional effects associated with dams and reservoirs may include the following:

- Slope flattening and headcutting of the downstream river and consequent destabilization of tributary streams due to sediment starvation, increased flow duration, and/or magnitude of flows (Fig. 1-8).
- Wave erosion around the shorelines.
- In circumpolar regions, collapse of shorelines by thawing of permafrost.

Engineering works such as flood protection levees, which do not generally produce increased sediment inputs, may nevertheless have significant erosional effects because they increase in-channel flows and as well as average channel velocities. The downstream channel gradient may flatten by channel incision and headcutting, resulting in undercutting of channel banks and undermining of engineering works such as bridge and pipeline crossings (U.S. Army Corps of Engineers [USACE] 1994).

River channel alterations designed to augment hydraulic capacity for drainage purposes can cause serious erosion, particularly when meandering channels are straightened and cleared of vegetation without introducing resistant linings or grade control structures (Schumm et al. 1984; USACE

**Fig. 1-8.** Severe erosion and headcutting in former natural channel below Grapevine Dam Spillway, Texas, resulting mainly from greatly increased maximum outflows from collected urban flood runoff. Photograph by C. R. Neill.

1994). Chapters 6 through 9 present relevant information regarding these topics.

**1.2.4.7 Warfare and Population Migrations** The main potential erosional effect of these activities results from construction of defense works and the neglect or abandonment of traditional agricultural methods, water conveyance systems, or engineering works that previously protected land and streams against erosion. Heavy armored transport, shelling, bombing, and fires can also cause significant destruction of forests and erosion protection and land conservation systems. Rose (2005) discusses how historical military activities have impacted local and regional geological conditions by changing the nature and rate of erosion and deposition processes.

**1.2.4.8 Multiple Causes** Accelerated erosion in many world regions may arise from a combination of causes. For example, a publication edited by Walling et al. (1992) presents a regional approach for evaluating basin-wide changes and deals with interrelated problems of erosion, debris flows, and the environment in mountain regions, with particular attention to the Pacific Rim.

## 1.2.5 Estimation of Erosion Rates and Quantities

Estimation of erosion rates and sediment yield from river basins can involve large uncertainties due to the sparsity of reliable data. The problem can be approached indirectly by considering source quantities of erosion or soil loss, or more directly by considering sediment yield—that is, the quantity delivered to the river system—which is usually much less than the source erosion. The first approach tends to be favored by geographers, soil scientists, and agriculturists and the second by urban planners and water resource engineers. Extensive literature exists for both approaches (see, e.g., Barfield et al. 1981; Simons and Senturk 1992; Haan et al. 1994; Reid and Dunne 1996; de Boer et al. 2003). In many basins, a significant proportion of the material eroded from the land surface does not reach the river system because of intermediate topographic features that act as sediment sinks (traps or temporary storage areas).

Erosion from land surfaces can be considered on a large scale in the context of typical rates per unit area from specific regions or specific types of terrain, or at small scale in the context of experimental plots that measure erosion from different types of soil under different vegetation covers and land uses. Experimental plots often tend to overpredict effective sediment production and delivery rates from larger areas. On the other hand, estimates based only on land surface erosion may overlook erosion from valley slopes, gullies, and stream channels. In the case of migrating stream channels, reliable determination of net erosion quantities is difficult because erosion at one location is often compensated by deposition at another.

Sediment yield can be considered globally in the form of typical rates per unit area from various regions or terrain types,

or more locally from measured deposition quantities in lakes and reservoirs or measured rates of sediment transport in rivers. Uninterrupted, long-term sediment delivery data from monitored basins produce the most reliable sediment yield estimates. Unfortunately, very few basins have such data, so sediment yield estimates must usually be developed from empirical relationships. For specific regions, empirical correlations are available relating sediment “delivery ratio” (the ratio of net sediment yield to gross erosion) to drainage area or other physiographic parameters. There are also methods (Barfield et al. 1981; Haan et al. 1994; Reid and Dunne 1996) for estimating sediment yield in unmonitored basins from regional soil erosion and yield maps, empirical yield estimation relationships, or simplified soil loss and delivery models, as well as methods for translating measured sediment yield values from a monitored basin to an unmonitored basin of similar character. Sediment yield is addressed in Chapter 17.

### 1.2.6 Local Erosion and Scour Associated with Engineering Works

Many types of engineering works in water bodies with erodible beds cause local erosion, usually referred to as scour when it proceeds downward into a channel bed (Fig. 1-9). This problem is an important consideration in the design of bridge foundations, dams, culverts, weirs, riverbank protection, and other works. Scour associated with bridges is treated in Chapters 10 and 11; references include Melville and Coleman (2000), Richardson and Davis (2001), and Transportation Association of Canada (2001). Rock scour is addressed in Appendix A. Other publications covering a broader range of local scour and erosion problems include USACE (1994), Julien (2002), and May et al. (2002). Thompson (2005) discusses the history of the use and effectiveness of in-stream structures on river processes in the United States. Appendix B discusses erosion countermeasures.

**Fig. 1-9.** 1995 photo of bed scour and bank erosion under Highway 162 Bridge on Sacramento River, California. Long lengths of formerly buried piles are exposed by bank recession associated with toe scour. Photograph by R. C. MacArthur.

## 1.3 OVERVIEW OF SEDIMENT TRANSPORT

### 1.3.1 General

Sediment transport is treated extensively in several chapters of Manual 54 (Vanoni 1975). That earlier treatment includes transport by wind and transport in pipes, neither of which is addressed in the present volume. Substantial parts of the material in the original Manual 54 are of a fundamental nature and retain their validity. Chapters 2 through 5 of Manual 110 mainly update selected aspects of the topic. Chapters 14 through 16 and 23 cover numerical modeling, a topic that has developed rapidly since 1975 and was not covered in the original Manual 54. Appendix D discusses methods for estimating sediment discharge.

### 1.3.2 Modes of Sediment Transport

The term *sediment* covers a wide range of grain sizes transported by flowing water, ranging from fine clay particles to large boulders. These are often viewed in specific size classes, such as fine sand, coarse gravel, and so on, using one of several alternative classification systems (ASCE 1962). Depending on grain sizes and sediment material density, fluid density and viscosity, and the strength and turbulence of the flow, sediment transport may occur in a variety of modes involving different size classes at the same time or the same classes at different times.

In rivers and channels with moderate gradients, there are two overlapping systems of classifying transport modes: (1) as *bed load* plus *suspended load* or (2) as *bed-material load* plus *wash load* (see Chapter 2). Under the first system, *suspended load* consists of the finer sediment maintained in suspension by turbulence, whereas *bed load* consists of the coarser particles transported along the bed intermittently by rolling, sliding, or saltating. Under the second system, *bed-material load* comprises all sizes normally found in the bed, whether transported as bed load or in suspension, whereas *wash load* consists of fine sizes that always travel in suspension and are not found in significant quantities in the bed.

*Bed-load transport* may take place similarly to a “conveyor belt” (or “moving layers”) or by evolution and migration of various bed and channel forms (dunes, bars, bends, and so on). In some environments, unusual and rare forms of bed-load transport may occur, such as the development and movement of “armored mud balls” (Fig. 1-10).

*Suspended load* is generally transported within and at the same velocity as the water, whereas *bed-load* transport may occur only occasionally during high-flow events. The boundary between suspended sediment and bed-load transport is not precise and may vary with the flow strength. The higher the flow, the coarser the sediment that can be suspended by turbulence. Suspended load plus bed load, or wash load plus bed-material load, together compose the *total sediment load* (see Table 2-4 in Chapter 2).

**Fig. 1-10.** Mud ball train in ephemeral Arroyo Hondo, western San Joaquin Valley, California. These rare bed-load features, up to 1 meter in diameter, formed and were transported during an intense flood in March 1997. Flow direction is from right to left. Such ball-like sediment agglomerations are found in some ephemeral streams in California with high loads of clay, silt, and sand. *Photograph by R. Leclerc.*

Particles that can move either as suspended load or as bed load and that periodically exchange with the nonmoving bed constitute the bed-material load. At least in theory, this part of the total sediment load can be calculated from hydraulic parameters and the composition of the bed material. On the other hand, wash load consists of the finer particles (usually silt and clay) in the suspended load that are continuously maintained in suspension by the flow turbulence and that are not found in significant quantities in the bed. This part of the total load is usually related to watershed supply and cannot be determined theoretically in most cases.

Another form of transport that occurs only in limited settings and steep channels is referred to as *hyperconcentrated flow*, where water and very high concentrations of sediment move as an integrated mass having properties somewhere between those of a Newtonian and a non-Newtonian fluid. Flows of this type, which include mud flows, debris flows, lahars, and rock and boulder torrents, form a special group of sediment hazards with unique fluid properties, high energy, and very destructive capabilities. Snow avalanches and ocean density currents represent somewhat analogous phenomena in other environments. Chapter 19 addresses this class of fluids and associated sediment hazards.

### 1.3.3 Sediment Transport Mechanics

*Sediment transport mechanics* as used herein (Chapters 2 through 5) refers to theories and experiments concerning physical factors that determine sediment displacement and transport and methods of estimating quantities transported. Although the fundamentals were fairly well established before 1975, the output of publications treating the subject has continued. Significant references since 1975 include

Raudkivi (1976), Garde and Ranga Raju (1977), Yalin (1977), Parker (1978), Graf (1984), Thorne et al. (1987), Chang (1988), Ikeda and Parker (1989), Parker (1990), Simons and Senturk (1992), van Rijn (1993), Yang (1996), Chien and Wan (1999), and Julien (2002).

When estimating sediment transport rates for given hydraulic conditions, the engineer may select from a wide range of transport formulas, algorithms, or procedures, many of which are offered as options in computer programs for sediment transport modeling. Most of those have a partially theoretical background but depend importantly on laboratory experimental data for their quantitative aspects. A considerable degree of experience and judgment may be required to select those most appropriate for the particular circumstances. It is usually advisable to compare results from several methods because results may vary over a wide range. Wherever practicable, some degree of calibration against field measurements is highly desirable. Comparisons of sediment transport calculation procedures were summarized by Vanoni (1975) and more recently by Chang (1988), Gomez and Church (1989), Simons and Senturk (1992), Yang (1996), Chien and Wan (1999), and Julien (2002), among others. This topic is covered further in Chapters 2 through 5.

Published procedures may deal with one or more components of total sediment transport. In general, hydraulic-based relationships cannot predict wash load, which is usually supply limited and may constitute a significant portion of the total load. The wash load portion of the total load is generally determined from field measurements. Some hydraulic relationships predict bed load only and are limited mainly to gravel and coarser sediment. Others predict total bed-material load and are more appropriate where sand is an important size class. Although theoretical relationships cannot predict wash load in quantitative terms, they can predict the competence of the flow to transport given sizes in suspension and their distribution with depth. This can greatly assist interpretation and extrapolation of suspended sediment data obtained from field measurements.

Basic issues in sediment transport mechanics are the definition of hydraulic conditions required to (1) initiate movement of a given sediment grain size on the bed of a channel and (2) lift it into suspension. These issues which are closely linked to sediment transport calculations and in the first case to the determination of stable sizes for erosion protection, have been addressed both theoretically and experimentally since the early days of hydraulic engineering and form the subject of numerous studies and publications. Chapters 2 through 5 address these topics in considerable detail.

### 1.3.4 Sediment Transport Measurements

Sediment measurement techniques are discussed in detail in Chapter 5 and Appendix D. Edwards and Glysson (1999) also

provide a thorough summary of sediment measurement methods according to USGS-approved protocols. Field data are often needed to develop reliable sediment budgets and are essential for proper calibration and validation of numerical models used to predict sediment dynamics in rivers and reservoirs. Borgen et al. (2003) report advances in these techniques.

Suspended load concentrations are often reported routinely along with stream-flow data at certain river gauging stations. Limited data on grain size distributions in suspended loads and in the bed may also be reported. Suspended load data reports are usually based on sampling the water column down to a short distance above the bed. Measured suspended-load data include virtually all the wash load and, especially in the case of sand transport, part of the bed-material load. Where routine data are not available, special measurements may be undertaken over a limited time period.

For estimation of sedimentation in reservoirs and related problems, measured suspended-load data over a period of years are generally correlated with flow data to develop a sediment rating curve. Total sediment delivery over a period is then determined by applying the sediment rating curve to a flow-duration relationship. An allowance on the order of 10% is often added to account for bed load or other unmeasured load. However, the percentage of bed load can be substantially greater than 10% in steep rivers and streams with large supplies of gravel and coarse materials.

Sediment rating curves usually show wide scatter because the transport-flow relationship may vary widely with season, basin cover conditions, and other factors. Where the available data do not include much information on high flows, extrapolation of the curve to flood flows—which may account for a large proportion of the transport—may introduce a high degree of uncertainty. Testing and validation of extrapolated values is always recommended.

Bed load is difficult to measure and is not normally measured on a routine basis. For project purposes, special field measurements may be undertaken using techniques described in Chapter 5 and Appendix D.

### 1.3.5 Sediment Modeling

After the publication of Manual 54 in 1975, the use of integrated computer programs for numerical modeling of sediment erosion, transport, and deposition in time and space became increasingly common (see Chapters 14 and 15). Some are one-dimensional, typically applied for evaluation of sedimentation processes along rivers and channels. Others are two- or three-dimensional, typically applied for evaluation of sedimentation processes in broad floodplains, estuaries, coastal regions, and stratified water bodies. Numerical models are particularly valuable for examining the effects of historical or proposed changes and of alternative project proposals. Chapter 23 presents methods for modeling the effects of sediment transport associated with dam removal, while Chapter 16 discusses turbulence modeling associated with sedimentation processes.

Modeling programs generally contain default values of various parameters that are meant to be adjusted by calibration against real data, typically consisting of observed morphological changes (erosion or deposition) or observed sediment transport rates. In the absence of model calibration, results may differ widely from reality. There is also a danger of redefining the actual problem to suit the limitations of the model being used. In modeling future conditions, past data may not provide reliable guidance because of shifts in trends or changes in controlling factors. Experience and insight are often needed to select a reasonable range for key variables and hydrologic conditions. It may also be necessary to consider the potential for catastrophic events that are not represented in the historical record (see Chapter 19).

Physical modeling of sediment displacement and transport for proposed civil engineering projects or facilities can provide an alternative means for assessing project performance and testing project alternatives. This is accomplished in a hydraulic laboratory with a mobile-boundary modeling facility. The reproduction on a small scale of both bed-load and suspended-load behavior may present severe difficulties, and modeling compromises are often necessary with concentration on key aspects for the problem in hand. Where the prototype setting involves sand beds, it is usually advisable to use low-density granular material in the model in order to achieve sufficient mobility and transport. Sediment transport scaling for physical models is addressed in Appendix C.

Numerical sedimentation models are sometimes referred to as morphological models because the processes being simulated involve the interaction and feedback between the flow structure and the movable channel boundaries. Typically, sediment erosion, transport, and deposition are simulated along the long profile (i.e., down-channel) through a one-dimensional formulation. The St. Venant equations for open channel flow (or some simplification of these equations) are typically coupled to a solution of the conservation of sediment mass—often referred to as the Exner equation (USACE 1993a). The simulation progresses forward in time, with user-specified boundary conditions defining the hydrologic events of interest. Numerical model results typically consist of the time history of river stage, discharge, channel bed elevation, bed material gradation, and quantity and gradation of sediment transport, all at specified locations along the long profile axis. Additional details on the formulation, assumptions, and typical applications of one-dimensional numerical models can be found in Chapter 14.

As of 2006, application of multidimensional (two- and three-dimensional) numerical models is becoming more common, given the relative economy of powerful computers, the continued development and testing of efficient numerical approximation schemes, and the ongoing training and experience gained by practitioners as the tools become more widely available and affordable (Gessler et al. 1999). Chapter 15 provides extensive information on issues associated with the theoretical formulation and application of these computational tools. Graphical user interfaces (GUIs) are usually

applied for the setup, execution, and evaluation of the extensive databases typically generated by the time-variant solution of multidimensional equations of hydrodynamics and conservation of sediment mass. On the other hand, the convenience of GUIs enables inexperienced users to unknowingly set up poorly formulated or erroneous simulations. (This dilemma is not unique to multidimensional sedimentation modeling.) It is, therefore, highly recommended that modelers seek thorough independent review of their problem formulations and results.

Additional subsets of computational numerical models presented in Chapter 8 were developed specifically to depict and quantify the response of channel cross-sectional geometry and planform to changes in water and sediment inputs. Although not as extensively applied in engineering practice as the one-dimensional and multidimensional models described in Chapters 14 and 15, these models utilize advances in understanding of complex morphological processes and provide a means of assessing erosion risk for infrastructure located in the vicinity of active fluvial systems. (Chapter 7 summarizes the extensive research and analysis on stream-bank erosion and channel width adjustment conducted since publication of Manual 54.) Recent models address the effects of human-induced influences such as flow regulation by reservoirs, land use changes and associated changes in runoff and sediment yield, and alteration of floodplain boundaries due to levee construction (Parker 1978; Paola et al. 2006). Chapter 8 discusses the physical processes and numerical modeling of river meandering and channel planform adjustment. Planform response models are based on linkages between channel curvature, velocity redistribution, and bank erodibility (Ikeda and Parker 1989). Chapter 19 addresses the computational modeling of sediment hazards such as mud and debris flows and flooding in alluvial fans.

## 1.4 OVERVIEW OF SEDIMENT DEPOSITION

### 1.4.1 General

As in the case of erosion, sediment deposition can be categorized into geological (or natural) and accelerated (or human-induced) deposition. Geologic deposition occurs because of natural processes of tectonic uplift, volcanic eruptions, earthquakes, climate warming, glacial movements, and so on. This category of processes usually occurs over long periods but may also result from severe episodic events. On the other hand, human-induced deposition resulting from various human activities usually results in relatively rapid changes in river morphology and sedimentation.

Products of erosion may be transported and deposited over a wide range of distances from their source. Where there are long distances to the ultimate sink of the oceans, only a minor fraction of the source load may arrive there. It has been estimated that in the United States, only about 10% of the material eroded from upland basins reaches the

oceans, the remainder being stored in lakes, reservoirs, channels, and land surfaces (Curtis et al. 1973; Holeman 1981).

Deposited sediment may be harmful or beneficial according to circumstances and viewpoints. Although sediment may fill reservoirs and eliminate their storage capacity or aggrade riverbeds and lead to increased flooding, silt deposits on floodplains may eventually form valuable agricultural soils, and gravel deposits in rivers may provide valuable fish habitat and a source for building materials. Where deposition in downstream reaches of rivers poses problems, settlement basins are sometimes provided to store deposited sediment at upstream locations. These may offer only temporary relief unless the deposits can be removed at regular intervals. Construction of dams and other flow control structures that encourage sediment deposition can reduce sediment delivery downstream to coastal areas and may lead to long-term beach erosion and shoreline retreat.

Problems and studies involving sediment deposition have greatly expanded beyond concerns over engineering works (structures) into environmental concerns such as effects on fish habitat and benthic communities and the role of sediment in storing and releasing toxic contaminants. Chapters 21 through 23 address these topics further. Acute problems of sediment deposition may follow catastrophic events such as earthquakes, volcanic eruptions, dam failures, massive landslides, and debris flows (see MacArthur et al. 1985, 1990; Costa and Wieczorek 1987; Committee on Alluvial Fan Flooding (CAFF) 1996; Chen 1997; Wieczorek and Naeser 2000). Chapter 19 discusses these topics further.

### 1.4.2 Causes of Sediment Deposition

**1.4.2.1 Upland River Deposits** Deposits at the base of eroding slopes are discussed in Manual 54. Some other forms of near-source deposits are described briefly below.

Debris flows in steep streams produce run-out deposits containing large woody debris mixed with finer organic material and sediment of a wide range of sizes up to large boulders (Fig. 1-11). Such deposits may block roads and

**Fig. 1-11.** Debris flow deposit from small tributary of Tinau River in Nepal. Photograph by V. J. Galay.

railroads, redirect the course of streams, or destroy buildings and properties. Debris flows may have natural causes but may also be initiated or aggravated by logging and road construction on steep forest slopes.

Alluvial fans (or inland deltas) generally form where a stream emerges from a mountain zone, becomes laterally unconfined, and undergoes an abrupt reduction in gradient. Fans, which may be of any size, may contain sand, gravel, and boulders and are characterized by multiple shifting stream channels with sudden “avulsions” during floods. Fans may exist in an aggrading, degrading, or stable state. The morphology and hydraulics of fans are discussed by French (1987), Rachocki and Church (1990), and CAFF (1996).

Braided river deposits (or outwash valley trains) somewhat resemble narrow elongated fans, with multiple shifting channels (Fig. 1-12). They may be found downstream of eroding mountain ranges or glaciers. Gravel deposits are most common in braided river systems; however, braided sand or boulder rivers also occur (Ikeda and Parker 1989; Best and Bristow 1993).

**1.4.2.2 Intermediate and Lowland River Deposits** Channel and floodplain deposits are discussed in Manual 54. Other forms are discussed briefly below.

Deposits of riverborne sediment often cause problems in engineered conduits such as canals, tunnels, culverts, and pipelines that divert river water for irrigation, hydropower, and so on (Fig. 1-13). The sediment may deposit at shallow depths over a long length and may not be noticed until hydraulic capacities are severely reduced by loss of area, increased roughness, and weed growth.

Meandering rivers with their adjacent floodplains generally represent large volumes of stored sediment that gradually work downstream through a process of meander migration, eroding sediment from one place and depositing it farther downstream (Fig. 1-14). A section through the floodplain generally exhibits coarser riverbed sediments up to a certain level and fine overbank deposits above. Installation of dikes,

**Fig. 1-12.** Braided river system located on the Rio Maule, Chile, comprised primarily of cobble and boulder materials. Photograph by C. R. Neill.

levees, and bank protection may disrupt natural processes and cause unforeseen problems, such as channel aggradation or degradation or accelerated erosion of unprotected banks.

**1.4.2.3 Sedimentation Due to Mining Activities** Mining activities in river basins and failures of mine tailings dams can produce disastrous sedimentation and contamination of downstream rivers/water bodies (Figs. 1-15 and 1-16). The design, construction, and maintenance of such facilities have often been inadequate (see, e.g., United Nations Environment Program and International Commission on Large Dams [UNEP/ICOLD] 2001). Once constructed, mines and tailings dams often result in long-term hazards that may culminate in costly mitigation having to be performed by future generations of landowners and governments. When mines and tailing ponds are eventually abandoned, extensive engineering measures may be needed to prevent future erosion or release of contaminated sediments.

**1.4.2.4 Deposits in Lakes and Reservoirs** Deposits in larger lakes and reservoirs that receive riverborne sediment generally consist of coarser sediment (sand and gravel) forming a delta at the inlet end and finer sediment (silt and clay)

**Fig. 1-13.** Box culvert and sediment detention basin on urbanized reach of Upper Berryessa Creek in Milpitas, California. Basin filled with gravel is shown in top photo and after cleaning in bottom photo. View is upstream. Photographs by R. C. MacArthur.

**Fig. 1-14.** Meandering reach of Walker River, California. Photograph by E. Wallace.

**Fig. 1-15.** Copper and gold mine on Mount Fubilan in Papua New Guinea. Since the mid-1980s, the mine has discharged 70 million tons per year of contaminated rock and tailings into the Ok Tedi and Fly rivers. Photograph by B. Hall.

**Fig. 1-16.** Fly River in Papua New Guinea: an example of man-induced ecological disaster. Sediment deposition from the Ok Tedi mine continues to aggrade riverbeds and amplifies flooding and sedimentation of forest areas, killing fish, forcing animals to migrate, and destroying vegetation over vast areas. Photograph by B. Hall.

spread out over all or a substantial part of the bottom area (Figs. 1-17 and 1-18). In smaller water bodies, the delta may eventually extend to occupy most of the volume. Lake-bottom sediments in some regions exhibit annual layers (“varves”) that reflect different conditions of deposition between seasons. These can sometimes be used to determine the variation of deposition rates over long periods of time. Deposition patterns of finer sediment may be affected by weak currents, wind, and density currents arising from the different densities of sediment-bearing inflows and clear lake water.

During the middle part of the twentieth century, when large numbers of dams and reservoirs were constructed worldwide in regions of unstable physiography for purposes such as hydropower, irrigation, and water supply, the problem of reservoir sedimentation tended to receive insufficient attention in many preproject planning studies. Sediment deposition severely affects operations and

**Fig. 1-17.** High sediment concentration turbidity currents from Frosst Creek, British Columbia, Canada, plunging through delta into Cultus Lake. Photograph by V. J. Galay.

**Fig. 1-18.** Lake Solano, California: example of significant reservoir siltation. Photograph by R. C. MacArthur.

the useful life of the facility. A related problem is how to manage reservoir sediment deposits to avoid adverse downstream consequences when a dam is removed or decommissioned because of disuse, structural deterioration, and so on. Chapter 23 discusses how numerical models can be used to assess potential changes in sediment transport associated with dam removal.

Morris and Fan (1997) provide extensive information regarding deposition in reservoirs and lakes, including dam removal, and cite numerous case studies. They provide an overview that emphasizes sustainable development and the need for long-term viewpoints in planning and design. White (2001) presents information devoted to removal of sediment from reservoirs. The morphodynamics of reservoir sedimentation is addressed in Chapter 2. Chapter 12 provides an additional overview of reservoir sedimentation issues.

### 1.4.3 Environmental and Habitat Effects of Sediment Deposition

Sediment deposition may have major effects on zoological habitat, particularly for salmonid and other non-warmwater fish species in streams. Problems tend to occur whenever the natural hydrologic and sediment regime is disrupted in such a way that changes occur in quantities and gradation of delivered sediment or in the physical characteristics of the riverbed. In many jurisdictions, regulations regarding both short- and long-term disturbances have become increasingly stringent.

Where sediment is trapped in new reservoirs, downstream fishery effects may be beneficial or harmful. If the stream formerly carried high suspended loads of fine sediment, trapping may be beneficial to aquatic species. On the other hand, if sand and gravel is trapped from a relatively clear stream, downstream reaches may downcut to a flatter gradient and become paved with large stones that offer poor habitat and biological environment for a variety of benthic and pelagic species. Reduction of flood peaks by reservoir regulation may adversely affect annual flushing of fine sediment from spawning areas. Chapter 3 contains material useful to addressing these topics.

Where land use changes increase inputs of fine sediment to a river, its deposition downstream may clog spawning beds (Huang and Garcia 2000). Construction operations for bridge and pipeline crossings may temporarily increase fine sediment inputs, with similar results.

Many toxic substances and contaminants in water become preferentially attached to sediment (particularly to fine sediments) and accumulate within deposition zones. Contaminated sediments may become buried if the source is discontinued but may be exposed later by erosion and channel shifting. Concentration by bioaccumulation, especially of heavy metals and pesticides, is often a major concern. Deposits behind mine tailings dams are often highly contaminated, requiring massive cleanup operations in

cases of failures of such structures (UNEP/ICOLD 2001). These topics are discussed further in Chapters 21 and 22.

### 1.4.4 Estimation of Deposition Rates and Quantities

Estimation of past rates and quantities of deposition in static water bodies is usually based on periodic bathymetric surveys aided by core sampling and dating. Reservoirs subject to significant sediment deposition should be surveyed and sampled at regular intervals. Statistics on reservoir deposition are often available from owners, operators, and regulatory agencies.

Estimation of future deposition rates for new reservoirs, flood control facilities, and sediment basins may be based empirically on data from other water bodies in similar environments with regard to dimensions and trap efficiency or semiempirically on studies of sediment yield and delivery with regard to grain size distributions and settlement rates or based on comprehensive numerical modeling that accounts for currents, wind, and turbulence. Depending on the dimensions of the water body, one- or two-dimensional modeling may be appropriate and beneficial during project evaluations.

## 1.5 MANAGEMENT AND TREATMENT OF SEDIMENTATION PROBLEMS

### 1.5.1 General

In general, management and treatment of sedimentation engineering problems can be addressed upstream at the sources of the sediment production, downstream at the site of the problem, or at intermediate locations. However, the efficacy of sediment management can be enhanced by addressing and managing sediment problems at a whole-watershed level rather through a series of disconnected locally independent projects. Obviously, the best solution is to avoid problems through good planning and design. More important, restoration of process is more likely to address the causes of river degradation, whereas restoration toward a fixed endpoint addresses only the symptoms (Wohl et al. 2005). Some problems, such as scour at bridge foundations, are clearly local and require only local treatment. Others, such as deposition in reservoirs, often derive from an extensive drainage basin and might be addressed either on a local or on a basinwide basis. In many sedimentation problems, a complete “solution” is not possible, and the best that can be achieved is a reliable system for management and monitoring. Attention should generally be given to the feasibility of nonengineering as well as engineering approaches.

Treatment of erosion at the source would often be the most satisfactory solution in the long term, but in many cases it may not be physically, economically, or socially feasible because the sources are too widely distributed and are associated with natural geological processes or human activities regarded as inviolable. The engineer must then design works

and develop methods for handling sediment at or nearer to the site of interest to ensure that the performance and life of the works are not unreasonably affected. In the case of a storage reservoir liable to fill too rapidly with sediment, consideration could be given to land reclamation in the basin, to the provision of intermediate sediment detention basins upstream of the site, or to methods of bypassing sediment past the reservoir or flushing it out at intervals to minimize downstream impacts. The relative advantages of alternative approaches may depend on the planned life of the facility and on environmental concerns upstream or downstream.

Sediment control methods are treated extensively in Manual 54. As of 2005, much of the material contained therein is still valid. In the present volume, coverage and updating are limited. Chapter 9 addresses the restoration of streams adversely affected by human activities or extreme natural events, Chapter 11 addresses prevention of scour around bridge foundations, Chapter 12 addresses reservoir sedimentation, Chapter 19 discusses “sediment hazards,” Chapter 23 discusses the use of modeling to determine changes in sediment transport associated with dam removal, and Appendix B addresses the design of riprap erosion protection.

### 1.5.2 Problem Identification and Definition

During planning and design of new projects and before attempting to devise alternative solutions to existing sedimentation engineering problems, it is important to develop a clear definition of existing and potential problems, which may be complex and may ultimately involve other interdisciplinary concerns. To do this, each important component of a problem (or potential problems) must be identified and quantified to some level of certainty. Thorough project planning and evaluation of future project performance can greatly increase project reliability while reducing maintenance and possible future sediment-related problems. Chapter 3 in the Corps of Engineer’s EM 1110-2-1416, *River Hydraulics* (USACE 1993b), outlines procedures for conducting hydraulic engineering studies so as to avoid unforeseen sediment or project performance problems. Questions to consider during plan formulation and problem identification and definition phases may include the following:

- Where are the sources of erosion and sediment, and what are their relative significances?
- Is the problem ascribable mainly to fine wash-load sediment such as silt and clay; to coarser bed-material sediment such as sand, gravel, and boulders; or to both? In what modes will the material be transported under various stream-flow conditions?
- Is the problem associated mainly with river flood conditions or with a wide range of stream flows?
- Is the problem new or has it been developing for a long period of time? Is the problem periodic or chronic? What is the history of the sources of erosion?

- Is the problem localized or more regional in nature? Is its scale small or large?
- Is the problem associated with scour, deposition of materials, or both?
- What information is available on rates and quantities and grain sizes of sediment in transport?
- Have rates and quantities been increasing, and, if so, why? Have there been significant changes in land use or river works and management, or have extreme events occurred recently?
- If sediment will be stored in reservoirs or detention basins, how fast will this occur, and what will happen when these are filled? What are the downstream engineering and environmental implications of periodic storage and release of materials from the reservoir in the future?
- What are the degrees of uncertainty in quantitative estimates, and what are the project implications of under- or overestimating future quantities? What allowances should be made for land use change and climate change?
- What essential data are needed to better define potential problems and solutions?
- What alternative solutions are there, and how sustainable are alternative solutions in both engineering and environmental terms?

Many of these important questions are addressed in the following chapters and appendices of this manual. The key to successful problem avoidance and solution is to achieve objective, credible problem identification early in project planning. This will facilitate more effective field and office investigations and the development of feasible alternatives. Careful attention to this step can produce economies in investigations and avoid the formulation of inappropriate solutions. Chapter 20, “American Sedimentation Law and Physical Processes,” discusses changes in legal requirements and liabilities associated with standards of care, responsible project planning, and design.

Since the printing of Manual 54 in 1975, the focus of sedimentation engineering has greatly expanded from the identification and solution of individual problems (however complex they may be) to much broader involvement in multidisciplinary planning, analysis, and design of multi-purpose projects. This role often requires careful balancing of engineering science, environmental concerns, public interests, and affordability.

### 1.5.3 Engineering Treatment

Engineering (or engineered) treatment embraces the planning and design of civil engineering works and operational systems to deal with and manage sedimentation processes so as to avoid serious problems. The chapter on sediment control methods in Manual 54 is devoted mainly to this type of treatment. Engineering treatments and erosion countermeasures are usually associated with more traditional structural “hardscape” solutions (see Chapters 11 and 19 and Appendices A and B).

Examples of works and projects most amenable to engineering treatment include (1) intakes from rivers into pipelines and canals for purposes of hydropower, irrigation, or water supply, where the aim is to reduce or eliminate the inflow of specific size classes of sediment that would clog or deposit in diversion conduits and facilities; (2) bank protection and channel maintenance in large or fast-flowing rivers and streams (Fig. 1-19); (3) protection of river-crossing facilities against bank erosion and bed scour; (4) dams and reservoirs, where it is infeasible to deal with upstream basin conditions and sediment inflows must be accepted as delivered to the site; and (5) flood control facilities to provide public safety during severe flood events.

The design of intakes to reduce the entry of sediment is addressed, among others, by Bouvard (1992), Raudkivi (1993), and ASCE (1995). Riverbank protection is addressed by Appendix B and USACE (1991, 1994), CUR (1995), Thorne et al. (1995), and Escarameia (1998). Scour at bridges is addressed in Chapters 10 and 11 herein, and reservoir sedimentation is addressed in Chapter 12.

In formulating and presenting engineering solutions, it is important to identify limitations in knowledge and uncertainties as to future outcomes and to provide flexibility for future changes if quantitative estimates and performance of works prove to be less favorable than expected. The limitations and uncertainties inherent in quantitative sediment estimates and sediment modeling are not always fully understood by project planners, environmentalists, and structure designers. Legal aspects and responsibilities of sediment engineers are discussed in Chapter 20.

#### 1.5.4 Nonengineering (Nonstructural) Treatment

In the latter part of the twentieth century, a trend developed to replace engineering treatment of sedimentation problems by nonengineering, or nonstructural, treatment with apparently greater environmental benefits; fewer hardscape-type

**Fig. 1-19.** Bank protection works in urban setting consisting of riprap toe armor and bank revetment materials with horizontal rows of willow pole plantings, as installed on Soquel Creek, California. Photograph by S. Seville.

structures; more bioengineering features; and more environmental acceptability. Project planning and design specifications began to seek opportunities and requirements for enhancing and restoring natural aspects of water resource systems and to discourage engineered “hardscaping.” Examples of nonengineering treatments include the following: (1) for reservoirs, upstream improvements in soil conservation and land use, such as reforestation, reduction of grazing pressure, or restriction of urban development; (2) for shifting streams, bank stabilization and restoration using vegetation and bioengineering techniques instead of rock or concrete erosion protection (Figs. 1-20 and 1-21); and (3) for flood control projects, restoring wetlands and natural water and sediment storages instead of constructing artificial sediment detention basins or excavating larger

**Fig. 1-20.** Planting vegetation to reduce flow velocities, capture debris, and encourage sediment deposition to provide protection along an eroding bank of the Russian River, California. Photograph by D. Ripple.

**Fig. 1-21.** Bioengineered logjams being installed to protect eroding river banks, to increase habitat complexity, and to provide deep pools for fish on the Mahatta River, British Columbia, Canada. Photograph by B. Walsh.

flood conveyance channels. Chapter 9 presents detailed discussions of the benefits and methods for restoring river systems using a variety of bioengineering techniques.

Some publications and guidelines prepared by nonengineers have tended to recommend the application of non-engineering and bioengineering measures in circumstances where they are unlikely to be successful—for example, vegetation plantings for bank protection in steep streams with high velocities and turbulence. It is therefore an unfortunate misrepresentation associated with recent movement toward nonengineered or bioengineered methods to imply that less engineering analyses and judgment is required in order to achieve better results. To the contrary, significant hydraulic, river, and sedimentation engineering experience and analyses are required with input from other biological and ecological disciplines to ensure successful project planning and design. Also of importance is the movement toward “restoration of function” as opposed to piecemeal treatment of site-specific problems. In general, a holistic view should be taken of sedimentation management to utilize both engineering and nonengineering measures where appropriate and feasible (Petts and Calow 1996; Federal Interagency Stream Restoration Working Group 1998; Copeland et al. 2001). In locations that have been severely damaged by poor land use practices and neglect, the benefits of such an approach may extend far beyond the project under consideration (see Natural Resource Conservation Service 1992, 1996; Gray and Sotir 1996).

### 1.5.5 Fish Habitat and Environmental Issues

Since publication of Manual 54 in 1975, many jurisdictions in technically advanced countries have enacted strict requirements for the design and construction of works in water bodies to avoid or mitigate erosion and sedimentation effects on fish habitat and aquatic resources. Engineers and planners have sometimes considered certain regulatory controls to be excessive—for example, when placement of small areas of rock riprap around river bridge piers is prohibited or made conditional on the provision of artificially constructed “habitat” elsewhere. In general, however, recognition by engineers of the necessity for tough legal requirements for environmental protection (see Chapter 20) has improved significantly since the mid-1980s (Bass and Herson 1993a, 1993b).

Stream restoration projects are often designed to improve or restore fish habitat (Fig. 1-21) or improve fish passage (Fig. 1-22) (Clay 1995) and to support ecosystems in streams that have been adversely affected by logging or other human activities (Committee on Restoration of Aquatic Ecosystems 1992; Cooke et al. 1993; Wohl et al. 2005). As of 2006, the success of such projects in terms of biological productivity was not universally accepted. Kellerhals and Miles (1996) stated that the scientific basis linking morphological change, habitat, and fish productivity was weak in terms of prediction and that some stream restoration projects had been undertaken

**Fig. 1-22.** Photos show barrier to fish passage through bridge culvert before (top) and after (bottom) construction of log step weirs and gravel-bottom pool and step approach aprons on Little Salmon Creek, Toledo, Washington. View is upstream. *Photographs by J. Johnson.*

without a proper understanding of biological limiting factors or a sound basis for predicting the results of habitat manipulations. In some cases, long periods of many years may be needed to re-establish a viable habitat, and the effort may be largely nullified by overexploitation of the fish resource. This complex topic is discussed further in Chapter 9.

## CHAPTER 2

# *Sediment Transport and Morphodynamics*

Marcelo H. García

ASCE Manual 54, *Sedimentation Engineering*, prepared under the leadership of Professor Vito A. Vanoni, has provided guidance to theoreticians and practitioners' world wide on the primary topic of sediment problems involved in the development, use, and conservation of water and land resources. First published in 1975, Manual 54 gives an understanding of the nature and scope of sedimentation problems, of the methods for their investigation, and of practical approaches to their solution. It is essentially a textbook on sedimentation engineering, as its title accurately reflects. Manual 54 was the first and most comprehensive text of its kind and has been circulated throughout the world for the past 30 years as the most complete reference on sedimentation engineering in the world. It has recently been published again as the *Classic Edition* (Vanoni 2006). In the spirit of its predecessor, this chapter of Manual of Practice 110, *Sedimentation Engineering*, aims at presenting the state of the art concerning the hydraulics of sediment transport in fluvial systems based on the knowledge gained in the last three decades. A concerted effort is made to relate the mechanics of sediment transport in rivers and by turbidity currents to the morphodynamics of lake and reservoir sedimentation, including the formation of fluvial deltas.

### 2.1 SEDIMENT TRANSPORT MECHANICS AND RELATED PHENOMENA

The field of sediment transport might just as well be called "transport of granular particles by fluids." As such, it embodies a type of two-phase flow, in which one phase is fluid and the other phase is solid. The prototype for the field is the river. Here, the fluid phase is river water, and the solid phase is sediment grains, e.g., quartz sand. The most common modes of sediment transport in rivers are those of bed load and suspended load. In bed load, particles roll, slide, or saltate over each other, never rising too far above the bed. In

suspended load, fluid turbulence comes into play, carrying the particles well up into the water column. In both cases, the driving force for sediment transport is the action of gravity on the fluid phase; this force is transmitted to the particles via drag. Whether the mode of transport is saltation or suspension, the volume concentration of solids anywhere in the water column tends to be rather dilute in rivers. As a result, it is generally possible to treat the two phases separately.

In the geophysical domain, the field is much broader than rivers alone. The same phenomena of bed load and suspended load transport occur in a variety of other geophysical contexts. Sediment transport is accomplished in the near-shore of lakes and oceans by wave action. Turbidity currents act to carry suspended sediment into lakes, reservoirs, and the deep sea. Landslides, debris flows and mud flows provide mass transport mechanisms for the delivery of sediment from highlands to lowlands.

The solid phase can vary greatly in size, ranging from clay particles to silt, sand, gravel, cobbles, and boulders. Rock types can include quartz, feldspar, limestone, granite, basalt, and other less common types such as magnetite. The fluid phase can, in principle, be almost anything that constitutes a fluid. In the geophysical sense, however, the two fluids of major importance are water and air.

The phenomenon of sediment transport can sometimes be disguised as rather esoteric phenomena. When water is supercooled, large quantities of particulate frazil ice can form. As the water moves under a frozen ice cover, one has the phenomenon of sediment transport in rivers stood on its head. The frazil ice particles float rather than sink, and thus tend to accumulate on the bottom side of the ice cover rather than on the riverbed. Turbulence tends to suspend the particles downward rather than upward.

In the case of a powder snow avalanche, the fluid phase is air and the solid phase consists of snow particles. The dominant mode of transport is suspension. These flows are close analogues of turbidity currents, insofar as the driving

force for the flow is the action of gravity on the solid phase rather than the fluid phase. That is, if all the particles drop out of suspension, the flow ceases. In the case of sediment transport in rivers, it is accurate to say that the fluid phase drags the solid phase along. In the cases of turbidity currents and powder snow avalanches, the solid phase drags the fluid phase along.

Desert sand dunes provide an example for which the fluid phase is air, but the dominant mode of transport is saltation rather than suspension. Because air is so much lighter than water, quartz sand particles saltate in long, high trajectories, relatively unaffected by the direct action of turbulent fluctuations. The dunes themselves are created by the effect of the fluid phase acting on the solid phase. They, in turn, affect the fluid phase by changing the resistance.

In the limiting case of vanishing solids, the field reduces to pure fluid mechanics. As a result, sediment transport must be considered to be a subfield of fluid mechanics. In the limiting case of vanishing fluid, the problem reduces to that of the flow of a granular substance in a vacuum. The driving force now typically, but not always, becomes gravity. This problem, as well, can be treated with the techniques of fluid mechanics, as long as one is willing to move far afield of traditional Newtonian fluid mechanics. Martian rock avalanches constitute a geophysical realization of grain flows in a near vacuum, and it is likely that the fluid phase plays only a subsidiary role in many terrestrial rock avalanches. Another example of grain flow is a slab avalanche of snow. If they attain sufficient speed, slab avalanches tend to devolve into more dilute powder snow avalanches in which the fluid phase plays a greater role.

Among the more interesting intermediate cases are debris flows, mud flows, and hyperconcentrated flows. In all of these cases, the solid and fluid phases are present in similar quantities. A debris flow typically carries a heterogeneous mixture of grain sizes ranging from boulders to clay. Mud flows and hyperconcentrated flows are generally restricted to finer grain sizes. In most cases, it proves useful to think of such flows as consisting of a single phase, the mechanics of which is highly non-Newtonian.

The study of the movement of grains under the influence of fluid drag and gravity constitutes a fascinating field in its own right. The subject becomes even more interesting when one considers the link between sediment transport and morphology. In the laboratory, the phenomenon can be studied in the context of a variety of containers, such as flumes and wave tanks, specified by the experimentalist. In the field, however, the fluid-sediment mixture constructs its own container: the river. This new degree of freedom opens up a variety of intriguing possibilities for river and coastal morphodynamics (Parker and Garcia 2006).

Consider a river. Depending on the existence or lack thereof of a viscous sublayer and the relative importance of bed load and suspended load, a variety of rhythmic structures can form on the riverbed. These include ripples, dunes,

antidunes, and alternate bars. The first three of these can have a profound effect on the resistance to flow offered by the riverbed. Thus, they act to control river depth. Riverbanks themselves can also be considered to be a self-formed morphological feature, thus specifying the entire container.

The container itself can deform in plan. Alternate bars cause rivers to erode their banks in a rhythmic pattern, thus allowing the onset of meandering. Fully developed river meandering implies an intricate balance between sediment erosion and deposition. If a stream is sufficiently wide, it will braid rather than meander, dividing into several intertwining channels. Braided rivers are an important component of the Earth's surface. The deposits of ancient braided rivers may contain significant reserves of water and hydrocarbon.

Rivers create morphological structures on much larger scales as well. These include canyons, alluvial fans, and deltas. Turbidity currents act to create similar structures in the oceanic environment. In the coastal environment, the beach profile itself is created by the interaction of water and sediment. On a larger scale, offshore bars, spits, and capes constitute rhythmic features created by wave-current-sediment interaction. The boulder levees often created by debris flows provide another example of a morphological structure created by a sediment-bearing flow.

This chapter is an introduction to the mechanics of sediment transport and river morphodynamics. Rivers evolve over time in accordance with the interaction between the flow and sediment-transport fields over an erodible bed (which changes the bed) and the changing morphology of the bed (which changes the flow and sediment-transport fields). This co-evolution is termed morphodynamics. Sediment transport by turbidity currents and the mechanics of lake and reservoir sedimentation are also considered in this chapter. The approach is intended to be as mechanistic and deductive as possible so that readers will be able to gain a firm foundation in the mechanics of sediment transport. This should be beneficial both for understanding the rest of the material presented in the manual as well as for sedimentation engineering and teaching purposes.

### 2.1.1 The Sediment Cycle in the Environment

The sediment cycle starts with the process of erosion, whereby particles or fragments are weathered from rock material. Action by water, wind, and glaciers as well as plant and animal activities, contributes to the erosion of the earth's surface. Fluvial sediment is the term used to describe the case where water is the key agent for erosion. Natural, or geological, erosion takes place slowly, over centuries or millennia. Erosion that occurs as a result of human activity may take place much faster. It is important to understand the role of each when studying sediment transport.

The dynamics of sediment in the environment and its morphological consequences are schematized in Fig. 2-1. Any material that can be dislodged is ready to be transported. The

**Fig. 2-1.** Sedimentation processes and associated morphological changes in a Watershed (adapted from Dietrich and Gallinatti 1991).

transportation process is initiated on the land surface when raindrops result in sheet erosion. Rills, gullies, streams, and rivers then act as conduits for sediment movement. The greater the discharge, or rate of flow, the higher the capacity for sediment transport. Mass sediment transport can also occur through landslides, debris flows, and mudflows. Hyperconcentrated flows have also a tremendous capacity to transport vast amounts of sediment as observed after the release of large amounts of sediment following the eruption of Mt. St. Helens in Washington State, USA (Chapter 19).

The final process in the sediment transport cycle is deposition. When there is not enough energy to transport the sediment, it comes to rest. Sinks, or depositional areas, can be visible as newly deposited material on a floodplain, bars and islands in a channel, and deltas. Considerable deposition occurs that may not be apparent, as on lake and river beds. Alluvial fans are depositional environments typically encountered at the base of a mountain front. Flooding processes occurring on alluvial fans are considerably different from those occurring along single-thread rivers with well-defined floodplains (French 1987; Bridge 2003). Active

erosion, rapid deposition, and uncertainty in flow path make the prediction of flood evolution and extent rather difficult (NRC 1996).

### 2.1.2 Scope of this Chapter

This chapter presents fundamental aspects of the erosion, entrainment into suspension, transport, and deposition of sediment in fluvial systems. The emphasis is on providing an introduction to the fluid mechanics of sediment transport in rivers and the morphodynamics of lake and reservoir sedimentation by turbidity currents, with the objective of establishing the background needed for sedimentation engineering and management. Emphasis is placed on the transport of noncohesive sediment, where the material involved is in granular form and ranges in size from fine silt to coarse sand. The transport of gravel and sediment mixtures is treated in Chapter 3, whereas the transport of fine-grained, cohesive sediment is considered in Chapter 4. Fluvial processes are addressed in Chapter 6 while engineering aspects of geomorphology are covered in Chapter 16. Sediment

transport in ice-covered rivers is the subject of Chapter 13. Hyperconcentrated flows, including mud flows and debris flows as well as sediment hazards related to flows in alluvial fans, are treated in Chapter 19. This chapter is intended to provide the foundation for the rest of the manual.

## 2.2 FLUID MECHANICS AND HYDRAULICS FOR SEDIMENT TRANSPORT

In this section, basic fluid mechanics and hydraulics concepts needed for the analysis of sedimentation processes are presented.

### 2.2.1 Flow Velocity Distribution: Law of the Wall

Consider a steady, turbulent, uniform, open-channel flow having a mean depth  $H$  and a mean flow velocity  $U$  (Fig. 2-2). The channel has a mean width  $B$  that is much greater than the mean flow depth  $H$ , and its bottom has a mean slope  $S$  and a surface roughness that can be characterized by the effective height  $k_s$  (Brownlie 1981). For very wide channels (i.e.  $B/H \gg 1$ ), the hydraulic radius of the channel,  $R_h$  (cross-sectional area over wetted perimeter), can be approximated by the mean flow depth  $H$ . When the bottom of the channel is covered with sediment having a mean size or diameter  $D$ , the roughness height  $k_s$  will be proportional to this diameter. Due to the weight of the water, the flow exerts on the bottom a tangential force per unit bed area known as the bed shear stress  $\tau_b$ , which in the case of steady, uniform flow can be expressed as:

$$\tau_b = \rho g H S \quad (2-1)$$

where

$\rho$  = water density and  
 $g$  = gravitational acceleration.

This equation is simply the one-dimensional momentum conservation equation for the channel reach under

**Fig. 2-2.** Definition diagram for open-channel flow over a sediment bed.

consideration. With the help of the boundary shear stress, it is possible to define the shear velocity  $u_*$  as

$$u_* = \sqrt{\tau_b / \rho} \quad (2-2)$$

The shear velocity, and thus the boundary shear stress, provides a direct measure of the flow intensity and its ability to entrain and transport sediment particles. The size of the sediment particles on the bottom determines the surface roughness, which in turn affects the flow velocity distribution and its sediment transport capacity. Because flow resistance and sediment transport rates are interrelated, it is important to be able to determine the role played by the bottom roughness.

In the case of steady, uniform flow the shear stress varies linearly in the vertical direction as shown in Fig. 2-2 and is given by the following expression:

$$\tau = \tau_b \left( 1 - \frac{z}{H} \right) \quad (2-3)$$

It is well established, both experimentally and from dimensional arguments (Schlichting 1979; Nezu and Rodi 1986) that the flow velocity distribution is well represented by:

$$\frac{u}{u_*} = \frac{1}{\kappa} \ln \left( \frac{z}{z_0} \right) \quad (2-4)$$

Here

$u$  = time-averaged flow velocity at a distance  $z$  above the bed;

$z_0$  = bed roughness length (i.e., distance above the bed where the flow velocity goes to zero); and

$\kappa$  is known as von Karman's constant and has a value of approximately 0.41 (Nezu and Rodi 1986; Long et al. 1993). The above law is known as the "law of the wall." It strictly applies only in a relatively thin layer ( $z/H < 0.2$ ) near the bed (Nezu and Nakagawa 1993). It is commonly used as a reasonable approximation throughout most of the flow in many streams and rivers.

If the bottom boundary is sufficiently smooth, a condition rarely satisfied in rivers, turbulence will be drastically suppressed in an extremely thin layer near the bed, known as the viscous sublayer. In this region, a linear velocity profile holds (O'Connor 1995):

$$\frac{u}{u_*} = \frac{u_* z}{\nu} \quad (2-5)$$

where  $\nu$  is the kinematic viscosity of water. This law merges with the logarithmic law near  $z = \delta_\nu$ , where

$$\delta_v = 11.6 \frac{\nu}{u_*} \quad (2-6)$$

denotes the height of the viscous sublayer. In the logarithmic region, the constant of integration introduced above has been evaluated from data to yield

$$\frac{u}{u_*} = \frac{1}{\kappa} \ln \left( \frac{u_* z}{\nu} \right) + 5.5 \quad (2-7)$$

Comparing Eqs. (2-7) and (2-4), it follows that  $z_o = \nu / 9u_*$  for a hydraulically smooth flow.

Understanding the physics of the flow in the viscous sublayer is of relevance in benthic boundary layer flows (e.g., Boudreau and Jorgensen 2001). For example, sediment oxygen demand is affected by viscous effects as well as near-bed turbulence levels, as is shown in Chapter 22 of this manual. Also, the existence of a viscous sublayer seems to be a necessary condition for the development of ripples in unidirectional flows (e.g., Raudkivi 1997; Coleman and Melville 1994, 1996).

Most boundaries in alluvial rivers are hydraulically rough. Let  $k_s$  denote an effective roughness height. If  $k_s / \delta_v > 1$ , then no viscous sublayer will exist, because the roughness elements will protrude through such layer. In this case the corresponding logarithmic velocity profile is given by

$$\frac{u}{u_*} = \frac{1}{\kappa} \ln \left( \frac{z}{k_s} \right) + 8.5 = \frac{1}{\kappa} \ln \left( 30 \frac{z}{k_s} \right) \quad (2-8)$$

It follows that  $z_o = k_s / 30$  for a hydraulically rough flow. As noted above, the logarithmic velocity distribution often holds as a first approximation throughout the flow depth in a river. It is by no means exact since wake effects near the free surface can be important (Coleman 1981; Lyn 1991). Sediment-induced stratification as well as the presence of bed forms can also influence the flow velocity distribution. For many years, the effect of suspended sediment was understood to be in a change of von Karman's constant  $k$  (Einstein and Chien 1955; Vanoni 1975). However, there is now conclusive evidence that von Karman's constant is not affected by the presence of suspended sediment as previously believed, and its clear-water value ( $k \approx 0.41$ ) can be considered to be a universal one (Smith and McLean 1977; Coleman 1981, 1986; Lyn 1991; Soulsby and Wainright 1987; Wright and Parker 2004a).

As is to be shown, it is not uncommon under field conditions to find that the flow regime is neither hydraulically smooth nor hydraulically rough. The conditions  $k_s / \delta_v \gg 1$  for hydraulically rough flow and  $k_s / \delta_v \ll 1$  for hydraulically smooth flow can be rewritten to indicate that the roughness Reynolds number, given by  $u_* k_s / \nu$ , should be much larger than 11.6 for turbulent rough flow, and much smaller than 11.6 for turbulent smooth flow. A composite form that

represents both ranges, as well as the transitional range between them, can be written as (Yalin 1992)

$$\frac{u}{u_*} = \frac{1}{\kappa} \ln \left( \frac{z}{k_s} \right) + B_s \quad (2-9a)$$

with  $B_s$  as a function of  $Re_* = u_* k_s / \nu$  which can be estimated with the following empirical fit

$$B_s = 8.5 + [2.5 \ln(Re_*) - 3] e^{-0.121 [\ln(Re_*)]^{2.42}} \quad (2-9b)$$

A plot of this function can be seen in Fig. 2-3.

An alternative way of writing Eq. (2-9a) is

$$\frac{u}{u_*} = \frac{1}{\kappa} \ln \left( A_s \frac{z}{k_s} \right) \quad (2-9c)$$

It follows then that  $A_s$  and  $B_s$  are related by

$$A_s = e^{\kappa B_s} \quad (2-9d)$$

Another useful fit to the vertical velocity distribution in open-channel flows, which also covers the entire range from hydraulically smooth to hydraulically rough as well as the transition, was proposed by Swamee (1993),

$$\frac{u}{u_*} = \left\{ \left( \frac{\nu}{u_* z} \right)^{10/3} + \left[ \kappa^{-1} \ln \left( 1 + \frac{9(u_* z / \nu)}{1 + 0.3(u_* k_s / \nu)} \right) \right]^{-10/3} \right\}^{-0.3} \quad (2-10)$$

Typically, muddy bottoms as well as beds covered with silt and fine sand are hydraulically smooth, whereas the presence of coarse sands and gravel leads, in general, to hydraulically rough conditions.

### 2.2.2 Flow Velocity Distribution: Velocity-Defect and Log-Wake Laws

The flow velocity distribution given by the law of the wall, Eq. (2-4), requires some knowledge of the bed roughness characteristics. An alternative formulation can be obtained if the flow depth  $H$  is introduced as the relevant length scale. Assuming that the maximum flow velocity  $u_{\max}$  takes place at the water surface,  $z = H$ , Eq. (2-4) can be manipulated to obtain the so-called velocity-defect law, also known as the outer form of the law of the wall (Schlichting 1979)

$$\frac{u_{\max} - u}{u_*} = -\frac{1}{\kappa} \ln \frac{z}{H} \quad (2-11)$$

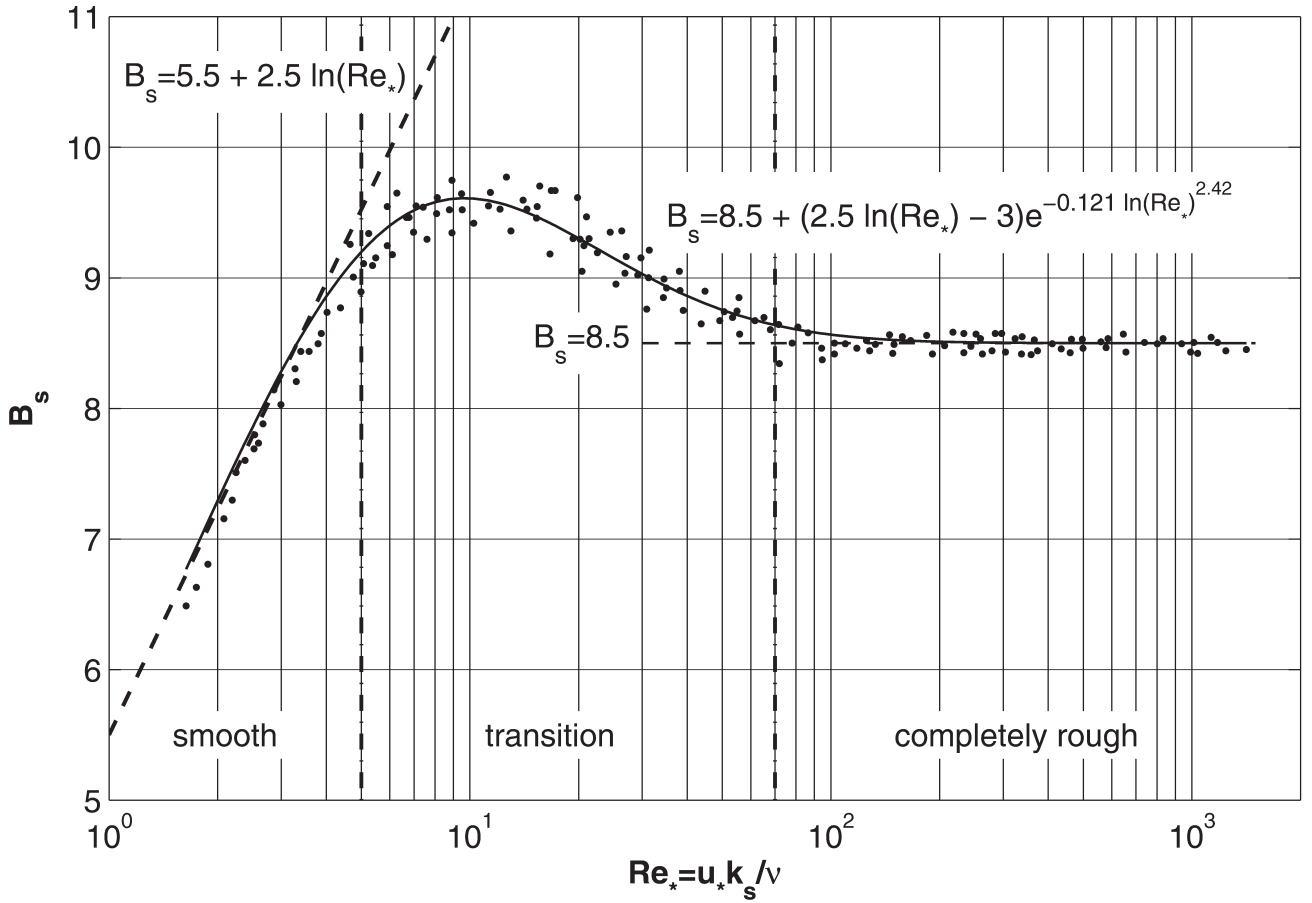

Fig. 2-3. Plot of  $B_s$  function in log-law velocity distribution.

A number of researchers have argued that the logarithmic behavior of the velocity distribution, either in the inner form given by Eq. (2-4) or in the outer form given by Eq. (2-11), can be justified only for a restricted region near the bed ( $z/H < 0.2$ ), and that, for  $z/H > 0.2$ , a correction of the logarithmic function is necessary (Coleman and Alonso 1983; Sarma et al. 1983).

Nezu and Nakagawa (1993) added a wake function to the standard log law given by Eq. (2-7), calling it the “log-wake law,” as follows,

$$\frac{u}{u_*} = \frac{1}{\kappa} \ln\left(\frac{u_* z}{\nu}\right) + 5.5 + w\left(\frac{z}{H}\right) \quad (2-12a)$$

where  $w(z/H)$  is the wake function first proposed by Coles (1956) for turbulent boundary-layer flows, which takes the form

$$w\left(\frac{z}{H}\right) = \frac{2W_0}{\kappa} \sin^2\left(\frac{\pi}{2} \frac{z}{H}\right) \quad (2-12b)$$

In this relation  $W_0$  is known as the Coles wake parameter, expressing the strength of the wake function. Through trigonometric substitution, Eq. (2-11) can also be written in log-wake form (Coleman 1981; Coleman and Alonso 1983).

$$\frac{u_{\max} - u}{u_*} = -\frac{1}{\kappa} \ln\left(\frac{z}{H}\right) + \frac{2W_0}{\kappa} \cos^2\left(\frac{\pi z}{2H}\right) \quad (2-13)$$

A procedure to estimate the Coles wake parameter from flow velocity measurements, originally proposed by Coleman (1981), can be found in Julien (1995 p. 103). Nezu and Rodi (1986), in experiments on flat-bed, smooth-bed, turbulent flows, found  $W_0$  to vary from 0 to 0.253, with a mean value of  $W_0 \approx 0.2$ . This result was confirmed independently by Lyn (1991). Coleman (1981) and Parker and Coleman (1986) demonstrated that for the case of sediment-laden flows over flat beds,  $W_0$  increases with increasing sediment concentration, ranging from 0.191 to 0.861. Lyn (1993) found that for flow over artificial bed forms,  $W_0$  ranged from  $-0.05$  to  $0.1$ , and suggested that negative values of  $W_0$  are the result of

strong, favorable pressure gradients. Lyn (1993) also found good results in replicating measured velocity profiles over bed forms with the log-wake law.

Most knowledge of flow velocity distribution in turbulent, free-surface flows stems from laboratory studies (e.g., Nezu and Rodi 1986; Nelson et al. 1993; Song et al. 1994; Bennett and Best 1995; 1996; Best et al. 2001; Lemmin and Rolland 1997; Muste and Patel 1997; Graf and Cellino 2002). In the past few years, however, new acoustic technology for flow measurement has made possible the observation of velocity profiles in streams and rivers as well (Kostaschuk et al. 2004; Dinehart and Burau 2005). With the help of observations made in the Missouri river, Holmes (2003) has found that the velocity-defect law, Eq. (2-13), works well for field conditions and the Coles wake parameter takes values ranging from  $-0.035$  to  $0.36$ . In all cases, dune-like bed forms were present, suggesting that such features might be responsible for the deviations from the logarithmic velocity distribution, observed away from the bottom. More field observations need to be made to quantify the effect of bed forms on the velocity distribution in alluvial rivers as well as the role played by stratification induced by suspended sediments. A recent review of mean flow, turbulence and bed form dynamics in alluvial rivers can be found in Best (2005).

### 2.2.3 Relations for Channel Flow Resistance

Most river flows are commonly considered to be hydraulically rough. Neglecting wake effects, Eq. (2-8) can be used to obtain an approximate expression for depth-averaged velocity  $U$  that is reasonably accurate for most flows. Integrating the mean flow velocity distribution given by Eq. (2-8) and dividing by the mean flow depth yields

$$U = \frac{1}{H} \int_0^H u dz \quad (2-14)$$

Now by slightly changing the lower limit of integration to avoid the fact that the logarithmic law is singular at  $z = 0$ , the following result is obtained:

$$\frac{U}{u_*} = \frac{1}{H} \int_{k_s}^H \left[ \frac{1}{\kappa} \ln \left( \frac{z}{k_s} \right) + 8.5 \right] dz \quad (2-15)$$

or after the integration is performed

$$\frac{U}{u_*} = \frac{1}{\kappa} \ln \left( \frac{H}{k_s} \right) + 6 = \frac{1}{\kappa} \ln \left( 11 \frac{H}{k_s} \right) \quad (2-16)$$

This relation is known as Keulegan's resistance law for rough flow (Keulegan 1938) and it has been extensively used

to estimate grain-induced resistance in gravel-bed streams (e.g. Bray 1979; Parker 1990).

It can be shown that the logarithmic form of Eqs. (2-8) and (2-16) can be approximated by power laws of the Manning-Strickler form, as follows:

$$\frac{u}{u_*} = \frac{1}{\kappa} \ln \left( 30 \frac{z}{k_s} \right) \cong 9.34 \left( \frac{z}{k_s} \right)^{1/6} \quad (2-17a)$$

$$\frac{U}{u_*} = \frac{1}{\kappa} \ln \left( 11 \frac{H}{k_s} \right) \cong 8.1 \left( \frac{H}{k_s} \right)^{1/6} \quad (2-17b)$$

To facilitate their comparison, a plot of Eqs. (2-17a) and (2-17b) is shown in Fig. 2-4. It is similar to the one presented by Brownlie (1983). The relative error between the log law and the power law is less than 4.2% in Eq. (2-17a) and less than 3% in the case of Eq. (2-17b). Keulegan (1938) was the first to point out the equivalence between the log-law and the power-law, given by Eq. (2-17b), in the context of open-channel flows. Chen (1991) provides a rigorous discussion of logarithmic and power-law velocity distributions, including a comparison of the associated flow resistance relations for both hydraulically smooth flows and fully rough flows.

Now, between Eqs. (2-2) and (2-16), a resistance relation can be found for the bed shear stress:

$$\tau_b = \rho C_f U^2 \quad (2-18)$$

where the friction coefficient  $C_f$  is given by

$$C_f = \left[ \frac{1}{\kappa} \ln \left( 11 \frac{H}{k_s} \right) \right]^{-2} \quad (2-19)$$

**Fig. 2-4.** Comparison of logarithmic laws versus power laws for velocity distribution and flow resistance.

If Eq. (2-17b) is used instead of Eq. (2-16), the friction coefficient takes the form:

$$C_f = \left[ 8.1 \left( \frac{H}{k_s} \right)^{1/6} \right]^{-2} \quad (2-20)$$

It is important to emphasize that Eq. (2-18) provides a local point estimate of bed shear stress, while Eq. (2-1) gives a reach-averaged value of the bed shear stress (Yen 2002).

It is useful to show the relationship between the friction coefficient  $C_f$  and the roughness parameters in open-channel flow relations commonly used in practice. Between Eqs. (2-1) and (2-18), a form of Chezy's law can be derived (Chow 1959):

$$U = C_z H^{1/2} S^{1/2} \quad (2-21)$$

where the Chezy coefficient  $C_z$  is given by the relation

$$C_z = \left( \frac{g}{C_f} \right)^{1/2} \quad (2-22)$$

A specific evaluation of Chezy's coefficient can be obtained by substituting Eq. (2-19) into Eq. (2-22). It is seen that the coefficient is not constant, but varies as the logarithm of the relative roughness  $H/k_s$ . A logarithmic dependence is typically a weak one, partially justifying the common assumption that Chezy's coefficient in Eq. (2-21) is roughly a constant. By substituting Eq. (2-20) into Eq. (2-21) and Eq. (2-22), Manning's equation in metric units is obtained

$$U = \frac{1}{n} H^{2/3} S^{1/2} \quad (2-23a)$$

Here Manning's  $n$  is given by

$$n = \frac{k_s^{1/6}}{8.1 g^{1/2}} \quad (2-23b)$$

This relation is often called the *Manning-Strickler* form of Manning's  $n$  (Brownlie 1983). It is deceptively simple but it also contains important information. Even for large increases in roughness height  $k_s$ , Manning's  $n$  does not change much. The opposite behavior is seen if large values of Manning's  $n$  are considered, and the corresponding value of  $k_s$  is estimated with the help of Eq. (2-23b). Often the back-calculated values of  $k_s$  turn out to be larger than the mean flow depth  $H$ , suggesting that the value of Manning's  $n$  being used is not a realistic one. From the analysis above, it should also be apparent that Manning's equation can only be applied to uniform,

hydraulically rough, fully turbulent flows. Extensive tables of Manning's  $n$  values for different channel characteristics are given in Chow (1959) and Yen (1991).

It is also important to notice that according to Eq. (2-23b), Manning's  $n$  is not a dimensionless parameter. Yen (1992, 2002) and Dooge (1991), as well as Mostafa and McDermid (1971), have proposed dimensionally homogeneous forms of Manning's equation. Such dimensionless equation can be readily obtained from Eqs. (2-23a) and (2-23b) as follows:

$$U = M \left( \frac{H}{k_s} \right)^{1/6} \sqrt{gHS} \quad (2-24a)$$

Where the dimensionless constant  $M = 8.1$  in this case and is valid for very wide channels. Different values for  $M$  can be found in the literature depending on the Strickler (1923) coefficient used in Eq. (2-23b). Yen (1993) reports values of  $M$  between 6.71 and 12.82, while Julien (2002) fits a value of  $M = 5$  to field observations. With the help of Eq. (2-23b), it is possible to define a dimensionless Strickler number

$$St = \frac{n \sqrt{g}}{k_s^{1/6}} = \frac{1}{8.1} = 0.12 \quad (2-24b)$$

It follows that the constant  $M$  in Eq. (2-24a) is the inverse of the Strickler number  $St$ . An alternative way to express the Strickler number is with Keulegan's equation and power-law equivalent. Assuming that  $k_s = D$ , the identity given in Eq. (2-17b) can also be used to estimate the Strickler number

$$St = \frac{(H/D)^{1/6}}{(1/\kappa) \ln(11H/D)} \quad (2-24c)$$

This relation gives values of  $St$  close to 0.12, as obtained from Eq. (2-24b) in the range of relative flow depth  $H/D$  from 10 to 1,000 (Niño 2002). For values  $H/D$  lower than about 10, a sharp increase of  $St$  has been reported (e.g., Limerinos 1970), due to form resistance added to the grain (skin) friction, associated with flow separation in the wake of large bed elements relative to the flow depth. For instance, Ayala and Oyarce (1993) calibrated the following relation from field data obtained in the Mapocho River in the Chilean side of the Andean mountains, for values of  $H/D$  lower than 10 and taking  $D = D_{90}$ ,

$$St = 0.30 \left( \frac{H}{D_{90}} \right)^{-0.40} \quad (2-24d)$$

This implies that  $M$  in the relation to estimate the mean flow velocity (Eq. 2-24a) would no longer be constant but would change as a function of flow depth for  $H/D < 10$ .

There is no accepted standard equation for predicting flow velocities in channels with large relative roughness, i.e. where channel bed material is large relative to water depth. This is typical of mountain streams (Jarrett 1984; Aguirre-Pe and Fuentes 1990). Smart et al. (2002) conducted an analysis of existing flow resistance equations which points to the difficulties associated with the definition of depth and hydraulic radius when the bed roughness is large relative to the flow depth. They found that the log law, or the equivalent power law, is only applicable when the roughness is of sufficiently small scale, and recommended the use of a square-root power law to estimate flow velocity in the presence of large-scale roughness.

In the case of sand-bed streams, flow resistance is influenced by both grain or skin friction as well as form drag induced by the development of bed forms such as ripples, dunes and bars, so any estimate of Manning's  $n$ , or any other roughness coefficient, has to account for the possibility of different flow regimes (i.e., lower and upper regimes). Bruschin (1985), Camacho and Yen (1991), Wu and Wang (1999), and Hager and Del Giudice (2001) have proposed equations to estimate Manning's  $n$  for the case of sand-bed rivers. A modified Manning-Strickler formula for flow in alluvial channels with sand beds has also been advanced by Yu and Lim (2003). Flow resistance predictors for sand-bed streams are discussed later in the chapter.

## 2.2.4 Fixed-Bed (Skin or Grain) Roughness

It is clear that to use these relations for channel flow resistance, a criterion for evaluating the equivalent roughness height  $k_s$  is necessary. Friction factors for turbulent flow in pipes and in fixed-bed channels have their roots in the classic sand-roughened pipe experiments conducted by Nikuradse (1933). He conducted a set of pioneer experiments and proposed the following criterion. Suppose a rough surface is subjected to a flow. Then the equivalent roughness height  $k_s$  of the surface would be equal to the diameter of sand grains that, when glued uniformly to a completely smooth wall, and then subjected to the same external conditions, yields the same velocity profile. Nikuradse used sand glued to the inside of pipes to conduct this evaluation.

To analyze the work of Nikuradse, it is convenient to introduce another relation that can be used to estimate mean flow velocity in open-channel flows, known as the Darcy-Weisbach equation

$$U = \sqrt{\frac{8}{f}} \sqrt{g R_h S} = \sqrt{\frac{8}{f}} u_* \quad (2-26)$$

In this equation

$g$  = gravitational acceleration;

$u_*$  = shear velocity;

$R_h$  is the hydraulic radius (approximately equal to the flow depth  $H$  for very wide channels); and  $f$  is the

dimensionless Darcy-Weisbach friction coefficient, which, for a pipe with diameter  $D$  is known to be a function of the flow Reynolds number  $R_e = UD/\nu$  and the relative roughness  $D/k_s$ .

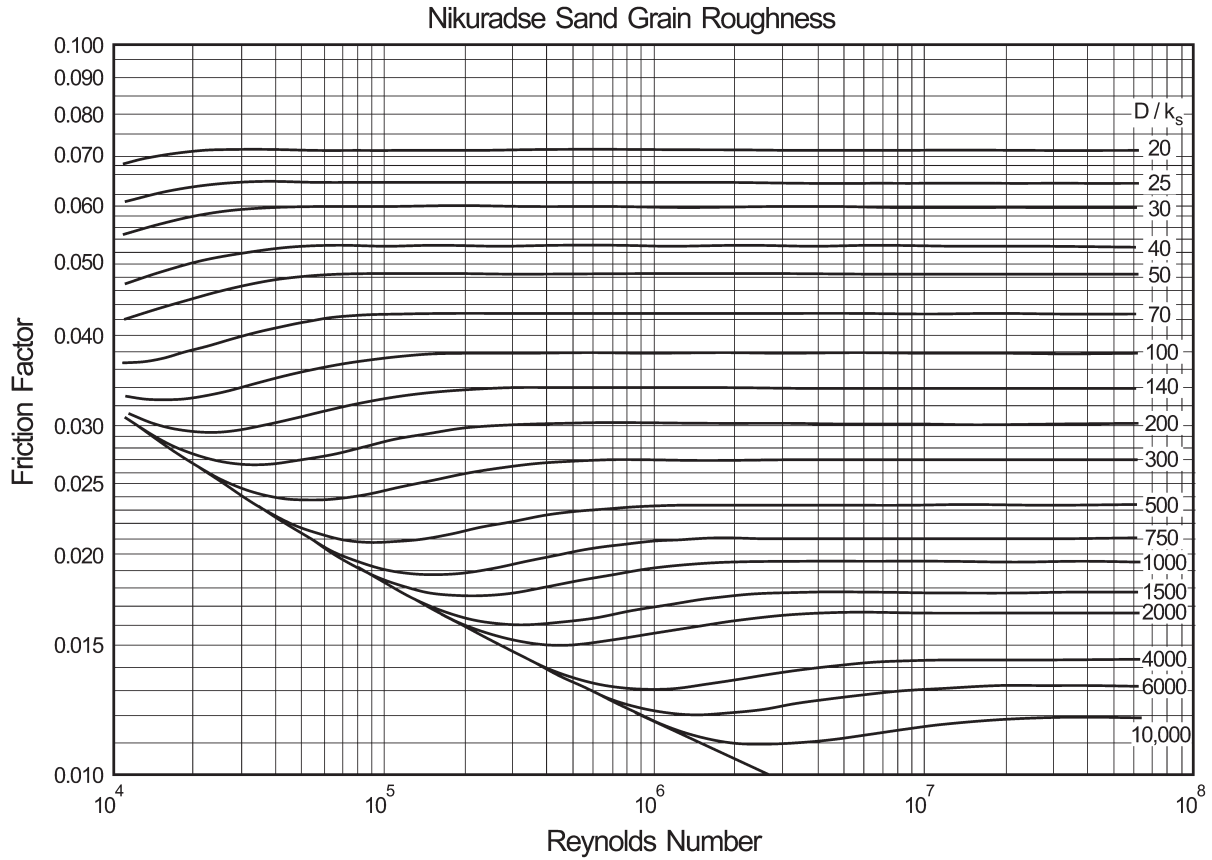

Brownlie (1981) re-examined Nikuradse's data and proposed the friction factor diagram shown in Fig 2-5. The diagram provides the values of the friction factor  $f$ , introduced in Eq. (2-26), as a function of the Reynolds number  $R_e = UD/\nu$  and the relative roughness  $D/k_s$ . This diagram is equivalent to the well known Moody diagram shown in Fig. C-2 of Appendix C, and can be used for sidewall corrections in laboratory experiments (Vanoni and Brooks 1957) as well as for separating total resistance into grain resistance and form resistance in alluvial streams with dunes (Brownlie 1981; Fedele and García 2001). For open-channel flow calculations, the pipe diameter  $D$  should be replaced by  $4R_h$ , in which  $R_h$  is the hydraulic radius. Again, for a very wide channel, the hydraulic radius can be replaced by the mean flow depth. The sidewall correction procedure is explained in detail both in Brownlie (1981) as well as in *ASCE Manual 54* (Vanoni 2006) and therefore is not repeated here.

In the late 1930s, Zegzhda conducted a set of experiments in straight rectangular flumes of varying roughness, using an experimental method (gluing sand to the walls) similar to the one used by Nikuradse for flow in pipes (see Novak and Cabelka 1981, p. 124). Because this work was not published in English, it is not as well known as Nikuradse's work on pipes. However, this experimental study was conducted for a set of relative-roughness ( $R_h/k_s$ ) values more representative of the conditions observed in the field for the case of sand-bed streams with plane beds. In fact, the relation obtained by Zegzhda for fully-rough hydraulic conditions is very similar to the expression advanced independently at about the same time by Keulegan (Eq. 2-16).

A fit to the experimental results of Nikuradse that can be used to estimate the roughness length parameter  $z_0$  in Eq. (2-4) as a function of  $k_s$  was proposed by Christofferson and Jonsson (1985)

$$z_0 = \frac{k_s}{30} \left[ 1 - \exp\left(\frac{-u_* k_s}{27\nu}\right) \right] + \frac{\nu}{9u_*} \quad (2-27)$$

Smith (1977) seems to have been the first to plot Nikuradse's data in a way useful to estimate the roughness length. Similar empirical relations have been proposed by Fuentes and Carrasquel (1981) and Dade et al. (2001). For  $u_* k_s/\nu < 3$ , the flow is hydraulically smooth and  $z_0 = 0.11\nu/u_*$ ; whereas for  $u_* k_s/\nu > 100$  the flow is hydraulically rough and  $z_0 = 0.033k_s$ . In many interesting sediment transport situations the flow is hydraulically transitional and an equation such as Eq. (2-27) has to be used to estimate the roughness length in Eq. (2-4) associated with grain-induced roughness (Kamphuis 1974). Typically, muds and flat fine sands are

**Fig. 2-5.** Revised Nikuradse friction factor diagram for flow in pipes of diameter  $D$  or open-channel flows with hydraulic radius  $R_h = D/4$  (after Brownlie, 1981).

hydraulically smooth or transitional, and coarse sands and gravels are hydraulically rough (Soulsby, 1997). It is common practice to treat all flows over sands as being hydrodynamically rough since this simplifies the analysis. This simplifying approximation makes less than 10% error in the estimation of the shear velocity  $u_{*}$  for all values  $u_{*}$  above the threshold of motion (see Section 2.4.2) of grains larger than  $60 \mu m$ .

Although it is clear that the sediment size distribution in most rivers is not as uniform as the material used in his experiments, Nikuradse's concept of grain-induced roughness for pipe flows has been extended to estimate friction factors in streams and rivers as well (Yen 1992). Nikuradse's equivalent sand-grain roughness,  $k_s$ , is commonly taken to be proportional to a representative sediment size  $D_x$ ,

$$k_s = \alpha_s D_x \quad (2-28)$$

Suggested values of  $\alpha_s$  which have appeared in the literature are listed in Table 2-1, originally compiled by Yen (1992; 2002) and updated for this manual. Different sediment sizes have been suggested for  $D_x$  in Eq. (2-28). Statistically,  $D_{50}$  (the grain size for which 50% of the bed material is finer) is most readily available. Physically, a representative

size larger than  $D_{50}$  is more meaningful to estimate flow resistance because of the dominant effect of large sediment particles. The range of  $\alpha_s$  values and the diverse representative sediment size used for  $D_x$  indicate that further research on this concept is necessary.

In a study of flow resistance associated with rip-rapped surfaces, Maynard (1991) reviewed a number of formulations commonly used to estimate the Darcy-Weisbach friction coefficient and found that a power-law equation can be used for most riprap (i.e., fixed-bed) problems in very wide open-channel flows, as follows:

$$\left(\frac{8}{f}\right)^{1/2} = 6.89 \left(\frac{H}{D_{50}}\right)^{1/6} \quad (2-29)$$

Notice the similarity with the power-law equations for flow resistance presented earlier. Maynard (1991) also found a logarithmic expression for flow resistance, based on his own experiments as well as on data from other sources, given by

$$\left(\frac{8}{f}\right)^{1/2} = 3.92 \log \left(\frac{H}{D_{50}}\right) + 6.86 \quad (2-30)$$

**Table 2-1 Ratio of Nikuradse Equivalent Roughness Size and Sediment Size for Rivers**

Investigator	Measure of sediment size, $D_x$	$\alpha_s = k_s/D_x$
Ackers and White (1973)	$D_{35}$	1.23
Aguirre-Pe and Fuentes (1990)	$D_{84}$	1.6
Strickler (1923)	$D_{50}$	3.3
Katul et al (2002)	$D_{84}$	3.5
Keulegan (1938)	$D_{50}$	1
Meyer-Peter and Muller (1948)	$D_{50}$	1
Thompson and Campbell (1979)	$D_{50}$	2.0
Hammond et al. (1984)	$D_{50}$	6.6
Einstein and Barbarossa (1952)	$D_{65}$	1
Irmay (1949)	$D_{65}$	1.5
Engelund and Hansen (1967)	$D_{65}$	2.0
Lane and Carlson (1953)	$D_{75}$	3.2
Gladki (1979)	$D_{80}$	2.5
Leopold et al. (1964)	$D_{84}$	3.9
Limerinos (1970)	$D_{84}$	2.8
Mahmood (1971)	$D_{84}$	5.1
Hey (1979), Bray (1979)	$D_{84}$	3.5
Ikeda (1983)	$D_{84}$	1.5
Colosimo et al. (1986)	$D_{84}$	3.6
Whiting and Dietrich (1990)	$D_{84}$	2.95
Simons and Richardson (1966)	$D_{85}$	1
Kamphuis (1974)	$D_{90}$	2.0
Van Rijn (1982)	$D_{90}$	3.0

which applies in the range  $2.2 < H/D_{50} < 23$ . Similar empirical relations have been advanced by Hey (1979), Thompson and Campbell (1979), Griffiths (1981), Pyle and Novak (1981), and Bathurst (1985).

From these equations, it follows that for wide, open channel flows the Darcy-Weisbach friction coefficient and Manning's roughness coefficient are related by

$$\left(\frac{8}{f}\right)^{1/2} = \frac{K_n H^{1/6}}{ng^{1/2}} = \frac{U}{\sqrt{gHS}} \quad (2-31)$$

in which  $K_n$  is a constant equal to 1 in metric units and equal to 1.486 in English units (Yen 2002). The velocity distribution in high-gradient streams with relatively low values of relative submergence  $H/D_{50}$  is no longer logarithmic near the bed due to the wake effect produced by large roughness elements. Wiberg and Smith (1991) have developed a model for the velocity field in steep streams with coarse gravel beds that is capable of reproducing the field observations made by

Marchand et al. (1984). At about the same time, Aguirre-Pe and Fuentes (1990) proposed a theory for flow resistance in steep, rough streams that takes into account the existence of the highly turbulent wake zone near a very rough bed. Their model predictions compare favorably against field observations by several authors. As shown by Smart (1999; 2002), most of the uncertainty when dealing with coarse gravel and cobbles in shallow channels is in the determination of the mean bed location so that the origin of the flow velocity profile can be ascertained. In relation to the difficulties associated with defining the mean bed elevation, Nikora et al. (2001) show the importance of spatial averaging when dealing with shallow flows over gravel bed streams. In the absence of a logarithmic velocity distribution, Katul et al. (2002) developed a velocity distribution equation based on mixing-length theory capable of reproducing flow resistance characteristics observed in shallow streams with large relative roughness. More recently, Buffington et al. (2004) studied the effects of channel type and associated hydraulic roughness on salmonid spawning-gravel availability in mountain catchments.

### 2.2.5 Movable Flat-Bed Roughness

In flows over geometrically smooth, fixed boundaries, the apparent roughness of the bed  $k_s$  can be computed using Nikuradse's approach, as shown above. However, once the transport of bed material has been instigated, the characteristic grain diameter and the viscous sublayer thickness no longer provide the relevant length scales. The characteristic length scale in this situation is the thickness of the layer where the sediment particles are being transported by the flow, usually referred to as the bed-load layer height (Wiberg and Rubin 1989). As the grains start to roll and saltate along the bed, they take momentum away from the mean flow via drag, resulting in an increase in flow resistance that translates into an increase in bed roughness.

Once the bed shear stress  $\tau_b$  exceeds the critical shear stress for particle motion  $\tau_c$ , the roughness length can be estimated with an expression inspired by the work of Owen (1964) for wind-induced sediment transport, and first proposed by Smith (1977) for sediment transport by water currents,

$$z_0 = \alpha_0 \frac{(\tau_b - \tau_c)}{(\rho_s - \rho)g} + z_{0N} \quad (2-32a)$$

where

$$\begin{aligned} \alpha_0 &= 26.3; \\ z_{0N} &= 0.033k_s \text{ and } k_s = \text{Nikuradse roughness length; and} \\ \rho_s &= \text{bed sediment density.} \end{aligned}$$

This approach is particularly suitable for sand-bed rivers and has been widely used in coastal sedimentation (e.g., Smith and McLean 1977).

The roughness parameter also can be estimated with a scheme proposed by Dietrich and Whiting (1989),

$$z_0 = \alpha_1 \delta_b + z_{0N} \quad (2-32b)$$

where

$$\begin{aligned} \alpha_1 &= \text{empirical constant equal to 0.077;} \\ z_{0N} &= 0.033k_s \text{ and } k_s = \text{Nikuradse roughness length; and} \\ \delta_b &= \text{bedload-layer height,} \end{aligned}$$

which is computed as

$$\delta_b = \frac{1.2D(1 - \cos\phi) \left[ \frac{\tau_b}{\tau_c} \right]}{1 + 0.2 \left[ \frac{\tau_b}{\tau_c} \right]} \quad (2-32c)$$

where

$$\begin{aligned} \phi &= \text{angle of friction, and} \\ D &= \text{mean diameter of the bed material.} \end{aligned}$$

Since both estimators depend on the flow intensity as given by the bed shear stress, Eqs. (2-32a) and (2-32b) provide an estimate of a variable roughness appropriate for movable beds without the presence of bed forms.

Wiberg and Rubin (1989) evaluated several expressions for characterizing bed roughness produced by a layer of saltating sediment grains; they proposed with the help of a formulation for the vertical eddy diffusivity coefficient (Gelfenbaum and Smith 1986; Long et al. 1993) a formulation which makes use of a vertical flow velocity distribution given by the following expression

$$u(z) = \frac{u_*}{\kappa} \int_{z_0}^z \frac{1 - (z/H)}{z \exp \left[ -(z/H) - 3.3(z/H)^2 + 2.2(z/H)^3 \right]} dz \quad (2-33)$$

where

$$\begin{aligned} z &= \text{distance from the bed;} \\ H &= \text{flow depth; and} \\ \kappa &= 0.41 = \text{von Karman's constant.} \end{aligned}$$

Seven upper plane-bed experiments of Guy et al. (1966) were used to obtain best fit values for the shear velocity  $u_*$  and bed roughness length  $z_0$  with the help of Eq. (2-33). The analysis of Wiberg and Rubin (1989) shows that the bed roughness associated with sediment transport can reach values about an order of magnitude larger than the Nikuradse grain roughness in plane-bed flows, but this roughness will in general be significantly smaller than the roughness associated with ripples and dunes when they are present on the bed surface.

At high bed shear stresses and sediment transport intensities in sand-bed streams, dunes are washed out and the bed becomes plane. In this regime, sediment is transported near the bed in a layer with a thickness that is much larger than the grain size. Collisions between grains are intense in this layer, resulting in a grain flow or granular fluid flow. This regime is known as sheet flow and measurements taken by researchers (Wilson 1987, 1989; Nnadi and Wilson 1992) have shown that flow resistance increases drastically with flow intensity in this regime. Sumer et al (1996) found that flow resistance induced by the sheet-flow layer can be expressed in terms of the ratio of Nikuradse's equivalent sand roughness to the grain diameter ( $k_s/D$ ). This ratio was found to behave differently whether or not the grains became suspended near the bed. In the absence of suspension mode,  $k_s/D$  depends only on the Shields parameter ( $\tau^*$ ) defined by Eq. (2-56). In the suspension mode,  $k_s/D$  depends not only on  $\tau^*$  but also on a dimensionless sediment fall velocity parameter  $R_f$  defined by Eq. (2-46b). There is also evidence that sediment transport in the sheet-flow layer is influenced by the turbulent bursting process (e.g., Sumer et al. 2003).

## 2.2.6 Equivalent Roughness of Bed Forms

As the flow intensity increases, bed forms such as ripples and dunes can develop (e.g., Raudkivi 1997). In this situation, the bed roughness also will be influenced by form drag due to the presence of bed forms. The fundamental problem is that the bed form characteristics and, hence, the bed roughness depend on the main flow characteristics (e.g., mean velocity, depth) and sediment characteristics (e.g., grain size, density). Thus, the hydraulic roughness in the presence of bed forms is a dynamic parameter that depends strongly on flow conditions as well as on the bed sediment properties. The equivalent roughness of alluvial beds in the presence of ripples and dunes was addressed with the Nikuradse hydraulic roughness approach by Brownlie (1981) and van Rijn (1982, 1984c). In van Rijn's approach, the height due to grain-induced roughness (Eq. 2-28) was added to an estimate of the equivalent roughness height produced by ripples and dunes obtained from field and laboratory observations, to obtain a measure of the total (grain plus form resistance) effective roughness,

$$k_s = \alpha_s D_{90} + \gamma_{sf} 1.1 \Delta (1 - e^{-25\Delta/\lambda}) \quad (2-34a)$$

where

- $\alpha_s$  = 3 (see Eq. 2-28);
- $D_{90}$  = grain size for which 90% of the bed material is finer;
- $\gamma_{sf}$  = dune shape factor = 1.
- $\Delta$  and  $\lambda$  = bed form height and length, respectively; and
- $\Delta / \lambda$  = bedform steepness.

The effective roughness height was then used to estimate the Chezy friction coefficient (Eq. 2-22),

$$C_Z = \left( \frac{g}{C_f} \right)^{1/2} = 18 \log \left( \frac{12 R_{hb}}{k_s} \right) \quad (2-34b)$$

In this equation,  $R_{hb}$  = hydraulic radius of the river bed (i.e., subtracting streambank effects on flow resistance) according to Vanoni-Brooks (1957) (see Vanoni 2006, p. 91). Notice that the Chezy coefficient is not dimensionless. A dimensionless expression of the Chezy coefficient applicable to bank-full sand bed and gravel bed streams can be found in Chapter 3.

Application of Eq. (2-34a) to field conditions resulted in considerable overestimation of the hydraulic roughness (van Rijn 1996). Further analysis showed that the lee-side slopes of natural sand dunes in rivers were less steep than those of dunes in the laboratory and a shape factor  $\gamma_{sf} = 0.7$  was recommended for application to natural river dunes.

A different approach based on boundary-layer theory and measured velocity profiles was proposed by Fedele and García (2001). When spatially-averaged velocity profiles

of flow (Nikora et al. 2001) over dunes are available, this method can be used to estimate a spatially-averaged composite roughness  $k_c$  due to the combined effect of both grain friction and form drag due to bed forms in large sand-bed rivers. Boundary layer studies have shown that an alternative to Eq. (2-9a) for describing the vertical flow velocity distribution in flows where the geometry and size of the roughness elements is such that skin friction and form drag are present, is given by the following equation

$$\frac{u}{u_*} = \frac{1}{\kappa} \ln \left( \frac{zu_*}{\nu} \right) + A - \frac{\Delta u}{u_*} \left[ \frac{u_* k_c}{\nu} \right] \quad (2-35a)$$

In Eq. (2-35a),  $\kappa = 0.41$  and  $A = 5.5$  are universal constants previously introduced, and  $\Delta u/u_*$  is a roughness function which is equal to zero for smooth walls (square brackets indicate functional relationship). When plotting  $u/u_*$  versus  $\ln(u_* z/\nu)$ , this equation represents a family of parallel lines, each being displaced downwards from the smooth-wall velocity profile by an amount  $\Delta u/u_*$  (Schlichting 1979).

The roughness function for alluvial streams with dunes is shown in Fig. 2-6. It shows  $\Delta u/u_*$  as a function of the parameter  $k_c u_*/\nu$  for laboratory and field streams with fully-developed dunes (Fedele and García 2001). It is observed that for values of the roughness Reynolds number  $k_c u_*/\nu$  larger than 100-200, most of the data collapse along a straight line, along the fully-rough hydraulic regime, which is well represented by the following fit,

$$\frac{\Delta u}{u_*} = 2.43 \ln \left( \frac{u_* k_c}{\nu} \right) - 3.24 \quad (2-35b)$$

An application of the alluvial roughness function is its potential use to assess the effect of temperature changes on flow structure and bed morphology. It is observed in Fig. 2-6 that even though the flows are under fully-rough hydraulic conditions, temperature variations will affect the viscosity of the water and this in turn will cause variations in the roughness Reynolds number and the flow structure.

**Fig. 2-6.** Roughness function for alluvial streams with dunes (after Fedele and García 2001).

Fedele and García (2001) also found that the composite roughness  $k_c$  could be approximated with

$$\frac{k_c}{D} = 1.45 \times \tau^{*3/2} R_{ep} \left( \frac{H}{D} \right)^{1/3} \quad (2-35c)$$

which is valid for  $(H/D) > 10^3$  and  $R_{ep} < 30$ , which are commonly found conditions for large alluvial rivers with sand dunes.

Here,

$\tau^*$  = dimensionless bed shear stress (i.e., Shields parameter) for uniform flow =  $(HS)/(RD)$ ;

$H$  = flow depth;

$S$  = channel slope;

$R = \rho_s/\rho - 1$  = submerged specific gravity of sediment;

$D$  = sediment size;

$R_{ep} = \sqrt{gRDD}/\nu$  = particle Reynolds number; and

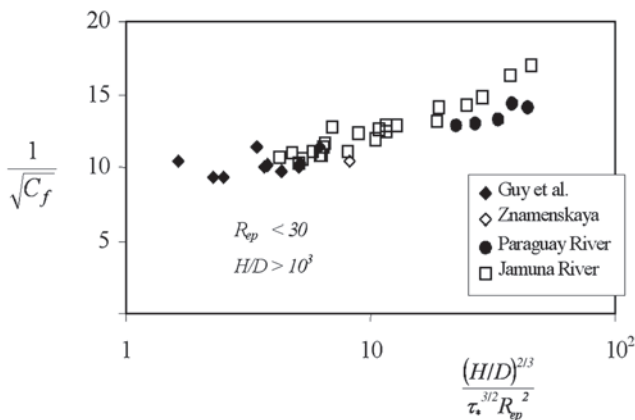

$H/D$  = relative flow depth.

A simple method to estimate the composite roughness  $k_c$  has been proposed by Wright and Parker (2004b) and can be found in Section 2.8.3.3 below.

The total friction coefficient for flow in an alluvial channel in the presence of dunes can be estimated with the help of Keulegan's Eq. (2-16), Eq. (2-19), and Eq. (2-35c),

$$C_f^{-1/2} = \frac{U}{u_*} = \frac{1}{\kappa} \ln \left[ \frac{(H/D)^{3/2}}{\tau^{*3/2} R_{ep}} \right] + 5.1 \quad (2-35d)$$

The data used to by Fedele and García (2001) to obtain this fit are shown in Fig. 2-7. This expression provides only a crude approximation for the friction factor, but clearly indicates that the roughness in alluvial streams with dunes is a dynamic parameter that depends nonlinearly on the flow intensity given by the Shields stress parameter ( $\tau^*$ ), the relative flow depth ( $H/D$ ), and the particle Reynolds number ( $R_{ep}$ ).

**Fig. 2-7.** Total friction coefficient for alluvial flows with sand dunes (after Fedele and García 2001).

## 2.3 SEDIMENT PROPERTIES

In this section, rock types, as well as fundamental characteristics of sediment particles such as size, size distribution, density, and fall velocity are considered. The role of sediment size on stream morphology is analyzed also, with the goal of understanding the behavior of sand-bed and gravel-bed streams.

### 2.3.1 Rock Types

The solid phase in sediment transport can be any granular substance. In terms of engineering applications, however, the granular substance in question typically consists of fragments ultimately derived from rocks—hence the name “sediment” transport. The properties of these rock-derived fragments, taken singly or in groups of many particles, all play a role in determining the transportability of the grains under fluid action. The important properties of groups of particles include porosity and size distribution. The most common rock type one is likely to encounter in the river or coastal environment is quartz. Quartz is a highly resistant rock and can travel long distances or remain in place for long periods of time without losing its integrity. Another highly resistant rock type that is often found together with quartz is feldspar. Other common rock types include limestone, basalt, granite, and more esoteric types such as magnetite. Limestone is not a resistant rock; it tends to abrade to silt rather easily. Silt-sized limestone particles are susceptible to solution unless the water is sufficiently buffered. As a result, limestone is not typically found to be a major component of sediments at locations distant from its source. On the other hand, it can often be the dominant rock type in mountain environments.

Basaltic rocks tend to be heavier than most rocks composing the crust of the earth. They are typically brought to the surface by volcanic activity. Basaltic gravels are relatively common in rivers that derive their sediment supply from areas subjected to volcanism in recent geologic history. Basaltic sands are much less common. Regions of weathered granite often provide copious supplies of sediment. The particles produced by weathering are often in the granule size but often quickly break down to sand sizes.

Sediments in the fluvial or coastal environment in the size range of silt, or coarser, are generally produced by mechanical means, including fracture or abrasion. The clay minerals, on the other hand, are produced by chemical action. As a result, they are fundamentally different from other sediments in many ways. Their ability to absorb water means that the porosity of clay deposits can vary greatly over time. Clays also display cohesiveness, which renders them more resistant to erosion.

### 2.3.2 Specific Gravity

Sediment specific gravity is defined as the ratio between the sediment density  $\rho_s$  and the density of water  $\rho$ . Some typical

specific gravities for various natural and artificial sediments are listed in Table 2-2.

### 2.3.3 Model Laboratory Sediments

In the laboratory, it is often of value to employ light weight model sediment (Shen 1990). To see the utility of this, it is useful to consider a movable-bed scale model of an actual river. Consider a reach of the Minnesota River, Minnesota, with a bank-full width of 90 m, a bank-full depth of 4 m, a streamwise slope of 0.0002, and a median sediment size  $D_{50}$  of 0.5 mm. The reach is scaled down by a factor of 100 to fit into a typical laboratory model basin, resulting in a bank-full width of 90 cm and a bank-full depth of 4 cm. In an undistorted model, slope remains constant at 0.0002.

If the sediment employed in the model were to be the same as in the field, it would most likely not move at all in the scale model. Carrying the analogy to its logical conclusion, it would be as if the sediment in the field Minnesota River had a median size of  $0.5 \text{ mm} \times 100 = 0.5 \text{ m}$ , i.e., boulders. It should be clear that, in this case, the field sediment cannot be employed directly in the model. The obvious alternative is to scale down sediment size by the same factor as all other lengths, i.e., by a factor of 100. This would yield a size of  $5 \text{ } \mu\text{m}$ , which is so close to the clay range that it can be expected to display some kind of pseudocohesiveness. In addition, viscous effects are expected to be greatly exaggerated due to the small size. The net result is model sediment that is much less mobile than it ought to be and, in addition, behaves in ways radically different from the prototype sediment.

There are several ways out of this dilemma. One of them involves using artificial sediment with a low specific gravity. Let  $\rho$  denote the density of water, and  $\rho_s$  denote the specific gravity of the material in question. The weight  $W$  of a particle of volume  $V_p$  is given by

$$W = \rho_s g V_p \quad (2-36a)$$

**Table 2-2 Specific Gravity of Rock Types and Artificial Materials**

Rock type or material	Specific gravity $\rho_s/\rho$
Quartz	2.60–2.70
Limestone	2.60–2.80
Basalt	2.70–2.90
Magnetite	3.20–3.50
Bakelite	1.30–1.45
Coal	1.30–1.50
Ground walnut shells	1.30–1.40
PVC	1.14–1.25

where

$g$  = acceleration of gravity.

Quartz, for example, is a mineral with a specific gravity  $\rho_s/\rho$  near 2.65. If a grain of the same volume were modeled in the laboratory using crushed coal with a specific gravity of 1.3, it would follow from Eq. (2-36a) that the coal grain would be only  $1.3/2.65$  or 0.49 times the weight of the quartz grain. Rephrasing, the coal grain is 2.04 times lighter than the quartz grain, and thus, in some sense, twice as mobile.

In fact, the benefit of using lightweight material is much greater than this, because the effective weight determining the mobility of a grain is the submerged weight  $W_s$ , i.e., the actual weight minus the buoyancy force associated with the hydrostatic pressure distribution about the particle. That is,

$$W_s = (\rho_s - \rho) g V_p = \rho R g V_p \quad (2-36b)$$

where

$$R = \left( \frac{\rho_s}{\rho} - 1 \right) \quad (2-36c)$$

denotes the submerged specific gravity of the sediment. Comparing coal and quartz again in terms of submerged weight, it is seen that

$$\frac{(W_s)_{\text{coal}}}{(W_s)_{\text{quartz}}} = \frac{(R)_{\text{coal}}}{(R)_{\text{quartz}}} = \frac{0.30}{1.65} = 0.18 \quad (2-36d)$$

It follows that under water, the coal grain is  $1/0.18 = 5.5$  times lighter than a quartz grain of the same size. Lightweight model sediments are thus a very effective way of increasing mobility in laboratory experiments (Zwamborn 1981; ASCE 2000, p. 105). More material on physical modeling of sedimentation processes can be found in Appendix C.

### 2.3.4 Size

The notation  $D$  will be used to denote sediment size, the typical units of which are millimeters (mm—sand and coarser material) or micrometers ( $\mu\text{m}$ —clay and silt). Another standard way of classifying grain sizes is the sedimentological  $\Phi$  scale, according to which

$$D = 2^{-\Phi} \quad (2-37a)$$

Taking the logarithm of both sides, it is seen that

$$\Phi = -\log_2(D) = -\frac{\ln(D)}{\ln(2)} \quad (2-37b)$$

Note that the size  $\Phi = 0$  corresponds to  $D = 1 \text{ mm}$ . The utility of the  $\Phi$  scale will become apparent upon a consideration of grain size distributions. The minus sign has been

inserted into Eq. (2-37b) simply as a matter of convenience to sedimentologists, who are more accustomed to working with material finer than 1 mm rather than coarser material. The reader should always recall that larger  $\Phi$  implies finer material.

The  $\Phi$  scale provides a very simple way of classifying grain sizes into the following size ranges in descending order: boulders, cobbles, gravel, sand, silt, and clay. This is illustrated in Table 2-3.

It should be noted that the definition of clay according to size ( $D < 2 \mu\text{m}$ ) does not always correspond to the definition of clay according to mineral. That is, some clay mineral particles can be coarser than this limit, and some silt particles produced by grinding can be finer than this. In general, however, the effect of viscosity makes it quite difficult to grind up particles in water to sizes finer than  $2 \mu\text{m}$ .

In practical terms, there are several ways to determine grain size. The most popular way for grains ranging from  $\Phi = 4$  to  $\Phi = -4$  (0.0625 to 16 mm) is with sieves. Each sieve has a square mesh, the gap size of which corresponds to the diameter of the largest sphere that would fit through. The grain size  $D$  thus measured exactly corresponds to diameter only in the case of a sphere. In general, the sieve size  $D$  corresponds to the smallest sieve gap size through which a given grain can be fitted.

For coarser grain sizes, it is customary to approximate the grain as an ellipsoid. Three lengths can be defined. The length along the major (longest) axis is denoted as  $a$ , that along the intermediate axis is denoted as  $b$ , and that along the minor (smallest) axis is denoted as  $c$ . These lengths are typically measured with a caliper. The value  $b$  is then equated to grain size  $D$ .

**Table 2-3 Sediment Grade Scale**

Class Name	Millimeters	Size range		Inches	Approximate sieve mesh openings per inch	
		F	Microns		Tyler	U.S. standard
Very large boulders	4096 ~ 2048			160 ~ 80		
Large boulders	2048 ~ 1024			80 ~ 40		
Medium boulders	1024 ~ 512			40 ~ 20		
Small boulders	512 ~ 256	-9 ~ -8		20 ~ 10		
Large cobbles	256 ~ 128	-8 ~ -7		10 ~ 5		
Small cobbles	128 ~ 64	-7 ~ -6		5 ~ 2.5		
Very coarse gravel	64 ~ 32	-6 ~ -5		2.5 ~ 1.3		
Coarse gravel	32 ~ 16	-5 ~ -4		1.3 ~ 0.6	2 ~ 1/2	
Medium gravel	16 ~ 8	-4 ~ -3		0.6 ~ 0.3	5	5
Fine gravel	8 ~ 4	-3 ~ -2		0.3 ~ 0.16	9	10
Very fine gravel	4 ~ 2	-2 ~ -1		0.16 ~ 0.08	16	18
Very coarse sand	2.000 ~ 1.000	-1 ~ 0	2000 ~ 1000		32	35
Coarse sand	1.000 ~ 0.500	0 ~ 1	1000 ~ 500		60	60
Medium sand	0.500 ~ 0.250	1 ~ 2	500 ~ 250		115	120
Fine sand	0.250 ~ 0.125	2 ~ 3	250 ~ 125		250	230
Very fine sand	0.125 ~ 0.062	3 ~ 4	125 ~ 62			
Coarse silt	0.062 ~ 0.031	4 ~ 5	62 ~ 31			
Medium silt	0.031 ~ 0.016	5 ~ 6	31 ~ 16			
Fine silt	0.016 ~ 0.008	6 ~ 7	16 ~ 8			
Very fine silt	0.008 ~ 0.004	7 ~ 8	8 ~ 4			
Coarse clay	0.004 ~ 0.002	8 ~ 9	4 ~ 2			
Medium clay	0.002 ~ 0.001		2 ~ 1			
Fine clay	0.001 ~ 0.0005		1 ~ 0.5			
Very fine clay	0.0005 ~ 0.00024		0.5 ~ 0.24			

For grains in the silt and clay sizes, many methods (hydrometer, sedigraph, etc.) are based on the concept of equivalent fall diameter. That is, the terminal fall velocity  $v_s$  of a grain in water at a standard temperature is measured. The equivalent fall diameter  $D$  is the diameter of the sphere having exactly the same fall velocity under the same conditions. Sediment fall velocity is discussed in more detail below.

A variety of other more recent methods for sizing fine particles rely on blockage of light beams. The area blocked can be used to determine the diameter of the equivalent circle, i.e., the projection of the equivalent sphere. It can be seen that all of these methods can be expected to operate consistently as long as grain shape does not deviate too greatly from that of a sphere. In general, this turns out to be the case. There are some important exceptions, however. At the fine end of the spectrum, mica particles tend to be platelike; the same is true of shale grains at the coarser end. Comparison with a sphere is not necessarily a particularly useful way to characterize grain size for such materials. More recently, techniques employing light-scattering are becoming more popular for both particle-size analysis and settling velocity measurements (e.g., Pedocchi and García 2006). More material can be found in Chapter 5.

### 2.3.5 Size Distribution

Any sediment sample normally contains a range of sizes. An appropriate way to characterize these samples is in terms of a grain size distribution. Consider a large bulk sample of sediment of given weight. Let  $p_f(D)$ —or  $p_f(\Phi)$ —denote the fraction by weight of material in the sample of material finer than size  $D(\Phi)$ . The customary engineering representation of the grain size distribution consists of a plot of  $p_f \times 100$

(percent finer) versus  $\log_{10}(D)$ —that is, a semilogarithmic plot is employed. The plot, then, would look like the one in Fig. 2-8(a).

The same size distribution plotted in sedimentological form would involve plotting  $p_f \times 100$  versus  $\Phi$  on a linear plot, like shown in Fig. 2-8(b).

Note that  $\Phi$  on a linear axis is completely equivalent to  $D$  on a logarithmic axis because  $\Phi$  is related linearly to  $\log_{10}(D)$ :

$$\Phi = -\frac{1}{\log_{10}(2)} \log_{10}(D) \quad (2-38)$$

The utility of a logarithmic scale for grain size now becomes apparent. Consider a sediment sample in which one-third of the material lies in the range 0.1–1.0 mm, one-third lies in the range 1.0–10 mm, and one-third lies in the range 10–100 mm. In Fig. 2-8(c)  $p_f \times 100$  is plotted versus  $D$  on a linear scale, and in Fig. 2-8(d)  $p_f \times 100$  is plotted versus  $D$  on a logarithmic scale— $p_f \times 100$  is plotted against  $\log_{10}(D)$ . Plot (c) is virtually unreadable, as the finest two ranges are crowded off the scale. Plot (d) provides a useful and consistent characterization of the distribution. It can be concluded that for the purposes of statistics, the relevant grain size should be on a logarithmic scale, e.g.,  $\Phi$  rather than  $D$  itself.

The size distribution  $p_f(\Phi)$  and size density  $p(\Phi)$  by weight (Fig. 2-8(e)) can be used to extract useful statistics concerning the sediment in question. Let  $x$  denote some percentage, say 50%; the grain size  $\Phi_x$  denotes the size such that  $x\%$  of the weight of the sample is composed of finer grains. That is,  $\Phi_x$  is defined such that

**Fig. 2-8.** Sediment grain size distribution in (a) semilog scale, (b) sedimentological scale  $\Phi$ , (c) linear scale, (d) log scale, (e) size distribution and size density, and (f) discretization of grain size distribution.

(c)

(d)

(e)

(f)

**Fig. 2-8.** Sediment grain size distribution in (a) semilog scale, (b) sedimentological scale  $\Phi$ , (c) linear scale, (d) log scale, (e) size distribution and size density, and (f) discretization of grain size distribution. (*Continued*)

$$p_f(\Phi_x) = \frac{x}{100} \quad (2-39a)$$

It follows that the corresponding grain size in terms of equivalent diameter is given by  $D_x$ , where

$$D_x = 2^{-\Phi_x} \quad (2-39b)$$

The most commonly used grain sizes of this type are the median size  $D_{50}$  and the size  $D_{90}$  such that 90% of the sample by weight consists of finer grains. The latter size is

particularly useful for characterizing bed roughness, as discussed previously.

The density  $p(\Phi)$  can be used to extract statistical moments. Of these, the most useful are the mean size  $\Phi_m$  and the standard deviation  $\sigma$ . These are given by the relations

$$\Phi_m = \int \Phi p(\Phi) d\Phi \quad (2-40a)$$

$$\sigma^2 = \int (\Phi - \Phi_m)^2 p(\Phi) d\Phi \quad (2-40b)$$

The corresponding geometric mean diameter  $D_g$  and geometric standard deviation  $\sigma_g$  are given as

$$D_g = 2^{\Phi_m} \quad (2-41a)$$

$$\sigma_g = 2^\sigma \quad (2-41b)$$

Note that for a perfectly uniform material,  $\sigma = 0$  and  $\sigma_g = 1$ . As a practical matter, a sediment mixture with a value of  $\sigma_g$  of less than 1.3 is often termed well-sorted and can be treated as a uniform material. When the geometric standard deviation exceeds 1.6, the material can be said to be poorly-sorted.

In point of fact, one never has the continuous function  $p(\Phi)$  with which to compute the moments of Eqs. (2-40a) and (2-40b). One must rather rely on a discretization. To this end, the size range covered by a given sediment sample is discretized in terms of  $n$  intervals bounded by  $n + 1$  grain sizes  $\Phi_1, \Phi_2, \dots, \Phi_{n+1}$  in ascending order of  $\Phi$ , as illustrated in Fig. 2-8(f). The following definitions are made from  $i = 1$  to  $n$ :

$$\bar{\Phi}_i = \frac{1}{2} (\Phi_i + \Phi_{i+1}) \quad (2-42a)$$

$$p_i = p_f(\Phi_i) - p_f(\Phi_{i+1}) \quad (2-42b)$$

Relations (2-40a) and (2-40b) now discretize to

$$\Phi_m = \sum_{i=1}^n \bar{\Phi}_i p_i \quad (2-43a)$$

$$\sigma^2 = \sum_{i=1}^n (\bar{\Phi}_i - \Phi_m)^2 p_i \quad (2-43b)$$

In some cases, especially when the material in question is sand, the size distribution can be approximated as Gaussian on the  $\Phi$  scale (i.e., log-normal in  $D$ ). For a perfectly Gaussian distribution, the mean and median sizes coincide:

$$\Phi_m = \Phi_{50} = \frac{1}{2} (\Phi_{84} + \Phi_{16}) \quad (2-43c)$$

Furthermore, it can be demonstrated from a standard table that in the case of the Gauss distribution the size  $\Phi$  displaced one standard deviation larger than  $\Phi_m$  is accurately given by  $\Phi_{84}$ ; by symmetry, the corresponding size one standard deviation smaller than  $\Phi_{84}$  is  $\Phi_{16}$ . The following relations thus hold:

$$\sigma = \frac{1}{2} (\Phi_{84} + \Phi_{16}) \quad (2-44a)$$

$$\Phi_m = \frac{1}{2} (\Phi_{84} + \Phi_{16}) \quad (2-44b)$$

Rearranging the relations with the aid of Eqs. (2-40a), (2-40b) and (2-43) and (2-44a), it is found that

$$\sigma_g = \left( \frac{D_{84}}{D_{16}} \right)^{1/2} \quad (2-45a)$$

$$D_g = (D_{84} D_{16})^{1/2} \quad (2-45b)$$

It must be emphasized that the relations are exact only for a Gaussian distribution in  $\Phi$ . This is often not the case in nature. As a result, it is strongly recommended that  $D_g$  and  $\sigma_g$  be computed from the full size distribution via Eqs. (2-43a), (2-43b), (2-41a), and (2-41b) rather than the approximate form embodied in the above relations.

### 2.3.6 Porosity

The porosity  $\lambda_p$  quantifies the fraction of a given volume of sediment that is composed of void space. That is,

$$\lambda_p = \frac{\text{volume of voids}}{\text{volume of total space}}$$

If a given mass of sediment of known density is deposited, the volume of the deposit must be computed assuming that at least part of it will consist of voids. In the case of well-sorted sand, the porosity can often take values between 0.3 and 0.4. Gravels tend to be more poorly-sorted. In this case, finer particles can occupy the spaces between coarser particles, reducing the void ratio to as low as 0.2. So-called open work gravels are essentially devoid of sand and finer material in their interstices; these may have porosities similar to that of sand. Freshly deposited clays are notorious for having high porosities. As time passes, clay deposits tend to consolidate under its own weight so that porosity slowly decreases. Wu and Wang (2006) proposed an empirical relation to estimate the initial porosity of sediments, which have been deposited within a year or less, as a function of the median diameter  $D_{50}$  of the sediment mixture. In situ measurements of porosity indicate that biological activity can have an important effect on the porosity of sediments (Wheatcroft 2002).

The issue of porosity becomes of practical importance as regards, for example, salmon spawning grounds in gravel-bed rivers (Alonso and Mendoza 1992; Huang and García 2000). The percentage of sand and silt contained in the

sediment is often referred to the percentage of “fines” in the gravel deposit. When this fraction rises above 20–26 % by weight, the deposit is often rendered unsuitable for spawning. Salmon bury their eggs within the gravel, and high fines content implies low porosity and thus reduced permeability. The flow of groundwater necessary to carry oxygen to the eggs and remove metabolic waste products is impeded. In addition, newly hatched fry may encounter difficulty in finding pore space through which to emerge to the surface. All of the above factors dictate lowered survival rates. An empirical relationship between percent embryo survival and the geometric mean diameter of the substrate in

**Fig. 2-9.** Relationship between percent embryo survival and the geometric mean diameter of the substrate (after Shirazi and Seim, 1981).

gravel-bed rivers is shown in Fig. 2-9 (Shirazi and Seim 1981). It is clear that as the material becomes coarser, the substrate porosity can be expected to increase accordingly, augmenting the embryo survival rates. Chief causes of elevated fines in gravel-bed rivers include road building and clear-cutting of timber in the watershed.

### 2.3.7 Shape

There are a number of ways in which to classify grain shape (Vanoni 2006). One of these, the Zingg classification scheme, is illustrated here. According to the definitions introduced earlier, a simple way to characterize the shape of an irregular clast (stone) is in terms of the lengths  $a$ ,  $b$ , and  $c$  of the major, intermediate, and minor axes, respectively. If these three are all equal, the grain can be said to be close to a sphere in shape. If  $a$  and  $b$  are equal but  $c$  is much smaller, the grain is rodlike. Finally, if  $c$  is much smaller than  $b$ , which is, in turn, much smaller than  $a$ , the resulting shape should be bladelike. This is illustrated in terms of the Zingg diagram in Fig. 2-10.

In studies of the fall velocity of geometric shapes and sand grains by McNown, Albertson and others, the shape of the particles has been expressed by the Corey shape factor  $SF$ , which makes use of the characteristic lengths, defined above, and is given by (Vanoni 2006, p. 14)

$$SF = \frac{c}{\sqrt{ab}}$$

It follows that a spherical particle will have a  $SF = 1$ . For natural sands  $SF = 0.7$ . The shape factor has been used in

**Fig. 2-10.** Definition of Zingg diagram.

studies of particle fall velocity (Dietrich 1982; Jimenez and Madsen 2003; Wu and Wang 2006). More material on sediment particle shape and its effect on particle fall velocity can be found in Vanoni (2006, p. 14).

### 2.3.8 Fall Velocity

A fundamental property of sediment particles is their fall or settling velocity. The fall velocity of sediment grains in water is determined by their diameter and density and by the viscosity of the water. Falling under the action of gravity, a particle will reach a constant, terminal velocity once the drag equals the submerged weight of the particle. The relation for terminal fall velocity for a spherical particle in quiescent fluid  $v_s$  can be presented as

$$R_f = \left[ \frac{4}{3} \frac{1}{C_D (R_p)} \right]^{1/2} \quad (2-46a)$$

where

$$R_f = \frac{v_s}{\sqrt{gRD}} \quad (2-46b)$$

$$R_p = \frac{v_s D}{\nu} \quad (2-46c)$$

and the functional relation  $C_D = f(R_p)$  denotes the drag coefficient for spheres (García 1999). Here  $g$  is the acceleration of gravity,  $R = (\rho_s - \rho)/\rho$  is the submerged specific gravity of the sediment, and  $\nu$  is the kinematic viscosity of water. This relation is not very useful because it is not explicit in  $v_s$ ; one must compute fall velocity by trial and error. One can use the following equation for the drag coefficient  $C_D$

$$C_D = \frac{24}{R_p} \left( 1 + 0.152 R_p^{1/2} + 0.0151 R_p \right) \quad (2-46d)$$

and the definition

$$R_{ep} = \frac{\sqrt{gRD} D}{\nu} \quad (2-46e)$$

to obtain an explicit relation for fall velocity in the form of  $R_f$  versus  $R_{ep}$ . Such a diagram is presented in Fig. 2-11, where

the ranges for silt, sand, and gravel are plotted for a kinematic viscosity  $\nu = 0.01 \text{ cm}^2/\text{s}$  (clear water at 20°C) and a submerged specific gravity  $R = 1.65$  (quartz). An equivalent diagram to estimate fall velocity of particles was proposed earlier by Parker (1978).

Notice that for fine silts,  $R_p$  is smaller than one and the drag coefficient given by Eq. (2-46d) reduces to

$$C_D = \frac{24}{R_p} \quad (2-46f)$$

Substitution of (2-46f) into (2-46a) yields the well-known Stokes law for settling velocity of fine particles,

$$v_s = \frac{gRD^2}{18\nu} \quad (2-46g)$$

A useful empirical relation to estimate the kinematic viscosity of clear water is:

$$\nu = \frac{1.79 \cdot 10^{-6}}{1 + 0.03368T + 0.00021T^2} (\text{m}^2/\text{s}) \quad (2-46h)$$

where

$T$  = temperature of the water in degrees centigrade (°C).

A number of relations for terminal fall velocity for the case of nonspherical (natural) particles can be found in the literature. Dietrich (1982) analyzed fall velocity data for natural particles and used dimensional analysis to obtain the useful fit

$$R_f = \exp \left\{ -b_1 + b_2 \ln(R_{ep}) - b_3 [\ln(R_{ep})]^2 - b_4 [\ln(R_{ep})]^3 + b_5 [\ln(R_{ep})]^4 \right\} \quad (2-47a)$$

where

$$\begin{aligned} b_1 &= 2.891394, b_2 = 0.95296, b_3 = 0.056835, \\ b_4 &= 0.002892, b_5 = 0.000245 \end{aligned} \quad (2-47b)$$

In an attempt to obtain a more practical relation, Jimenez and Madsen (2003) fitted the formula of Dietrich (1982) to the expression

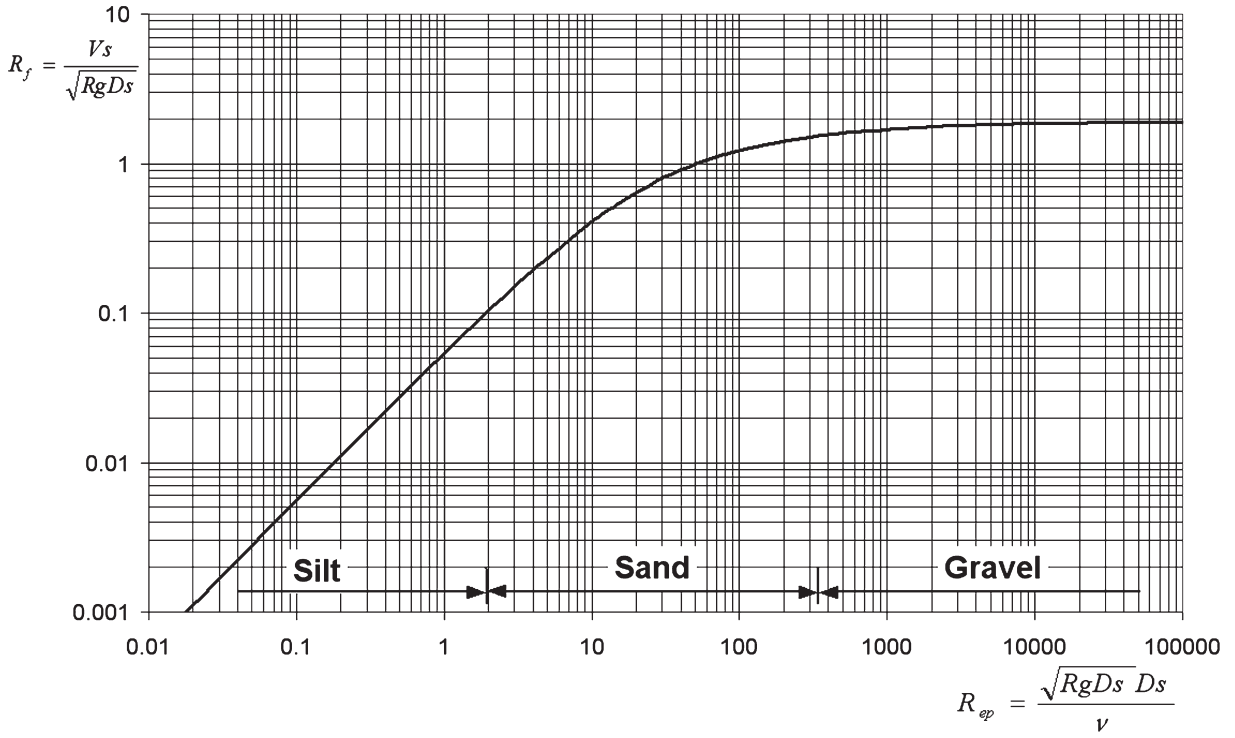

Fig. 2-11. Diagram of  $R_f$  versus  $R_{ep}$  calculated from the drag coefficient for spheres.

$$W_* = \frac{v_s}{\sqrt{g R D_N}} = \left( A + \frac{B}{S_*} \right)^{-1} \quad (2-48a)$$

$$v_s = \frac{\nu}{D} \left[ (10.36^2 + 1.049 D_*^3)^{1/2} - 10.36 \right] \quad (2-49a)$$

in which

$$S_* = \frac{D_N}{4\nu} \sqrt{g R D_N} \quad (2-48b)$$

where

$$D_* = \left[ \frac{g R}{\nu^2} \right]^{1/3} D \quad (2-49b)$$

Here

$g$  = acceleration of gravity;  
 $\nu$  = kinematic viscosity of water;  
 $D$  = mean sieve diameter of grains; and  
 $R = (\rho_s - \rho)/\rho$  is the submerged specific gravity of the grains.

Equations very similar to (2-49a) have been proposed independently by Zanke (1977) and van Rijn (1984).

At high concentrations the flows around adjacent settling grains interact resulting in a larger drag than for the same grain in isolation. This phenomenon is known as hindered settling and results in the hindered settling velocity  $v_{sC}$  for high sediment concentrations to be smaller than the fall velocity  $v_s$  at low sediment concentrations (less than 0.05). Applying reasoning similar to the one that led to Eq. (2-49a),

Here,  $D_N$  = nominal particle diameter. The coefficients  $A$  and  $B$  in Eq. (2-48a) are functions of Corey shape factor and particle roundness and are expressed graphically by Jimenez and Madsen (2003). In many practical applications, the sediment is naturally worn quartz sands characterized by their sieve diameter  $D_s$ . For this typical application,  $D_N = D_s/0.9$ ,  $A = 0.954$  and  $B = 5.12$ , are recommended. With these values incorporated in to it, Eq. (2-48a) was found to provide reliable predictions of fall velocity for natural quartz sediment with sieving diameters ranging from 0.063 mm up to 2 mm (Jimenez and Madsen 2003).

Another simple relation to estimate the fall velocity of natural sand particles has been proposed by Soulsby (1997) for use in the marine environment,

Soulsby (1997) proposed the following relation for the hindered fall velocity  $v_{sc}$  of grains in a dense suspension having a volumetric sediment concentration  $C$ :

$$v_{sc} = \frac{v}{D} \left[ (10.36^2 + 1.049(1-C)^{4.7} D_*^3)^{1/2} - 10.36 \right] \quad (2-49c)$$

which is valid for all values of  $D_*$  and  $C$ . When  $C = 0$ , Eq. (2-49c) reduces to Eq. (2-49a).

The subject of sediment fall velocity is far from being resolved. However, the empirical fits presented here should suffice for engineering purposes. Other useful relations to estimate sediment fall velocity can be found in Swamee and Ojha (1991), Cheng (1997), Ahrens (2000), and Ahrens (2003). Recently, Wu and Wang (2006) compared different formulations and developed another empirical fit to estimate fall velocity which accounts for the effect of particle shape through the Corey shape factor ( $SF = c/\sqrt{ab}$ ).

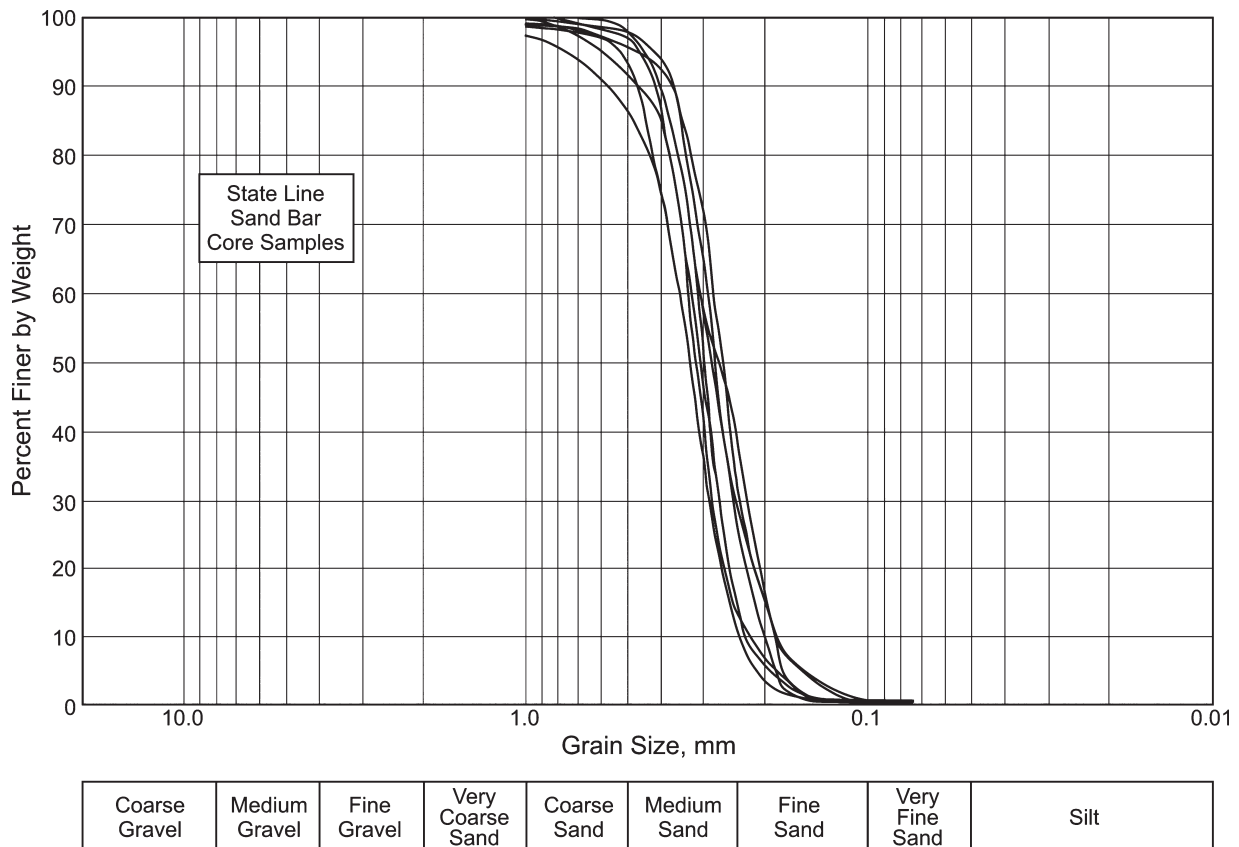

Material on particle settling for the case of fine-grained cohesive sediment is presented in Chapter 4.

### 2.3.9 Relation between Size Distribution and Stream Morphology

The study of sediment properties, and in particular size distribution, is most relevant in the context of stream morphology. The material that follows is intended to point out some of the more interesting issues, and in particular, morphological differences between sand-bed and gravel-bed streams. More discussion on the subject can be found in Chapters 3 and 6.

In Fig. 2-12, several size distributions from the sand-bed Kankakee River, Illinois, are shown (Bhowmik et al. 1980). The characteristic S-shape suggests that these distributions might be approximated by a Gaussian curve. The median size  $D_{50}$  falls near 0.3–0.4 mm. The distributions are very tight with a near-absence of either gravel or silt. For practical purposes, the material can be approximated as uniform.

In Fig. 2-13, several size distributions pertaining to the gravel-bed Oak Creek, Oregon, are shown (Milhous 1973). In gravel-bed streams, the surface layer (“armor” or “pavement”) tends to be coarser than the substrate (identified as “subpavement” in the figure). Whether the surface or substrate is

**Fig. 2-12.** Particle size distributions of bed materials in Kankakee River, Illinois (after Bhowmik et al. 1980).

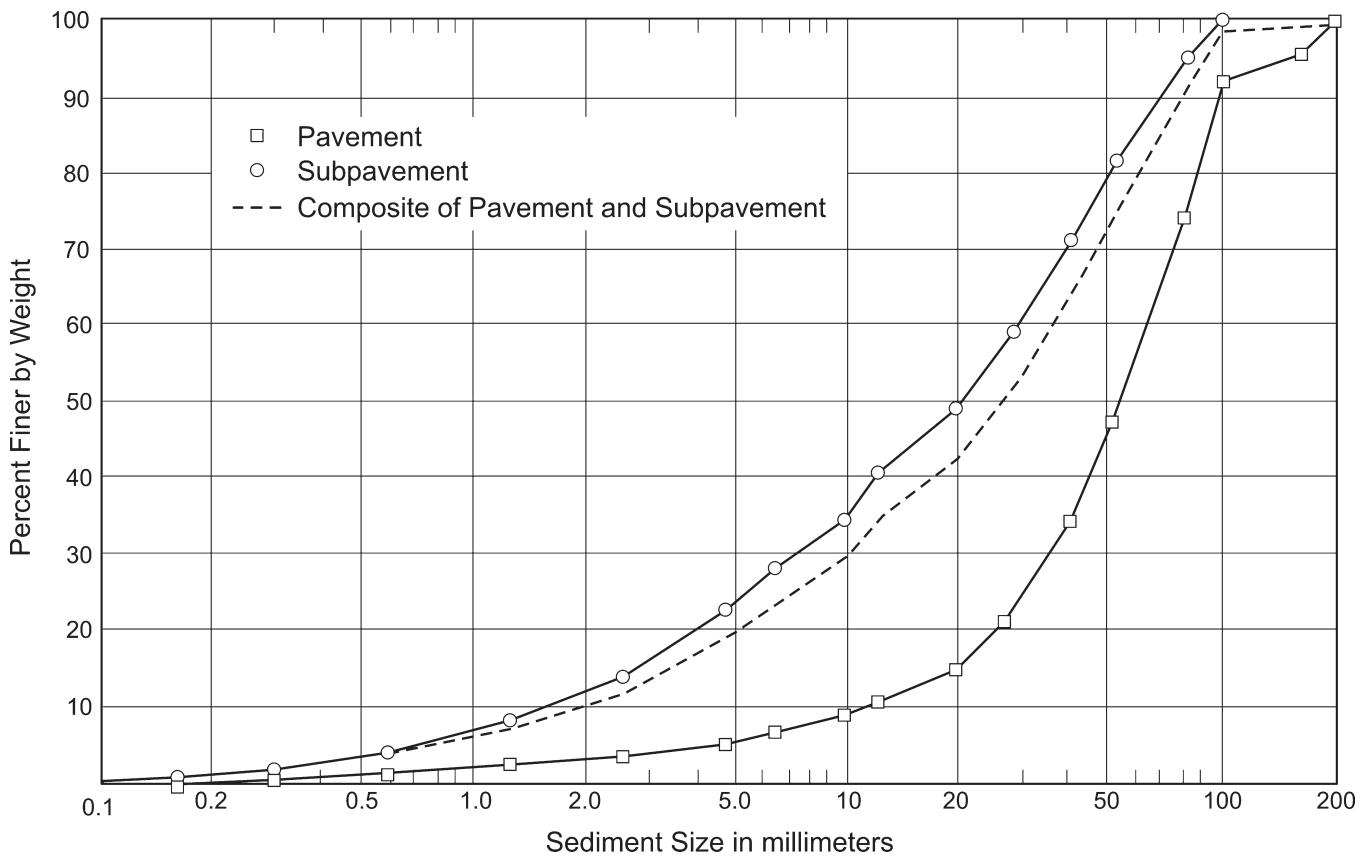

Fig. 2-13. Size distribution of bed material samples in Oak Creek, Oregon (after Milhous 1973).

considered, it is apparent that the distribution ranges over a much wider range of grain sizes than in the case of Fig. 2-12. More specifically, in the distributions of the sand-bed Kankakee River,  $\Phi$  varies from about 0 to about 3, whereas in Oak Creek,  $\Phi$  varies from about -8 to about 3. In addition, the distribution of Fig. 2-13 is upward concave almost everywhere, and thus deviates strongly from the Gaussian distribution.

These two examples provide a window toward generalization. A river may loosely be classified as sand-bed or gravel-bed according to whether the median size  $D_{50}$  of the surface material or substrate is less or greater than 2 mm. The size distributions of sand-bed streams tend to be relatively narrow and also tend to be S-shaped. The size distributions of gravel-bed streams tend to be much broader and to display an upward-concave shape. There are, of course, many exceptions to this behavior, but it is sufficiently general to warrant emphasis.

More evidence for this behavior is provided in Fig. 2.14. Here, the grain size distributions for a variety of stream reaches have been normalized using the median sediment size  $D_{50}$ . Four sand-bed reaches are included with three

gravel-bed reaches. All of the sand-bed distributions are S-shaped, and all have a lower spread than the gravel-bed distributions. The figure indicates that the standard deviation of the grain size distribution can be expected to increase systematically with increasing sediment size (White et al. 1973). The three gravel-bed size distributions differ systematically from the sand-bed distributions in a fashion that accurately reflects Oak Creek (Fig. 2-13). The standard deviation is, in all cases, markedly larger than for any of the sand-bed distributions, and the distributions are upward concave except perhaps near the coarsest sizes.

## 2.4 THRESHOLD CONDITION FOR SEDIMENT MOVEMENT

In this section the threshold conditions for initiation of motion are analyzed. A mechanistic model for initiation of motion is presented. The Shields diagram and other methods for assessing initiation of motion are introduced. The analysis is limited to noncohesive granular sediments such as silt, sand and gravel.

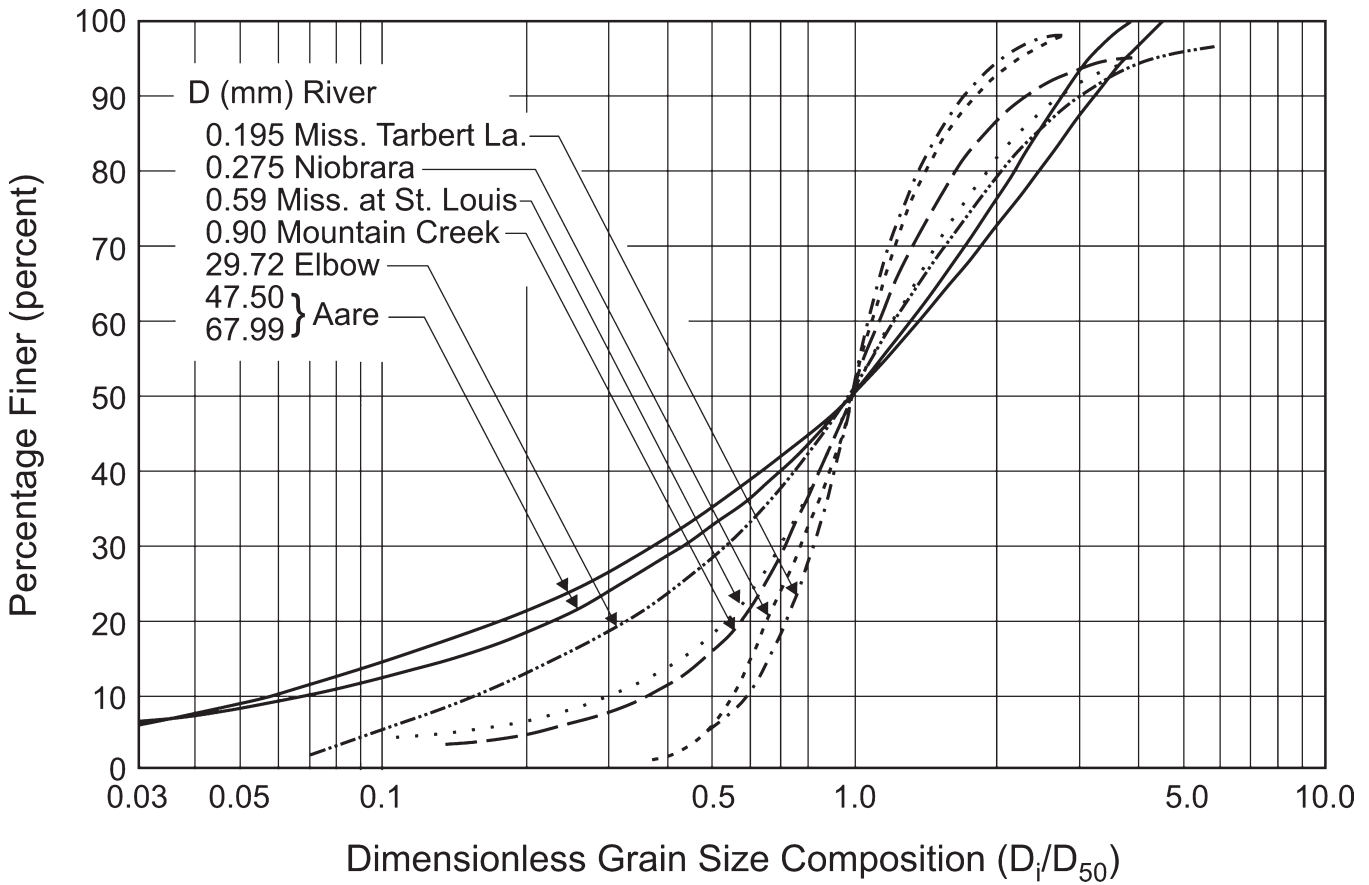

Fig. 2-14. Dimensionless grain-size distribution for different rivers (after White et al. 1973).

### 2.4.1 Submerged Angle of Repose

If granular particles are allowed to pile up while submerged in a fluid, there is a specific slope angle  $\phi$  beyond which spontaneous failure of the slope occurs. This angle is termed the angle of repose, or alternatively, the friction angle. To study this in more detail, consider a typical grain resting on the surface of such a slope as shown in Fig. 2-15.

The coefficient of Coulomb friction is defined to be  $\mu$ , where

$$\mu = \frac{\text{tangential resistive force}}{\text{downward normal force}} \quad (2-50a)$$

The forces acting on the particle along the slope are the submerged force of gravity (gravitational force minus buoyancy force), which has a downslope component  $F_{gt}$  and a normal component  $F_{gn}$ , and a tangential resistive force  $F_r$  due to Coulomb friction. These are given by

$$F_{gt} = (\rho_s - \rho)gV_p \sin\phi \quad (2-50b)$$

$$F_{gn} = (\rho_s - \rho)gV_p \cos\phi \quad (2-50c)$$

$$F_r = \mu F_{gn} \quad (2-50d)$$

The condition for incipient motion is given by

$$F_{gt} = F_r \quad (2-50e)$$

That is, the downslope impelling force of gravity should just balance with the Coulomb resistive force. From the above four relations, it is found that

$$\mu = \tan\phi \quad (2-50f)$$

The angle of repose is an empirical quantity. Tests with well-sorted material indicate that  $\phi$  is near  $30^\circ$  for sand, gradually increasing to  $40^\circ$  for gravel. Poorly sorted, angular material tends to interlock, giving greater resistance to failure, and as a result, a higher friction angle  $\phi$ . Such material is thus often chosen for riprap (see Appendix B).

Friction angle measurements obtained in gravel-bed streams, including implications for critical shear stress estimations, can be found in Kirchner et al. (1990) and Buffington et al. (1992).

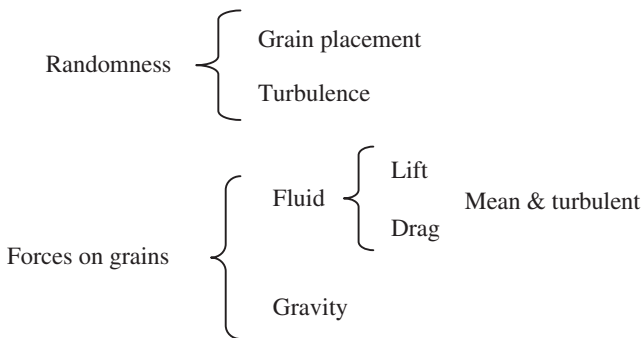

Fig. 2-15. Definition diagram for angle of repose.

#### 2.4.2 Critical Stress for Flow over a Granular Bed

When a granular bed is subjected to a turbulent flow, it is found that virtually no motion of the grains is observed at some flows, but that the bed is noticeably mobilized at other flows (Cheng and Chiew 1998; Papanicolau et al. 2002; Niño et al. 2003). Literature reviews on incipient motion can be found in Miller et al. (1977); Lavelle and Mofjeld (1987); and Buffington and Montgomery (1997).

Factors that affect the mobility of grains subjected to a flow are summarized as follows,

In the presence of turbulent flow, random fluctuations typically prevent the clear definition of a critical or threshold condition for motion: the probability of grain movement is never precisely zero (Paintal 1971; Graf and Paziz 1977; Lopez and García 2001; Zanke 2003). It is, nevertheless, possible to define a condition below which movement can be neglected for many practical purposes.

The following analysis is a slightly generalized version of the derivation of the full Shields curve for the threshold

of motion presented by Ikeda (1982), which is based on the work of Iwagaki (1956) and Coleman (1967). A similar analysis was presented by Wiberg and Smith (1987) for the case of nonuniform sediment size. Consider the granular bed of Fig. 2-16. The flow forces on a dangerously placed spherical sediment particle protruding upward from the mean bed are considered in order to analyze the threshold of motion.

Certain assumptions enter into the Ikeda-Coleman-Iwagaki analysis. The flow is taken to follow the logarithmic law near the boundary (Eq. 2-4). The origin of the  $z$ -coordinate for evaluating the logarithmic law is taken to be the base of the dangerously exposed particle. Turbulent forces on the particle are neglected. Drag and lift forces act through the particle center (in general, they do not, giving rise to torque as well as forces). The value of the drag coefficient  $c_D$  can be approximated by the free-stream value (Coleman 1967). The coordinate  $z$  is taken to be vertically upward, corresponding to very low streamwise slopes  $S$ . The roughness height  $k_s$  is equated to the particle diameter  $D$ .

Fig. 2-16. Forces acting on a "dangerously" placed particle.

It is seen from the above assumptions that the particle center is located at  $z = D/2$ . It is necessary to use some information about turbulent boundary layers to define the effective fluid velocity  $u_f$  acting on the particle in order to facilitate computation of the fluid forces. A viscous sublayer exists (see Eq. 2-6) when  $D/\delta_v$  is less than about 0.5, or  $(u_*D/\nu) < 5$ . In this case, the effective fluid velocity  $u_f$  acting on the particle is estimated with Eq. (2-5) as

$$\frac{u_f}{u_*} = \frac{1}{2} \frac{u_* D}{\nu} \quad (2-51a)$$

On the other hand, if  $D/\delta_v > 2$ , no viscous sublayer exists, and the logarithmic law applies near (but not at) the bed. So the flow velocity acting on the particle can be estimated by

$$\frac{u_f}{u_*} = 2.5 \ln \left( 30 \frac{z}{D} \right) \Big|_{z=\frac{1}{2}D} = 6.77 \quad (2-51b)$$

It follows then that Eqs. (2-51a) and (2-51b) can be written in the more general form

$$\frac{u_f}{u_*} = F \left( \frac{u_* D}{\nu} \right) \quad (2-51c)$$

where

$$F = \frac{1}{2} \frac{u_* D}{\nu} \text{ for } \frac{u_* D}{\nu} < 13.5 \quad (2-51d)$$

and

$$F = 6.77 \text{ for } \frac{u_* D}{\nu} > 13.5 \quad (2-51e)$$

However, it would be more convenient to have a continuous function  $F$ , so that the transition between hydraulically smooth and fully rough condition, is smooth. The fit proposed by Swamee (1993) can be used to evaluate  $F$  in Eq. (2-51c) by setting  $z=D/2$  and  $k_s = D$  in Eq. (2-10),

$$F = \left\{ \left( \frac{2\nu}{u_* D} \right)^{10/3} + \left[ \kappa^{-1} \ln \left( 1 + \frac{\frac{9}{2} \frac{u_* D}{\nu}}{1 + 0.3 \frac{u_* D}{\nu}} \right) \right]^{-10/3} \right\}^{-0.3} \quad (2-51f)$$

Now the forces acting on the particle can be considered. The streamwise fluid drag force  $D_f$ , upward normal (vertical in this case) fluid lift force  $L_f$ , and downward vertical submerged gravitational force  $F_g$  acting on the particle of the previous figure are thus

$$D_f = \rho \frac{1}{2} \pi \left( \frac{D}{2} \right)^2 c_D u_f^2 \quad (2-52a)$$

$$L_f = \rho \frac{1}{2} \pi \left( \frac{D}{2} \right)^2 c_L u_f^2 \quad (2-52b)$$

$$F_g = \rho R g \frac{4}{3} \pi \left( \frac{D}{2} \right)^3 \quad (2-52c)$$

From Eq. (2-50d), it is seen that the Coulomb resistive force  $F_r$  is given by

$$F_r = \mu (F_g - L_f) \quad (2-52d)$$

The critical condition for incipient motion of the particle is that the impelling drag force is just balanced by the resistive Coulomb frictional force:

$$D_f = F_r \quad (2-53)$$

That is, if  $D_f < F_r$ , the particle will not move, and if  $D_f > F_r$ , it will move. Between Eqs. (2-52a), (2-52b), (2-52c), (2-52d), and (2-53), the following relation is obtained for critical fluid velocity  $u_f$  at  $z = D/2$ :

$$\frac{u_f^2}{R g D} = \frac{4}{3} \frac{\mu}{c_D + \mu c_L} \quad (2-54)$$

This relation is now converted to a relation in terms of boundary shear stress. It may be recalled that by definition  $\rho u_*^2 = \tau_b$ , where  $\tau_b$  denotes the boundary shear stress. In this case, the shear stress in question is the critical one for the onset of motion and is denoted by  $\tau_{bc}$ . Between Eqs. (2-51c) and (2-54), the Ikeda-Coleman-Iwagaki relation is obtained for the critical shear stress:

$$\tau_c^* = \frac{4}{3} \frac{\mu}{(c_D + \mu c_L)} \frac{1}{F^2 (u_{*c} D / \nu)} \quad (2-55a)$$

The equation is valid for nearly horizontal beds but the effect of channel slope can be readily incorporated. For a channel with a downstream slope angle  $\alpha$ , the downslope

effect of gravity has to be included in the force balance presented earlier, resulting in the following expression for the critical shear stress

$$\tau_c^* = \frac{4}{3} \frac{(\mu \cos \alpha - \sin \alpha)}{(c_D + \mu c_L)} \frac{1}{F^2(u_{*c} D / \nu)} \quad (2-55b)$$

Notice that for  $\alpha = 0$ , Eq. (2-55b) reduces to Eq. (2-55a).

A predecessor of all these equations was advanced by Egiazaroff (1965). It can be found in Vanoni (2006, p. 58) and is used for sediment mixtures in Chapter 3. Similar relations were also obtained by Fredsøe and Deigaard (1992, p. 203) and can also be found, albeit without derivation, in Chien and Wan (1999, p. 319).

In the above relation,  $\tau_c^*$  is a dimensionless measure of boundary shear stress known as the Shields parameter and given by the definition

$$\tau_c^* = \frac{\tau_{bc}}{\rho g R D} \quad (2-56)$$

where

- $\tau_{bc} = \rho u_{*c}^2$  = critical bed shear stress for initiation of motion;
- $u_{*c}$  = critical shear velocity;
- $\rho$  = water density;
- $R = (\rho_s - \rho)/\rho$  is the submerged specific gravity of the sediment;
- $g$  = acceleration of gravity; and
- $D$  = sediment particle diameter.

The most relevant fact about the mechanistic approach to this problem of initiation of motion relates to the possibility of obtaining an explicit formulation of the relation explored by Shields with dimensional analysis and experiments. Eq. (2-55a) can be evaluated with the aid of Eq. (2-51f) and certain realistic assumptions about the internal angle of friction  $\phi$ , and the drag  $c_D$  and lift  $c_L$  coefficients. As an example, two internal friction angles are considered,  $\phi = 40^\circ$  ( $\mu = 0.84$ ) and  $\phi = 60^\circ$  ( $\mu = 1.73$ ), and the following assumptions are made:  $k_s = 2D$ , and  $c_L = 0.85 c_D$ . It is furthermore assumed that  $c_D$  is given as a function of  $u_* D / \nu$  according to the standard drag curve for spheres (i.e., Eq. 2-46d). A plot of Eq. (2-55a) is shown in Fig. 2-17, together with the data of Shields (1936). Considering all the assumptions made for developing the theoretical model, the agreement is quite reasonable. The best agreement between the Ikeda-Coleman-Iwagaki model and Shields observations is found for  $\phi = 60^\circ$  ( $\mu = 1.73$ ). Such friction angle is rather high but is not possible to know the exact value of this parameter for the sediment used by Shields in his experiments, and whether or not incipient transport conditions were present

**Fig. 2-17.** Comparison of Ikeda-Coleman-Iwagaki model for initiation of motion with Shields data.

(Buffington 1999). The theoretical model developed here is for idealized spherical particles for which the friction angle can be expected to be lower than for natural sediments. For the case of  $\phi = 40^\circ$  ( $\mu = 0.84$ ), the curve predicted with Eq. (2-55a), follows the trend of Shields data but predicts values of critical shear stress that are smaller by a factor of about 1.6. It is interesting that several researchers have found that Shields critical shear stress values are indeed higher than those observed. More discussion on the internal friction angle is given below when the model of Wiberg and Smith (1987) is presented.

Although there are a number of assumptions made in its derivation, the mechanistic Ikeda-Coleman-Iwagaki model (Eq. 2-55a) makes it possible to visualize the sources of uncertainty (i.e., angle of repose, drag and lift coefficients, particle location, etc.) and helps to understand why it is so difficult to characterize the threshold condition with a deterministic model (e.g., Bettess 1984; Lavelle and Mojfeld 1987; Komar 1996; Papanicolaou et al. 2001; Shvidchenko and Pender 2001; Niño et al. 2001; Dancey et al. 2002). Recently the role played by turbulence on initiation of motion has been examined by Zanke (2003), who found that turbulence-induced fluctuations in the lift force make particles “lighter” and easier to move.

### 2.4.3 Shields Diagram

Shields (1936) conducted his set of pioneering experiments to elucidate the conditions for which sediment grains would be at the verge of moving. While doing this, Shields introduced the fundamental concepts of similarity and dimensional analysis and made a set of observations that have become legendary in the field of sediment transport (Kennedy 1995). Shields deduced from dimensional analysis and fluid mechanics considerations that  $\tau_c^*$  should be a function of shear Reynolds number  $u_{*c} D / \nu$ , as implied by Eq. (2-55a). The Shields diagram is expressed by dimensionless

combinations of critical shear stress  $\tau_{bc}$ , sediment and water specific weights  $\gamma_s$  and  $\gamma$ , respectively, sediment size  $D$ , critical shear velocity  $u_{*c} = \sqrt{\tau_{bc}/\rho}$ , and kinematic viscosity of water  $\nu$ . These quantities can be expressed in any consistent set of units. The Shields dimensionless parameters are related by a simple expression,

$$\tau_c^* = \frac{\tau_{bc}}{\rho g R D} = F_* \left( \frac{u_{*c} D}{\nu} \right) \quad (2-57)$$

The Shields diagram shown in Fig. 2-18 was originally prepared by Vanoni (1964). This diagram is the predecessor of the one that finally appeared when Manual 54 was first published in 1975 (Vanoni 2006, p. 57). A modern account of the Shields diagram and its history can be found in Kennedy (1995). Critical Shields values  $\tau_c^*$  are commonly used to denote conditions under which bed sediment particles are stable but on the verge of being entrained. The curve in the Shields diagram was originally introduced by Rouse (1939), whereas the auxiliary scale was proposed by Vanoni (1964) to facilitate the determination of the critical shear stress  $\tau_{bc}$  once the submerged specific gravity, the particle diameter  $D$  and the kinematic viscosity of water  $\nu$  are specified. It is known that the values obtained from the Shields diagram (Fig. 2-18) for initiation of motion are indeed larger than those observed by other researchers, in particular for coarse material. For example, Neill (1968) gives  $\tau_c^* = 0.03$  instead of 0.06 for the dimension-

less critical shear stress for values of  $Re_* = u_* D/\nu$  in excess of 500, while Gessler (1971) suggests using a value of  $\tau_c^* = 0.046$  for such condition.

The value of  $\tau_c^*$  to be used in design depends on the particular case at hand. If the situation is such that grains that are moved can be replaced by others moving from upstream, some motion can be tolerated, and the values from the Shields curve may be used. On the other hand, if grains removed cannot be replaced as on a stream bank, the Shields value of  $\tau_c^*$  are too large and should be reduced. As already mentioned it is well known from observations by Neill and Yalin (1969) and Gessler (1970) that Shields original values for initiation of motion of coarse material are too high and should be divided by a factor of 2 for engineering purposes.

As first noticed by Vanoni (1964), the Shields diagram is not practical in the form of Fig. 2-18, because in order to find the critical shear stress for incipient motion  $\tau_{bc}$ , one must know the critical shear velocity  $u_{*c} = \sqrt{\tau_{bc}/\rho}$ . The relation can be cast in explicit form by plotting  $\tau_c^*$  versus  $Re_{ep}$ , noting the internal relation

$$\frac{u_* D}{\nu} = \frac{u_*}{\sqrt{g R D}} \frac{\sqrt{g R D} D}{\nu} = (\tau^*)^{1/2} R_{ep} \quad (2-58)$$

where  $R = \frac{\rho_s - \rho}{\rho}$  is the submerged specific gravity of the sediment.

Fig. 2.18. Shields diagram for initiation of motion (source Vanoni, 1964).

Brownlie (1981) used this relation to convert the original Shields diagram into one with  $\tau_c^*$  versus  $R_{ep}$ . Similar diagrams using  $D^*$  (see Eq. 2-49b) instead of  $R_{ep}$  have been advanced among others by Bonnefille (1963), Smith (1977), van Rijn (1984a), García and Maza (1997), and Soulsby and Whitehouse (1997). A useful fit to the Shields data was proposed by Brownlie (1981, p.161):

$$\tau_c^* = 0.22 R_{ep}^{-0.6} + 0.06 \exp(-17.77 R_{ep}^{-0.6}) \quad (2-59a)$$

With this relation, the value of  $\tau_c^*$  can be readily computed when the properties of the water and the sediment are given. As already mentioned, to be on the safe side the values given by Eq. (2-59a) should be divided by 2 for engineering purposes, resulting in the following expression

$$\tau_c^* = \frac{1}{2} \left[ 0.22 R_{ep}^{-0.6} + 0.06 \exp(-17.77 R_{ep}^{-0.6}) \right] \quad (2-59b)$$

This equation is plotted in the modified Shields diagram shown in Fig. 2-19, where the size ranges for silt, sand and gravel are also shown.

For fine-grained sediments (silt and finer), the Shields diagram does not provide realistic results. Mantz (1977)

conducted a series of experiments and observed that for fine-grained, noncohesive sediments the critical shear stresses can be estimated with the following relation

$$\tau_c^* = 0.135 R_{ep}^{-0.261} \quad (2-59c)$$

which is valid for the range  $0.056 < R_{ep} < 3.16$ . Equations (2-59a) and (2-59c) merge for  $R_{ep} = 4.22$ .

Lavelle and Mofjeld (1987) used the pioneering bed-stability observations made by Grass (1970) to question the existence of a deterministic value of critical stress for incipient motion as foreseen by Shields and to promote a probabilistic approach to address threshold conditions for initiation of motion and entrainment into suspension. Along the same line of thought, Lopez and García (2001) have proposed a risk-based approach showing that the Shields diagram can be interpreted in a probabilistic way. At the same time, there is also evidence that the Shields diagram is quite useful for field application. For instance, Fisher et al. (1983) experimentally investigated incipient motion of organic detritus and inorganic sediment particles on sand and gravel beds and found that their observations followed the characteristics of the Shields diagram. Recently, Marsh et al (2004) tested the Shields approach together with three other methods available in the literature and showed that it is still one of the best methods available for sand-bed streams. More

Fig. 2-19. Modified Shields diagram (after Parker 2005).

recently, Sarmiento and Falcon (2006) introduced the novel idea of using spatially-averaged (over many particles) shear stresses to define incipient conditions for particle motion at low transport rates.

Buffington (1999) thoroughly reanalyzed Shields' work, pointing out some inconsistencies in the way Shields observations had been interpreted and used by others. This motivated a discussion that analyzed the universality of the Shields diagram in the context of sand- and gravel-bed rivers (García 2000), resulting in the river sedimentation diagram presented below (Fig. 2-29).

**2.4.3.1 Application to Riprap Sizing and Flow Competence** It is worthwhile to show how knowledge about velocity distribution and initiation of motion can be used for a practical problem. Consider the design of a riprap cap to protect contaminated river-bed sediment against erosion. A geotextile or a filter layer can be used to cover the contaminated river-bed portion and then this layer can be protected with riprap material having a size  $D_{RR}$ . The riprap size has to be determined to ensure the stability of the cap design.

As introduced earlier, the Manning-Strickler relation for flow resistance is

$$(i) \quad \frac{U}{u_*} = 8.1 \left( \frac{H}{k_s} \right)^{1/6}$$

Here

$$(ii) \quad k_s = \alpha_s D_{RR}$$

Typical values for the coefficient  $\alpha_s$  can be found in Table 2-1.

The critical condition for motion of the coarse material making up the riprap can be written as

$$(iii) \quad \tau_c^* = \frac{u_{*c}^2}{R g D_{RR}}$$

Where  $\tau_c^*$  should be between 0.02 and 0.03 depending upon how broadly the bed is covered with riprap (see Fig. 2-19). Combining the above relations yields

$$(iv) \quad \frac{U}{\sqrt{R g D_{RR}}} = 8.1 (\tau_c^*)^{1/2} \alpha_s^{-1/6} \left( \frac{H}{D_{RR}} \right)^{1/6}$$

For example, if  $\tau_c^* = 0.03$  and  $\alpha_s = 2.5$ , this relation reduces to:

$$(v) \quad \frac{U}{\sqrt{R g D_{RR}}} = 1.204 \left( \frac{H}{D_{RR}} \right)^{1/6}$$

This equation is very similar to the many empirical equations that have been determined for riprap design (see

Eq. B.5 in Appendix B). In particular, this relation is very similar to the one proposed by Neill (1968) for initiation of motion of coarse material

$$(vi) \quad \frac{U}{\sqrt{R g D_{RR}}} = 1.204 \left( \frac{H}{D_{RR}} \right)^{1/6}$$

Suppose that the riprap is to be designed to be able to withstand a 10-year flood, at which the mean flow velocity  $U$  is estimated to be 3 m/s and the flow depth  $H$  is estimated to be 2.5 m. Using a submerged specific gravity  $R = 1.65$ , Eq. (v) gives a riprap size  $D_{RR} = 15.2$  cm (6 inches), and Neill's relation yields  $D_{RR} = 9.3$  cm (3.65 inches). A safety factor should be built into the design and if the material is poorly-sorted, the riprap size should be selected so that  $D_{RR} = D_{90}$ . The reader is referred to Appendix B for a full treatment of this topic.

A similar analysis can be used to estimate the flow competence to move coarse river-bed material of a given size. In this case, the question would be what mean flow velocity and depth are needed to move coarse material of a certain size? This is a typical problem when analyzing salmonid spawning gravel streams (e.g., Buffington et al. 2004).

## 2.4.4 Yalin and Karahan Diagram

In a study of temperature effects on initiation of motion, Taylor and Vanoni (1972) reported that small but finite amounts of fine-grained sediment were transported in flows with values of  $\tau_c^*$  well below those given by the Shields curve. They found that as the size of sediment grains decreases, the dimensionless critical shear stress increases more slowly than one would infer by extrapolating the Shields curve. Similar observations were made by Mantz (1977; 1980) but the most conclusive evidence for such behavior was provided by Yalin and Karahan (1979) through carefully conducted experiments.

Yalin and Karahan (1979) compiled a substantial number of data while conducting their own set of experiments with sand sizes ranging from 0.10 to 2.86 mm for both laminar and turbulent flow conditions. In this diagram,  $Y_{cr} = \tau_c^*$  and  $X_{cr} = Re_*$ . They used glycerine in some of the experiments to increase the thickness of the viscous sublayer, thus making it possible to observe initiation of motion under laminar and turbulent flow conditions. As shown in Fig. 2-20, Yalin and Karahan were able to elucidate the nature of transport inception conditions for a wide range of grain Reynolds number  $Re_* = u_{*c} D / \nu$ . For  $Re_* > 70$ , hydraulically rough conditions,  $\tau_c^*$  takes a value of about 0.045. For values of  $Re_* < 10$ , the relation between  $\tau_c^*$  and  $Re_*$  depends on the flow regime, i.e., whether the flow is laminar or turbulent.

Like the original Shields diagram, the Yalin-Karahan diagram can only be used in an iterative way since  $\tau_c^*$  appears

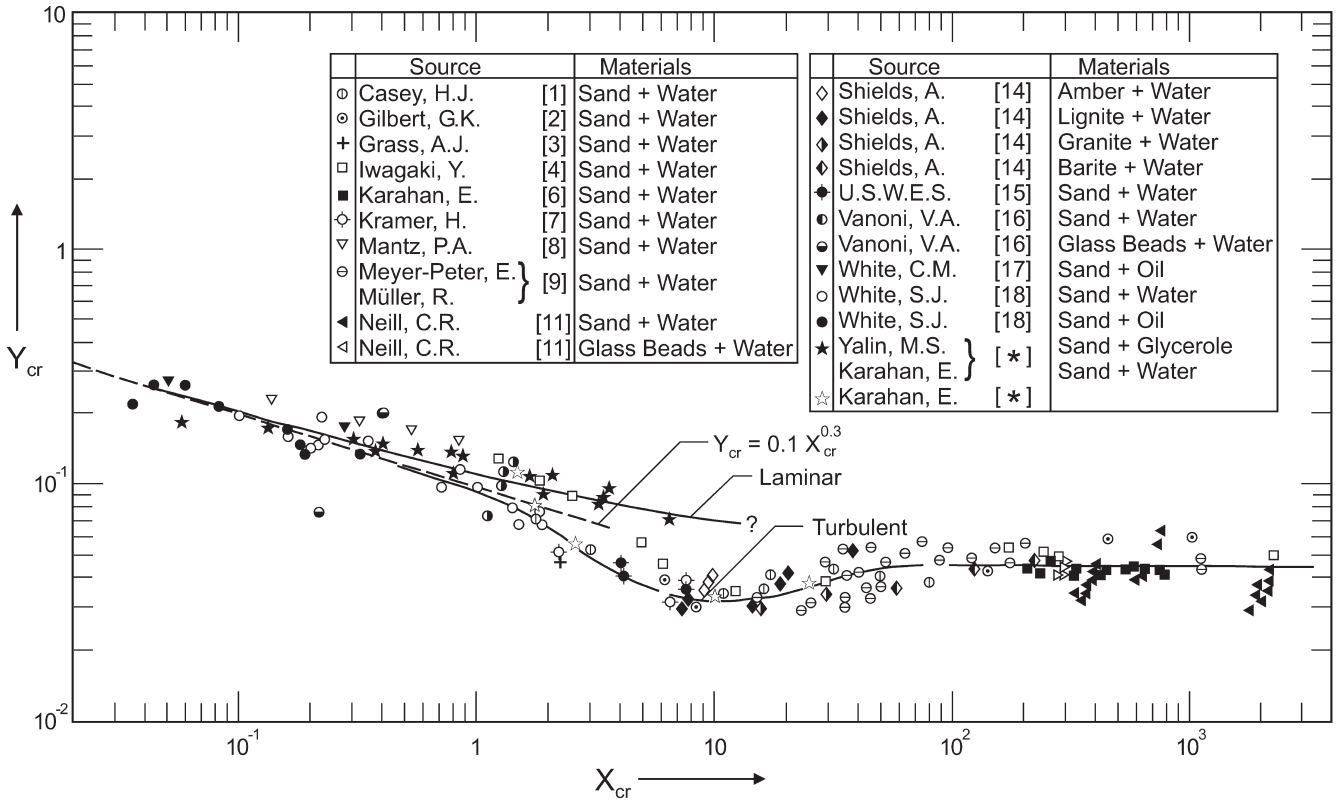

Fig. 2-20. Diagram for Initiation of Motion, Yalin and Karahan (1979).

both in the abscissas and in the ordinates. To obtain an explicit set of curves, a transformation similar to Eq. (2-58) can be introduced, as follows

$$D_{*c} = \left( \frac{Re_{*c}^2}{\tau_{*c}} \right)^{1/3} = D \left( \frac{(\gamma_s - \gamma) g}{\gamma v^2} \right)^{1/3} \quad (2-60)$$

Here  $\gamma$  and  $\gamma_s$  = specific weight of water and sediment, respectively. García and Maza (1997) have proposed the following useful fit to the Yalin-Karahan data:

For turbulent flow conditions,

$$\tau_{*c} = 0.137 D_{*c}^{-0.377}; \quad 0.1074 < D_{*c} < 2.084 \quad (2-61a)$$

$$\tau_{*c}^* = \frac{0.178}{D_{*c}^{0.7303}} + 0.0437 \exp - \left[ \frac{31.954}{D_{*c} + 10} \right]^{2.453} \quad (2-61b)$$

$2.084 < D_{*c} < 47.75$

$$\tau_{*c}^* = 0.045; \quad D_{*c} > 47.75 \quad (2-61c)$$

For laminar flow conditions,

$$\tau_{*c} = \frac{0.1439}{D_{*c}^{0.352}} + 0.0084 \exp - \left[ \frac{5.6243}{D_{*c}} \right]^{9.21}; \quad (2-61d)$$

$0.2164 < D_{*c} < 11.252$

These relations can be used to estimate critical shear stress for a wide range of sediment sizes and flow conditions. Dey (1999) has also proposed a rather simple model for threshold conditions that captures the behavior displayed by the Yalin and Karahan (1979) laboratory observations.

#### 2.4.5 Wiberg and Smith Diagram for Heterogeneous Sediments

Most of the work on initiation of motion has been done for uniform size sediment. One exception is the model advanced by Wiberg and Smith (1987). They derived an expression for the critical shear stress of noncohesive sediment using a balance of forces on individual particles very similar to the one shown previously. For a given grain size and density, the resulting equation depends on the near-bed drag force, lift force to drag force ratio, and particle angle

of repose. They were able to reproduce the observations of Shields for uniform size sediments as well as initiation of motion in the case of sediment mixtures. They found that for mixed grain sizes the initiation of motion also depends on the relative protrusion of the grains into the flows and the particle angle of repose. The relation obtained by Wiberg and Smith (1987) for natural sediment is practically identical to the Ikeda-Coleman-Iwagaki relation (Eq. 2-55b) presented earlier for nearly spherical particles, and can be written as

$$\tau_c^* = \frac{4}{3} \frac{(\tan \phi_0 \cos \alpha - \sin \alpha)}{(c_D + \tan \phi_0 c_L)} \frac{1}{F^2(z/z_o)} \quad (2-62a)$$

where

$\alpha$  = bed slope angle;

$\phi_0$  = angle of repose of the grains;  $c_D$  and  $c_L$  drag and lift coefficients, respectively;

and the function  $F = u(z)/u_*$  is the logarithmic function (i.e. Eq. 2-4) that relates the effective fluid velocity acting on the particle to the shear velocity. Wiberg and Smith (1987) evaluate the logarithmic function with an equation for the velocity distribution first proposed by Reichardt in the early 1950s, which provides a smooth transition between the viscous sublayer and the outer portion of the velocity profile (Schlichting 1979, p. 601). Critical shear velocities computed with Eq. (2-62a) as a function of nominal grain diameter for quartz density sediment are shown in

Fig. 2-21. The agreement with observations made by a number of authors is excellent.

To evaluate the angle of repose  $\phi_0$  of natural particles in mixed-size beds, the observations made by Miller and Byrne (1966) with naturally sorted sediments were used. The following geometric relationship was found to represent the data well,

$$\phi_0 = \cos^{-1} \left[ \frac{D/k_s + z_*}{D/k_s + 1} \right] \quad (2-62b)$$

where  $z_* = -0.02$  is the average level of the bottom of an “almost moving” grain and depends on particle sphericity and roundness. Here  $k_s$  is the equivalent Nikuradse roughness length. Equation (2-62b) was found to represent the data of Miller and Byrne (1966) well for  $D/k_s > 0.5$ . Computed curves for nondimensional critical shear stress for a range of ratios of particle diameter to bed roughness,  $D/k_s = 0.5 - 5.0$ , are shown in Fig. 2-22a. A large ratio of  $D/k_s$  indicates a larger particle on a smaller bed, and vice versa. In this plot, the critical roughness Reynolds number  $(R_*)_{cr} = (u_*)_{cr} k_s / \nu$  is a characteristic of the bed. Thus, for any bed roughness, the intersections of a vertical line through some  $(R_*)_{cr}$  and the  $(\tau_*)_{cr}$  curves for the appropriate  $D/k_s$  values determine the critical shear stress for the sizes of material present in the bed.

Wiberg and Smith (1987) found that their model (i.e., Eqs. (2-62a) and (2-62b)) reproduced such observations. As in the case of the original Shields diagram, Wiberg and

**Fig. 2-21.** Calculated critical shear velocity as a function of grain diameter (after Wiberg and Smith 1987).

(a)

(b)

**Fig. 2-22.** (a) Calculated nondimensional critical shear stress as a function of critical roughness Reynolds number for values of particle diameter to bed roughness scale. (b) Calculated nondimensional critical shear stress as a function of nondimensional particle diameter for values of particle diameter to bed roughness scale ratio (after Wiberg and Smith, 1987).

Smith found it more useful to express the critical shear stress in terms of a parameter that depends only on grain size and density and on fluid density and viscosity. As shown in Fig. 2-22b, the abscissa in the critical shear stress diagram is given by a variable  $K_* = 0.0047(\zeta_*)^{1/3}$  where

$$\zeta_* = \frac{D^3}{v^2} \frac{\rho_s - \rho}{\rho} g = \frac{[(R_*)_{cr} D / k_s]^2}{(\tau_*)_{cr}} \quad (2-62c)$$

In this fashion, iteration is not needed to find the critical shear stress for a particle of diameter  $D$  in a bed with characteristic roughness length  $k_s$ .

A systematic analysis of eight decades of incipient motion studies, with special reference to gravel-bed rivers was conducted by Buffington and Montgomery (1997). Different models available in the literature to estimate entrainment into motion of sediments having mixed grain sizes and densities are reviewed by Komar (1996). The work of James (1990) with spheres and Carling et al (1992) employing regularly shaped particles (rods, cylinders, discs and cubes) illustrates that grain-shape variability and grain orientation are important to entrainment, resulting in a range of stresses for particles that have otherwise the same weight. Bridge and Bennett (1992) have developed a mathematical model for entrainment and transport, which accounts for different grain sizes, shapes and densities. Niño et al (2003) were able to measure the effect of grain-size variability on sediment entrainment into suspension with the help of laboratory experiments. More information about initiation of motion and transport of gravel and sediment mixtures can be found in Chapter 3.

#### 2.4.6 Lischtnan-Lebediev Diagram for Maximum Permissible Flow Velocity

In practice, it is often convenient to estimate the flow velocity necessary for initiation of motion and sediment erosion. A number of researchers have conducted flume experiments to collect data relating grain sizes and densities to flow velocities, discharges and mean stresses needed to initiate particle movement (e.g. Miller et al. 1977). In the early 1920s, Fortier and Scobey first introduced the concept of maximum permissible flow velocity (Chow 1959, p. 165). The maximum permissible flow velocity, or the nonerosible flow, is the greatest mean velocity that will not cause erosion of the channel bed. Lischtnan and Lebediev used observations made in Russian channels (Lebediev 1959) for wide ranges of quartz sediment sizes ( $0.005 \text{ mm} < D < 500 \text{ mm}$ ) and flow depths ( $0.40 \text{ m} < H < 10 \text{ m}$ ) to obtain values of the maximum permissible flow velocity  $U_c$  as a function of the relative flow depth  $H/D$  (Garcia and Maza 1997). The Lischtnan-Lebediev data are plotted in dimensionless form in Fig. 2-23. Two curves have been found to fit the data by García and Maza (1997).

For  $H/D \leq 744.2$

$$\frac{U_c}{\sqrt{RgD}} = 1.630 \left( \frac{H}{D} \right)^{0.1283} \quad (2-63a)$$

For  $H/D > 744.2$

$$\frac{U_c}{\sqrt{RgD}} = 1.453 \left( \frac{H}{D} \right)^{0.3221} \quad (2-63b)$$

An inspection of Fig. 2-23 suggests that Eq. (2-63a) corresponds to flow conditions representative of gravel-bed and cobble-bed streams (i.e., low relative flow depth), while Eq. (2-63b) corresponds conditions commonly found in sand-bed streams (i.e., large relative flow depth). Notice that the general form of these relations is very similar to the one obtained in Section 2.4.3.1. The Lischtnan-Lebediev relations are widely used in Latin America for the design of stable channels and to estimate potential sediment erosion conditions in sand-bed rivers (e.g. Schreider et al. 2001).

#### 2.4.7 Effect of Bed Slope on Incipient Motion

**2.4.7.1 Granular Sediment on a Sloping Bed** The work of Shields and others on initiation of motion applies only to the case of nearly horizontal slopes. Most streams, particularly in mountain areas, have steep gradients, creating a need to account for the effect of the downslope component of gravity on the initiation of motion. In fact, the model of Wiberg and Smith (1987) as given by Eq. (2-62a) does account for the effect of streamwise channel slope.

As shown for the case of negligible longitudinal slope, the effect of the streamwise bed slope on incipient sediment motion can be illustrated by considering the forces (lift, drag, buoyancy, and gravity) acting on a particle lying in a bed consisting of similar particles over which water flows. Such analysis yields the equation (Chiew and Parker 1994)

$$\frac{\tau_{c\alpha}^*}{\tau_{co}^*} = \cos \alpha \left( 1 - \frac{\tan \alpha}{\tan \phi} \right) \quad (2-65a)$$

where

- $\phi$  = angle of repose;
- $\tau_{c\alpha}^*$  = critical shear stress for sediment on a bed with a longitudinal slope angle  $\alpha$ ; and
- $\tau_{co}^*$  = critical shear stress for a bed with very small slope.

The value of  $\tau_{co}^*$  can be found from the Shields diagram with Eq. (2-59), or with Eq. (2-61). Eq. (2-65a) is for positive  $\alpha$ , which applies for downward sloping beds. For beds with adverse slope,  $\alpha$  is negative and the term  $\tan \alpha / \tan \phi$  in

Fig. 2-23. Lischtsvan-Lebediev diagram for maximum permissible flow velocity.

Eq. (2-65a) is positive. In terms of shear velocities the relation takes the form

$$\frac{u_{*c}}{u_{*o}} = \sqrt{\cos \alpha \left( 1 - \frac{\tan \alpha}{\tan \phi} \right)} \quad (2-65b)$$

An expression similar to Eq. (2-65a) was derived by Lysne (1969), who also performed a set of experiments on the effect of the bed slope on the incipient motion of sand in a closed channel. Lysne's results agree very well with the curve given by equation (2-65a) for a value of  $\phi = 47^\circ$ . A similar result was found by Fernandez-Luque and Van Beek (1976), who also fitted a relationship similar to Eq. (2-65a) to their results for the incipient motion of sand, gravel, and magnetite in open channel flow on sloping beds.

Chiew and Parker (1994) conducted a set of laboratory experiments with a closed duct, to test the validity of Eq. (2-65b) for both positive and adverse slopes. The results are plotted in Fig. 2-24. In general, good agreement is observed between the experimental observations and the values predicted with Eq. (2-65b).

Lau and Engel (1999) used dimensional analysis coupled with the observations made by Fernandez-Luque and Van Beek (1976) and Chiew and Parker (1994) to obtain an

equation mathematically equivalent to Eq. (2-65a) of the form

$$\frac{\tau_{c\alpha}^*}{\tau_{co}^*} = \frac{\sin(\phi - \alpha)}{\sin \phi} \quad (2-65c)$$

They found that the condition for inception of motion depends on the slope angle as well as on the Reynolds number of the flow. Their recommendation is that Eq. (2-65c) can be used for slope angles all the way up to the angle of repose together with Shields criteria to estimate  $\tau_{co}^*$ . Whitehouse et al. (2000) tested Eq. (2-65c), finding good agreement with experimental observations. This relation has been rediscovered many times since Armin Schoklitsch introduced it for the first time in the early 1900s.

Several investigators, such as Stevens et al. (1976), Fernandez Luque and van Beek (1976), Howard (1977), Allen (1982), Smart (1984), Dyer (1986), Whitehouse and Hardisty (1988); Chiew and Parker (1994), Iversen and Rasmussen (1994), Dey (1999), and Dey and Debnath (2000), have used relationships similar to either Eq. (2-65a), Eq. (2-65b), Eq. (2-65c) to determine the critical shear stress for sediment lying on a nonhorizontal slopes. Stevens et al. (1976) used such relationship to investigate the factor of safety

**Fig. 2-24.** Effect of streamwise bedslope on critical shear velocity. Curve correspond to Eq. 2.65b (modified from Chiew and Parker 1994).

for riprap protection, whereas Smart (1984) used them to evaluate sediment transport rates in a steep channel. Kostic et al. (2002) used Eq. (2-65a) to study the foreset slope of prograding deltas in lakes and reservoirs. Whitehouse and Hardisty (1988), Graf et al. (2000), and Damgaard et al. (2003) used similar concepts to study the inception of bed load transport on steep slopes. The effect of seepage on initiation of motion has been analyzed by Oldenziel and Brink (1974), Cheng and Chiew (1999), and Dey and Zanke (2004).

**2.4.7.2 Threshold Condition on Side Slopes** The analyses presented above apply strictly to the case of flow on a nearly horizontal or sloping bed in the streamwise direction that is horizontal in the transverse direction (i.e., negligible transverse bed slope). An important problem in engineering applications is the case of sediment particles on a side slope (Simons and Senturk 1992). This problem is of particular relevance to the design of riprap protection and

stable channels in coarse material (see Appendix B). Thus it is worthwhile to present a more detailed analysis.

In the present simplified analysis, the flow velocity profile is again taken to be logarithmic upward normal from the bed. A force balance is done for a particle located on a side slope, as shown in Fig. 2-25. The flow is taken to be in the streamwise direction, parallel to the side slope. The vectorial fluid drag force  $D_f$  acting on a particle is thus given as

$$D_f = \rho \frac{1}{2} \pi \left( \frac{D}{2} \right)^2 c_D u_f^2 \vec{e}_1 \quad (2-66a)$$

The gravitational force  $F_g$  has a transverse as well as a downward normal component:

$$F_g = F_{g2} \vec{e}_2 + F_{g3} \vec{e}_3 \quad (2-66b)$$

where  $\vec{e}_1$ ,  $\vec{e}_2$ , and  $\vec{e}_3$  are unit vectors in the streamwise, transverse, and downward normal to the side directions, respectively.

$$(F_{g2}, F_{g3}) = -\rho Rg \frac{4}{3} \pi \left( \frac{D}{2} \right)^3 (\sin\theta, \cos\theta) \quad (2-66c)$$

and  $\theta$  denotes the local transverse angle of the side slope, as illustrated in Fig. 2-25.

The lift force is given as

$$L_f = \rho \frac{1}{2} \pi \left( \frac{D}{2} \right)^2 c_L u_f^2 \vec{e}_3 \quad (2-67)$$

The Coulomb resistive force acting on a grain has a magnitude given by  $\mu |F_{g3} \vec{e}_3| + L_f$ . As shown in the diagram, under critical conditions, it must precisely balance the vectorial sum of the impelling forces due to flow ( $D_f$ ) and due to the transverse downslope pull of gravity ( $F_{g2} \vec{e}_2$ ).

These conditions on magnitude and direction lead to the following result for threshold conditions:

$$\mu^2 |F_{g3} \vec{e}_3 + L_f|^2 = |D_f|^2 + |F_{g2} \vec{e}_2|^2 \quad (2-68)$$

Substituting Eqs. (2-66a), (2-66b), (2-66c) and (2-67) into Eq. (2-68) and reducing, the following relation is obtained:

$$\begin{aligned} & \left[ \left( \frac{u_f^2}{RgD} \right)^2 + \left( \frac{4}{3c_D} \sin\theta \right)^2 \right]^{1/2} \\ &= \mu \left( \frac{4}{3c_D} \cos\theta - \frac{c_L}{c_D} \frac{u_f^2}{RgD} \right) \end{aligned} \quad (2-69a)$$

Fig. 2-25. Definition diagram for particle located on a side slope.

Further reducing with the aid of Eqs. (2-54) and (2-55), it is found that

$$\begin{aligned} & \left[ \left( \tau_c^* \right)^2 + \left( \frac{4}{3c_D F^2} \sin\theta \right)^2 \right]^{1/2} \\ &= \frac{4\mu}{3c_D F^2} \cos\theta - \mu \frac{c_L}{c_D} \tau_c^* \end{aligned} \quad (2-69b)$$

The case of a transversely horizontal bed is recovered by setting  $\theta = 0$ . The critical Shields stress is found to be given by Eq. (2-55a) for this case. This value is denoted as  $\tau_{co}^*$ , the subscript  $o$  denoting that the bed is horizontal in the transverse direction. Using this value to normalize the value  $\tau_c^*$  obtained on a side slope of angle  $\theta$ , Eq. (2-69b) reduces to

$$\begin{aligned} & \left\{ \left( \frac{\tau_c^*}{\tau_{co}^*} \right)^2 + \left[ \frac{(1 + \mu c_L / c_D)}{\mu} \sin\theta \right]^2 \right\}^{1/2} \\ &= (1 + \mu c_L / c_D) \cos\theta - \mu \frac{c_L}{c_D} \left( \frac{\tau_c^*}{\tau_{co}^*} \right) \end{aligned} \quad (2-69c)$$

Equation (2-69c) is a quadratic polynomial in  $\tau_c^* / \tau_{co}^*$ , and as such is easily solved. A solution is shown in Fig. 2-26, which has been evaluated for the case  $\mu = 0.84$  ( $\phi = 40^\circ$ ) and  $c_L = 0.85c_D$ . It is also assumed that  $c_D$  is given as a function of  $u_f D / \nu$  according to the standard drag curve for spheres (i.e. Eq. 2-46d). As can be seen there, the Shields stress takes the value  $\tau_{co}^*$  on a horizontal bed ( $\theta = 0$ ). It progressively decreases as the side slope angle  $\theta$  increases, reaching a value of 0 at the angle of repose.

Many methods for stable channel design, starting with the classic work of Glover and Florey in the early 1950s, make use of Eq. (2-69c) to design a channel in coarse alluvium that is at the threshold for sediment motion but is stable (e.g., Li et al. 1976; Diplas and Vigilar 1992). Parker (1978) also used this approach to analyze flow in self-formed straight rivers with mobile beds and stable banks. More material on stable movable-bed channels can be found in Chapter 7.

If the lift force is neglected (i.e.,  $c_L = 0$ ), Eq. (2-69c) reduces to the well-known Lane (1955) relation,

$$\frac{\tau_c^*}{\tau_{co}^*} = \cos\theta \sqrt{1 - \left( \frac{\tan\theta}{\tan\phi} \right)^2} \quad (2-70)$$

Equation (2-70) has also been derived for application to coastal sediment transport problems by Fredsøe and Deigaard (1992, p. 204). Whitehouse et al (2000) tested

**Fig. 2-26.** Variation of normalized critical Shields stress for initiation of motion as a function of side slope angle as predicted by Eq. 2.69c.

the values predicted by Eq. (2-70) with the observations made by Ikeda (1982) and found reasonable agreement. Christensen (1972) found out that the critical shear stresses estimated with Eq. (2-70) have a tendency to be too conservative and proposed an alternative method that takes into account the ratio between the bed roughness and the grain size. As this ratio increases, Lane's Eq. (2-70) and Christensen's method give identical results. The method of Wiberg and Smith (1987) presented above also takes into account the effect of the relative roughness  $D/k_s$  on the evaluation of critical shear stress condition for motion. James (1990) has also provided useful information on the effect of such parameter on initiation of motion. Similar approaches, which follow the so-called grain pivoting model, have been suggested by Slingerland (1977) and Komar and Li (1988) among others (Komar, 1996). Bridge and Bennett (1992) have also advanced a model that accounts for bed slope effects on initiation of motion.

**2.4.7.3 Threshold Condition for Motion on an Arbitrarily Sloping Bed** The general case of an arbitrarily sloping bed was first treated analytically by Kovacs and Parker (1994), who developed a vectorial equation for sediment threshold on a combined transverse and longitudinal

sloping bed. Their analysis was extended by Seminara et al. (2002) to include the effect of lift force. While studying coastal sediment transport, Calantoni (2002, p. 77) generalized the analysis of Fredsøe and Deigaard (1992) and obtained a quadratic equation for the threshold condition for motion, similar to Eq. (2-69c), which shows promise for practical use. The positive root of the equation gives an equation that can be used to estimate the critical shear stress for motion of a particle located on a bed surface having a longitudinal (parallel the flow direction) slope angle  $\alpha$  and a transverse (perpendicular to flow direction) slope angle  $\theta$ ,

$$\frac{\tau_c^*}{\tau_{c0}^*} = \cos \alpha \left( \cos \theta \sqrt{1 - \left( \frac{\tan \theta}{\tan \phi} \right)^2} - \frac{\tan \alpha}{\tan \phi} \right) \quad (2-71a)$$

Notice that when  $\alpha = 0$ , Eq. (2-71a) reduces to Eq. (2-70) and when  $\theta = 0$ , Eq. (2-71a) reduces to Eq. (2-65a). Calantoni and Drake (1999) used Eq. (2-71) to develop a discrete-particle model for bed load transport in the surf zone that accounts for variations in bottom slope.

Duan et al. (2001) and Duan and Julien (2005) have used the following formulation for sediment transport modeling in meandering channels,

$$\frac{\tau_c^*}{\tau_{co}^*} = \cos \theta \left[ 1 - \left( \frac{\tan \theta}{\tan \phi} \right)^2 \right]^{1/2} \left( \frac{\sin(\phi - \alpha)}{\sin \phi} \right) \quad (2-71b)$$

Notice that when  $\theta = 0$ , Eq. (2-71b) reduces Eq. (2-65c) which is also equivalent to Eq. (2-65a). When  $\alpha = 0$ , Eq. (2-71b) reduces to Eq. (2-65a). It should be clear that Eqs. (2-71a) and (2-71b) are mathematically equivalent. In the early 1960s, Norman Brooks provided an excellent theoretical analysis of this problem in the context of river bends. It can be found in Vanoni (2006, p.64).

Other efforts to estimate critical shear stress values for sediments on arbitrarily sloping beds include the work of Dey (1999, 2003). More research, including experiments over a wide range of conditions that can be used to test and improve different formulations, is needed on this important topic. Stream channel stability, bank erosion, and meandering channels are topics where the material covered previously plays a crucial role. This will become apparent in Chapter 7, Chapter 8, and in Appendix B “RipRap design.”

## 2.5 SEDIMENT TRANSPORT

Sediment load in this manual refers to the sediment that is in motion in a river. There are two common ways of classifying the sediment load as shown in Table 2-4. The first divides the sediment load according to the mechanism for transport into bed load and suspended load. The second classifies the load based on particle size into wash load and bed sediment load. The suspended load, as the term denotes, moves in suspension and is that part of the load which is not bed load. Wash load is fine sediment moving in suspension which makes up a very small part, usually a few percent, of the sediment on the bed. Wash load is commonly taken as the silt and clay fraction of the bed sediment, i.e., that fraction with grain sizes finer than 0.062 mm. The bed sediment load consists of particles that are coarser than the wash load. The transport rate or discharge of wash load tends not to be correlated with water discharge while discharge of bed sediment, both in suspension and as bed load, is usually correlated with water discharge. The total sediment load is made up of wash load, suspended (bed-material) load and bed load. Methods and technologies for measuring sediment transport are covered in Chapter 5.

In some rivers the different components of the sediment load can be clearly differentiated. This is the case of the Niger River, Nigeria, depicted in Fig. 2-27, where the different components of the sediment load were measured in cubic meters per year by NEDECO (1959). In this particular

**Table 2-4 Sediment Load Classification**

	Classification system	
	Based on mechanism of transport	Based on particle size
Total sediment load		
Wash load	Suspended load	Wash load
Suspended bed-material load	Suspended load	Bed-material load
Bed load	Bed load	Bed-material load

example the wash load is many times larger than the load of bed material transported as suspended and bed load. Notice also that there are two peaks for the wash load associated with sediment grain sizes of about 0.001 mm and 0.025 mm. These might be related to the watershed activities taking place at the time the observations were made.

### 2.5.1 Sediment Transport Modes: Bed-Material Load and Wash Load

The sediment transport processes that can be characterized with fluid and sediment dynamics principles are those of bed load and suspended load. In the former case, the particles roll, slide, or saltate along the bed, never deviating too far above the bed. In the latter case, the fluid turbulence comes into play carrying the particles well up into the water column. In both cases, the driving force for sediment transport is the action of gravity on the fluid phase; this force is transmitted to the particles via drag. While it is possible to quantify the mechanics of bed-material transport as suspended load and bed load, a similar analysis to assess the wash load has proved rather elusive. Before considering bed-material transport in more detail, the wash load will be considered next. Important questions are what is role of sediment in the flow energy balance and how the division between wash load and bed-material load in sand-bed streams can be made?

The floodplains of most sand-bed rivers often contain copious amounts of silt and clay finer than about 0.062 mm. This material is known as wash load because it often moves through the river system in suspension without being present in the bed in significant quantities (Colby 1957). Increased wash load does not cause deposition on the bed, and decreased wash load does not cause erosion, because it is transported at well below capacity. This is not meant to imply that the wash load does not interact with the river system. Wash load in the water column exchanges with the banks and the floodplain rather than the bed. Greatly increased washload, for example, can lead to thickened floodplain deposits with a consequent increase in bank-full channel depth. Soil fertility depends

**Fig. 2-27.** Total Sediment Load in the upper Niger River, Nigeria (adapted from Jansen et al. 1979). Ordinates are in hundreds of thousands of cubic meters per year for each sediment size fraction.

largely on the amount of wash load deposited by floods on a given floodplain over the years. This fact was well known by the Egyptians, who practice agriculture in the floodplains of the Nile River. Also of relevance, is the fact that contaminants such as PCBs and heavy metals are often attached to the fine-grained sediments that constitute the wash load. The wash load is controlled by land surface erosion (rainfall, vegetation, land use) and not by channel-bed erosion. However,

cohesive stream banks can contribute to the wash load during bank full flow events. Mining activities can also contribute substantially to the wash load of river systems, with potential environmental effects on estuarine and coastal areas (e.g., coral reefs). Despite its importance, a physical characterization of the wash load is not an easy task.

By definition, the wash load is not determined by the hydraulic characteristics of a given river reach; hence it can not be computed (Einstein and Chien 1953). At the same time, sediment transport formulae apply only to bed-material transport and do not account for wash load. De Vries (1993) argues that there are at least two reasons why a quantitative distinction between bed-material load and wash load is necessary.

- (i) For comparison of sediment transport predictions with values measured in the field it is necessary to subtract the wash load component.
- (ii) A reduction of the flow velocity in the direction of the current will make a fraction of the wash load become bed-material load (e.g., reservoir sedimentation).

Vlugter (1962) discriminated between *sinking* material and *floating* material. He argued that fine sediment particles (i.e., floating material) being moved downstream in a river add part of their potential energy to the flow and can be transported in suspension indefinitely as long as the flow conditions do not change. On the other hand, coarse grains (i.e., sinking material) require kinetic energy from the mean flow to remain in suspension. Bagnold (1962) arrived to a similar conclusion while studying turbidity currents, and called this condition “autosuspension.” Interestingly, both Vlugter and Bagnold ideas were very similar to those articulated a few years earlier by Knapp (1938) while looking at the energy balance in streams carrying suspended sediment. As pointed out by Jansen et al (1979) in their river engineering book, the energy balance concept underlying the Vlugter and Bagnold arguments has not yet been accepted by everyone (e.g., Parker 1982). In order to better understand some of these ideas it is useful to consider the energy balance in sediment-laden flows.

Consider a steady, uniform sediment-laden open-channel flow in a channel with a bed slope  $S$ , as described in Fig. 2-31. The role of fine sediment in the energy balance can be observed by considering the average rate of work  $P_g$  (i.e., dot product of momentum and velocity) done by gravity on the flow which can be approximated as follows,

$$P_g \cong \underbrace{\rho g S U H}_{(1)} + \underbrace{\rho R g S C U H}_{(2)} - \underbrace{\rho R g H C v_s}_{(3)} \quad (2-72a)$$

In this simplified energy balance relation,  $U$  = mean flow velocity,  $H$  = flow depth,  $C$  = mean volumetric concentration of suspended sediment,  $R = (\rho_s/\rho - 1)$  = submerged

specific gravity of the sediment,  $\rho_s$  = sediment density,  $\rho$  = water density,  $v_s$  = sediment fall velocity, and  $g$  = gravitational acceleration.

The physical significance of the terms in Eq. (2-72a) can be identified as follows:

- (1) Mean rate of energy input to the fluid phase (i.e., water).
- (2) Mean rate of energy input to the mean flow through the solid phase (i.e. sediment).
- (3) Mean rate of energy loss by mean flow through turbulent mixing required for maintaining sediment in suspension.

The main input of energy to the mean flow through the sediment phase can thus be positive or negative, depending on whether or not term (2) is greater than term (3). If term (2) is larger than (3), it means that the suspended sediment contributes energy to the flow. On the other hand, if (3) is larger than (2) it means that the flow is expending energy to keep the sediment in suspension. However for a dilute open-channel suspension ( $C \ll 1$ ), terms (2) and (3) are very small compared to term (1). Thus the flow energetics is to a first approximation independent of sediment concentration. It follows that whether or not term (2) is greater than term (3) has essentially nothing to do with whether the flow has enough energy to sustain itself, since almost all the energy enters through the water via term (1).

In the case of a turbid underflow or turbidity current overlain by clear, still, nonstratified water and flowing down a submarine channel with a slope  $S$  (Fig. 2-59), the situation is drastically changed. Clear water will not flow down a submarine channel or canyon due to gravity in the absence of suspended sediment. An analysis of the equations of motion (see Section 2.11.3) shows that the work done by the hydrostatic pressure gradient of the fluid phase just cancels term (1), so that in fact there is no positive energy input to the fluid phase. In the case of turbidity currents, gravity acts on the solid phase which in turn drags the fluid phase downslope forming an underflow. The net mean energy input through the solid phase  $P_{gs}$  is simply

$$P_{gs} = \rho R g S C U H - \rho R g H C v_s \quad (2-72b)$$

(2)
(3)

Thus the only positive energy input into the turbidity current is via term (2). It follows that term (2) must exceed term (3) for a self-sustaining turbidity current,

$$\rho R g S C U H > \rho R g H C v_s \quad (2-72c)$$

This relation can be reduced to

$$\frac{U S}{v_s} > 1 \quad (2-72d)$$

This is the classical Bagnold criterion for turbidity currents (Bagnold 1962). It ensures that the sediment supplies more energy than it consumes. The Bagnold criterion must be satisfied if a self-sustaining turbidity current is to occur. This is a necessary condition but is not sufficient as described by Parker et al (1986) since the flow has to be capable of entraining sediment into suspension to sustain itself.

The analogous energy constraint for a self-sustaining, dilute ( $RC \leq 0.1$ ), open-channel suspension is found to be from Eq. (2-72a),

$$\frac{U S}{v_s} > \frac{RC}{1 + RC} \equiv RC \quad (2-72e)$$

This condition was first articulated by Knapp (1938) and expressed mathematically by Vlugter (1942, 1962). An open-channel suspension can guarantee that the Knapp-Vlugter criterion is satisfied, by lowering the suspended sediment concentration  $C$ , and thus its excess fractional density  $RC$ , via sediment deposition. Vlugter (1962) used the above criterion to design stable irrigation channels in Indonesia. According to Vlugter, sediment with a fall velocity  $v_s$  that satisfies the above condition constitutes the *floating* material that does not require energy from the flow to be transported. The *floating* material is equivalent to the wash load. On the other hand, sediment with fall velocities that do not satisfy the Knapp-Vlugter condition and that take energy away from the flow to be transported is dubbed the *sinking* material. The *sinking* material can be regarded as the bed-material load. Vlugter states that in practice, when the mean flow velocity  $U > 0.5$  m/s, all silt particles smaller than 0.07 mm appear to behave as *floating material* (i.e., wash load). This is close to the grain diameter of 0.062 mm commonly used to define the wash load (e.g., Colby 1957).

De Vries (1993) has suggested that the Knapp-Vlugter criterion (Eq. 2-72e) could be used to find a tentative division between wash load and bed-material load in sand-bed streams. There have also been attempts to use Bagnold's ideas, which are applicable only to turbidity currents as previously shown, for the analysis of self-sustaining suspensions in open-channels flows (e.g., Southard and Mackintosh 1981; Wang 1984). As could be expected, this has generated a substantial amount of discussion in the literature (e.g., Parker 1982; Paola and Southard 1983; Nordin 1985a; Brush 1989). It should be clear that Bagnold's criterion does not correspond to an energy constraint on open-channel suspensions. The fundamental differences and similarities between sediment transport by rivers and turbidity currents are addressed in Section 2.11.

While conducting sedimentation studies in the Orinoco River in Venezuela, Nordin and Perez-Hernandez (1985) defined the wash load as the material that can be suspended (i.e.,  $u_* / v_s \geq 1.25$ ) as soon as its motion at the bed is initiated

(i.e.,  $\tau_b = \tau_{bc}$ ). Mathematically, this condition can be defined in dimensionless form by the relations

$$\tau^* \geq 1.11 R_f^2 \text{ when } \tau^* = \tau_c^* \quad (2-72f)$$

where

$\tau^*$  = dimensionless Shields stress parameter defined by Eq. (2-73a);

$\tau_c^*$  = dimensionless critical Shields stress for incipient motion (Fig. 2-19);

$$R_f = \frac{v_s}{\sqrt{gRD}} = \text{dimensionless fall velocity (Eq. 2-46b)}$$

which is a function of

$$R_{ep} = \frac{\sqrt{gRDD}}{v} \text{ and can be evaluated, for example, with}$$

Dietrich's relation (Eq. 2-47).

Nordin (1985b) suggests that the most practical way to apply this criterion in the field is to plot the largest particle size that can be suspended and the largest particle size that can be moved at the bed, as functions of the shear velocity ( $u_*$ ). The sediment diameter at which the two curves intersect defines the upper limiting size of the wash load, and particles finer than this would not be found in appreciable quantities in the bed because they would go into suspension as soon as their motion is initiated. In the case of the Orinoco River, Nordin (1985b) found that the upper limiting size for the wash load is 0.095 mm for a water temperature of 25°C. A limiting size for the wash load in dimensionless form which implicitly includes the effect of temperature, can be found from the dimensionless particle Reynolds number ( $R_{ep}$ ) where the curves for initiation of motion and suspension intersect, as shown in Fig. 2-28 below. However, the relations proposed by Mantz (Eq. 2-59c) or Yalin and Karahan (Eq. 2-61a) for incipient motion of fine-grained sediment should be used instead of the Shields criterion (Eq. 2-59b) which does not work for the grain sizes found in the wash-load.

While Nordin's approach can provide an idea of the size of the particles making up the wash load, because this fine-grained material is transported well below capacity what ultimately determines how much sediment is transported as wash load is the supply of fine sediment to a given river from its watershed and not the transport capacity of the river itself. Watershed sediment yield is addressed in Chapter 17.

In what follows, the emphasis is placed on understanding the mechanics of bed load and suspended load transport in open-channel flows, including morphological changes in rivers, lakes and reservoirs, with the goal of providing the knowledge needed for sedimentation engineering. The mechanics of transport by turbidity currents is also considered, and used to analyze delta formation and reservoir sedimentation.

## 2.5.2 Shields-Parker River Sedimentation Diagram

Alluvial rivers that are free to scour and fill during floods can broadly be divided into two types: sand bed streams and

gravel bed streams. Sand bed streams typically have values of median bed sediment size between 0.1 mm and 1 mm (Fig. 2-12). The sediment tends to be relatively well sorted, with values of geometric standard deviation of the bed sediment size varying from 1.1 to 1.5. Gravel bed streams typically have values of median size of the bed sediment exposed on the surface of 15 mm to 200 mm or larger; the substrate is usually finer by a factor of 1.5 to 3 (Fig. 2-13). The geometric standard deviation of the substrate sediment size is typically quite large, with values in excess 3 being quite common. Although gravel and coarser material constitute the dominant sizes, there is usually a substantial amount of sand stored in the interstices of the gravel substrate (Chapter 3).

Two dimensionless parameters provide an effective delineator of rivers into the above two types (García 2000). The first of these parameters is the dimensionless Shields stress for uniform flow conditions, defined as:

$$\tau^* = \frac{\tau_b}{\rho g RD} = \frac{HS}{RD} \quad (2-73a)$$

where

$\tau_b$  = bed shear stress;

$g$  = gravitational acceleration

$\rho$  and  $\rho_s$  water and sediment density, respectively;

$R = (\rho_s - \rho)/\rho$  = submerged specific gravity of the sediment;

$D$  = mean sediment diameter;

$H$  is the flow depth; and

$S$  is the stream slope which for steady, uniform flow is the same as the energy gradient.

The second of these parameters is the particle Reynolds number  $R_{ep}$  defined as:

$$R_{ep} = \frac{\sqrt{gRDD}}{v} \quad (2-73b)$$

where  $v$  is the kinematic viscosity of water. This second parameter can be considered as a dimensionless surrogate for grain size.

Rivers were first introduced into the Shields diagram by Gary Parker in the early-1980s. Parker used these two parameters but his diagram, shown in Fig. 2-28, did not include field data (García 1999). Parker's diagram, however, gave an indication of the areas in the modified Shields diagram corresponding to sand-bed and gravel-bed streams.

Motivated by a thorough review of the Shields diagram done by Buffington (1999), García (2000) used field and laboratory data to confirm the early ideas of Parker, resulting in Fig. 2-29. This figure shows a plot of the values of the Shields stress (Eq. 2-73a) evaluated at bankfull flow versus particle Reynolds number (Eq. 2-73b) for six sets of field

Fig. 2-28. Parker's River Sedimentation Diagram (García 1999).

data: a) gravel bed rivers in Wales, UK (Wales); b) gravel bed rivers in Alberta, Canada (Canada); c) gravel bed rivers in the Pacific Northwest, USA (Pacific); d) single-thread sand streams (Sand sing); e) multiple-thread sand streams (Sand mult); f) large sand-bed rivers (Parana, Missouri, etc.); and g) large-scale laboratory experiments on bridge-pier scour conducted at St Anthony Falls Laboratory (SAFL), University of Minnesota.

There are three curves in the Shields-Parker river sedimentation diagram of Fig. 2-29 that make it possible to know, for different values of  $(\tau^*, R_{ep})$ , if a given bed sediment grain will go into motion, and if this is the case, whether or not the prevailing mode of transport will be suspended load or bed load. The diagram can also be used to estimate what kind of bed forms can be expected for different flow conditions and sediment characteristics. For example, ripples will develop in the presence of a viscous sublayer and fine-grained sediment. If the viscous sublayer is disrupted by coarse sediment particles, then dunes will be the most common type of bed form.

As could be expected, the Shields-Parker diagram (Fig. 2-29) also shows that in gravel-bed rivers, bed material is transported mainly as bed load. On the other hand, in sand-bed rivers, suspension and bed load transport of bed material coexist, particularly at high flows. The diagram is valid for steady, uniform flow conditions, where the bed shear stress can be estimated with  $\tau_b = \rho g H S$  (Eq. 2-1). The ranges for silt, sand, and gravel are also included. In this diagram, the critical Shields stress for motion was plotted with Eq. (2-59a).

The critical condition for suspension is given by the ratio (Niño and García 1998; Lopez and García 2001)

$$\frac{u_*}{v_s} = 1 \quad (2-74)$$

where  $u_*$  is the shear velocity; and  $v_s$  is the sediment fall velocity. Eq. (2-74) can be transformed into:

$$\tau_s^* = R_f^2 \quad (2-75)$$

where:

$$\tau_s^* = \frac{u_*^2}{g R D} \quad (2-76)$$

denotes a threshold Shields number for suspension and  $R_f$  is given to be Eq. (2-46b), and can be computed for different values of  $R_{ep}$  with the help of Dietrich's fall velocity relation given by Eq. (2-47a).

Finally, the critical condition for viscous effects (ripples) was obtained with the help of the definition for the viscous sublayer thickness (Eq. 2-6) as follows,

$$11.6 \frac{v}{u_* D} = 1 \quad (2-77)$$

Fig. 2-29. Shields-Parker River Sedimentation Diagram (after García 2000).

which in dimensionless form can be written as

$$\tau_v^* = \left( \frac{11.6}{R_{ep}} \right)^2 \quad (2-78)$$

In this equation,  $\tau_v^*$  denotes the threshold Shields number below which ripples can be expected.

Relations (2-59a), (2-75), and (2-78) are the ones plotted in Fig. 2-29. The Shields-Parker diagram should be useful for studies concerning stream restoration and naturalization (Chapter 9), for it provides the range of dimensionless shear stresses corresponding to bankfull flow conditions for gravel-bed streams ( $0.01 < \tau^* < 0.2$ ) and for sand-bed streams ( $0.6 < \tau^* < 6$ ). Notice that the bank-full dimensionless Shields shear stress is in general, an order of magnitude larger for sand-bed streams than for gravel-bed streams.

An interesting observation is that sand-bed streams are in the transition between smooth and hydraulically rough conditions, while gravel-bed streams are always hydraulically rough. This has implications, for instance, for the use of Manning's relation (Eq. 2-23a) which applies only to fully rough and turbulent hydraulic conditions (Yen 2002).

The Shields-Parker diagram also shows a very clear distinction between the conditions observed in sand-bed and

gravel-bed rivers at bank-full stage, which has implications for movable-bed physical modeling. If one wanted to model in the laboratory sediment transport in rivers, the experimental conditions would be quite different depending on the river type in question. In order to satisfy similarity in a small-scale, river model, it would be necessary to satisfy the identities (García 2000)

$$\tau^*|_{model} = \tau^*|_{prototype} \quad (2-79a)$$

$$R_{ep}|_{model} = R_{ep}|_{prototype} \quad (2-79b)$$

for bank-full flow conditions. In most movable-bed models, Froude similarity is enforced and Eq. (2-79a) is used to achieve sediment transport similarity. However, sediment transport conditions and the associated bed morphology in a model, seldom precisely reproduce prototype conditions because the second condition given by Eq. (2-79b) is rarely satisfied. This leads to the common practice of using lightweight material (Table 2-2) to reproduce prototype conditions in small-scale models (e.g., Shen 1990). However, this does not imply that the bedforms observed in the model will be the same as those in the prototype. The river sedimentation

diagram provides a tool to quickly determine potential scale effects in movable-bed model studies by simply plotting the values of  $(\tau^*; R_{ep})$  for model and prototype conditions in Fig. 2-29. As discussed in Henderson (1966, p. 504), the condition given by Eq. (2-79b) can be relaxed for sufficiently large values of  $R_{ep}$  (i.e. hydraulically rough flow) in both model and prototype. It is clear from Fig. 2-29, that this would be possible only for the case of gravel-bed streams. More information on movable-bed physical models can be found in Appendix C.

## 2.6 BED LOAD TRANSPORT

Since the publication of ASCE Manual 54 (Vanoni 1975), a significant amount of work has been done to understand the mechanics of bed load transport. Two schools of thought can be clearly identified and they bear the name of two giants in the field of sedimentation, Brigadier Ralph Alger Bagnold and Professor Hans Albert Einstein.

Bagnold (1956) defined the bed load transport as that in which the successive contacts of the particles with the bed are strictly limited by the effect of gravity, whereas the suspended load transport is defined as that in which the excess weight of the particles is supported by random successions of upward impulses imported by turbulent eddies. Einstein (1942, 1950), however, presented a somewhat different view of the phenomenon. Einstein defined bed load transport as the transport of sediment particles in a thin layer about two particle diameters thick just above the bed by sliding, rolling, and making jumps with a longitudinal distance of a few particle diameters. The bed load layer is considered to be a layer in which mixing due to turbulence is so small that it cannot directly influence the sediment particles, and therefore suspension of particles is impossible in the bed load layer. Further, Einstein assumed that the average distance traveled by any bed load particle (as a series of successive movements) is a constant distance of about 100 particle diameters, independent of the flow condition, transport rate, and bed composition. In Einstein's view, saltating particles belong to the suspension mode of transport, because the jump heights and lengths of saltating particles are greater than a few grain diameters. On the other hand, Bagnold (1956, 1973) regards saltation as the main mechanism responsible for bed load transport.

Most research works that provide a mechanistic description of bed load transport under uniform equilibrium conditions have fallen into one or the other school of thought. The centerpiece of the Einsteinian formulation is the specification of an entrainment rate of particles into bed load transport (pick-up function) as a function of boundary shear stress and other parameters. The work of Nakagawa and Tsujimoto (1980), van Rijn (1984a) and Tsujimoto (1991), for example, represent formulations of this type.

In the Bagnoldian formulation, however, a relation for the areal concentration of bedload particles as a function of boundary shear stress derives automatically from the imposition of a dynamic condition at the bed, according to which the fluid shear stress drops to the critical value for the onset of sediment motion. The physical implication is that moving grains will extract enough momentum from the fluid in the bed load layer, such that the fluid stress at the bed remains at the critical shear stress for motion. This dynamic condition is referred to as the Bagnold hypothesis or Bagnold constraint. The hypothesis was used by Owen (1964) to calculate sediment transport by saltation for the case of wind-blown sand. It is implicit in the bedload formulations of Ashida and Michiue (1972) and Engelund and Fredsøe (1976) for nearly horizontal beds. Wiberg and Smith (1989), Sekine and Kikkawa (1992) and Niño and García (1994; 1998), for example, have used the hypothesis to derive models of bed load transport on nearly horizontal beds based on an explicit calculation of grain saltation. Sekine and Parker (1992) used the Bagnold hypothesis to develop a saltation model for bed load on a surface with a mild transverse slope, and Kovacs and Parker (1994) extended the analysis of Ashida and Michiue (1972) to the case of arbitrarily sloping beds. Bridge and Bennett (1992) have employed the Bagnold hypothesis to study the bedload transport of sediment mixtures.

Based on the most recently published formulations of bed load transport, then, it is possible to say that the field as a whole has tended away from the Einsteinian and toward the Bagnoldian formulation. This notwithstanding, doubts have been expressed from time to time concerning the Bagnold hypothesis. For example, the experimental work of Fernandez-Luque and van Beek (1976) does not support the Bagnold hypothesis. A re-analysis of the data and formulation presented in Niño et al. (1994) and Niño and García (1994) caused Niño and García (1998) to cast further doubts on the hypothesis. Kovacs and Parker (1994) were forced to modify the hypothesis in order to obtain a well-behaved theory of bed load transport on arbitrarily sloping beds. With the help of numerical experiments, McEwan et al. (1999) have found that only in the case of high sediment availability does the fluid shear stress at the bed equal the critical stress for initiation of motion. Seminara et al. (2002) and Parker et al. (2003) have shown that Bagnold's hypothesis breaks down when applied to equilibrium bedload transport on beds with transverse slopes above a relatively modest value that is well below the angle of repose. All of the above suggests that formulae that make use of Bagnold's hypothesis might only be able to predict bed load transport for certain conditions (Niño and García 1998). This notwithstanding the ideas of Bagnold have nevertheless contributed substantially to the understanding the physics of the sediment transport problem. A collection of hallmark papers by R.A. Bagnold has been published by ASCE (Thorne et al 1988).

### 2.6.1 Bed Load Transport Analysis

Sediment can be transported in several ways. A grain will begin to move when the boundary shear stress just exceeds a critical value. At the lowest transport stages, particles move by sliding and rolling over the surface of the bed, but with a small increase in boundary shear stress these grains will hop up from the bed and follow ballistic-type trajectories. This latter mode of bed load transport is known as saltation. Gilbert (1914) seems to have been the first to use the term saltation, derived from the Latin verb *saltare*, which means to leap or dance, to describe the motion of sand particles in water.

Saltation is described as the unsuspended transport of particles over a granular bed by a fluid flow, in the form of consecutive hops within the near-bed region. It is governed mainly by the action of hydrodynamic forces that carry the particles through the flow, the downward pull of gravity and the collision of the particles with the bed, which transfers their streamwise momentum into upward momentum, thus sustaining the saltation motion (Niño and García 1998). This differs from an earlier definition given by Bagnold (1973) who assumed that the only upward impulses exerted on the saltating particles were those resulting from the impact of particles with the bed. Thus, Bagnold neglected the effect of hydrodynamic lift and vertical impulses owing to flow turbulence, which have been shown to play an essential role in the saltation phenomenon (e.g. Leeder 1979a; Bridge and Dominic 1984; Bridge and Bennett 1992; Niño et al., 1994; Niño and García 1994). Experimental studies on saltation of gravel and sand by Niño et al. (1994) and Niño and García (1998b) have given detailed information on the physics of particle saltation. In particular, they have provided a description of the particle collision with the bed, allowing calibration of a stochastic model for this phenomenon, and have also provided statistics for the geometric and kinematic properties of the saltation trajectories.

In addition to its significance for the flux of sediment moving as bed load, the bed load layer serves as an exchange zone between the bed and sediment transported in suspension; the upward flux of sediment at the top of the bed load layer provides the boundary condition for suspended sediment transport calculations. Once sediment starts moving and sliding along the bed, the prevalent mode for bed load transport will most likely be saltation for a range of bed shear stresses. At higher values of boundary shear stress, the surface layer of the bed may deform and move as a grain flow or granular fluid flow (Wilson 1987, 1989). Grain flow is also known as sheet flow (Fredsoe and Deigaard 1992; Sumer et al 1996). Collision of the moving particles with the bed exerts both a tangential and a normal stress on the bed surface. The work of Bagnold (1954), Hanes and Inman (1985), and Jenkins and Hanes (1998) on high-concentration, granular shear flows have shown that if the ratio of the applied tangential to normal shear stresses exceeds the critical yield criterion, the frictional resistance of the bed

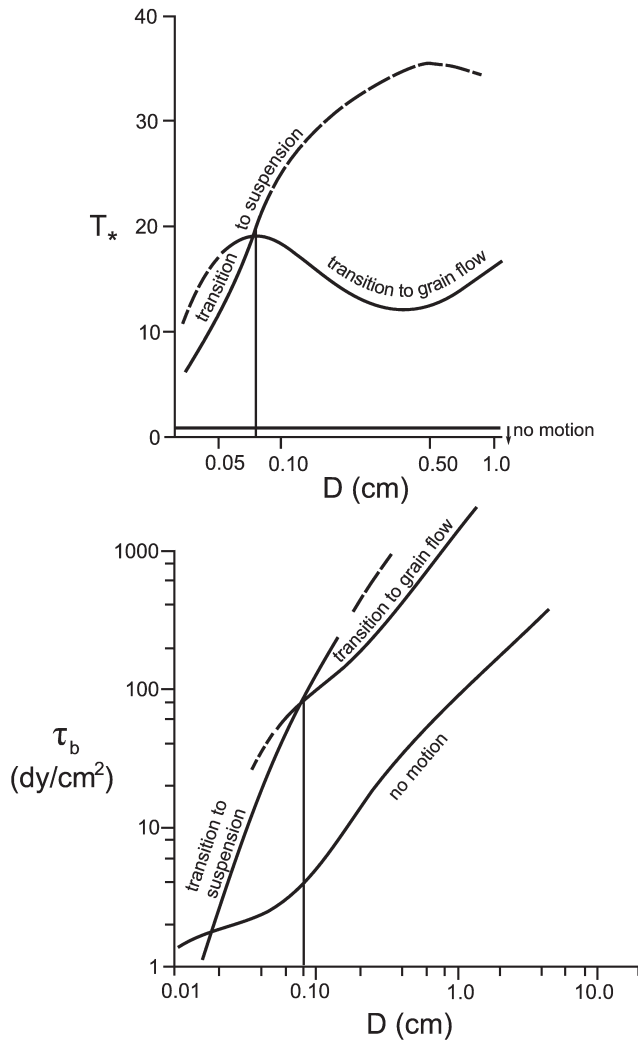

will be overcome, and a grain flow will be initiated in the surface layer of the bed (Fredsoe and Deigaard 1992). So it is important to be able to discriminate between different modes of sediment transport so that the domain of applicability of bed load transport models can be determined (Sumer et al 1996).

In an attempt to interpret different transport modes following initiation of motion, Wiberg (1987) used a mechanistic model of bed load transport (Wiberg and Smith 1985) to produce a diagram (Fig. 2-30) of transport stage ( $T_* = \tau_b / \tau_{bc}$ ) or bed shear stress ( $\tau_b$ ) versus quartz grain diameter ( $D$ ), depicting the range of conditions over which sediment moves strictly as bed load and a saltation-based model can be used to describe the phenomenon. Conditions for the initiation of motion, the transition to suspension and the transition to grain flow, are also included.

As shown in Fig. 2-30(a), at transport stages  $T_* < 1$  no sediment moves in a uniform bed of a given grain size. For grain sizes  $D < 0.08$  cm (coarse sand and finer), the conditions for incipient motion occur at transport stages lower than those at which the applied stresses at the bed are sufficient to overcome the bed's frictional resistance. For sizes  $D > 0.08$  cm, this situation is reversed, and the conditions for potential grain flow (sheet flow) at the bed surface are reached before the particles are significantly affected by the vertical turbulent velocity fluctuations that could entrain the grains into suspension (Niño and García 1996). Wiberg (1987, p. 94) indicates that the advent of either of these processes does not preclude the possibility of the other, but changes in the bed load dynamics produced by these processes are certain to influence the transport stage at which the other could occur. This is supported by the observations made by Wilson (2005), which show that when the ratio between the shear velocity ( $u_*$ ) and the sediment fall velocity ( $v_s$ ) increases over a critical value ( $u_* / v_s > 6.5$ ), a rapid increase in both flow resistance and sediment entrainment into suspension is observed.

For all sediment sizes, Fig. 2-30(a) suggests that a transport stage of about 20 is an upper limit for saltation-based bed load transport. A saltation model might still provide reasonable transport predictions for incipient grain-flow conditions beyond this limit, but the physics of the phenomenon becomes more complicated as grain-grain interaction becomes more intense (e.g., Kobayashi and Seung 1985).

Fig. 2-30(b) presents the same results as shown in Fig. 2-30(a), but in terms of dimensional boundary shear stress,  $\tau_b$  (dy/cm<sup>2</sup>), to give a better sense of when the transition to these transport modes are actually likely to occur. For sediment sizes  $D < 0.018$  cm (fine sand and finer) at initial motion, the moving particles go directly into suspension following initiation of motion. The corresponding critical shear stress  $\tau_b < 2$  dy/cm<sup>2</sup>, is quite low, and material of these sizes is frequently mobilized, provided cohesive effects are not large (see Chapter 4). Fine to coarse sand ( $D = 0.018$ – $0.08$  cm) moves initially as bed load, with particles starting to go into suspension at higher shear stresses. For example, medium

**Fig. 2-30.** Tentative ranges of conditions over which sediment moves strictly as bed load. (a) Initiation of motion, the transition to suspension and the transition to grain flow plotted in terms of transport stage versus grain size. (b) The same curves plotted in terms of dimensional boundary shear stress (in  $\text{dy/cm}^2$ ), versus grain size. The vertical line marks the particle size at the intersection of the incipient suspension and incipient grain flow curves,  $D \cong 0.08 \text{ cm}$  (adapted from Wiberg 1987).

sand begins to move at  $\tau_b = 2$  to  $3 \text{ dy/cm}^2$  and incipient suspension begins at  $\tau_b = 10$  to  $30 \text{ dy/cm}^2$ . Shear stresses of such magnitude can be reached during moderate river flows and during storms on continental shelves.

In very energetic environments, such as the surf zone in coastal areas or during large river floods, it may also be possible for a grain flow (sheet flow) to develop (Wilson 1987, 1989; Sumer et al 1996). For coarse sand and gravel ( $D = 0.08$ – $6 \text{ cm}$ ), a relatively large boundary shear stress is required just to initiate the motion of the sediment. For example, for  $D = 0.5 \text{ cm}$  (fine gravel), the critical shear stress is  $\tau_{bc} = 45 \text{ dy/cm}^2$  and a grain flow is possible at a shear stress  $\tau_b > 550 \text{ dy/cm}^2$ ; these conditions are only likely to occur in very

large sand-bed rivers or in high-gradient mountain streams. Thus for the grain sizes commonly encountered, suspended-load transport is an important mode of transport for fine sediment, whereas high-concentration grain flows are probably relatively uncommon except in a few specific environments. For a large range of sediment sizes in the medium to coarse sand range and above, if the sediment is moving at all, it is certainly moving as bed load.

### 2.6.2 Bed Load Transport Definition

Bed load particles roll, slide, or saltate along the bed. The transport thus is tangential to the bed. When all of the transport is directed in the streamwise, or  $s$  direction, the volume bed load transport rate per unit width ( $n$ -direction) is given by  $q_b$ ; the units are  $\text{length}^3/\text{length}/\text{time}$ , or  $\text{length}^2/\text{time}$ . In general,  $q_b$  is a function of boundary shear stress  $\tau_b$  and other sediment parameters; that is,

$$q_b = q_b(\tau_b, \text{other parameters}) \quad (2-80)$$

In general, bed load transport is vectorial, with components  $q_{bs}$  and  $q_{bn}$  in the  $s$  (streamwise) and  $n$  (lateral) directions, respectively. Basically the bed load transport rate can be defined as the product of particle concentration, particle velocity, and bed load layer thickness,

$$q_b = u_b c_b \delta_b \quad (2-81)$$

in which  $q_b$  is the volumetric bed load transport rate ( $\text{m}^2/\text{s}$ ),  $c_b$  is the volumetric sediment concentration (i.e. volume of sediment/volume of water-sediment mixture),  $u_b$  is particle velocity ( $\text{m}/\text{s}$ ), and  $\delta_b$  is the thickness of the bed load layer ( $\text{m}$ ). Bagnoldian bed load transport models use this definition of the bedload transport rate (Ashida and Michiue 1972; Engelund and Fredsøe 1976; Van Rijn 1984a; Wiberg and Smith 1987; Sekine and Kikkawa 1992; Niño and García 1994; Lee and Hsu 1994; Niño and García 1998; Lee et al., 2000).

The bed load transport rate can also be defined as the product of the number of moving particles per unit area, the particle volume and the particle velocity (García 2000),

$$q_b = N_b V_b u_b \quad (2-82)$$

in which  $N_b$  is the number of particles per unit bed area ( $\text{m}^{-2}$ ),  $V_b$  is the particle volume ( $\text{m}^3$ ), and  $u_b$  is the particle velocity ( $\text{m}/\text{s}$ ). If the particle velocity is defined as the ratio of the saltation or step length  $\lambda$  and the saltation or movement period  $T$  (i.e.  $u_b = \lambda / T$ ), then

$$q_b = N_b V_b \lambda / T = E_p \lambda = D_p \lambda \quad (2-83)$$

Here,  $E_p$  and  $D_p$  = eroded and deposited volume of particles per unit bed area per unit time (m/s), respectively. Equilibrium bed load transport conditions imply that  $E_p = D_p$ .

The idea of a pick-up rate and a step length was first proposed by Einstein (1942; 1950) and constitutes the basis of Einsteinian bedload transport models (Nakagawa and Tsujimoto, 1980; Tsujimoto, 1992). A comparison of several pick-up rate functions and their applications can be found in Van Rijn (1984b; 1986). Einstein defined the particle step length as the particle travel distance from entrainment to deposition (i.e., when the particle stops moving and comes to rest) and estimated it to be equal to about 100 times the particle diameter. Einstein's particle length can be expected to be several times the saltation length  $\lambda$  previously defined. This assumption will be considered below in light of the experimental observations made by Wong and Parker (2006a).

### 2.6.3 Conservation of Sediment Mass: The Exner Equation and Morphodynamics

Before considering bed load transport relations in more detail, it is useful to formulate the interaction between bed sediment and the water column through erosion and deposition, so that the sediment mass conservation can be formulated. Consider the definition diagram for a sediment-laden, uniform, open-channel flow shown in Fig. 2-31. The volume rate of erosion of bed material into suspension per unit time per unit bed area is denoted as  $E_r$ . The units of  $E_r$  are length<sup>3</sup>/length<sup>2</sup>/time, or velocity. A dimensionless sediment entrainment rate  $E_s$  can thus be defined in terms of the sediment fall velocity  $v_s$ :

$$E_r = v_s E_s \quad (2-84)$$

In general,  $E_s$  can be expected to be a function of boundary shear stress  $\tau_b$  and sediment related parameters (García

**Fig. 2-31.** Definition diagram for sediment-laden open channel flow.

and Parker 1991; Niño et al. 2003). Erosion into suspension can be taken to be directed upward normal, i.e., in the positive  $z$  direction.

Let  $\bar{u}$  denote the mean flow velocity (m/s) at a point located at a distance  $z$  normal to the bed, and  $\bar{c}$  denote the mean volumetric concentration of suspended sediment (m<sup>3</sup> of sediment/m<sup>3</sup> of sediment-water mixture), averaged over turbulence. The streamwise volume transport rate of suspended sediment per unit width is given by

$$q_s = \int_0^H \bar{u} \bar{c} dz \quad (2-85)$$

Let  $s$  denote the streamwise direction and  $n$  denote the lateral direction in a two-dimensional case; then two components,  $q_{ss}$  and  $q_{sn}$  result, where

$$q_{ss} = \int_0^H \bar{u} \bar{c} dz \quad (2-86a)$$

$$q_{sn} = \int_0^H \bar{v} \bar{c} dz \quad (2-86b)$$

where  $\bar{v}$  is the mean lateral ( $n$ -direction) velocity at a distance  $z$  above the bed.

Deposition onto the bed is by means of settling. The rate at which material is fluxed vertically downward onto the bed (volume/area/time) is given by  $v_s \bar{c}_b$ , where  $\bar{c}_b$  is a near-bed value of the volumetric sediment concentration  $\bar{c}$ . Some authors assume that the value of the near-bed concentration is the same as the sediment concentration in the bed load layer defined previously (Einstein 1950; Engelund and Fredsøe 1976; Zyserman and Fredsøe 1994). The deposition rate  $D_r$  realized at the bed is obtained by computing the component of this flux that is actually directed normal to the bed as

$$D_r = v_s \bar{c}_b \quad (2-87)$$

which gives the volume of sediment deposited per unit bed area per unit time (García 2001).

Now it is possible to formulate the sediment mass conservation for bed material taking into account both bed load transport and sediment erosion into and from suspension. Consider a portion of river bottom (Fig. 2-32), where the bed material is taken to have a constant porosity  $\lambda_p$ . Mass balance of sediment requires that the following equation be satisfied:

$$\frac{\partial}{\partial t} [\text{mass of bed material}] = \text{net mass bedload inflow rate} \\ + \text{net mass rate of deposition from suspension}$$

A datum of constant elevation is located well below the bed level, and the elevation of the bed with respect to

Fig. 2-32. Definition diagram for sediment mass conservation.

the datum is given by  $\eta$ . The mass balance equation translates to

$$\begin{aligned} \rho_s (1 - \lambda_p) \frac{\partial}{\partial t} (\eta ds dn) &= \rho_s (q_{bs}|_s - q_{bs}|_{s+ds}) dn \\ &+ \rho_s (q_{bn}|_n - q_{bn}|_{n+dn}) ds \\ &+ \rho_s (D_r - E_r) ds dn \end{aligned} \quad (2-88a)$$

Or upon reduction with Eqs. (2-84) and (2-87), Eq. (2-88a) takes the final form

$$(1 - \lambda_p) \frac{\partial \eta}{\partial t} = - \frac{\partial q_{bs}}{\partial s} - \frac{\partial q_{bn}}{\partial n} + v_s (\bar{c}_b - E_s) \quad (2-88b)$$

Bed level changes with time  $t$  due to bed load transport, sediment entrainment into suspension, and sediment deposition onto the bed can be predicted with this partial differential equation. To solve this equation, it is necessary to have relations to compute bed load transport (i.e.,  $q_{bs}$  and  $q_{bn}$ ), near-bed suspended sediment concentration  $\bar{c}_b$  and sediment entrainment into suspension  $E_s$  (García and Parker 1991; García 2001). The basic form of Eq. (2-88b), without the suspended sediment component, was first proposed for the case of a one-dimensional flow interacting with a sediment-covered bed by Felix Exner (1925).

Felix Maria Exner was an Austrian researcher who was active in the early part of the 20th Century. His main area of interest was meteorology. At some point he became interested in the formation of dunes in rivers (see Leliavsky 1966). In the course of his research on the subject, he derived and employed one version of the various statements of conservation of bed sediment that are now referred to as “Exner equations.” In addition, he made an important early contribution to one-dimensional nonlinear wave dynamics (Exner 1920). Felix Exner was the first researcher to state a morphodynamic problem in quantitative terms. The term “morphodynamics”

itself evolved many decades afterward and is now used for river, coastal, and estuarine problems (e.g., Parker and García 2006). This notwithstanding, Exner deserves recognition as the founder of morphodynamics (Parker 2005).

The field of morphodynamics consists of the class of problems for which the flow over a bed interacts strongly with the shape of the bed, both of which evolve in time. An introduction to morphodynamics of rivers and turbidity currents is given in Section 2.11 of this chapter. The Exner equation is generalized to the case of sediment mixtures in Chapter 3.

#### 2.6.4 Bed Load Transport Relations

A large number of bed load relations can be expressed in the general dimensionless form

$$q^* = q^*(\tau^*, R_{ep}, R) \quad (2-89)$$

Here,  $q^*$  is a dimensionless bed load transport rate known as the Einstein bed load number, first introduced by Hans Albert Einstein in 1950, and given by

$$q^* = \frac{q_b}{D\sqrt{gRD}} \quad (2-90a)$$

where  $q_b$  is the volumetric bedload transport rate,  $g$  is the acceleration of gravity,  $R = (\rho_s - \rho) / \rho$  is the submerged specific gravity of the sediment,  $D$  is the particle diameter, and  $R_{ep} = \sqrt{gRD}D/\nu$  is the particle Reynolds number. Einstein’s bed load transport model can be expressed in dimensionless form as follows,

$$q^* = E_p^* L_s^* \quad (2-90b)$$

with

$$E_b^* = \frac{E_b}{\sqrt{gRD}} \quad (2-90c)$$

and

$$L_s^* = \frac{L_s}{D} \quad (2-90d)$$

In these relations  $E_b$  = volumetric rate of sediment entrainment per unit area; and  $L_s$  = particle step length (i.e., the particle travel distance from entrainment to deposition).

In a study of sand bed instability, Nakagawa and Tsujimoto (1980) found that the dimensionless entrainment rate  $E_b^*$  is a function of the Shields parameter  $\tau^*$  and tried to develop a probabilistic model for the dimensionless particle

step length  $L_s^*$  but did not find a simple way to characterize this parameter (Tsujimoto and Nakagawa 1983). Sechet and Le Guennec (1999) found experimentally that the particle step length is related to the bursting phenomenon (i.e., ejections and sweeps) which is in agreement with observations of near-wall particle-turbulence interactions made earlier by Sumer and Deigaard (1981), García et al. (1996), and Niño and García (1996). This might explain some of the difficulties encountered in trying to characterize Einstein's step length. Recently, Sumer et al (2003) were able to observe directly the influence of turbulence on bed load transport of sand ( $D_{50} = 0.22$  mm) with a set of carefully conducted lab experiments. The Shields parameter together with the root-mean-square value (RMS) of the streamwise velocity fluctuations, were correlated with the sediment transport rate. They found that the sediment transport rate increases markedly with increasing turbulence levels. A few years earlier, Drake et al (1988) observed a similar influence of the flow turbulence while observing bed load transport of fine gravel with motion-picture photography.

Recently, Wong and Parker (2006a) conducted a tracer study involving transport of uniform-size gravel in a large flume at St. Anthony Falls Laboratory, University of Minnesota. The sediment used in all the experiments was uniform gravel, with geometric mean size  $D_g = 7.2$  mm, geometric standard deviation  $\sigma_g = 1.2$ , median particle size  $D_{50} = 7.1$  mm, particle size for which 90% of the sediment is finer  $D_{90} = 9.6$  mm, and a specific gravity of 2.55 ( $R = 1.55$ ). Based on these observations they found empirical equations for the dimensionless entrainment rate  $E_b^*$  and particle step length  $L_s^*$  as functions of the Shields parameter  $\tau^*$ , as follows,

$$E_p^* = 0.06(\tau^* - 0.0549)^{1.97} \quad (2-90e)$$

and

$$L_s^* = 44.33(\tau^* - 0.0549)^{-0.47} \quad (2-90f)$$

Equation (2-90e) predicts values very close to those observed by Fernandez Luque and van Beek (1976). On the other hand, Eq. (2-90f) contradicts the original ideas of Einstein (1950) who did not include a critical shear stress for motion and assumed that the dimensionless step length  $L_s^* = 100$  for all flow conditions. Also of interest is the fact that the step length is found to decrease as the flow intensity characterized by  $\tau^*$ , increases.  $L_s^*$  takes values between 160 and 270 for the range of experimental conditions covered in the experiments. Wong and Parker (2006a) argued that since the chances of a given particle being captured and trapped into a resting position increases with sediment transport rate, it is reasonable to assume that the step length becomes smaller

when the excess dimensionless shear stress gets larger, as indicated by Eq. (2-90f). Substituting (2-90e) and (2-90f) into (2-90b), yields

$$q^* = 2.66(\tau^* - 0.0549)^{3/2} \quad (2-90g)$$

This empirical fit has a structure which is very similar to several formulations presented below.

Bagnold's approach is considered next. A dimensionless bed load transport equation, such as the one implied by Eq. (2-89), can be obtained by simply dividing both sides of Eq. (2-81) by a characteristic length given by the particle diameter  $D$  and a characteristic velocity given by  $\sqrt{gRD}$ , which yields

$$q^* = \frac{q_b}{D\sqrt{gRD}} = \frac{c_b\delta_b}{D} \frac{u_b}{\sqrt{gRD}} \quad (2-91)$$

Bagnold's (1956) hypothesis makes it possible to estimate the volumetric sediment concentration in the bedload layer per unit bed area, given by the product of sediment concentration  $c_b$  and the thickness of the bed load layer  $\delta_b$ , as follows

$$\frac{c_b\delta_b}{D} = \frac{\tau^* - \tau_c^*}{\mu_d} \quad (2-92)$$

where  $\mu_d$  is a dimensionless dynamic friction coefficient (Abott and Francis 1977; Sekine and Kikkawa 1992). Niño and García (1998) have used a Lagrangian particle-saltation model to estimate values of  $\mu_d$  and found that it takes values in the range between 0.25 and 0.4, which are smaller than  $\mu_d = \tan\phi = 0.63$  proposed by Bagnold (1973) but are in good agreement with laboratory observations of sand transport (Niño and García 1998c). Simulated values of  $\mu_d$  for the case of sand saltation are much closer to the corresponding observed values than in the case of saltation of gravel (Niño and García 1994). Bagnold's hypothesis used to obtain to Eq. (2-92) would be only valid for intense transport conditions involving very high sediment concentrations of sand-size material. The mean velocity of the particles in the bedload layer  $u_b$  can also be estimated with the help of numerical modeling and experimental observations of particle motion (Reizes 1978; Leeder 1979; Murphy and Hooshiari 1982; Bridge and Dominic 1984; van Rijn 1984a; Wiberg and Smith 1985, 1989; Sekine and Kikkawa 1992; Lee and Hsu, 1994; Niño and García 1994, 1998b, 1998c; Lee et al. 2000, 2006; Lukerchenko et al. 2006).

Ashida and Michiue (1972) presented a macroscopic analysis that does not account for the complexity of the saltation process, in particular the treatment of the particle collision

with the bed. In their analysis, a simplified particle equation of motion is used to obtain the following expression for the dimensionless mean particle velocity in the bedload layer:

$$\frac{u_b}{\sqrt{gRD}} = 8.5 \left[ (\tau^*)^{1/2} - (\tau_c^*)^{1/2} \right] \quad (2-93)$$

Upon substitution of Eqs. (2-92) and (2-93) into (2-91) and assuming a value for  $\mu_d$  of 0.5, the following final form for bed load transport is obtained

$$q^* = 17(\tau^* - \tau_c^*) \left[ (\tau^*)^{1/2} - (\tau_c^*)^{1/2} \right] \quad (2-94)$$

Ashida and Michiue recommend a value for  $\tau_c^*$  of 0.05 in their relation. It has been verified with uniform material ranging in size from 0.3 mm to 7 mm. The Ashida-Michiue bed load transport equation is a good example of a Bagnoldian formulation. It is very similar to the one developed independently by Engelund and Fredsøe (1976) and more recently by Niño and García (1998) using a Lagrangian particle-saltation model for bed load transport.

In addition to the relation of Ashida and Michiue (1972), the following bed load transport relations are of interest.

**Meyer-Peter and Muller (1948):**

$$q^* = 8(\tau^* - \tau_c^*)^{3/2} \quad (2-95a)$$

where  $\tau_c^* = 0.047$ . This formula is empirical in nature; it has been verified with data for uniform coarse sand and gravel. Even though it was developed for alpine streams in Switzerland, it enjoys wide use in coastal sediment transport (e.g. Soulsby, 1997). Recently, Wong and Parker (2006b) reanalysed the data used by Meyer-Peter and Muller and found that a better fit is provided by one of the two alternative forms;

$$q^* = 4.93(\tau^* - 0.047)^{1.6} \quad (2-95b)$$

$$q^* = 3.97(\tau^* - 0.0495)^{3/2} \quad (2-95c)$$

**Einstein (1950):**

$$q^* = q^*(\tau^*) \quad (2-96a)$$

where the functionality is implicitly defined by the relation

$$1 - \frac{1}{\sqrt{\pi}} \int_{-(0.413/\tau^*)}^{(0.413/\tau^*)-2} e^{-t^2} dt = \frac{43.5 q^*}{1 + 43.5 q^*} \quad (2-96b)$$

This relation constitutes the first attempt to derive a bed load function. Note that this relation contains no critical shear stress. It has been used for uniform sand and gravel. Gomez and Church (1989) recommend its use for cases where the local bed load transport rate needs to be calculated. Yang and Wan (1991) found that it could predict sediment transport rates in large rivers but not in small rivers and flumes.

**Yalin (1963):**

$$q^* = 0.635s(\tau^*)^{1/2} \left[ 1 - \frac{\ln(1 + a_2 s)}{a_2 s} \right] \quad (2-97a)$$

where

$$a_2 = 2.45(R+1)^{0.4} (\tau_c^*)^{1/2} \quad s = \frac{\tau^* - \tau_c^*}{\tau_c^*} \quad (2-97b)$$

and  $\tau_c^*$  is evaluated from the Shields curve. Two constants in this formula have been evaluated with the aid of data quoted by Einstein (1950), pertaining to 0.8 mm and 28.6 mm material. Wiberg and Smith (1985, 1989) were able to reproduce Yalin's relation, with their saltation-based bed load transport model.

**Wilson (1966):**

$$q^* = 12(\tau^* - \tau_c^*)^{3/2} \quad (2-98)$$

where  $\tau_c^*$  is determined from the Shields diagram. This relation is empirical in nature; most of the data used to fit it pertain to very high rates of bed load transport. It has been used extensively to estimate transport of sand and industrial materials such as nylon in pressurized flows (e.g., Wilson 1987).

**Paintal (1971):**

$$q^* = 6.56 \times 10^{18} \tau^{*16} \quad (2-99)$$

was obtained though extensive measurements of very low bed load transport rates. It is valid for  $0.007 < \tau^* < 0.06$  and sediment grain sizes between 1 mm (coarse sand) and 25 mm (gravel). This relation shows that for low shear stresses, the

sediment transport phenomenon is highly nonlinear. That is, for small changes in bed shear stress, the rate of bed load transport increases dramatically.

**Engelund and Fredsøe (1976):**

$$q^* = 18.74(\tau^* - \tau_c^*) \left[ (\tau^*)^{1/2} - 0.7(\tau_c^*)^{1/2} \right] \quad (2-100a)$$

where  $\tau_c^* = 0.05$ .

This formula resembles that of Ashida and Michiue because its derivation, albeit obtained independently, is almost identical. This relation was rederived by Fredsøe and Deigaard (1992, p. 214), resulting in a very similar relation,

$$q^* = \frac{30}{\pi \mu_d} (\tau^* - \tau_c^*) \left[ (\tau^*)^{1/2} - 0.7(\tau_c^*)^{1/2} \right] \quad (2-100b)$$

Fredsøe and Deigaard tested the formula for different values of the dynamic friction coefficient  $\mu_d$ . For  $\mu_d = 1.0$ , Eq. (2-96b) gives results very close to those of the Meyer-Peter and Muller formula (Eq. 2-95a). However, both formulations were found to overpredict bed load transport at high shear stresses.

**Fernandez-Luque and van Beek (1976):**

$$q^* = 5.7(\tau^* - \tau_c^*)^{3/2} \quad (2-101)$$

where  $\tau_c^*$  varies from 0.05 for 0.9-mm material to 0.058 for 3.3-mm material. The relation is empirical in nature and was obtained through laboratory observations.

**Parker (1979):**

$$q^* = 11.2 \frac{(\tau^* - 0.03)^{4.5}}{\tau^{*3}} \quad (2-102)$$

developed as a simplified fit to the relation of Einstein (1950) for the range of Shields numbers likely to be encountered in gravel-bed streams. This formula was used to analyze the hydraulic geometry of gravel-bed streams (Parker 1979).

**Van Rijn (1984a):**

$$q^* = 0.053 \frac{T^{2.1}}{D_*^{0.3}} \quad (2-103a)$$

can be used to estimate bed load transport rates of particles with mean sizes in the range between 0.2 and 2.0 mm. This

equation is based on a dimensionless particle diameter and the transport stage parameter  $T$ , defined, respectively, as

$$D_* = D_{50} \left( \frac{gR}{\nu^2} \right)^{1/3} = R_{ep}^{2/3} \quad (2-103b)$$

and

$$T = \frac{\tau_s^* - \tau_c^*}{\tau_c^*} \quad (2-103c)$$

Here  $\tau_s^*$  is the bed shear stress due to skin or grain friction, and  $\tau_c^*$  is the critical shear stress for motion from the Shields diagram.

**Madsen (1991):**

$$q^* = F_M (\tau^{*1/2} - 0.7\tau_c^{*1/2})(\tau^* - \tau_c^*) \quad (2-104a)$$

where  $F_M = 8 / \tan \phi$  for rolling/sliding sand grains and  $F_M = 9.5$  for saltating sand grains in water.

**Nielsen (1992):**

$$q^* = 12\tau^{*1/2}(\tau^* - \tau_c^*) \quad (2-104b)$$

obtained by fitting to uniform size sand and gravel bed load transport data. This relation was also independently derived by Soulsby (1997). Equations (2-104a) and (2-104b) have been used mainly in coastal engineering.

**Niño and García (1998b):**

$$q^* = \frac{12}{\mu_d} (\tau_s^* - \tau_{*c}) (\tau_s^{*1/2} - 0.7\tau_{*c}^{1/2}) \quad (2-104c)$$

obtained with a Lagrangian description of bed load transport by saltating particles and tested with experimental observations of gravel transport (Niño and García 1994) and sand transport (Niño and García 1998c). A dynamic friction coefficient  $\mu_d = 0.23$  was determined, almost three times smaller than the value proposed for the same coefficient by Bagnold (1973). This relation basically has the same structure as Madsen's Eq. (2-104a).

**Cheng (2002):**

$$q^* = 13\tau^{*3/2} \exp\left(-\frac{0.05}{\tau^{*3/2}}\right) \quad (2-104d)$$

This relation gives results similar to those obtained with Meyer-Peter and Muller (1948) and Einstein (1950) equation for moderate dimensionless shear  $\tau^*$  values. It also agrees

well with the values predicted with Paintal (1971) for weak transport conditions under low shear stresses.

For intense transport conditions associated with large values of the dimensionless Shields stress  $\tau^*$ , Eq. (2-104d) reduces to

$$q^* \cong 13 \tau^{*3/2} \quad (2-104e)$$

In fact, most of the bed load transport equations display the same asymptotic behavior for high values of shear stress as can be observed in Fig. 2-33. That is, for  $\tau^* \gg \tau_c^*$ ,  $q^* \approx \tau^{*3/2}$ . However, a word of caution is necessary because this does not seem to be the case according to the observations made by several investigators who have found a different relation for high transport rates. For instance, Rickenmann (1991) has indicated that for intense sediment transport conditions, when  $\tau^* > 0.4$ , grain flow (or sheet flow) conditions develop and  $q^*$  is actually proportional to  $\tau^{*5/2}$  as found by Hanes and Bowen (1985) with a granular fluid model for coastal sediment transport and Takahashi (1987) for debris flows on steep slopes. Hanes (1986) showed that under these conditions transport rates can be approximated with

$$q^* = 6 \tau^{*5/2} \quad (2-104f)$$

**Fig. 2-33.** Plot of several bed load functions found in the literature.

These findings indicate a stronger dependence of  $q^*$  on  $\tau^*$  at very high transport intensities that one might expect from bed load transport equations. In fact, Abrahams (2003) has recently revisited the concepts advanced by Bagnold (1973) and found that transport rates under sheet flow (grain flow) conditions are much higher than previously thought.

Most of the bed load equations shown above apply to the case of mild slopes or nearly horizontal flows. For steep channels, the effect of the downslope gravitational component cannot be neglected. Smart (1984), Bathurst et al. (1987), Graf and Suszka (1987), Tsujimoto (1989), Rickenmann (1991), Damgaard et al. (1997), and Aguirre-Pe and Fuentes (1995), among others, have proposed equations for bed load transport in steep slopes.

Only a few research groups have attempted complete derivations of the bed load function in water. They include Wiberg and Smith (1989); Sekine and Kikkawa (1992); Niño and García, (1994, 1998); Seminara et al (2002); and Parker et al (2003). These results are encouraging because they show that bed load transport can be predicted with a mechanics-based approach. More recently, discrete particle simulations of bed load transport which account for the effect of near-bed turbulence, particle location and particle-particle interaction, have been conducted, among others, by Jiang and Haff (1993), Drake and Calantoni (2001), Nelson et al. (2001) and Schmeeckle and Nelson (2003). Undoubtedly, the role played by turbulence in bed-load transport is still a subject that deserves more research (Nelson et al. 1995; García et al. 1996; Niño and García 1996; Best et al., 1997; Sechet and Le Guennec 1999; Schmeeckle et al., 2001; Papanicolau et al. 2001; Sumer et al. 2003). It is also clear that direct field observations provide the best information for both developing and testing of new formulations (e.g., Almedeij and Diplas 2003). Several bed-load transport relations for gravel and sediment mixtures are considered in Chapter 3.

## 2.6.5 Two-Dimensional Transport of Bed Load

The relations presented above for bed load transport are all one-dimensional in nature. That is, they provide the magnitude of a bed load transport vector that is oriented in the direction of the boundary shear stress. That is, if the  $s$  coordinate is directed along the bed parallel to the boundary shear stress and the  $n$  coordinate is directed along the bed and perpendicular to the  $s$  coordinate,

$$\vec{q} = (q_s, q_n) = (q, 0) \quad (2-105)$$

where  $\vec{q}$  denotes the two-dimensional vector of bed load transport rate and  $q$  denotes the magnitude of that vector, which is computed using one of the relations presented above.

In point of fact bed load transport is fundamentally two-dimensional in nature. This is illustrated in Fig. 2-34, which illustrates the bed at a river bend. In the diagram  $s$  is a boundary-embedded centerline streamwise component and  $n$  is a boundary-embedded transverse component. Because a bend generates secondary flow in addition to the downstream primary flow, the boundary shear stress vector  $\vec{\tau}_b$  is not parallel to the  $s$  direction, but is skewed somewhat inward. This drives a component of bed load transport in the negative  $n$  direction, i.e., inward (Brooks 1963). The bed itself slopes downward from inside to outside in the transverse direction with magnitude  $|\partial\eta / \partial n|$ . As a result, gravity pulls bed load particles down the slope, driving a component of bed load transport in the positive  $n$  direction. Depending on the magnitude of the forces involved, the bed load vector  $\vec{q}$  may have a positive or negative component in the transverse direction.

These competing transverse effects play an important role in determining the morphology of rivers in meander bends (Engelund 1974; Falcon and Kennedy 1983; Ikeda and Nishimura 1986; Bridge 1992). Secondary flow tends to drive erosion at the outside of a bend and deposition on the inside (Johannesson and Parker 1989a, 1989c). This creates a transverse component to the bed slope, which in turn acts to drive sediment down the slope from inside to outside. An equilibrium condition can be obtained in which secondary forces and gravity forces balance. The desire to understand bend morphodynamics has been one of the motivators in the development of two-dimensional bed load transport relations (van Bendegom 1947; Engelund, 1974; Ikeda and Parker (1989). Meandering channels are considered in more detail in Chapter 8.

Fig. 2-34. Illustration of two-dimensional bed load transport in a river bend.

A second problem that has played a major role in the development of two-dimensional bed load relations is the quantification of the erosion of a river bank composed of noncohesive sediment. Banks in noncohesive material form side slopes; as bed load is moved downstream by the flow, gravity pulls it down the side slope, accomplishing bank erosion. Hirano (1973) was among the first to develop a quantitative formulation for this problem. Streambank erosion is addressed in Chapter 7.

Gravity can influence bed load transport in the downstream as well as transverse direction. In most cases of interest, however, gravity acts only indirectly to drive bed load transport. That is, gravity pulls the flow downslope, and the flow in turn drags the bed material downslope. If the streamwise slope of the bed is sufficiently high, however, the direct contribution of gravity acting on the bed load grains can increase the bed load transport rate (Fernandez-Luque and van Beek 1976).

The first generation of two-dimensional bed load relations was developed based on a linearized formulation for small transverse slope and streamwise bed slopes. These all take the general form

$$\vec{q} = |\vec{q}| \left[ \frac{\vec{\tau}_b}{|\vec{\tau}_b|} - \beta \left( \frac{\tau_{mag}^*}{\tau_c^*} \right)^{-n_0} \vec{\nabla} \eta \right] \quad (2-106a)$$

where the absolute values denote the magnitude of the vector in question,  $\beta$  and  $n_0$  are constants and

$$\vec{\tau}_b = (\tau_{bs}, \tau_{bn}) \quad (2-106b)$$

$$\tau_{mag}^* = \frac{|\vec{\tau}_b|}{\rho R g D} \quad (2-106c)$$

$$\vec{\nabla} \eta = \left( \frac{\partial \eta}{\partial s}, \frac{\partial \eta}{\partial n} \right) \quad (2-106d)$$

The derivations of these formulations are based on the following constraints, which allow linearizing an otherwise nonlinear formulation:

$$\frac{\tau_{bn}}{\tau_{bs}} \ll 1 \quad (2-107a)$$

$$\frac{\partial \eta}{\partial n} \ll 1 \quad (2-107b)$$

$$\frac{\partial \eta}{\partial s} \ll 1 \quad (2-107c)$$

If in turn the streamwise slope is  $\partial\eta/\partial s$  is so small that direct streamwise gravitational forces on bed load can be neglected, Eq. (2-106a) can be further cast in the approximate form

$$|\bar{q}| = q_s \quad (2-108a)$$

$$q_n = q_s \left[ \frac{\tau_{bn}}{\tau_{bs}} - \beta \left( \frac{\tau_s^*}{\tau_c^*} \right)^{-n_0} \right] \frac{\partial\eta}{\partial n} \quad (2-108b)$$

$$\tau_s^* = \frac{\tau_{bs}}{\rho R g D} \quad (2-108c)$$

Engelund (1974) proposed the following values of  $\beta$  and  $n_0$

$$\beta = \frac{1}{\mu_d}, \quad n_0 = 0 \quad (2-109a), (2-109b)$$

where  $\mu_d$  denotes a dimensionless coefficient of dynamic Coulomb friction for particles in bed load transport. Koch and Flokstra (1980) and Struiksmas et al. (1985) proposed the form

$$\beta = \frac{1}{f_*}, \quad n_0 = 1 \quad (2-110a), (2-110b)$$

where  $f_*$  is a calibration coefficient between 1 and 2. Hasegawa (1989) proposed the form

$$\beta = \frac{1}{\sqrt{\mu_s \mu_d}}, \quad n_0 = \frac{1}{2} \quad (2-111a), (2-111b)$$

where  $\mu_s$  denotes a dimensionless coefficient of static Coulomb friction for bed particles. The Ikeda-Parker relation (Parker 1984, based on Ikeda 1982; see also Kikkawa et al., 1976) takes a very similar form (and in fact has a very similar derivation) to that of Hasegawa (1989),

$$\beta = \frac{1 + r\mu_d}{\mu_d f_*}, \quad n_0 = \frac{1}{2} \quad (2-112a), (2-112b)$$

where  $r$  denotes the ratio of lift force to drag force on a particle in bed load motion and  $f_*$  is again a calibration coefficient. Johansson and Parker (1989b) obtained the following evaluations based on bend topography in rivers;

$$\mu_d = 0.43, \quad r = 0.85, \quad (2-112c), (2-112d),$$

$$f_* = 1.19 \quad (2-112e)$$

Sekine and Parker (1992) modeled the saltation trajectories of bed load grains over a bed sloping mildly in the transverse direction to obtain the evaluations

$$\beta = 0.75, \quad n_0 = \frac{1}{4} \quad (2-113a), (2-113b)$$

Olesen (1987) has suggested calibrating  $\beta$  and  $n_0$  to site-specific data.

In applying the above formulation the streamwise sediment transport  $q_s$  is evaluated using one of the one-dimensional formulations of the previous section and the transverse sediment transport is evaluated from Eq. (2-108b).

In recent years fully nonlinear formulations of two-dimensional bed load transport have become available. Kovacs and Parker (1994) used the underlying mechanics of the one-dimensional formulation of Ashida and Michiue (1972) for uniform material as a basis for a fully nonlinear generalization for arbitrary streamwise and transverse bed slopes. The analysis is involved and is beyond the scope of this chapter. It suffices to mention that (1) when applied to one-dimensional transport of bed load at low slopes it reduces to Eq. (2-66) of Ashida and Michiue (1972), and (2) when it is linearized to the form of Eq. (2-108b) the following evaluations are realized,

$$\beta = \frac{1}{\mu_d}, \quad n_0 = \frac{1}{2} \quad (2-114a), (2-114b)$$

with a value of  $\mu_d$  of 0.5. A treatment allowing the numerical implementation of the formulation can be found in Kovacs and Parker (1994).

The formulations of Ashida and Michiue (1972) and thus Kovacs and Parker (1994) employ forms of a criterion due to Bagnold (1956) that contains a conceptual error. Parker et al. (2003) have repeated the analysis using a bed load entrainment formulation due to Tsujimoto (e.g., 1991) (and ultimately due to Einstein 1950) that does not rely on the Bagnold criterion in question. Their two-dimensional bed load formulation is similarly involved; a source for software is referenced in their paper. When applied to one-dimensional transport of bed load at low slopes it reduces to a slightly modified form of Eq. (2-101) of Fernandez Luque and van Beek (1976), and when it is linearized to the form of Eq. (2-108b) the following evaluations are realized:

$$\beta = 0.7, \quad n_0 = \frac{1}{2} \quad (2-115a), (2-115b)$$

Despite very promising recent attempts (Kovacs and Parker 1994; Seminara et al. 2002; Dey 2003; Parker et al. 2003), prediction of bed load transport on arbitrarily sloping beds remains a challenge. This is mainly due to the fact that direct observations of transverse bed load transport are also very challenging (e.g., Talmon et al. 1995). To predict

morphological changes in rivers, coastal areas, and estuaries, such technology is necessary and should be given priority in sediment transport research (Seminara and Blondeaux 2001; Parker and García 2006).

## 2.7 BED FORMS

Sediment waves produced by moving water are, in equal measure, intellectually intriguing and of great engineering importance. For example, seasonal water-temperature changes influence stage-discharge and depth-discharge relations in rivers (e.g., Missouri River) and in conveyance channels and navigation channels where water discharge is constant (Shen et al. 1978). The major influence is related to changes in bed configuration following changes in water temperature (Southard 1989). Large bed forms, such as mega-dunes, can make navigation difficult by increasing shoaling rates and endangering the stability of pipelines and tunnels (Kennedy and Odgaard 1991; Nemeth et al. 2002). The threat to infrastructure caused through sediment transport associated with dunes in the Rio Paraná, Argentina is highlighted by Amsler and García (1997), Amsler and Prendes (2000) and Amsler and Schreider (1999), who describe channel erosion near the city of Paraná as part of the disastrous floods of 1983 and 1992 (Best 2005). In one region of the river, where the Paraná narrows to  $\sim 1.5$  km in width, a 2.4 km long subfluvial tunnel was built in 1968 and the depth of its placement was determined from a combination of regime theory and physical modeling, with a minimum sand cover thickness of 4 m above the tunnel (Amsler and García 1997). A cross section of the tunnel is shown in Fig. 2-35(a). However, the long duration of high floods in 1983 led to the formation of large dunes, up to 6.5 m in height and 320 m in length, that migrated through this river section (Fig. 2-35(b)). These large dunes caused temporary exposure of the tunnel to the flow over a distance of 250 m each time the trough of a large dune moved over the tunnel (Amsler and García 1997; Amsler and Schreider 1999), thus threatening its stability. Remedial actions were required to ensure the stability of the tunnel, involving placing trucks loaded with sand bags within the tunnel to prevent uplifting during most of the flood. This reach is now an area that is receiving much study and monitoring to assess the longer-term changes in bed elevation and the hysteresis effects of dune morphology through floods (e.g., Serra and Vionnet 2006). Shifting of the Paraná River thalweg makes the protection of both the tunnel itself and the river margin where one of the entrances to the tunnel is located (Santa Fe) even more challenging due to lateral migration experienced by the river (Ramonell et al. 2002).

Because of the important role they play in river sedimentation and their significance in ancient sedimentary structures, bed forms in general and dunes in particular have received extensive attention from engineers, sedimentologists and

geomorphologists (e.g., Ashley 1990; Southard 1991; Julien and Klaassen 1995, Julien et al. 2002, Bridge, 2003; Best 2005). Dunes are one of the most common depositional bed forms, forming in a range of sediment sizes from silt and sand to gravel (Dinehart 1992; Seminara 1995; Best 1996; Carling 1999; Kleinhans 2001, 2002). Recent studies of subsurface alluvium also demonstrate that dunes can form the majority of the deposits of sandy braided rivers (Best et al. 2003; Bridge 2003; Best 2005). The depositional patterns created by dunes can result in heterogeneous and anisotropic permeability fields in the subsurface, thus complicating prediction of subsurface flow in both aquifers and hydrocarbon reservoirs (Weber 1986). Shoaling rates and dredging times are largely controlled by the regeneration time of sand waves (Knaapen and Hulscher 2002), pointing to the practical significance of understanding the dynamics of bed forms. Experimental work has also shown the critical role of bed forms, and particularly dunes, in influencing convective flow within the bed sediment that is generated by the differential pressure gradient caused by the bed form (Thibodeaux and Boyle 1987). Packman and

(a)

**Fig. 2-35.** (a) Cross section of tunnel under Paraná River bottom that links Santa Fe and Paraná city, Argentina. The structure needs a sand cover about 4-m-thick on top of it to provide a safety weight  $W_s$  to counteract the net buoyancy force  $F_B - W$  (adapted from Serra and Vionnet 2006).

**Fig. 2-35.** (b) Echosound bottom profile of large dunes ( $\Delta_D \approx 6.5\text{m}$  and  $\lambda_D \approx 250\text{m}$ ) with superimposed smaller dunes ( $\Delta_d \approx 1\text{m}$  and  $\lambda_d \approx 10\text{m}$ ) passing by the tunnel during the flood of June 1992 in the middle reach of the Parana River. Each time the trough of a large dune moved over the tunnel, the sand-cover protection was removed and the tunnel was in danger of experiencing uplifting due to buoyancy effects (Echosound courtesy of Mario Amsler). (*Continued*)

Brooks (2001), Packman and Mackay (2003) and Packman et al. (2004) have also demonstrated the importance of bed forms in hyporheic exchange (i.e., the mixing of stream water with pore water beneath the sediment bed). They show the importance of dunes for both the clogging of the porous bed by finer grains, such as kaolinite, and that the exchange of solutes and colloids is also linked to the rate of bed form migration and scour, with faster-moving bedforms reworking the bed and leading to a greater turnover of sediment. Rutherford (1994, p. 316) has also analyzed the role of dune turnover on benthic oxygen uptake in the Tarawera River, New Zealand. This river receives treated pulp mill effluent and experiences high rates of deoxygenation. The role of dunes in contaminant exchange at sediment-water interfaces is also considered in Chapter 21.

### 2.7.1 Background Knowledge and Recent Advances

A major advance in the theory of alluvial channel flows has been the application of stability theory to identify the regions

of flow for which the stream bed would be stable, that is the flow conditions under which a small disturbance of an initially plane bed would be dampened. The formation of sand waves is considered by most scientists as an instability problem (e.g., Fredsøe 1996). For instance, if a plane sand bed is slightly perturbed, the flow and sediment transport will be also affected. Two possibilities exist:

- (1) The changes in flow pattern and sediment transport will attenuate the amplitude of the perturbation and eventually the bed will go back to the original plane bed state (i.e., the bed is stable); or,
- (2) The flow and sediment transport changes cause the perturbation of the bed to grow in time, resulting in the formation of ripples, dunes, and/or antidunes (i.e., the bed is unstable).

In stability analysis, a plane bed is usually upset with a small sinusoidal bed perturbation having a certain amplitude and wave length. The goal of the analysis is to observe if the

perturbation will grow (unstable) or decay (stable) with time. In his pioneering work on morphodynamics, Exner (1920, 1925) studied the behavior of sand waves with a simple model that related the local sediment transport to the depth-averaged flow velocity, and predicted instability of the bed but no stable regions. Exner's work is described in Graf (1984, p. 289). Anderson (1953) improved upon Exner's flow description and was the first to apply stability theory to the analysis and prediction of bedforms (ripples, dunes, antidunes), although his analysis predicted only neutral instability. Kennedy (1961, 1963) was the first to advance a comprehensive theory to account for dunes, a plane bed, and antidunes by means of linear stability analysis. Kennedy used a potential flow model with an empirical relation between flow velocity and sediment transport; in later studies the theory was extended to the formation of ripples in closed ducts (Kennedy 1964) and to ripples formed in oscillatory flows (Kennedy and Falcon 1965). Potential flow models for bed stability analysis were also advanced by Reynolds (1965) and Gradowczyk (1968). Kennedy (1963) emphasized the need to include a lag between the local sediment transport rate and the local flow velocity. The main two factors causing Kennedy's lag in sand bed rivers are (1) fluid friction, and (2) delayed response of sediment transport to spatial changes in flow velocity. Hayashi (1970) made theoretical studies on bed form development using the St. Venant equations and further interpreted the lag distance introduced by Kennedy. A decade later, Engelund (1970) developed a model which did not require the lag distance and accounted for velocity and suspended sediment distribution as well as turbulent diffusion.

The instability due to bed friction was recognized independently by Frank Engelund (1970) and J. Dungan Smith (1970). Both applied an eddy-viscosity model to compute the flow over a wavy bottom. The Engelund-Smith approach succeeded in predicting the instability of the bed, but could not predict the wave length for which the perturbation growth rate was largest. In both of these cases the perturbation increases monotonically with decreasing wave length. Fredsøe (1974) improved this description by including a bed-slope effect (i.e., gravity) on the bed load movement. When gravitational effects are included, the sediment transport rate becomes smaller on the upslope part of the perturbation and larger on the downslope part. The net result is that less sediment makes it to the top of the perturbation and more sediment is transported downslope from the top of the perturbation, thus the bed-slope effect stabilizes the bed (Fredsøe 1996).

Different types of sand waves may occur simultaneously on a flat bed, but as the flow evolves only one type may reach fully-developed conditions. As will be described below, usually ripples and dunes are the most common bed forms observed for low Froude-number conditions (i.e., lower regime). Ripples are steeper and shorter than dunes and their length depends on particle diameter. Whereas dune height

and length are both mainly functions of the flow depth and display a more complex dependency on particle size. The co-existence of bed forms makes it more difficult to conduct a stability analysis capable of distinguishing between ripples and dunes. This problem was addressed by Richards (1980), who improved the eddy-viscosity description of the flow over a hydraulically-rough wavy bottom by introducing a one-equation turbulence model. His analysis discovered two peaks in the growth rate of the perturbations. The higher peak corresponds to the maximum found independently by Engelund and Smith in 1970, and later corroborated by Fredsøe (1974) when including the bed-slope (i.e., gravity) effect. Richards (1980) found that the location of this peak depends strongly on the flow depth indicating that it is related to the instability of dunes. The lower peak in perturbation amplification is not affected by changes in the flow depth, and according to Richards this maximum can be related to the instability of ripples. Sumer and Bakioglu (1984) considered only the ripple mode and extended the work of Richards to the case of hydraulically smooth and transition bed-roughness conditions. This extension is important since experimental observations have shown that ripples disappear and dunes are the prevailing bed form instability when the flow transitions from hydraulically-smooth to hydraulically-rough conditions.

The effect of sediment transport on bed stability was first included by Engelund (1970) for suspended load and by Parker (1975) for bed load to assess the role of sediment inertia on the development of antidunes. Reynolds (1976) indicated that Kennedy's lag was indeed related to the relaxation time associated with settling of suspended sediment and with less obvious adjustments in bed load. The stabilizing effect of sediment was used by Engelund and Fredsøe (1976) to explain the transition from dunes to plane bed in the lower flow regime. For low Froude numbers, bed load transport is the dominant mode due to low dimensionless Shields' numbers, thus giving place to the formation of dunes. At higher Shields' numbers, suspended load will become the predominant transport mode, resulting in a stable plane bed for sufficiently high shear stresses. The linear stability analysis of Engelund and Fredsøe (1976) was applied by Chen and Nordin (1976) to explain the transition from dunes to plane bed in the Missouri River. Recently, Coleman and Fenton (2000) have revisited potential flow analysis of bed instabilities.

Linear stability theories apply strictly to the inception of bed forms (Nakagawa and Tsujimoto 1984; Coleman and Melville 1996). They are only able to predict whether or not sand waves are generated. Another limitation is that the outcome is independent of the initial perturbation amplitude. Unsteady perturbations amplify or decay forever. Ji and Mendoza (1997) applied weakly nonlinear stability theory to the set of equations governing the motion of turbulent flow and transport of sediment in rivers proposed by Fredsøe (1974). They found that nonlinearities play an important

role in the formation of dunes. A comparison between the results of linear and nonlinear models indicated that for a nonlinear model, dunes are less unstable and less sensitive to changes in the intervening variables. Ji and Mendoza (1997) conducted a weakly nonlinear stability analysis to derive an equation of the Landau-Stuart type for the amplitude time evolution in steady, unidirectional turbulent flow over a movable boundary. It was found that nonlinear effects affect both dune growth and celerity, and the dune height reaches an equilibrium value at large time. A nonlinear model was also used by Zhou and Mendoza (2005) for analyzing the growth of sand wavelets from an initially flat bed. The results of the model were supported by the observations made by Coleman and Melville (1994, 1996). Stability analyses have also been used by Colombini et al. (1987) to study finite-amplitude bars and Seminara and Tubino (1989) to assess the role played by sediment bars on the initiation of river meandering, and by Seminara (1995) to study the effect of sediment sorting on the evolution and characteristics of bed forms. Komarova and Newell (2000) have also studied the nonlinear dynamics of sand banks and sand waves in the ocean. Coastal bed forms have been reviewed by Blondeaux (2001).

Recent years have seen great progress in our knowledge of bed form dynamics that has often been linked to significant advances in our ability to monitor flow and dune morphology in the laboratory and field, and the increasing sophistication of numerical modeling to capture not only the characteristics of the mean flow field but realistically simulate the origins and motions of coherent flow structures above dune beds (Best 2005). Most of this work has been summarized in several review articles, reports, and books, which have appeared since the publication of ASCE Manual 54 (Vanoni 1975). They include those by Reynolds (1976), Engelund and Fredsøe (1982), Ikeda and Parker (1989), McLean (1990), Southard (1991), Kennedy and Odgaard (1991), Seminara (1995), Best (1996), Seminara and Blondeaux (2001), Yalin and da Silva (2001), ASCE (2002), Bridge (2003), Best (2005), and Parker and García (2006).

As detailed in Best (2005), in recent years there has been great progress in our knowledge of bed form dynamics, which has often been linked to significant advances in our ability to monitor flow and dune morphology in the laboratory and field, and the increasing sophistication of numerical modeling to capture not only the characteristics of the mean flow field but realistically simulate the origins and motions of coherent flow structures above dune beds. Some of these advances are considered next.

Significant advances in our understanding have been achieved through studies that have been concerned both with the origin of bed forms (e.g. Yalin 1992; Nelson and Smith 1989; McLean 1990; Southard 1991; Bennett and Best 1996; Coleman and Melville 1996; Nikora and Hicks 1997; Gyr

and Kinzelbach 2004), their stability and transformations (Leeder 1983; Bennett and Best 1996; Robert and Uhlman 2001; Schindler and Robert 2004), uses in estimating bed load transport (e.g. Engel and Lau 1980; Mohrig and Smith 1996; Vionnet et al. 1998; Zhou and Mendoza 2005) and their role in determining flow resistance (e.g., Ogink 1988; Yoon and Patel 1996; Fedele and García 2001; Julien et al. 2002; Wilbers 2003). Additionally, these studies have been conducted both in increasingly sophisticated and quantitative laboratory studies (e.g. van Mierlo and de Ruiter 1988; Shen et al. 1990; Lyn 1993; McLean et al. 1994, 1996, 1999; Nelson et al. 1993; Bennett and Best 1995a; Bennett and Venditti 1997; Kadota and Nezu 1999; Nelson et al. 2001; Best and Kostaschuk 2002; Maddux 2002; Maddux et al. 2003a, 2003b; Coleman et al. 2003; Fernandez et al. 2006) and a growing quantification of bed forms within the natural environment (e.g., Kostaschuk 1989; Gabel 1993; Julien and Klaassen 1995; Kostaschuk and Church 1993; Kostaschuk and Ilersich 1995; Kostaschuk and Villard 1996; Roden 1998; Villard and Kostaschuk 1998; Carling et al. 2000a,b; Best et al. 2001; Williams et al. 2003; Sukhodulov et al. 2004; Parsons et al. 2005).

The simplified problem of flow over fixed (nonerodible) bedform shapes, motivated by the equilibrium problem, has received intense attention. Several laboratory studies have been conducted to elucidate the mean flow and turbulence characteristics above dunes (e.g., van Mierlo and de Ruiter 1988; Lyn 1993; Nelson et al. 1993; McLean et al. 1994; Nelson et al. 1995; Bennett and Best 1995; Best and Kostaschuk 2002; Fernandez et al. 2006). Flow resistance measurements over fixed bedforms have been made by Shen et al. (1990) and Maddux et al. (2003a, 2003b). Such studies have been restricted to flows without mobile-bed material; only recently studies of sediment-transporting flows over, though still artificial, bed forms have appeared (Cellino and Graf 2000; Venditti and Bennett 2000). Observations by Ikeda and Asaeda (1983) of a sediment-laden flow over a rippled bed are an exception.

Numerical simulations of flow over fixed-bed forms have been performed by, among others, Mendoza and Shen (1990); Yoon and Patel (1996); and Zedler and Street (2001). Recently, Tjerry and Fredsøe (2005) replaced the semi-empirical flow model used earlier by Fredsøe (1982) with a two-equation turbulence model, to compute numerically the morphology of dunes. More information on flow and turbulence modeling over dunes can be found in Chapter 16. Coherent turbulent structures in flows over bed forms have also received considerable attention (Ashworth et al. 1996). Their dynamics, even in simpler flows such as uniform flat-bed flows, is still complicated (e.g. Nelson et al. 1995; García et al. 1996; Niño and García 1996). Some interpretations of suspended sediment flux measurements in the presence of dunes have been formulated within a coherent-structures conceptual framework (Lapointe

1992, 1996; Bennett et al. 1998; Nikora and Goring 2000; Venditti and Bennett 2000). Jackson (1976) was among the first to bring attention to the sedimentological effect of coherent structures, in particular the turbulent bursting phenomenon, in rivers.

Field studies (e.g., Kostachuk and Villard 1996; Holmes 2003; Kostachuk et al. 2004; Parsons et al. 2005) with detailed measurements not only of dune characteristics, but also of flow and transport, are valuable and daunting for the same reason: they indicate the complexity of the real problem, which, together with practical constraints on field measurements, make the analysis and interpretation of the data more difficult (van den Berg and van Gelder 1993). Field measurements present additional difficulties in interpretation and raise the question of how meaningful are direct comparisons between field and laboratory/theoretical results. Keulegan (1978) had to address this issue while attempting to estimate the channel roughness of interoceanic canals and recommended that reliance should be placed on field calibration of bed form predictors.

Accurate prediction of stage and flow developments during a flood event must recognize the transient nature of erodible-boundary roughness, implying clear knowledge about bed-form generation and development processes as flows increase and decrease in intensity (Julien and Klaasen, 1995; Julien et al. 2002). Amsler and García (1997) cite that large dunes on the Parana River, Argentina, decreased in magnitude with increasing discharge, however, smaller superimposed dunes increased in size (Fig. 2-46). Large dunes with superimposed smaller dunes are shown in Fig. 2-35b.

For sedimentation engineering purposes, a minimum contribution desired of a theory or model for bed form development would be a reliable means of determining which equilibrium bed configuration would be established, i.e. delineating stability boundaries, as well as a reliable predictor for bed form dimensions under equilibrium conditions (i.e. wavelength and amplitude). As explained above, many attempts have been made to base such boundaries on theoretical stability models, but engineering approaches have been primarily based on dimensional analysis and empiricism.

Recent experimental and theoretical work (e.g., Coleman and Melville 1996; Coleman and Fenton 2000; Coleman et al. 2003; Zhou and Mendoza 2005) has focused on the bed form initiation process, in particular the conditions leading to the development of wavelets, the precursors of ripples (Coleman and Eling 2000). Although the mechanics of bed form development (e.g., Coleman and Melville 1994) and rates of bed form growth for steady flows (e.g., Nikora and Hicks 1997) have been clarified, practical implications and models accessible to the engineer remain to be elaborated. For example, how and at what rates bed forms change with increasing and decreasing flows remains to be quantified. Recent computations by Tjerry and Fredsøe (2005) of

dune morphology have shown promising results for laboratory-scale dunes. Particularly lacking, however, are similar bed form predictors for large alluvial rivers (Schumm and Winkley 1994; Sambrook-Smith et al. 2006). Research needs in this area have been recently addressed by an ASCE Task Committee (ASCE 2002), Best (2005), and Hulscher and Dohmen-Jansen (2005).

## 2.7.2 Dunes, Antidunes, Ripples, and Alternate Bars

The ripples, dunes, and antidunes illustrated in Fig. 2-36 are the classic bed forms of erodible-bed, open-channel flow. On the one hand, they are the product of flow and sediment transport, and on the other hand, they profoundly influence flow and sediment transport. In fact, all of the bed load equations quoted previously are strictly invalid in the presence of bed forms. The adjustment necessary to render them valid (i.e., removal of form drag) is discussed later in the chapter.

Ripples, dunes, and antidunes are undular (wavelike) features that have wavelength  $\lambda$  and wave height  $\Delta$  that scale with the flow depth  $H$ , as defined below.

**2.7.2.1 Dunes** Well-developed dunes tend to have wave heights  $\Delta$  scaling up to about one-sixth of the depth; i.e.,

$$\frac{\Delta}{H} \leq \frac{1}{6} \quad (2-116)$$

Dune wavelength can vary considerably. A fairly typical range can be quantified in terms of dimensionless wavenumber  $k$ , where

$$k = \frac{2\pi H}{\lambda} \quad (2-117)$$

This range is given by

$$0.25 < k < 4.0 \quad (2-118)$$

Dunes invariably migrate downstream. They are typically approximately triangular in shape and usually (but not always) possess a slip face, beyond which the flow is separated for a certain length.

A dune progresses forward as bed load accretes on the slip face. Generally, very little bed load is able to pass beyond the face without depositing on it, whereas most of the suspended load is not directly affected by it.

Dunes are characteristic of subcritical flow in the Froude sense. In a shallow-water (long-wave) model, the Froude criterion dividing subcritical ( $Fr < 1$ ) and supercritical ( $Fr > 1$ ) flow is

$$Fr = 1 \quad (2-119a)$$

Fig. 2-36. Schematic of different bedforms. Note:  $F$  = Froude number;  $d$  = sediment size.

where the Froude number is given by,

$$Fr = \frac{U}{\sqrt{gH}} \quad (2-119b)$$

Dunes, however, do not qualify as long waves, in that their wavelength is of the order of the flow depth. A detailed potential flow analysis over a wavy bed yields the following (wave number-dependent) criterion for critical flow over a bedform (Kennedy 1963),

$$Fr^2 = \frac{1}{k} \tanh(k) \quad (2-120a)$$

Note that as  $k \rightarrow 0$  ( $\lambda \rightarrow \infty$ ),  $\tanh(k) \rightarrow k$ , and condition (2-119a) is recovered in the long-wave limit. For dunes to occur, then, the condition

$$Fr^2 < \frac{1}{k} \tanh(k) \quad (2-120b)$$

must be satisfied. Both dunes and antidunes cause the water surface to undulate as well as the bed. In the case of dunes, the undulation of the water surface is usually of much smaller amplitude than that of the bed; the two are nearly  $180^\circ$  out of phase.

Let  $c$  denote the wave speed of the dune. The bed load transport rate by dunes can be estimated as the volume of material transported forward per unit bed area per unit time by a migrating dune (Simons et al. 1965b). If the dune is approximated as triangular in shape, the following approximation holds (Engel and Lau 1980; Havinga 1983)

$$q \cong \frac{1}{2} \Delta c (1 - \lambda_p) \quad (2-122)$$

where

$\Delta$  and  $c$  = amplitude and celerity, respectively, of the bed form; and  
 $\lambda_p$  = porosity of the sediment bed.

Rubin and Hunter (1982) proposed that the transport rate given by Eq. (2-122) be called the bed form transport rate instead of the bed load transport rate. An elegant derivation of this equation can be found in Ten Brinke et al. (1999). The celerity of dunes  $c$  as a function of the Froude number  $Fr$  can be estimated with an empirical relation proposed by Kondap and Garde (1973),

$$\frac{c}{U} = 0.021 \times Fr^3 \quad (2-123)$$

The celerity of dunes is a small fraction of the mean flow velocity. Kondap and Garde found that for grain sizes in the range between 0.18 mm to 2.28 mm, sediment size seems to have a negligible effect on the celerity of dunes. The data were from laboratory experiments and low gradient streams having depths of less than 1 m. For the case of large sand bed rivers, Fedele (1995) obtained an empirical relation to estimate the velocity of dunes in the Paraná and Paraguay Rivers in South America. Vionnet et al (1998) have also proposed a methodology to compute sediment transport from dune celerity and amplitude based on kinematic-wave theory. More recently, Serra and Vionnet (2006) extended the analysis to account for the transport of smaller dunes superimposed on larger ones (see Fig. 2.35b).

**2.7.2.2 Antidunes** Antidunes are distinguished from dunes by the fact that the water surface undulations are nearly in phase with those of the bed. They are associated with supercritical flow, in the sense that

$$Fr^2 > \frac{1}{k} \tanh(k) \quad (2-124)$$

Antidunes may migrate either upstream or downstream. Upstream-migrating antidunes are usually rather symmetrical in shape and lack a slip face. Downstream-migrating antidunes are rather rarer; these have a well-defined slip face and look rather like dunes. The distinguishing feature is the water surface undulations, which are very pronounced in the case of antidunes.

The potential-flow criterion dividing upstream-migrating antidunes from downstream-migrating antidunes is (Kennedy 1963)

$$Fr^2 = \frac{1}{k \tanh(k)} \quad (2-125)$$

Values lower than the above are associated with upstream-migrating antidunes.

Relations (2-120a), (2-120b), (2-124) and (2-125) were obtained from a potential flow analysis over a wavy bed. A phase diagram showing these conditions is shown in Fig. 2-37. The boundaries they define are modified when turbulent shear flows transporting sediment are considered (e.g., Engelund and Fredsøe 1982). For instance, Wan and Wang (1994) have observed the absence of dunes for volumetric sediment concentrations greater than about 0.08.

**2.7.2.3 Ripples** Ripples are dune-like features that occur most of the time in the presence of a viscous sublayer. The existence of a viscous sublayer does not imply that the flow is either laminar or turbulent. Rather, when the flow is turbulent, the existence of a well-defined viscous sublayer implies flow in the turbulent smooth regime rather than the turbulent rough regime. Ripples look very much like dunes in that they migrate downstream and have a pronounced slip face. They generally are much more three-dimensional in structure than dunes, however, and have little effect on the water surface.

As mentioned earlier, many authors have suggested that a criterion for the existence of ripples is the existence of a viscous sublayer. Recalling that the thickness of the viscous sublayer is given by  $\delta_v = 11.6 \nu / u_*$ , it follows that ripples will form when

$$R_p = \frac{u_* D}{\nu} \leq 11.6 \quad (2-126)$$

Raudkivi (1990; 1997) indicates that ripples only develop in fine grained sediments having mean sizes of less than 0.7 to 0.9 mm, and for shear velocity Reynolds number ( $Re_* = u_* D / \nu$ ) of less than 10 to 27 (see Fig. 2-39b).

**Fig. 2-37.** Phase diagram for dunes and antidunes based on linear potential theory over a wavy bed (after Parker 2005).

Richards (1980) gave the following criteria for ripple formation

$$0.0007 < kz_0 < 0.16 ,$$

where  $k$  is the wave number ( $2\pi/\lambda$ ) and  $z_0$  is the Smith (1977) roughness-length parameter defined as

$$z_0 = 26.3 \frac{\tau_0 - \tau_c}{(\rho_s - \rho)g} + k_n \quad (2-127)$$

with  $k_n = 0.033 k_s$ , where  $k_s$  is the Nikuradse roughness height.

Karim (1999) proposed a relation for predicting ripples from laboratory data reported by Guy et al. (1966). He found that ripples would only occur if

$$N_* < 80 \quad (2-128a)$$

where  $N_* = \frac{u_* D_{50}}{\nu} \frac{U}{\sqrt{gRD_{50}}}$ ,  $U$  is the mean flow velocity, and  $D_{50}$  is the median grain size.

Coleman and Melville (1994) studied the relation between celerity of small bed forms (i.e., wavelets) as a function of bed-form height and found that such relation can be approximated by the expression

$$c'(\Delta - 3.5)^{1.3} = 40 \quad (2-128b)$$

where

$$c' = \text{dimensionless celerity} = c / \left[ (u_* - u_{*c}) (\tau^* - \tau_c^*) \right];$$

$$H' = \text{dimensionless bed-form height} = \Delta / D_g; \text{ and}$$

$$D_g = \text{geometric mean sediment diameter.}$$

When plotted this relation results in a hyperbolic parabola, which indicates that as the bed form increases in height, its celerity decreases according to Eq. (2-128b).

**2.7.2.4 Alternate Bars** Alternate bars are bed forms most commonly found in straight alluvial channels (Bridge 2003). Their geometry is three-dimensional. Navigation conditions and streambank stability can be affected by alternate bars. When alternate bars are present, pools develop on alternate sides of the channel and the floor meanders from pool to pool. Under these conditions, the flow might start to attack the stream banks, eventually causing bank erosion (e.g., Jang and Shimizu 2005) and leading to the initiation of stream meandering (Blondeaux and Seminara 1985; Rhoads and Welford 1991). The pools formed by alternate bars also provide habitat and play an important role in stream ecology.

In straight streams, the minimum channel slope  $S$  necessary for alternate-bar formation is given by (Jaeggi 1984)

$$S > \frac{\exp \left[ 1.07 \left( \frac{B}{D_g} \right)^{0.15} + M_b \right]}{12.9 \left( \frac{B}{D_g} \right)} \quad (2-129a)$$

$B$  is the channel width,  $D_g$  is the geometric mean size of the bed sediment as given by Eq. (2-41a), and  $M_b$  is a parameter that varies from 0.34 for uniform-size bed material to 0.7 for poorly-sorted material. Scour depth ( $S_d$ ) due to alternate bar formation can be estimated with:

$$S_d = 0.76 \Delta_{AB} = \frac{B}{6 \left( \frac{B}{D_g} \right)^{0.15}} \quad (2-129b)$$

where  $\Delta_{AB}$  is the total height of the alternate bar.

Using dimensional analysis and experimental observations, Sukegawa (1973) found that the condition for the formation of alternate bars in straight channels is given by the following:

$$\frac{u_*^2}{u_{*c}^2} \leq 5 \left( \frac{\sqrt{gB}}{u_{*c}} S \right)^{2/3} \quad (2-130)$$

The wavelength of alternate bars is approximately six to ten times the channel width (i.e.,  $\lambda = 6$  to  $10B$ ; Yalin 1992). Channel sinuosity will affect the celerity of alternate bars (García and Niño 1993). As the sinuosity increases, the migration speed of alternate bars decreases with respect to that observed in a straight channel. In general, the celerity of alternate bars is always less than 0.01% of the mean flow velocity in the channel.

Most of the experimental and theoretical work done to characterize alternate bars in straight channels has been done for steady flow conditions (e.g. Sukegawa 1973; Ikeda 1984, Jaeggi 1984; Kuroki and Kishi 1985, Seminara and Tubino 1989; García and Niño 1993; Lanzoni 2000a, 2000b; Knaapen et al. 2001). One exception is the work of Tubino (1991), who analyzed the growth of alternate bars in unsteady flow. Tubino (1991) noted that the characteristic time scale for bar development and the time scale of natural unsteady flow events are typically of the same order of magnitude. The effect of sediment sorting on both the growth and dynamics

of alternate bars has been analyzed by Seminara (1995) and Lanzoni and Tubino (1999).

### 2.7.3 Progression of Bed Forms

Various bed forms are associated with various flow regimes. In the case of a sand-bed stream with a characteristic size less than about 0.5 mm, a clear progression is evident as flow velocity increases. This is illustrated in Fig. 2-36 presented above. The bed is assumed to be initially flat. At very low imposed velocity  $U$ , the bed remains flat because no sediment is moved. As the velocity exceeds the critical value, ripples are formed. At higher values, dunes form and coexist with ripples. For even higher velocities, well-developed dunes form in the absence of ripples. At some point, the velocity reaches a value near the short-wave critical value in the Froude sense, i.e., Eq. (2-120a). Near this point, the dunes are often suddenly and dramatically washed out. This results in a flat bed known as an upper-regime (supercritical) flat bed. Further increases in velocity lead to the formation of antidunes, and finally to the chute and pool pattern. The last of these is characterized by a series of hydraulic jumps.

The effect of bed forms on flow resistance can be explained as follows. As noted earlier for equilibrium flows in wide straight channels, the relation for bed resistance can be expressed in the form

$$\tau_b = \rho C_f U^2 \quad (2-131)$$

where  $C_f$  is bed friction coefficient. If the bed were rigid and the flow rough,  $C_f$  would vary only weakly with the flow, according to the logarithmic law embodied in Eq. (2-19). As a result, the relation between  $\tau_b$  and  $U$  is approximately parabolic for a flat rough bed.

The effect of bed forms is to increase the bed shear stress to values often well above that associated with the skin friction of a rough bed alone. In Fig. 2-38, a plot of  $\tau_b$  versus  $U$  is given for the case of an erodible bed. At very low values of  $U$ , the parabolic law is followed. As ripples and then dunes are formed, the bed shear stress rises to a maximum value (Robert and Uhlman 2001). At this maximum value, the value of  $C_f$  is seen to be as much as five times the value without dunes. It is clear that dunes play a very important role as regards bed resistance. The increased resistance results from form drag in the lee of the dune.

As the flow velocity increases further, dune wavelength gradually increases and dune height diminishes, leading to a gradual reduction in resistance. At some point, the dunes are washed out, and the parabolic law is again satisfied. At even higher velocities, the form drag associated with

**Fig. 2-38.** Variations of bed shear stress  $\tau_b$  and Darcy-Weisbach friction factor  $f = 8 C_f$  with mean velocity  $U$  in flow over a fine-sand bed (after Raudkivi, 1990).

antidunes appears; it is usually not as pronounced as that of dunes.

In the case of a bed coarser than 1.0 mm, the ripple regime is replaced by a zone characterized by a lower-regime (subcritical) flat bed. Above this lie the ranges for dunes, upper-regime flat bed, and antidunes.

### 2.7.4 Dimensionless Characterization of Bed Form Regime

Based on the preceding arguments, it is possible to identify at least three dimensionless parameters that govern bedforms at equilibrium flow. These are Shields stress parameter  $\tau^*$ , shear Reynolds number  $R_p = u_* D / \nu$ , and Froude number  $Fr = U / \sqrt{gH}$ . A characteristic feature of sediment transport is the proliferation of dimensionless parameters (Vanoni 2006). This feature notwithstanding, Parker and Anderson (1977) have shown that equilibrium relations of sediment transport for uniform material in a straight channel can be expressed in terms of just two dimensionless hydraulic parameters, along with a particle Reynolds number (e.g.,  $R_p$  or  $R_{ep} = \sqrt{gRDD}/\nu$ ) and a measure of density difference (e.g.,  $R = (\rho_s - \rho) / \rho$ ).

In the case of bed forms, then, the following classification can be proposed:

$$\text{bedform type} = f(\pi_1, \pi_2; R_p, R) \quad (2-132)$$

Here, any independent pair of dimensionless hydraulic variables  $\pi_1, \pi_2$  applicable to the problem may be specified,

because any one pair can be transformed into any other independent pair. For example, the pair  $(\tau^*, Fr)$  might be used, or alternatively the pair  $(S, H/D)$ .

One of the most popular discriminators of bed form type is not expressed in dimensionless form at all. It is the diagram proposed by Simons and Richardson (1966), shown in Fig. 2-39a. In this diagram, regimes for ripples, dunes, transition to upper-regime plane bed, and upper-regime plane bed and antidunes are shown. The two hydraulic parameters are abbreviated to a single one, stream power  $\tau_b U$ , and particle Reynolds number is replaced by grain size  $D$ . The diagram is applicable only to sand-bed streams of relatively small scale. A similar bed phase discriminator which is popular in the geology community was proposed by Boguchwal and Southard (1990). An adaptation of the Boguchwal-Southard predictor made by Ashley (1990) is shown in Fig. 2-39b. It is a plot of laboratory observations of mean flow velocity against median sediment size covering the range of fine to coarse sand for flow depths between 0.20 and 0.40 m. Because the Boguchwal-Southard diagram uses a logarithmic scale for grain size instead of a normal scale like the Simons-Richardson discriminator, it shows that for finer grain sizes a marked increase in flow velocity can wash out existing ripples and transition abruptly to upper plane bed conditions without the appearance of dunes. The transition to the upper-regime is shown to take place for Froude numbers smaller

Fig. 2-39. Bed form discriminators proposed by (a) Simons and Richardson (1966) and (b) Boguchwal and Southard (adapted from Ashley 1990).

than one ( $Fr < 1$ ) depending on the sediment size. The fact that the bed phases shown in this diagram have been standardized to a given water temperature, highlights both the importance of accounting for temperature effects as well as the need to use dimensionless parameters to discriminate between bed-stability phases. Several dimensionless bed form and flow regime discriminators are presented next.

The discriminator originally proposed by Liu (1957) and later extended by Simons and Richardson (1961), is shown in Fig. 2-40. Liu's discriminator uses one dimensionless hydraulic parameter,  $u_* / v_s$  (a surrogate for  $\tau^*$ ), and the particle shear Reynolds number  $Re_* = u_* D / \nu$ . The diagram is of interest in that it covers sizes much coarser than those of Simons and Richardson and Boguchwal and Southard (Fig. 2-39). It is seen that the various regimes become compressed as grain size increases. For the case of very coarse material, the flow must be supercritical for any motion to occur. As a result, neither ripples nor dunes are to be expected. According to Simons and Senturk (1992), the Liu diagram does not give acceptable results for field conditions because few field data were used in the analysis. Nevertheless, the diagram should be useful for predictions of bed form type in

streams having mean flow depths less than 3 m (10 feet) and for the design of movable-bed laboratory experiments (e.g., Zwamborn 1966; 1981).

In fact, dunes can occur over a limited range in the case of coarse material (e.g., Dinehart 1989). This is illustrated in Figs. 2-41(a) and 2-41(b), which shows the discriminators originally advanced by Chaubert and Chauvin (1963) and Bonnefille-Pernecker (Vollmers and Giese 1970; Bechteler et al. 1991). The Chaubert-Chauvin diagram plots the Shields parameter ( $\tau^*$ ) versus the shear stress Reynolds number  $Re_*$ . A third parameter in this diagram is the Valenbois-Bonnefille dimensionless particle diameter given by

$$D^* = D \left( \frac{g R}{\nu^2} \right)^{1/3} \quad (2-133)$$

The Chaubert-Chauvin diagram shows that  $D^*$  must be less than about 15 for ripples to form. Employing  $R = 1.65$ ,  $g = 981 \text{ cm/s}^2$  and  $\nu = 0.01 \text{ cm}^2/\text{s}$ , it is seen that the condition  $D^* = 15$  corresponds to a value of  $D$  of approximately 0.6 mm.

For coarser grain sizes, the dune regime is preceded by a fairly wide range consisting of lower-regime flat bed. Many gravel-bed rivers never leave this lower-regime flat

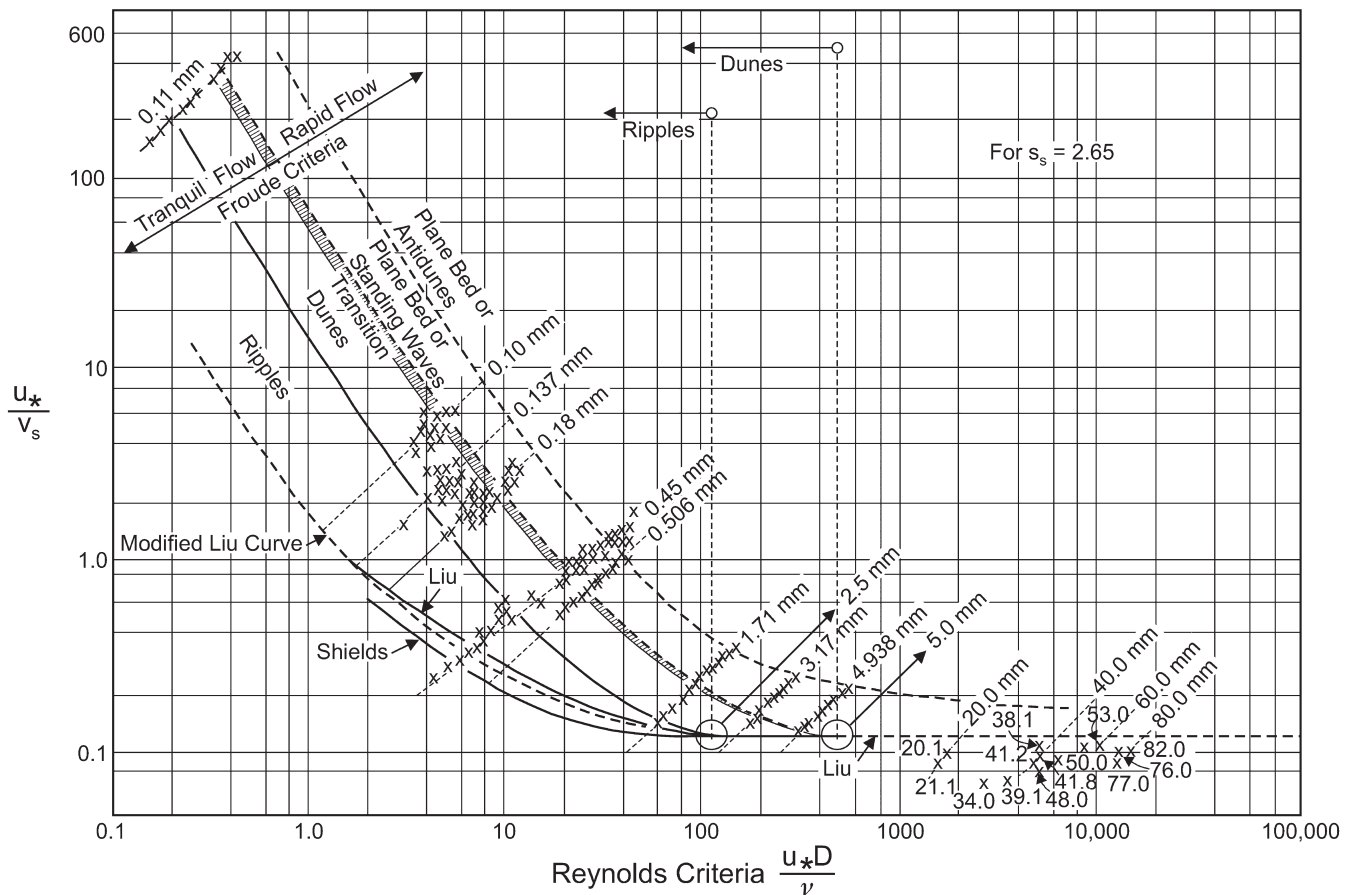

Fig. 2-40. Criteria for bed forms originally proposed by Liu (1957) and later extended by Simons and Richardson (1961).

bed region, even at bankfull flow. The Chaubert-Chauvin diagram in Fig. 2-41(a) is not suited for the description of upper-regime flow.

The Bonnefille-Pernecker diagram displayed in Fig. 2-41(b) plots values of  $D^*$  versus  $Re_*$ . This diagram shows the transition from the lower regime (ripples) to flat bed condition and then to the upper regime (antidunes), for  $D^* < 20$  as  $Re_*$  increases. For coarser sediment,  $D^* > 20$ , the diagram shows the lower regime conditions (dunes) following a narrow range of flat-bed transport conditions. An interesting aspect of this diagram is that it shows a narrow set of conditions, roughly defined by  $20 < Re_* < 45$  and  $7 < D^* < 20$ , for which ripples are superimposed on dunes. Bechteler et al. (1991) have used this diagram to analyze sediment transport conditions in alpine rivers.

A complete set of bed form diagrams for the case of sand is shown in Figs. 2-42(a) to 2-42(f); they are due to Vanoni (1974) and were not published in *ASCE Manual 54*. The two hydraulic parameters are the Froude number  $Fr$  and the relative flow depth  $H/D$  ( $= d/d_{50}$  in the diagram); the particle Reynolds number used in the plot is equal to the ratio  $Re_p / R^{1/2}$ , and the submerged specific gravity  $R$  is set constant at 1.65. Note how the transition to upper regime occurs at progressively lower values of  $Fr$  for relatively deeper flow (in the sense that  $H/D$  becomes large). Shen et al. (1978) confirmed that Vanoni's bedform discriminator fairly well captures temperature effects on river bottom configuration, such as those commonly observed in the Missouri River.

One of the most complete bed form classification schemes that includes both the lower and the upper regime

(Continued)

has been advanced by van Rijn (1984c, 1993). Both laboratory and field data were used to develop van Rijn's diagram. The scheme is based on the Bonnefille dimensionless particle diameter  $D_*$  introduced earlier and the transport-stage parameter  $T$ , defined, respectively, as:

$$D_* = D_{50} \left( \frac{gR}{v^2} \right)^{1/3} = R_{ep}^{2/3} \quad (2-134)$$

and

$$T = \frac{\tau_s^* - \tau_c^*}{\tau_c^*} \quad (2-135)$$

Here  $\tau_s^*$  is the bed shear stress due to skin or grain friction, and  $\tau_c^*$  is the critical shear stress for motion from the Shields diagram.

Van Rijn's diagram indicates that ripples form when both  $D_* < 10$  and  $T < 3$ , as shown in Fig. 2-43. Dunes are present elsewhere when  $T < 15$ , dunes wash out when  $15 < T < 25$ , and upper flow regime starts when  $T > 25$ . However in large rivers, large dunes are found to exist for  $T > 25$ , casting doubts on the applicability of van Rijn's predictor to large alluvial

ivers where the Froude number is never larger than 0.2 to 0.3, even during large floods, and the flows never reach upper regime conditions (Julien 1992; Julien and Klaassen 1995; Amsler and García 1997). For instance, in the Mississippi River large bed forms are observed for values of  $T$  as high as 50 (van Rijn 1996). More field observations in large rivers are needed to further test van Rijn's method.

Brownlie (1983) studied the transition regime and suggested that it can be delineated by the value of the grain Froude number or the sediment number,  $N_s = U / \sqrt{gRD_{50}}$ , and the ratio of grain diameter to viscous sublayer thickness,  $D_{50} / \delta_v$ , where  $\delta_v = 11.6\nu / u_*$ . For slopes greater than 0.006, Brownlie found that all the bed forms were in the upper regime, while for slopes less than 0.006, he suggested the following relationships for the lower limit of the upper regime based on both flume and river data:

$$\log \frac{N_s}{N_s^*} = -0.02469 + 0.1517 \log \frac{D_{50}}{\delta_v} + 0.8381 \left( \log \frac{D_{50}}{\delta_v} \right)^2$$

$$\text{for } \frac{D_{50}}{\delta_v} < 2$$

(2-136a)

$$\log \frac{N_s}{N_s^*} = \log 1.25 \quad \text{for } \frac{D_{50}}{\delta_v} > 2 \quad (2-136b)$$

Here  $N_s^* = 1.74 S^{-1/3}$  and  $S$  is the slope. For the upper limit of the lower regime, Brownlie proposed the following best-fit equations:

$$\log \frac{N_s}{N_s^*} = -0.2026 + 0.07026 \log \frac{D_{50}}{\delta_v} + 0.9330 \left( \log \frac{D_{50}}{\delta_v} \right)^2$$

for  $\frac{D_{50}}{\delta_v} < 2$  (2-137a)

$$\log \frac{N_s}{N_s^*} = \log 0.8 \quad \text{for } \frac{D_{50}}{\delta_v} > 2 \quad (2-137b)$$

Fig. 2-43. Bedform classification (after van Rijn 1984c, 1993).

These equations for the transition zone are shown in Fig. 2-44. It can be seen that the variable  $D_{50} / \delta_v$ , the ratio of grain size to viscous sublayer thickness, reflects the influence of viscous effects near the bed, thus indicating temperature dependence of the bedforms. A very similar flow-regime predictor, which accounts explicitly for viscous effects though the sediment fall velocity, was proposed earlier by Cruickshank and Maza (1973) and is presented below.

Karim (1995) developed bed form regime predictors in the form of limiting Froude numbers, defined as

$$F_t = 2.716 \left( \frac{H}{D_{50}} \right)^{-0.25}$$

$$F_u = 4.785 \left( \frac{H}{D_{50}} \right)^{-0.27} \quad (2-138a,b)$$

where  $F_t$  is the beginning of the transition regime (from the lower flow regime), and  $F_u$  gives the beginning of the upper regime. Based on these definitions for limiting Froude ( $Fr = U/\sqrt{gH}$ ) numbers proposed by Karim (1995), the bed form geometry type can be determined as follows:

Lower regime (ripples, dunes)

$$Fr \leq F_t$$

Transition regime (washed out dunes)

$$F_t \leq Fr \leq F_u$$

Upper regime (plane bed, antidunes)

$$Fr \geq F_u$$

Karim (1995) also used  $Fr \geq 0.8$  as a limit for the existence of antidunes.

Fig. 2-44. Delineation of bedform transition zone from lower regime to upper regime (after Brownlie, 1983). This diagram generally agrees with the more detail diagrams of Vanoni (Fig. 2-42).

As part of a study on the transition of ripples to plane bed in flows over fine sand and silt, resembling Chinese rivers, van den Berg and van Gelder (1993) proposed a stability diagram (Fig. 2-45) that considers the bed shear stress component responsible for sediment transport. In the Van der Berg-Van Gelder diagram a mobility parameter related to grain roughness  $\theta'$ , as proposed by van Rijn (1984c), appears on the ordinate given by

$$\theta' = \frac{U^2}{gRD_{50}(C')^2} \quad (2-139a)$$

with

$$C' = 18 \log \frac{4H}{D_{90}} \quad (2-139b)$$

and the Valenbois-Bonnefille dimensionless particle diameter  $D_*$  in the abscissa

$$D_* = D_{50} \left( \frac{gR}{\nu^2} \right)^{1/3} \quad (2-139c)$$

where  $U$  is the mean flow velocity,  $H$  is the flow depth,  $R = (\rho_s - \rho) / \rho$  is the submerged specific gravity of the sediment,  $D_{50}$  and  $D_{90}$  are the sediment sizes for which 50% and 90% of the bed sediment is finer, respectively, and  $\nu$  is the kinematic viscosity of water. In all, 372 flume experiments with median particle diameters ranging from 11 to 4,080  $\mu\text{m}$  and flow depths up to 1 m, were used to produce the bed stability diagram shown in Fig. 2-45. A total of 262 field observations

**Fig. 2-45.** Bed form in relation to grain mobility number and grain size parameter (after van den berg and van Gelder 1993).

with bed material particle sizes ranging from 80 to 5,100  $\mu\text{m}$  and flow depths ranging from 1 to 15 m were also included. This diagram shows the transition from lower regime (ripples) to upper-stage flat-bed conditions, taking place for  $D_* < 20$ . It appears that the position of the upper boundary of dune existence in fine sand as revealed from flume data is equally applicable to greater depths of natural river flows.

It is clear though that many more field observations using newer technology are needed in order to obtain more reliable bed stability diagrams (e.g., Parsons et al. 2005). The challenges associated with the production of a universal bed form stability diagram are discussed by Ashley (1990) and Best (1996).

## 2.7.5 Prediction of Equilibrium Bed Form Dimensions

The equilibrium dimensions of ripples have been studied for a wide range of sizes by a number of authors. Most studies indicate that ripple dimensions are controlled by sediment size and are independent of flow depth.

Baas (1999) proposed the following equations for ripple wavelength and height at equilibrium

$$\lambda = 75.4 \log D_{50} + 197 \quad (2-140a)$$

$$\Delta = 3.4 \log D_{50} + 18 \quad (2-140b)$$

or

$$\Delta = 18.16 D_{50}^{0.097} \quad (2-140c)$$

Raudkivi (1997) found that data on ripple length show a dependence on grain size as follows

$$\lambda = 245 D^{0.35} \quad (2-141a)$$

where the grain diameter  $D$  is in mm. According to Raudkivi (1997), the ripple steepness decreases with increasing grain size,

$$\Delta/\lambda = 0.074 D^{-0.253} \quad (2-141b)$$

Additional relations to estimate the characteristics of ripples can be found in Yalin (1985) and Mantz (1992). Coleman and Melville (1996), Nikora and Hicks (1997), Coleman and Eling (2000) and Coleman et al. (2003) provide details about the characteristics of sand wave development, in particular of wavelets, the precursors of ripples and dunes. Coleman et al. (2003) report that length of wavelets in open channels and closed conduits is a function only of particle size and

can be estimated with,  $\lambda = 175D^{0.75}$ , where both  $\Delta$  and  $\lambda$  are in mm.

For the case of dunes, Julien and Klaassen (1995) analyzed a large number of laboratory and field data and proposed the simple relation

$$\frac{\lambda}{H} = 6.25 \quad (2-143)$$

as a reasonable first approximation for dune length. They proposed the following equation for dune height;

$$\Delta = 2.5H \left( \frac{D_{50}}{H} \right)^{0.3} \quad (2-144)$$

In Julien and Klaassen's analysis, the dune length is described by

$$\lambda = 2.5\Delta \left( \frac{H}{D_{50}} \right)^{0.3} \quad (2-145)$$

In a discussion of the work of Julien and Klaassen (1995), Amsler and García (1997) noted that Julien and Klaassen's data indicate that large dune heights increased monotonically with increasing discharge (i.e., bed shear stress), which is contrary to what had been observed on the Paraná River, Argentina, and in other large rivers around the world. The Julien-Klaassen formulation implicitly assumes hydraulically rough flow conditions and does not account for the existence of viscous effects. Schreider and Amsler (1992) proposed an empirical set of curves for dune steepness which includes viscous effects. They used laboratory observation as well as data from the Missouri River, USA, the Paraná River, Argentina, and the ACOP channels in Pakistan. Their analysis implicitly accounts for the existence of smaller dunes superimposed on large dunes (see Fig. 2-35b).

In the lower regime, the geometry of bed forms refers to representative dune height  $\Delta$  and wavelength  $\lambda$  as a function of the average flow depth  $H$ , median bed particle diameter  $D_{50}$ , and other flow parameters such as the transport-stage parameter  $T$ , and the grain shear Reynolds number  $R_p$ . The bedform height and steepness predictors proposed by van Rijn (1984c) are

$$\frac{\Delta}{H} = 0.11 \left( \frac{D_{50}}{H} \right)^{0.3} (1 - e^{-0.5T}) (25 - T) \quad (2-146a)$$

and

$$\frac{\lambda}{H} = 0.015 \left( \frac{D_{50}}{H} \right)^{0.3} (1 - e^{-0.5T}) (25 - T) \quad (2-146b)$$

The bed form length obtained by dividing these two equations,  $\lambda = 7.3H$ , is close to the value,  $\lambda = 2\pi H$ , proposed by Yalin (1964). The agreement with laboratory data was found to be quite good, but both curves tend to underestimate the bedform height and steepness of field data (Julien 1992; Julien and Klaassen 1995). As mentioned above, lower-regime bedforms are observed in the Mississippi River at values of  $T$  well beyond 25. Van Rijn's curves largely underpredict the dimensions of bed forms in large rivers (van Rijn 1996).

Field measurement of bed forms in large sand-bed rivers such as the Paraná in South America, the branches of the Rhine in the The Netherlands, and the Mississippi in the USA, show that the flows never leave the lower flow regime and while large dunes might elongate and disappear as the flow discharge increases, the smaller bed forms, originally superimposed on the larger sand waves, do remain along the bottom. This behavior can be observed in Fig. 2-46 for the case of the Paraná River, where the amplitude  $\Delta_d$  and steepness  $\Delta / \lambda_d$  of large dunes as well as the amplitude  $\Delta_s$  and steepness of smaller dunes  $\Delta / \lambda_s$  are plotted as a function of mean flow discharge  $Q$  for the year 1987 (Amsler and García 1997). The smaller dunes are seen to readily respond to variations in flow discharge, reaching a maximum amplitude and steepness around the peak flow discharge. On the other hand, the larger dunes display more inertia with respect to flow change, responding with an increase in amplitude just before the peak discharge and a minimum in steepness when the flow discharge reaches its largest value. It is clear that bed form predictors that have been mainly developed with laboratory data cannot be expected to capture the non-linear behavior displayed in Fig. 2-46. More research using emerging technologies (e.g., ADCP, multibeam sonars' etc.) is needed to be able to understand the morphodynamics of bed forms in large alluvial rivers (e.g., Parsons et al. 2005).

Karim (1999) used an approach similar to that of Kennedy and Odgaard (1991) whereby energy loss because of form drag is related to the head loss across a sudden expansion in an open channel. Essentially this is Carnot's formula for head loss, which had been applied earlier to bed forms by Englund and Hansen (1967) and by Fredsøe (1989) to estimate stage-discharge relations in sand bed streams. Karim (1999) presents the following equation for the geometry of ripples, dunes, and transition bedforms as

$$\frac{\Delta}{H} = \left[ \frac{\left\{ S_e - 0.0168 \left( \frac{D_{50}}{H} \right)^{0.33} F^2 \right\} \left( \frac{\lambda}{H} \right)^{1.20}}{0.47 F^2} \right]^{0.73} \quad (2-147)$$

where  $S_e$  is the energy slope. Karim further recommends solving for  $\lambda / H$  using the equation of Julien and Klaassen

**Fig. 2-46.** Variation of bed form characteristics, large dunes with superimposed smaller dunes, with flow discharge for a reach of the middle Paraná River (After Amsler and García 1997).

(1995), i.e.,  $\lambda / H = 6.25$  for dunes; Yalin's (1964) relation for ripples, i.e.,  $\lambda = 1000 D$ ; and Kennedy's equation for the wavelength of antidunes, i.e.,  $\lambda / H = 2\pi Fr^2$ , where  $Fr$  is the Froude number. Karim (1999) compares his approach (Eq. 2-147) with the relations of Yalin (1964), Ranga Raju and Soni (1976), Allen (1978), van Rijn (1984), Kennedy and Odgaard (1991), Julien and Klaassen (1995), and Karim (1995). Karim's method performs as well as or better than the rest of the relations tested. However, although it performs fairly well when tested with laboratory data, it does not capture the behavior observed in the field. At the same time, Karim's approach is one of the few available methods for predicting sand wave equilibrium dimensions over a wide range of conditions. It can be applied to various bed forms, i.e., ripples, dunes, antidunes/standing waves, and transitional bed regimes. However, it needs to be tested with more observations from large alluvial rivers.

Most of the work in the literature has concentrated on obtaining equilibrium dimensions of ripples and dunes. One exception is the approach proposed by Fredsøe (1982) to estimate the evolution of dunes, all the way from inception

to fully developed stage. Using observations of flow over a negative bottom step, Fredsøe (1982) made an analogy with the flow separation that takes place over the top of a dune. Fredsøe's model accounts for the effect of suspended load and bed load on the dimensions of dunes as the flow intensity increases. Using computations of bed shear stress along a dune profile (e.g., McLean and Smith 1986; Mendoza and Shen 1990), Fredsøe's model was used to solve an approximate analytical expression for dune shape (Fredsøe and Deigaard 1992, p267). Recently, Tjerry and Fredsøe (2005) estimated the bed shear stress needed in Fredsøe's dune model with a two-equation turbulence model, and used these results to investigate the shape and dimensions of dunes caused by a turbulent flow over an erodible bed. Other attempts at developing analytical expressions similar to Fredsøe's for the shape of dunes and ripples include the work among others of Haque and Mahmood (1985, 1986).

The evolution from wavelets to ripples to dunes and to megadunes seems to suggest that there is self-similarity in the mechanics of sand waves, as implied by the work of Raudkivi and Witte (1990), Coleman and Melville (1994),

Nikora and Hicks (1997), and Jerolmack et al. (2006). This hypothesis is supported by the work of Flemming (2000) who prepared a log-log plot of height ( $\Delta$ ) versus wavelength ( $\lambda$ ) for 1,491 observations of subaqueous bedforms. The collapse of the data was rather remarkable and a single “discontinuity” could be observed in the continuum of lengths at slightly less than 1 m, which provides support for the distinction between current ripples and large-scale bed forms. The best fit to the data yields

$$\Delta = 0.0677\lambda^{0.81} \quad (2-148)$$

where both the wavelength  $\lambda$  and the wave height  $\Delta$  are in meters. The sandwave length covers the range from wavelets (a few centimeters long) observed in the laboratory to megadunes (several hundred meters long) observed in large alluvial rivers (Fig. 2-35b).

The development of a reliable bed form predictor for large alluvial flows is one of the outstanding problems in river sedimentation (e.g., Schumm and Winkley 1994). In order to more completely understand the morphodynamics of river dunes, a fuller appreciation is needed of the complex links between flow turbulence, bed morphology, and sediment transport (ASCE 2002; Best 2005; Parker and García 2006). Future research on relations between sediment transport mechanics and dune morphology should focus on:

- Numerical modeling applied to a wide range of flow and bed-material conditions that would allow an analysis of the adjustment of dune morphology, particularly steepness and lee slope angle, to both bed load and suspended load (e.g., Zedler and Street 2001; Tjerry and Fredsøe 2005).
- Detailed field studies of flow, sediment transport and the evolving morphology of individual dunes using modern technology such as acoustic Doppler current profilers and velocimeters, *in-situ* particle size transmissometers and multibeam echosounders to capture the three-dimensional river-bed morphology shown in the cover of this manual (e.g., Parsons et al. 2005).
- Laboratory experiments on and numerical simulations of fundamental processes such as sediment entrainment into suspension and particle-turbulence interaction in the presence of bed forms (e.g. Maddux et al. 2003a; Coleman et al. 2003; Schmeekle and Nelson 2003).
- Relations amongst dune celerity, crest planform, dune profile shape, water temperature, and sediment transport mechanics (e.g., Kostaschuk 2006; Serra and Vionnet 2006).

## 2.7.6 Effect of Bed Forms on River Stage

The presence or absence of bed forms on the bed of a river can lead to curious effects on river stage. According to the

standard Manning-type relation for a nonerodible bed, the following should hold:

$$U = \frac{1}{n} H^{2/3} S^{1/2} \quad (2-149a)$$

Here, the channel is assumed to be wide enough to allow the hydraulic radius to be replaced with the depth  $H$ . According to Eq. (2-149a), if energy slope remains relatively constant, depth should increase monotonically with increasing velocity. This would indeed be the case for a rigid bed. In a sand-bed stream, however, resistance decreases as  $U$  increases over a wide range of conditions.

At equilibrium,

$$\tau_b = \rho C_f U^2 = \rho g H S \quad (2-149b)$$

This decrease in resistance implies that depth does not increase as rapidly in  $U$  in a movable-bed stream as it would for a rigid-bed open channel. In fact, as the transition to upper regime is approached, the bed forms can be wiped out quite suddenly, resulting in a dramatic decrease in resistance. The result can be an actual decrease in depth as velocity increases. This phenomenon was documented for the case of the Padma River, Bangladesh, by Stevens and Simons (1973) and predicted numerically by Chollet and Cunge (1980), as shown in Fig. 2-47. This plot shows how Manning’s  $n$  decreases as the flow discharge increases and the dunes are first elongated and finally washed out. Notice that the numerical model predictions agree very well with the observations for the lower regime conditions but overestimate the value of Manning’s  $n$  in the upper regime where most of the flow resistance should be mainly due to grain friction. Even for one-dimensional computations, this remains a challenging problem for river engineers as shown in Chapter 14.

The effect of the transition phenomenon on flow-stage discharge is best illustrated with a flow resistance diagram first proposed by Cruickshank and Maza (1973) and shown in Fig. 2-48(a). Flume and river data were used to develop this dimensionless diagram showing the transition from the lower regime to the upper regime. In the transition region the flow depth is seen to decrease as the flow velocity increases. The straight part of the curves in the diagram can be expressed with exponential curves obtained by a least square regression analysis. The original Cruickshank-Maza empirical relations have been adapted to follow the notation used in this chapter.

For the lower regime, the mean flow velocity  $U$  can be estimated with

$$\frac{U}{\sqrt{gRD_{50}}} = 6.03 \frac{v_{s50}}{\sqrt{gRD_{50}}} \left( \frac{H}{D_{84}} \right)^{0.634} S^{0.456} \quad (2-150a)$$

**Fig. 2-47.** Variation of Manning's  $n$  with flow discharge for the Padma River, Bangladesh. (o) observations of Stevens and Simmons and (x) computations of Chollet and Cunge (1980).

(a)

(b)

**Fig. 2-48.** (a) Cruickshank-Maza Flow Resistance Predictor, and (b) Stage-Discharge curve for Rio Grande near Bernalillo, New Mexico, estimated with Cruickshank-Maza predictor.

which is valid for,

$$\frac{1}{S} \geq 70 \left( \frac{H}{D_{84}} \right)^{0.350} \quad (2-150b)$$

For the upper regime, the mean flow velocity  $U$  can be estimated with

$$\frac{U}{\sqrt{gRD_{50}}} = 5.45 \frac{v_{s50}}{\sqrt{gRD_{50}}} \left( \frac{H}{D_{84}} \right)^{0.644} S^{0.352} \quad (2-150c)$$

$$\frac{1}{S} \leq 55 \left( \frac{H}{D_{84}} \right)^{0.382} \quad (2-150d)$$

where,

- $U$  = mean flow velocity;
- $H$  = flow depth;
- $S$  = energy slope (same as channel slope for uniform flow);
- $v_{s50}$  = fall velocity for sediment size  $D_{50}$ ;
- $D_{50}$  = median grain size used to determine the fall velocity  $v_{s50}$ ; and
- $D_{84}$  = sediment size for which 84% of bed-material is finer;

These relations are recommended for median grain sizes ( $D_{50}$ ) in the range from 0.2 to 2 mm. The range of geometric standard deviation ( $\sigma_g$ ) of the bed-material size distribution data, went from 1.2 to 2.5. The submerged specific gravity was the same for all the data ( $R=1.65$ ). The exponents for the flow depth ( $H$ ) and energy slope ( $S$ ) are similar to those reported by Simmons and Albertson (1963) for stable alluvial channels. In fact, the exponents are not very different from those found in Manning's equation (Eq. 2-149a).

Cruickshank and Maza used these relations to compute the stage-discharge relation shown in Fig. 2-48(b). The data shown correspond to the Rio Grande near Bernalillo, New Mexico. It is seen that the Cruickshank-Maza relations capture the behavior of the hydraulic radius, which increases with flow velocity along the lower regime (ripples and dunes), remains almost constant for a wide range of flow velocities during the transition (flat bed), and continues to increase again in the upper regime due to the development of antidunes.

It is often found that the discharge at which the dunes are obliterated is a little below bank-full in sand-bed streams with medium to high bed slopes. As a result, flooding is not as severe as it would be otherwise. The precise point of transition is generally different, depending on whether the discharge is increasing or decreasing. This behavior can lead to double-valued stage-discharge relations as shown in

Fig. 2-48(b). The same behavior does not seem to occur in large, low-slope sand-bed streams, because such streams never enter upper-regime conditions, even at or above bank-full discharge (e.g., Amsler and Prendes 2000; Wright and Parker 2004b). In the case of the Paraná River, Argentina, shown in Fig. 2-46, it is observed that the larger dunes elongate and their steepness decreases as the flow discharge increases. On the other hand, the smaller dunes, originally superimposed on the larger ones (see Fig. 2-35b), persist along the bottom of the river and their steepness reaches a maximum for the peak flow discharge. The Froude number  $Fr$  is in general less than 0.25, even during large floods, hence the flow never leaves the lower regime (Amsler and García 1997).

In the case of the Missouri River, temperature effects seem to control the transition from plane bed to a bed with dunes (Shen et al 1978). Southard (1989) used the observations of Shen et al to produce a flow velocity versus sediment size diagram, showing that as the water gets colder and the temperature drops, dunes vanish and plane bed conditions are observed in the Missouri River. Temperature effect on the dynamics of bed forms is a topic that needs to be addressed in the future so that flood stages can be estimated for different climate conditions.

## 2.8 BED FORMS, FLOW RESISTANCE, AND SEDIMENT TRANSPORT

### 2.8.1 Form Drag and Skin Friction

As has been seen, bed forms can have a profound influence on flow resistance, and thus on sediment transport in an alluvial channel. To characterize the importance of bed forms in this regard, it is of value to consider the forces that contribute to the drag force on the bed.

Consider, for example, the case of normal flow in a wide, rectangular channel. In the presence of bed forms, Eq. (2-1) must be amended to

$$\bar{\tau}_b = \rho g H S \quad (2-151)$$

where  $\bar{\tau}_b$  is an effective boundary shear stress, where the overbar denotes averaging over the bed forms, and can be defined as the streamwise drag force per unit area, where  $H$  now represents the depth averaged over the bed forms.

In most cases of interest, the two major sources of the effective boundary shear stress  $\bar{\tau}_b$  are skin friction, which is associated with the local shear stresses, and form drag, which is associated with the pressure. That is,

$$\bar{\tau}_b \equiv \tau_{bs} + \tau_{bf} \quad (2-152)$$

where  $\tau_{bs}$  is the shear stress component due to skin friction and  $\tau_{bf}$  is the shear stress component due to form drag.

The important thing to realize is that form drag results from the net pressure distribution over an entire bed form. At any given point along the surface of the bed form, the pressure force acts normal to the body. For this reason, form drag is directly effective neither in moving sediment as bed load nor in entraining sediment into suspension. In the case of dunes in rivers, the flow usually separates in the lee of the crest, so that form drag is often substantial. The part of the effective shear stress that governs sediment transport is thus seen to be the skin friction.

To render any of the bed-load formulas presented in Section 2.6.4 valid in the presence of bed forms, it is necessary to replace the Shields stress  $\tau^*$  by the Shields stress  $\tau_s^*$  associated with skin friction only:

$$\tau_s^* = \frac{\tau_{bs}}{\rho g R D} \quad (2-153)$$

The fact that the form drag needs to be excluded for the purposes of computing sediment transport does not by any means imply that it is unimportant. It is often the dominant source of boundary resistance, and thus plays a crucial role in determining the depth of flow (e.g., Brownlie 1983). This will be considered in more detail below.

## 2.8.2 Shear Stress Partitions

**2.8.2.1 The Einstein Partition** Einstein (1950) was the first to recognize the necessity of distinguishing between skin friction and form drag. He proposed the following simple scheme to partition the two. Eq. (2-131) is amended to represent an effective boundary shear stress averaged over bed forms,

$$\bar{\tau}_b = \rho C_f U^2 \quad (2-154)$$

where  $C_f$  now represents a resistance coefficient that includes both skin friction and form drag. For given flow velocity  $U$ , Einstein computes the skin friction as

$$\tau_{bs} = \rho C_{fs} U^2 \quad (2-155)$$

where  $C_{fs}$  is the frictional resistance coefficient that would result if bed forms were absent. For example, in the case of rough turbulent flow, Eq. (2-19) may be used:

$$C_{fs} = \left[ \frac{1}{\kappa} \ln \left( 11 \frac{H_s}{k_s} \right) \right]^{-2} \quad (2-156)$$

In fact, Einstein presents a slightly different formula, which allows for turbulent smooth and transitional flow as well. Here the analysis is only done for rough flow conditions

without any loss of generality. The parameter  $H_s$  denotes the depth that would result in the absence of bedforms (but with  $U$  held constant). This depth is necessarily less than  $H$ , because the resistance is less in the absence of bed forms. The remaining problem is how to calculate  $H_s$ . Einstein restricts his arguments to the case of normal (steady, uniform) flow. In this case, Eq. (2-151) holds; that is,

$$\bar{\tau}_b = \rho C_f U^2 = \rho g H S \quad (2-157a)$$

$$\tau_{bs} = \rho C_{fs} U^2 = \rho g H_s S \quad (2-157b)$$

Now between Eqs. (2-154) and (2-157b), the following relation is obtained for  $H_s$ :

$$H_s = \frac{U^2}{g S} \left[ \frac{1}{\kappa} \ln \left( 11 \frac{H_s}{k_s} \right) \right]^{-2} \quad (2-158)$$

For given values of  $U$ ,  $k_s$ , and  $S$  (averaged over bedforms), Eq. (2-158) is easily solved iteratively for  $H_s$ . Once  $H_s$  is known, it is not difficult to complete the partition. From Eq. (2-152), it follows that

$$\tau_{bf} = \bar{\tau}_b - \tau_{bs} \quad (2-159)$$

In analogy to Eqs. (2-152), (2-153), and (2-155), the following definitions are made,

$$\tau_{bf} = \rho C_{ff} U^2 = \rho g H_f S \quad (2-160)$$

from which it follows that

$$C_f = C_{fs} + C_{ff} \quad (2-161a)$$

$$H = H_s + H_f \quad (2-161b)$$

Here  $C_{ff}$  denotes the resistance coefficient associated with form drag, and  $H_f$  denotes the extra depth (compared to the case of skin friction alone) that results from form drag.

Up to this point, it is assumed that  $U$ ,  $S$ , and  $k_s$  are given. If, for example,  $H$  is also known,  $\bar{\tau}_b$  can be calculated from Eq. (2-151). After  $H_s$ ,  $C_{fs}$ , and  $\tau_{bs}$  are computed from Eqs. (2-156) to (2-158), it is possible to compute  $\tau_{bf}$ ,  $H_f$ , and  $C_{ff}$  from Eqs. (2-159) and (2-161).

For example, consider a sand-bed stream at a given cross section with a slope of 0.0004, a mean depth of 2.9 m, a median bed sediment size of 0.35 mm, and a discharge per unit width  $q = U \times H = 4.4 \text{ m}^2/\text{s}$ . Assume that the flow

is under near-normal conditions. Compute values of  $\tau_{bs}$ ,  $\tau_{bf}$ ,  $C_{fs}$ ,  $C_{ff}$ ,  $H_s$ , and  $H_f$ .

The mean flow velocity is given by  $U = 4.4/2.9 = 1.52$  m/s. An appropriate estimate of  $k_s$  for a sand-bed stream is  $k_s = 2.5 D_{50}$ .

By solving Eq. (2-158) by successive approximations, it is found that  $H_s = 1.047$  m. The following values then hold:

$$\tau_{bs} = 4.11 \text{ N/m}^2 \quad (\tau_s^* = 0.725)$$

$$\tau_{bf} = 7.27 \text{ N/m}^2 \quad (\tau_f^* = 1.283)$$

$$\bar{\tau}_b = 11.38 \text{ N/m}^2 \quad (\tau^* = 2.008)$$

$$C_{fs} = 0.00178$$

$$C_{ff} = 0.00315$$

$$C_f = 0.00493 \quad (C_f^{-1/2} = 14.5)$$

$$H_s = 1.047 \text{ m}$$

$$H_f = 1.842 \text{ m}$$

$$H = 2.9 \text{ m}$$

In these relations,

$$\tau_f^* = \frac{\tau_{bf}}{\rho g R D} \quad (2-162)$$

denotes a form-induced Shield stress. In this case, only some 30% of the total Shields stress (skin + form) contributes to the transport of sediment.

The Einstein method provides a way of partitioning the boundary shear stress if the flow is known. It does not provide a direct means of computing form drag. A method proposed by Nelson and Smith (1989) overcomes this difficulty when dune height and wavelength are known.

**2.8.2.2 The Nelson-Smith Partition** Nelson and Smith (1989) consider flow over a dune; the flow is taken to separate in the lee of the dune. This method builds on the work of Smith and McLean (1977) and is very similar to the method proposed independently by Kikkawa and Ishikawa (1979). Based on experimental observations in the Columbia River, Nelson and Smith use the following relation for form drag:

$$D_{ffs} = \frac{1}{2} \rho c_D B \Delta U_r^2 \quad (2-163)$$

Here  $D_{ffs}$  denotes that portion of the streamwise drag force  $D_{fs}$  that is due to form drag,  $B$  is the channel width, and  $U_r$  denotes a reference velocity to be defined below.

They estimate the drag coefficient as  $c_D = 0.21$  from measurements taken in the Columbia River (Smith and McLean 1977).

It follows that

$$\tau_{bf} = \frac{1}{2} \rho c_D \frac{\Delta}{\lambda} U_r^2 = \frac{D_{ffs}}{B \lambda} \quad (2-164)$$

The reference velocity  $U_r$  is defined to be the mean velocity that would prevail between  $z = k_s$  and  $z = \Delta$  if the bed forms were not there. From the logarithmic profile represented by Eq. (2-17a), this is found to be given by

$$\frac{U_r}{\sqrt{\tau_{bs}/\rho}} = \frac{1}{\kappa} \left[ \ln \left( 30 \frac{\Delta}{k_s} \right) - 1 \right] \quad (2-165)$$

It is now assumed that a rough logarithmic law with roughness  $k_s$  prevails from  $z = k_s$  to  $z = \Delta$ , and a different rough logarithmic law with roughness  $k_c$  prevails from  $z = \Delta$  to  $z = H$ . Here  $k_c$  represents a composite roughness length, including the effects of both skin or grain friction and form drag. The two flow velocity distribution laws are thus given by

$$\frac{\bar{u}(z)}{\sqrt{\tau_{bs}/\rho}} = \frac{1}{\kappa} \ln \left( 30 \frac{z}{k_s} \right), \quad k_s < z < \Delta \quad (2-166a)$$

$$\frac{\bar{u}(z)}{\sqrt{(\tau_{bs} + \tau_{bf})/\rho}} = \frac{1}{\kappa} \ln \left( 30 \frac{z}{k_c} \right), \quad \Delta < z < H \quad (2-166b)$$

Nelson and Smith match the above two laws at the level  $z = \Delta$  (i.e., the top of the dune). After some manipulation, it is found that

$$\frac{\tau_{bs} + \tau_{bf}}{\tau_{bs}} = \left[ \frac{\ln(30 \Delta / k_s)}{\ln(30 \Delta / k_c)} \right]^2 \quad (2-167a)$$

The partition requires a prior knowledge of total boundary shear stress  $\bar{\tau}_b = \tau_{bs} + \tau_{bf}$ , as well as roughness height  $k_s$ , dune height  $\Delta$ , and dune wavelength  $\lambda$ . Between Eqs. (2-163) and (2-164),

$$\tau_{bf} = \bar{\tau}_b - \tau_{bs} = \frac{1}{2} c_D \frac{\Delta}{\lambda \kappa^2} \left[ \ln \left( 30 \frac{\Delta}{k_s} \right) - 1 \right]^2 \tau_{bs} \quad (2-167b)$$

This equation can be solved for  $\tau_{bs}$ , and thus  $\tau_{bf}$ . The value of the composite roughness  $k_c$  is then obtained from Eq. (2-167a).

For example, chosen to be rather similar to the previous one, let  $H = 2.9$  m,  $S = 0.0004$ ,  $k_s = 2.5 D_{50}$ ,  $D_{50} = 0.35$  mm,

$\Delta = 0.4$  m, and  $\lambda = 15$  m. The technique, which requires no iteration, yields the following results:

$$\tau_{bs} = 4.45 \text{ N/m}^2 \quad (\tau_s^* = 0.785)$$

$$\tau_{bf} = 6.93 \text{ N/m}^2 \quad (\tau_f^* = 1.223)$$

$$\bar{\tau}_b = 11.38 \text{ N/m}^2 \quad (\tau^* = 2.008)$$

$$k_c = 0.0311 \text{ m}$$

$$C_{fs} = 0.00130$$

$$C_{ff} = 0.00203$$

$$C_f = 0.00333 \quad (C_f^{-1/2} = 17.3)$$

$$H_s = 1.134 \text{ m}$$

$$H_f = 1.766 \text{ m}$$

$$H = 2.9 \text{ m}$$

In computing friction coefficients, the Keulegan relationship was used for the depth-averaged flow velocity:

$$\frac{U}{\sqrt{(\tau_{bs} + \tau_{bf})/\rho}} = \frac{1}{\kappa} \ln \left( 11 \frac{H}{k_c} \right) \quad (2-168a)$$

From this equation, an expression for the composite roughness is obtained,

$$k_c = \frac{11H}{e^{(\kappa U/u_*)}} \quad (2-168b)$$

Here the shear velocity includes the effect of grain friction and form drag, i.e.,  $u_* = \sqrt{(\tau_{bs} + \tau_{bf})/\rho}$ .

The Nelson-Smith method does not require the assumption of quasi-normal flow; the user must, however, have information about the bedform dimensions. This method has been extended by García and Parker (1993) to the case where the boundary is hydraulically smooth (i.e.,  $k_s < \delta_v = 11.6\nu / u_*$ ) and viscous effects are present. In this case, the bed shear stress associated with form drag can be estimated with

$$\tau_{bf} = \bar{\tau}_b - \tau_{bs} = \frac{1}{2} c_D \frac{\Delta}{\lambda \kappa^2} \left[ \ln \left( 9 \frac{u_{*s} \Delta}{\nu} \right) - 1 \right]^2 \tau_{bs} \quad (2-168c)$$

This expression was used to remove the effect of ripples in laboratory experiments on eroding density currents. It can also be applied to remove the effect of ripples on flow

resistance in open channel flows (e.g., Ikeda and Asaeda 1983).

**2.8.2.3 The Engelund-Fredsøe Partition** This method is based on the ideas of Engelund, who first suggested that the head loss due to the expansion of the flow right after a dune's crest, and thus form drag, could be estimated with Carnot's head loss formula (Fredsoe and Deigaard 1992, p. 280). Similar to the Einstein partition method, the total dimensionless bed stress due to skin friction plus form drag (Fredsoe 1982), is expressed as

$$\tau^* = \tau_s^* + \tau_f^* \quad (2-169a)$$

In this method, the component of the dimensionless shear stress due to skin (grain) friction is

$$\tau_s^* = \frac{u_{*s}^2}{gRD} = \frac{U^2}{RgD} \left( \frac{u_{*s}}{U} \right)^2 \quad (2-169b)$$

Here,  $R = (\rho_s / \rho) - 1 =$  submerged specific gravity of sediment ( $R = 1.65$  for sand), and  $C_{fs} = (u_{*s} / U)^2 =$  skin friction coefficient (Eq. 2-156). The contribution to the dimensionless shear stress by the form drag is estimated with Carnot's formula,

$$\tau_f^* = \frac{1}{2} \frac{U^2}{RgD} \frac{\Delta}{H} \frac{\Delta}{\lambda} \quad (2-169c)$$

Combining Eqs. (2-169a), (2-169b), and (2-169c), yields

$$\tau^* = \tau_s^* + \tau_f^* = \tau_s^* \left[ 1 + \frac{1}{2} \frac{\Delta}{H} \frac{\Delta}{\lambda} C_{fs}^{-1} \right] \quad (2-169d)$$

Fredsøe (1982) tested the relationship implied in Eq. (2-169d) between total dimensionless shear stress  $\tau^*$  and contribution made by skin friction  $\tau_{bs}^*$  with the experimental observations made by Guy et al. (1966) at Fort Collins, Colorado. Fredsøe (1989) has also used this approach to compute stage-discharge curves in small sand-bed streams.

Fredsøe (1982) and Fredsøe and Deigaard (1992) have formulated equations to estimate the dune parameters (i.e.,  $\Delta / H$  and  $\Delta / \lambda$ ) in Eq. (2-169d). Following the example presented earlier, let  $H = 2.9$  m,  $C_{fs} = 0.00178$  (from Eq. 2-156),  $\Delta = 0.4$  m, and  $\lambda = 15$  m. Substituting these values into Eq. (2-169d), yields  $\tau^* / \tau_s^* = 2.03$ . This value is close to those estimated for the same ratio with the Einstein ( $\tau^* / \tau_s^* = 2.77$ ) and Nelson-Smith ( $\tau^* / \tau_s^* = 2.56$ ) partitions. This is not surprising because the Engelund-Fredsøe partition combines elements of both of these approaches.

### 2.8.3 Empirical Techniques for Stage-Discharge Relations

To use either the Einstein, Nelson-Smith, or Engelund-Fredsoe partition, it is necessary to know in advance the total effective boundary shear stress  $\bar{\tau}_b$ . In general, this is not known. As a result, the relations in themselves cannot be used to predict the boundary shear stress (as well as the contributions from skin friction and form drag), and thus depth  $H$ , for a flow of, say, given slope  $S$  and discharge per unit width  $q_w$ .

A number of empirical techniques have been proposed to accomplish this. Only a few selected ones are presented herein; they are known to perform at least reasonably well for sand-bed streams with dune resistance.

**2.8.3.1 The Einstein-Barbarossa Method** The method of Einstein and Barbarossa (1952) is applicable for the case of dune resistance in sand-bed streams. It is of historical value and this is the main motivation for presenting it here. This method assumes an empirical relation of the following form:

$$C_{ff} = f(\tau_{s35}^*) \quad (2-170a)$$

Here

$$\tau_{s35}^* = \frac{\tau_{bs}}{\rho g R D_{35}} \quad (2-170b)$$

$$B = B(H) \quad (2-171)$$

An adaptation of the original Einstein-Barbarossa bar-resistance diagram, given implicitly by Eq. (2-170a), is shown in Fig. 2-49(a). Note that it implies that the friction coefficient for the bed forms  $C_{ff}$  declines for increasing  $\tau_{s35}^*$ . That is, the relation applies in the range for which increased intensity of flow causes a decrease in form drag (i.e., the transition from dunes to flat bed). A flow resistance diagram like the one shown in Fig. 2-49(a) can be developed for any sand-bed or gravel-bed stream provided that flow stage and discharge observations for a wide range of conditions, as well as bed-material characteristics, are available.

In the Einstein-Barbarossa method,  $C_{fs}$  is computed from a relation very similar to Eq. (2-156). That relation is used here to illustrate the method, which employs the Einstein partition for skin friction and form drag.

The method is now used to synthesize a depth-discharge relation; that is, a relation between  $H$  and water discharge  $Q$  is obtained. It is assumed that the river slope  $S$  and the sizes  $D_{50}$  and  $D_{35}$  are known. The river is taken to be sufficiently wide so that the hydraulic radius  $R_h \equiv H$ ; otherwise,  $R_h$  should be used in place of  $H$ . In addition, cross-sectional shape is known, allowing for specification of channel width as a function of flow depth:

**Fig. 2-49.** Flow resistance diagrams (a) Einstein and Barbarossa (1952) and (b) Engelund and Hansen (1967).

(b)

**Fig. 2-49.** Flow resistance diagrams (a) Einstein and Barbarossa (1952) and (b) Engelund and Hansen (1967). (Continued)

It is also assumed that auxiliary relations for area  $A$ , wetted perimeter  $P$  and hydraulic radius  $R_h$  as functions of  $H$  are known. A range of values of  $H_s$  is arbitrarily assumed, ranging from a very shallow depth to near-bankfull depth (recall that  $H_s < H$ ). For each value of  $H_s$ , the calculation proceeds as follows:

$$H_s \rightarrow C_{fs} \quad \text{Eq. (2-156)}$$

$$C_{fs}, H_s \rightarrow U \quad \text{Eq. (2-158)}$$

$$H_s \rightarrow \tau_{bs} \rightarrow \tau_{s35}^* \quad \text{Eqs. (2-157b), (2-170b)}$$

$$\tau_{s35}^* \rightarrow C_{ff} \quad \text{Eq. (2-170a); use the diagram in Fig. 2-49a}$$

$$C_{ff}, U \rightarrow H_f \quad \text{Eq. (2-160)}$$

$$H = H_s + H_f \quad \text{Eq. (2-161b)}$$

$$Q = U H B \quad \text{Eq. (2-171)}$$

The result may be plotted in terms of  $H$  versus  $Q$  for the desired depth-discharge relation.

The analysis may be continued for bed load transport rates. That is, the parameter  $\tau_{bs}$  may be computed from

$$\tau_s^* = \frac{\tau_{bs}}{\rho g R D_{50}} \quad (2-172)$$

and this parameter may be substituted into an appropriate bed load transport equation to obtain  $q_b$ . The volumetric bed-load transport rate  $Q_b$  is then computed as

$$Q_b = q_b B \quad (2-173)$$

Most depth-discharge predictors have been developed for sand-bed streams. One exception is the predictor

proposed by Parker and Peterson (1980) for gravel-bed streams. They obtained an empirical bar-resistance equation that displays the same behavior as the bedform resistance of Fig. 2-49a developed for sand-bed streams. The Parker-Peterson equation reads  $C_{ff} = 2.33 \times 10^{-6} \tau_s^{*-1.744}$ , and as expected it yields values that are at least an order of magnitude smaller than those predicted with the Einstein-Barbarossa relation for sand-bed streams. This is mainly due to the absence of dunes in most gravel-bed streams. Parker and Peterson (1980) found that for high flows, little of the resistance is due to alternate bars, but for the lowest stages bar resistance can reach 56% of the total. More information on flow-resistance predictors for gravel-bed streams can be found in Chapter 3.

**2.8.3.2 The Engelund-Hansen Method** The method of Engelund and Hansen (1967) also specifically applies to sand-bed streams. It is generally more accurate than the method of Einstein and Barbarossa, to which it is closely allied. The method assumes quasi-uniform material size; it is necessary to know only a single grain size  $D$ . Roughness height is estimated as  $k_s = 2.5 D_{50}$ .

The method uses the Einstein partition. Skin friction is computed via Eq. (2-153). Form drag is computed from the empirical relation

$$\tau_s^* = f(\tau^*) \quad (2-174)$$

$$\tau^* = \frac{\bar{\tau}_b}{\rho R g D} \quad (2-175a)$$

$$\tau_s^* = \frac{\tau_{bs}}{\rho R g D} \quad (2-175b)$$

Relation (2-174) is shown graphically in Fig. 2-58 in Vanoni (2006, p.81). It has two branches, corresponding to lower-regime and upper-regime flows. The two do not meet smoothly, implying the possibility of a sudden transition. The point of transition is not specified, suggesting the possibility of double-valued rating curves as shown in Fig. 2-48(b).

The lower-regime branch is given by

$$\tau_s^* = 0.06 + 0.4 (\tau^*)^2 \quad (2-176a)$$

The upper branch satisfies the relation

$$\tau_s^* = \tau^* \quad (2-176b)$$

over a range; this implies on upper-regime plane bed. For higher values of Shields stress,  $\tau^*$  again exceeds  $\tau_s^*$ , implying form drag due to the development of antidunes.

The procedure rather closely parallels that of the Einstein-Barbarossa method. It is assumed that values of  $S$  and  $D$  are known, as well as cross-sectional geometry. Values of  $H_s$  are selected, ranging from a low value to near bank-full. The calculation then proceeds as follows:

$$H_s \rightarrow C_{fs} \rightarrow U \quad \text{Eqs. (2-156) and (2-158)}$$

$$H_s \rightarrow \tau_{bs} \rightarrow \tau_s^* \quad \text{Eqs. (2-157b) and (2-175a)}$$

$$\tau_s^* \rightarrow \tau^* \quad \text{Eq. (2-174); use Equation (2-176a) or Fig. 2-49b}$$

$$\tau^* \rightarrow \bar{\tau}_b \rightarrow H \quad \text{Eq. (2-175b) and (2-157a)}$$

$$Q = UHB \quad \text{Eq. (2-171)}$$

The value of  $\tau_s^*$  can be used to calculate bed load transport rates, in a fashion completely analogous to the procedure outlined for the Einstein-Barbarossa method.

**2.8.3.3 The Wright-Parker Method** The method of Engelund and Hansen (1967) was developed using data from laboratory flumes (Guy et al. 1966), and verified in the field using relatively small sand-bed streams (Fredsoe 1989). Posada (1995) found that Eq. (2-176a) did not perform well for the large river data collected in her study. It was found that the relation tends to overpredict the skin-friction shear stress for large rivers at high flows, indicating that large rivers do not make the transition from dunes to a flat bed at shear stresses as low as those observed in laboratory flumes. A recent reanalysis of the problem by Wright and Parker (2004a, 2004b) indicates that the Engelund-Hansen method does indeed provide good results for laboratory flumes and small- to medium-scale sand-bed streams, but does not perform well for large, low-slope sand-bed streams such as the lower Mississippi River. They found, as mentioned earlier, that such streams rarely if ever enter the upper regime. The following modified relation not only provides good results for small and medium-sized sand-bed streams such as the Niobrara River, Middle Loup River, and Rio Grande, but also performs well for such large, low-slope sand-bed streams as the Mississippi River, Atchafalaya River and Red River. It reads

$$\tau_s^* = 0.05 + 0.7(\tau^* Fr^{0.7})^{0.8} \quad (2-177)$$

In this relation  $Fr$  denotes the Froude number of the flow, given as Eq. (2-119b).

The relationship between depth and discharge appropriate for lower-regime conditions is developed by first assuming

that the velocity profile over a rough bed with dunes has approximately the same shape as that over a flat bed. Instead of using the logarithmic velocity distribution, a power law is used for the mean flow velocity,

$$\frac{U}{u_*} = \frac{8.32}{\alpha_{st}} \left( \frac{H}{k_c} \right)^{1/6} \quad (2-178a)$$

$$\frac{U}{u_{*s}} = \frac{8.32}{\alpha_{st}} \left( \frac{H_s}{k_s} \right)^{1/6} \quad (2-178b)$$

Here

$$u_* = \sqrt{gHS};$$

$$u_{*s} = \sqrt{gH_s S};$$

$k_s = 3 D_{90}$  = roughness height due to skin friction; and  
 $k_c$  = composite roughness accounting for both skin friction and form drag.

Also,  $\alpha_{st}$  is a stratification parameter that can be estimated as a function of near-bed sediment concentration and channel slope as follows (Wright and Parker, 2004b),

$$\alpha_{st} = 1 - 0.06 \left( \frac{\bar{c}_b}{S} \right)^{0.77} \quad \text{for } \frac{\bar{c}_b}{S} \leq 10 \quad (2-179a)$$

$$\alpha_{st} = 0.67 - 0.0025 \left( \frac{\bar{c}_b}{S} \right) \quad \text{for } \frac{\bar{c}_b}{S} > 10 \quad (2-179b)$$

Here

$\bar{c}_b$  = volumetric sediment concentration at a distance  $b = 0.05H$  above the bed; and

$S$  = channel slope.

In the case of a sediment mixture, this concentration would be the total concentration for all sizes. Wright and Parker (2004b) used a somewhat modified version of the equation proposed by García and Parker (1991) to estimate  $\bar{c}_b$  (Eq. 2-224a), as given in Eq. (3-143e) of Chapter 3. Using the water continuity equation,  $q_w = UH$ , Eq. (2-178a) can be re-arranged into the dimensionless depth-predictor form

$$\frac{H}{D_{50}} = \left[ \frac{\alpha_{st}}{8.32} \frac{\tilde{q}}{\sqrt{S}} \left( \frac{k_c}{D_{50}} \right)^{1/6} \right]^{3/5} \quad (2-180)$$

Here  $\tilde{q} = q_w / \sqrt{gRD_{50}} D_{50}$  is a dimensionless water discharge. The composite roughness is related to the sand-grain roughness by eliminating  $U$  between Eqs. (2-178a) and (2-178b),

$$\frac{k_c}{k_s} = \left( \frac{H}{H_s} \right)^4 = \left( \frac{\tau^*}{\tau_s^*} \right)^4 \quad (2-181)$$

The relationship between  $\tau^*$  and  $\tau_s^*$  is given by the modified Engelund-Hansen formulation, Eq. (2-177), which provides all the information needed to solve for the flow depth.

The required known parameters are the unit flow discharge  $q_w$ , the river slope  $S$ , and the grain size distribution. To do the computations, guess the depth  $H$  and calculate  $\tau^*$  and the Froude number  $Fr$ . Then calculate  $\tau_s^*$  from Eq. (2-177) and  $k_c$  from Eq. (2-181), using  $k_s = 3D_{90}$ . Then compute the near-bed concentration with Eq. (3-143e) of Chapter 3, which allows computation of the stratification correction  $\alpha_{st}$  from Eqs. (2-179a) and (2-179b). Finally, compute the flow depth  $H$  with Eq. (2-180) and iterate to convergence.

The method has been tested with the large river data set of Toffaleti (1968) with excellent results (Wright and Parker 2004b). The depth predictor was then used to support the development of a suspended-load relation for mixtures which will be presented in Chapter 3.

The partition of bed shear stress into skin-friction and form-drag components is largely motivated by the hypothesis that sediment transport is directly linked to the former component. Recently McLean et al. (1999) have used detailed laboratory measurements to challenge the assumed linkage between sediment transport and bed shear stress due to skin friction. They suggest that the flow velocity at the crest of a bedform may be a better parameter with which to correlate sediment transport.

#### 2.8.3.4 The Brownlie & Cruickshank-Maza Methods

An empirical method offered by Brownlie (1981) has proved to be quite accurate (Brownlie 1983). Like the Cruickshank-Maza (1973) method presented earlier (Section 2.7.6), Brownlie's approach does not involve a decomposition of bed shear stress, but rather gives a direct predictor of depth-discharge relations based on nonlinear regression analysis of hundreds of data points from laboratory and field observations.

The complete method can be found in Section 2.10.3. Here the relation is presented only for the case of lower-regime dune resistance in sand-bed streams. It takes the form

$$\frac{HS}{D_{50}} = 0.3724 (\tilde{q} S)^{0.6539} S^{0.09188} \sigma_g^{0.1050} \quad (2-182a)$$

Here  $\sigma_g$  denotes the geometric standard deviation of the bed material, and  $\tilde{q}$  denotes dimensionless water discharge per unit width, given by

$$\tilde{q} = \frac{q_w}{\sqrt{g D_{50}} D_{50}} \quad (2-182b)$$

For known values  $S$ ,  $D_{50}$ , and  $\sigma_g$ ,  $q_w$ , and thus  $Q = q_w \times B$  can be computed directly as functions of depth  $H$  with the help of Eqs. (2-182a) and (2-182b). The water discharge per unit width is given by  $q_w = UH$  where  $U$  is the mean flow velocity and  $H$  is the flow depth.

Because of its similarity with Brownlie's relation, the empirical relation for lower regime proposed by Cruickshank and Maza (Eq. 2-150a), is reintroduced here. It can be used as a stage-discharge predictor by rewriting it as

$$\tilde{q} = 7.75 R_f \left( \frac{H}{D_{84}} \right)^{1.634} S^{0.456} \quad (2-182c)$$

where the dimensionless specific flow discharge (i.e., flow discharge per unit width) is

$$\tilde{q} = \frac{q_w}{\sqrt{g D_{50}} D_{84}} = \frac{UH}{\sqrt{g D_{50}} D_{84}} \quad (2-182d)$$

and the dimensionless fall velocity is

$$R_f = \frac{v_{s50}}{\sqrt{gRD_{50}}} \quad (2-182e)$$

Notice that the dimensionless fall velocity  $R_f$  is a function of the particle Reynolds number  $R_{ep} = (\sqrt{gRD_{50}} D_{50})/\nu$ , and can be estimated with Dietrich's fall velocity relation (Eq. 2-47a), the Jimenez-Madsen relation (Eq. 2-48a), or from Fig. 2-11.

For known values  $S$ ,  $D_{50}$ ,  $D_{84}$ , and kinematic viscosity of water  $\nu$ ,  $q_w$ , and channel width  $B$ ,  $Q = q_w B$  can be computed directly as functions of depth  $H$  with the help of Eqs. (2-182c), (2-182d), (2-182e), and (2-47). The water discharge per unit width is given by  $q_w = UH$  where  $U$  is the mean flow velocity and  $H$  is the flow depth.

Notice that the Cruickshank-Maza relation accounts for water temperature effects through the dimensionless fall velocity parameter (Eq. 2-182e). This approach can also be used to obtain a stage-discharge predictor for the upper-flow regime by rewriting Eq. (2-150c),

$$\tilde{q} = 7.0 R_f \left( \frac{H}{D_{84}} \right)^{1.644} S^{0.352} \quad (2-182f)$$

Equations (2-182c) for lower-flow regime and (2-182f) for upper-regime apply to the range of conditions defined by Eqs. (2-150b) and (2-150d), respectively. Although the Cruickshank-Maza method has not been tested as thoroughly as Brownlie's, it has been found to provide an effective approximation for both the design of movable-bed models as well as for computing stage-discharge relations in several Mexican sand-bed rivers with flows depths in the range from 1 to 8 m, and with bed-material size in the range from 0.2 to 2.0 mm (Berezowsky and Lara 1986).

**2.8.3.5 The Karim-Kennedy Method** An approach similar to the one used by Brownlie (1983) was employed by Karim and Kennedy (1981) to develop a depth-discharge predictor for alluvial streams. Nonlinear regression analysis was applied to a database consisting of 339 river flows and 608 flume flows to determine the most significant dimensionless variables affecting depth-discharge as well as sediment transport relationships. The flow resistance was formulated in terms of the ratio of friction factors  $f/f_o$ , in which  $f$  is the friction factor for flow over a moving sediment bed, and  $f_o$  is a reference friction factor for flow over a fixed sediment bed given by a Keulegan-type resistance relation as

$$f_o = \frac{8}{\left[5.75 \log(12H/k_s)\right]} \quad (2-183a)$$

in which  $k_s = 2.5 D_{50}$ . It was assumed, based on Engelund's analysis of flow in the lower regime that  $f/f_o$  varies linearly with the ratio of ripple or dune height to flow depth as follows:

$$\frac{f}{f_o} = 1.20 + 8.92 \frac{\Delta}{H} \quad (2-183b)$$

Karim and Kennedy used an expression proposed by Allen (1978) for the ratio of bed form height to flow depth, given by

$$\begin{aligned} \frac{\Delta}{H} = & 0.08 + 2.24 \left( \frac{\tau^*}{3} \right) - 18.13 \left( \frac{\tau^*}{3} \right)^2 \\ & + 70.9 \left( \frac{\tau^*}{3} \right)^3 - 88.33 \left( \frac{\tau^*}{3} \right)^4 \end{aligned} \quad (2-183c)$$

for  $\tau^* < 1.5$  and  $\Delta/H = 0$  for  $\tau^* > 1.5$ . They applied regression analysis to the data to obtain an relationship for dimensionless flow velocity as a function of relative roughness  $H/D_{50}$ , slope  $S$ , and  $f/f_o$ , given by

$$\frac{U}{\sqrt{gRD_{50}}} = 6.683 \left( \frac{H}{D_{50}} \right)^{0.626} S^{0.503} \left( \frac{f}{f_o} \right)^{-0.465} \quad (2-183d)$$

For a given flow depth, the mean flow velocity can be computed directly from Eq. (2-183d). The bed forms are identified as being in the lower regime for  $\tau^* < 1.2$ , transition for  $1.2 < \tau^* < 1.5$ , and upper regime for  $\tau^* > 1.5$ .

**2.8.3.6 Other Stage-Discharge Predictors** There are almost as many empirical resistance predictors for rivers as there are sediment transport relations. A fairly comprehensive summary of older methods can be found in ASCE Manual 54 (Vanoni 2006). Other flow-resistance predictors for sand-bed streams worth considering, besides the ones presented above, are those of van Rijn (1984c), Camacho and Yen (1991), and Bennett (1995).

## 2.9 SUSPENDED LOAD

### 2.9.1 Mass Conservation of Suspended Sediment

A phenomenon of considerable interest in river mechanics is the erosion, transport, and deposition of noncohesive material by turbulent open-channel flow. Suspended sediment differs from bed load sediment in that it may be diffused throughout the vertical column of fluid via turbulence. As long as the suspended sediment under consideration is sufficiently coarse not to undergo Brownian motion, molecular effects can be neglected. Suspended particles are transported solely by convective fluxes. These sediment fluxes have two components: one associated with the mean flow motion and one associated with the turbulence of the flow. A complete derivation of the mass conservation equation for suspended sediment can be found in García (2001). More material can also be found in Chapter 16. Here, only the main elements of the theory of equilibrium suspensions needed to estimate suspended load are presented.

The equation describing mass conservation of suspended sediment of uniform size and constant material density in a turbulent flow can be written as follows (García and Parker 1991)

$$\frac{\partial \bar{c}}{\partial t} + \frac{\partial F_i}{\partial x_i} = 0 \quad (2-184a)$$

where

$$F_i = (u_i - v_s \delta_{i3}) \bar{c} + \overline{u'_i c'} \quad (2-184b)$$

$x_i$  = Cartesian coordinate system such that  $x_3$  is directed upward vertically;

$t$  = time;

$u_i$  = fluid velocity field averaged over turbulence,

$u'_i$  = turbulent fluctuations;

$\bar{c}$  = volume suspended-sediment concentration averaged over turbulence;

$c'$  = instantaneous fluctuation in concentration;

$F_i$  = volume flux vector of suspended sediment averaged over turbulence;  
 $v_s$  = fall velocity of sediment in quiescent water; and  
 $\delta_{i3}$  = Kronecker delta (i.e.,  $\delta_{i3} = 1$  for  $i = 3$  and  $\delta_{i3} = 0$  otherwise).

Equations (2-184a) and (2-184b) are valid only for dilute suspensions (i.e.,  $\bar{c} \ll 1$ ) of particles that are not too coarse (i.e., size is less or equal than 0.5 mm). The mean volumetric sediment concentration  $\bar{c}$  is defined as the ratio between the volume of sediment and the volume of sediment-water mixture.

If  $x_3 = z$  is upward vertical, Eqs. (2-184a) and (2-184b) reduce to

$$\begin{aligned} \frac{\partial \bar{c}}{\partial t} + \bar{u} \frac{\partial \bar{c}}{\partial s} + \bar{v} \frac{\partial \bar{c}}{\partial n} + (\bar{w} - v_s) \frac{\partial \bar{c}}{\partial z} \\ = - \frac{\partial \overline{u'c'}}{\partial s} - \frac{\partial \overline{v'c'}}{\partial n} - \frac{\partial \overline{w'c'}}{\partial z} \end{aligned} \quad (2-185)$$

where

$\bar{u}$ ,  $\bar{v}$ , and  $\bar{w}$  = mean flow velocities in the  $s$ ,  $n$ , and  $z$  directions, respectively; and  
 $\overline{u'c'}$ ,  $\overline{v'c'}$ , and  $\overline{w'c'}$  = sediment fluxes due to turbulence, also known as Reynolds fluxes.

The main assumption here is that the sediment particles follow the fluid particles (i.e., have the same velocity as the fluid), except in the vertical  $z$  direction, where the effect of gravity introduces a slip velocity denoted by the sediment fall velocity  $v_s$  in quiescent water (see section 2.3.8).

It is seen from Eq. (2-184b) that the mean flux of suspended sediment  $F_i$  is composed of two components, i.e., a mean convective flux and a Reynolds flux. The Reynolds flux  $\overline{u'c'}$  in the above relation is clearly diffusive in nature. The simplest closure assumption to represent the Reynolds sediment fluxes is to assume these fluxes proportional to gradients in sediment concentration

$$\overline{u'_i c'} = -D_d \frac{\partial \bar{c}}{\partial x_i} \quad (2-186a)$$

In this equation, the kinematic eddy diffusivity  $D_d$  is assumed to be a scalar quantity. For the case of nonisotropic turbulence, Equation (2-186a) must be generalized to the form (García 2001)

$$\overline{u'_i c'} = -D_{dij} \frac{\partial \bar{c}}{\partial x_j} \quad (2-186b)$$

Here  $D_{dij}$  is a tensor quantity. It is often assumed to represent a diagonal matrix, such that  $D_{dij} = 0$  if  $i \neq j$ , and  $D_{d11} \neq D_{d22} \neq D_{d33}$ . Notes on tensor notation and turbulence can be found in the appendix at the end of Chapter 16.

The kinematic eddy diffusivity  $D_d$  has dimensions of  $L^2/T$ . Common practice is to treat the eddy diffusivity as a scalar. However, this is the case only for isotropic, homogeneous turbulence, as realized in the pioneering experiments conducted by Rouse (1938) on equilibrium suspensions with grid-generated turbulence in a jar (Ettema 2006). More insight into turbulence in sediment-laden flows can be found in Chapter 16. To solve Eq. (2-185), appropriate boundary conditions are needed. These are presented next.

## 2.9.2 Boundary Conditions for Sediment Advection-Diffusion Equation

Equation (2-185), coupled with a Fickian closure approximation such as Eqs. (2-186a) or (2-186b), represents an advection-diffusion equation for suspended sediment (García 2001). The condition of vanishing flux of suspended sediment across (normal to) the water surface defines the upper boundary condition.

If steady, uniform, turbulent flow over a flat bed (when averaged over bed forms) is considered, the water surface boundary condition for the net vertical flux of sediment reduces to

$$\bar{F}_{sz} \Big|_{z=H} = 0 \quad (2-187a)$$

where

$$\bar{F}_{sz} = -v_s \bar{c} + \overline{w'c'} \quad (2-187b)$$

gives the net vertical flux of sediment.

The boundary condition at the bed differs from the one at the water surface, in that it must account for entrainment of sediment into the flow from the bed and deposition of sediment from the flow onto the bed. For a flat (averaged over bedforms) bed, the mean depositional flux of suspended sediment onto the bed is given by  $-D_r$ , which needs to be evaluated at a distance  $z = b$  near the bed,

$$D_r = v_s \bar{c}_b \quad (2-188)$$

denotes the volume rate of deposition of suspended sediment per unit time per unit bed area. Here  $\bar{c}_b$  denotes a near-bed value of mean volumetric sediment concentration.

The component of the Reynolds flux of suspended sediment near the bed that is directed upward normal to the bed may be termed the rate of erosion, or more accurately, entrainment of bed sediment into suspension per unit bed area per unit time. The entrainment rate  $E_r$  is thus given by

$$E_r = \overline{w'c'} \quad (2-189)$$

where

$w'$  and  $c'$  = turbulent fluctuations around both the mean vertical fluid velocity and the mean sediment concentration, respectively.

The 'overbar' denotes averaging over turbulence. The terminology "near-bed" is employed to avoid possible singular behavior at the bed (located at  $z = 0$ ).

It is seen from these equations that the net-upward, normal flux of suspended sediment at (or rather just above) the bed is given by

$$\bar{F}_{sz}|_{z=b} = E_r - D_r = v_s (E_s - \bar{c}_b) \quad (2-190a)$$

where

$$E_s \equiv \frac{E_r}{v_s} \quad (2-190b)$$

denotes a dimensionless rate of entrainment of bed sediment into suspension (i.e., volume of entrained sediment per unit bed area per unit time). The required bed boundary condition, then, involves a specification of  $E_s$ , which can be used to estimate the sediment entrainment flux at the bed (i.e., Eq. 194b). Typically a relation is assumed of the form

$$E_s = E_s(\tau_{bs}, \text{other parameters}) \quad (2-191)$$

where  $\tau_{bs}$  denotes the boundary shear stress due to skin friction.

If it is furthermore assumed that an equilibrium steady, uniform suspension has been achieved. It follows that there should be neither net deposition on ( $\bar{F}_{sz} < 0$ ) nor erosion from ( $\bar{F}_{sz} > 0$ ) the bed. That is,  $\bar{F}_{sz}|_{z=b} = 0$ , yielding the result

$$E_s = \bar{c}_b \quad (2-192)$$

This relation simply states that the entrainment rate equals the deposition rate at equilibrium; thus there is no net normal flux of suspended sediment at the bed. García and Parker (1991) took advantage of this relation and developed a sediment entrainment formulation presented below.

Sediment entrainment and deposition fluxes were directly measured in Central Long Island Sound by Bedford et al. (1987) with the help of acoustic transducers. A control volume approach was used to estimate settling fluxes as well as Reynolds sediment fluxes. The sediment entrainment measurements correlated well with near-bed turbulent kinetic energy. Sediment resuspension has also been backcalculated from in-situ flow observations in the continental shelf off California by Wiberg et al. (1994).

### 2.9.3 Equilibrium Suspension in a Wide Channel

Consider normal flow in a wide, rectangular open channel. The bed is assumed to be erodible and has no curvature when averaged over bed forms such as ripples and dunes. The  $z$ -coordinate is quasi-vertical, implying low channel slope  $S$ . The suspension is likewise assumed to be in equilibrium. That is,  $\bar{c}$  is a function of  $z$  alone, as shown in Fig. 2-50. The flow and suspension are uniform in  $s$  (streamwise direction) and  $n$  (transverse direction) and steady in time, so that Eq. (2-185) reduces to

$$\frac{d}{dz} (\overline{w'c'} - v_s \bar{c}) = 0 \quad (2-193a)$$

indicating that for equilibrium conditions,  $(\overline{w'c'} - v_s \bar{c}) = \text{constant}$  for all values of  $z$  in the range  $z = b$  to  $z = H$ . It follows from the boundary condition at the water surface, given by Eqs. (2-187a) and (2-187b), that the constant = 0, thus Eq. (2-193a) reduces to

$$\overline{w'c'} - v_s \bar{c} = 0 \quad (2-193b)$$

It is appropriate to close this equation with the assumption of an eddy diffusivity as in Eq. (2-186a) so that Eq. (2-193b) becomes (Rouse 1937, Vanoni 1946)

$$D_d \frac{d\bar{c}}{dz} + v_s \bar{c} = 0 \quad (2-194a)$$

According to the literature, this equation was first developed by Wilhelm Schmidt in the mid 1920s for studies of dust transport in atmospheric flows and by M. P. O'Brien in the early 1930s for studies of suspended sediments in streams. It has a simple physical interpretation. The term  $v_s \bar{c}$  represents the rate of deposition of suspended sediment under the influence of gravity; it is always directed downward. If all of the sediment is not to settle out, there

Fig. 2-50. Definition diagram for sediment entrainment from and deposition on channel bed.

must be an upward flux that balances this term. The upward flux is provided by the effect of turbulence, acting to yield a Reynolds flux. According to Eq. (2-186a), this flux will be directed upward as long as  $d\bar{c}/dz < 0$ . It follows that the equilibrium suspended sediment concentration decreases for increasing  $z$ , so that turbulence diffuses sediment from zones of high concentration (near the bed) to zones of low concentration (near the water surface). Thus the general boundary conditions for Eq. (2-194a) are given by (Parker 1978; Fredsøe and Deigaard 1992, p. 246)

$$-D_d \frac{d\bar{c}}{dz} \Big|_{z=b} = v_s E_s \quad (2-194b)$$

$$D_d \frac{d\bar{c}}{dz} + v_s \bar{c} \Big|_{z=H} = 0 \quad (2-194c)$$

The first of these specifies the near-bed rate of entrainment of sediment into suspension, and the second specifies the condition of vanishing upward normal sediment flux at the water surface. It follows that at equilibrium, the flux boundary condition given by Eq. (2-194b) is equivalent to the identity given by Eq. (2-192). However, for nonequilibrium conditions, Eq. (2-194b) should be used as the near-bed boundary condition (Parker 1978; Fredsøe and Deigaard 1992; Admiraal and García 2000).

#### 2.9.4 Form of Eddy Diffusivity (Prandtl analogy)

Further progress requires an assumption for the kinematic eddy diffusivity  $D_d$ . The simple approach taken here is that of Rouse (1937). It involves the use of the Prandtl analogy. The argument is as follows. Fluid mass, heat, momentum, etc., should all diffuse at the same kinematic rate due to turbulence and thus have the same kinematic eddy diffusivity, because each is a property of the fluid particles, and it is the fluid particles that are being transported by Reynolds fluxes.

The Prandtl analogy is by no means exact but has been found to be a reasonable approximation for many turbulent flows. Its application to sediment is more problematic (e.g., Coleman 1970; Kerstens et al. 1979; Nielsen 1992). Inertial effects might cause the sediment particles to lag behind the fluid, resulting in lower eddy diffusivity for sediment than for the fluid (Niño and García 1998a). Furthermore, the mean fall velocity of sediment grains should reduce their residence time in any given eddy, again reducing the diffusive effect (Nielsen 1992). If the particles are not too large, however, it may be possible to equate the vertical diffusivity of the sediment with the vertical eddy viscosity (eddy diffusivity of momentum) of the fluid, as a first approximation. This is done here.

The velocity profile is approximated as logarithmic throughout the depth. To account for the possible

existence of bed forms, the turbulent rough law embodied in Eq. (2-166b) is employed.

$$\frac{\bar{u}}{u_*} = \frac{1}{\kappa} \ln \left( 30 \frac{z}{k_c} \right) \quad (2-195)$$

Here  $k_c$  is a composite roughness chosen to include the effect of bed forms, as outlined in Section 2.8.2.2. Furthermore, according to Eq. (2-2), the bed shear stress is given by

$$\tau_b = \rho u_*^2 \quad (2-196)$$

where  $b$  is chosen to be very close to the bed, i.e.,

$$\frac{b}{H} \ll 1 \quad (2-197)$$

Now the kinematic eddy viscosity  $D_d$  is defined such that

$$\tau = D_d \frac{d\bar{u}}{dz} \quad (2-198)$$

where the distribution of fluid shear stresses  $\tau$  is given by Eq. (2-3)

$$\tau = \tau_b \left( 1 - \frac{z}{H} \right) \quad (2-199)$$

From the above equations, the following equation is obtained

$$D_d = \kappa u_* z \left( 1 - \frac{z}{H} \right) \quad (2-200)$$

If  $D_d$  is averaged in the vertical, the following result is obtained:

$$\bar{D}_d = \frac{\kappa}{6} u_* H \equiv \frac{1}{15} u_* H \quad (2-201a)$$

This relation provides a good approximation to estimate the longitudinal dispersion of fine-grained sediment and contaminants in rivers and streams (e.g., Rutherford 1994; Huang and García 2000).

In the early 1940s, Lane and Kalinske tried to obtain a simple method to estimate suspended sediment load in the field. To this end, they used the average value for the eddy diffusivity given by Eq. (2-201a) to integrate Eq. (2-194a),

resulting in the following equation for suspended sediment distribution

$$\frac{\bar{c}}{\bar{c}_b} = \exp \left\{ -\frac{15v_s}{u_*} \left( \frac{z-b}{H} \right) \right\} \quad (\text{Eq. 201b})$$

where  $\bar{c}_b$  is a near-bed reference concentration measured at a distance  $z = b$  from the bed. This simple exponential equation provides a reasonable approximation to estimate the suspended sediment distribution in wide rivers (i.e.,  $H/B \ll 1$ ). It also yields a finite value of sediment concentration at the water surface (i.e.,  $z = H$ ), which is one weakness of the Rousean distribution presented below. The exponential decay in suspended sediment concentration with distance from the bed given by the Lane-Kalinske relation was the solution originally obtained by Rouse in his turbulence jar experiments. In Rouse's jar, however, the eddy diffusivity was also constant in the vertical direction but the turbulence was generated by an oscillating grid and not by a velocity gradient (i.e., shear stress) as in the case of Eq. (2-201a).

Equation (2-200) is known as the Rousean formulation for the vertical kinematic eddy viscosity. The form predicted is parabolic in shape. Although strictly applying to the turbulent diffusion of fluid momentum, it is equated to the eddy diffusivity of suspended sediment mass below. Coleman (1970) was among the first to estimate the variation of  $D_d$  with distance from the bed  $z$ , from laboratory and field observations of suspended sediment. He found that its variation is parabolic only in the lower portion of the flow and then it remains constant up to the water surface. Van Rijn (1984b), among others, has argued that the ratio between the diffusivity of sediment and the kinematic eddy viscosity is slightly larger than 1 and has proposed an empirical coefficient to adjust the values of  $D_d$  accordingly. On the other hand, Bennett et al. (1998) have found with the help of turbulence measurements in sediment-laden flow that  $D_d$  is a good surrogate for the sediment diffusivity as long as it is directly measured and not back-calculated from Eq. (2-194a). Nielsen (1992) argues that diffusion models do not capture the physics of the problem in coastal sediment transport. Muste and Patel (1997) have done detailed laboratory measurements that can be used to understand sediment diffusion in open-channel flows. Through an analysis of the turbulent kinetic energy budget, Niño and García (1998a) have found that near the bed, fine particles reduce the kinetic energy of the flow but coarser particles enhance turbulence because of the production of turbulent kinetic energy through vortex shedding mechanisms. Cellino and Graf (2000) have analyzed the effect of bed forms on open channel suspensions, showing that the turbulent diffusion is enhanced in the presence of bed forms. Greimann and Holly (2001) have used a two-phase flow model to estimate the role of cross trajectories on eddy diffusivity. A review of most of the experimental work, including sources of error, which has been done on

suspended sediment transport to determine parameters such as the eddy diffusivity, can be found in Muste (2002). Different approaches to estimate numerically the eddy diffusivity in sediment-laden flows are discussed in Chapter 16. In large, low-gradient, sand-bed streams, the diffusion coefficient has to be adjusted for stratification effects. This adjustment to account for stratification effects is presented below.

### 2.9.5 Rouse-Vanoni-Ippen Suspended Sediment Distribution

To integrate Eq. (2-194a) in the vertical, the nominal "near bed" elevation in applying the bottom boundary condition is taken to be  $z = b$ , where  $b$  is a distance taken to be very close to the bed (i.e., satisfying condition Eq. (2-197)). In the Rousean analysis, this value cannot be taken as  $z = 0$ , because Eq. (2-195) is singular there.

Equation (2-200) is now substituted into Eq. (2-194a), which is then integrated from the nominal bed level to distance  $z$  above the bed in  $z$ . The resulting form can be cast as

$$\int_b^H \frac{d\bar{c}}{\bar{c}} = -Z_R \int_b^z \frac{Hdz}{z(H-z)} = \ln \left[ \left( \frac{H-z}{z} \right)^{Z_R} \right] \Big|_b^z \quad (2-202)$$

where  $Z_R$  denotes the dimensionless Rouse Number, given as

$$Z_R = \frac{v_s}{\kappa u_*} \quad (2-203)$$

Integration yields the profile

$$\frac{\bar{c}}{\bar{c}_b} = \left[ \frac{(H-z)/z}{(H-b)/b} \right]^{Z_R} \quad (2-204)$$

Equation (2-204) is commonly recognized as the Rousean distribution for suspended sediment and is one of the milestones in the mechanics of sediment transport (Vanoni 1984). Profiles of suspended sediment obtained from laboratory observations are plotted in Rousean form in Fig. 2-51 (Vanoni 2006). It has also been found to work well in several large alluvial rivers. Sediment concentration profiles of suspended sediment observed in the Amazon River, Brazil, are plotted in Rousean coordinates (i.e.,  $(H-z)/z = (d-y)/y$ ) in Fig. 2-52 (Vanoni 1980). The slope of the straight lines in log-log paper corresponds to the Rouse number  $Z_R$  for a given grain size range. If the mean fall velocity of the particles in each size range can be estimated, it is possible to backcalculate the shear velocity  $u_*$ . Despite the wide range of sediment sizes present in the water column and the large

Fig. 2-51. Laboratory observations of suspended sediment distribution (Vanoni 2006).

Fig. 2-52. Distribution of Suspended Sediment plotted in Rousean Coordinates for the Amazon River at Manacapuru, where the flow depth is 44 m. Each line shows the particle size range and the corresponding value of the Rouse number (adapted from Vanoni 1980).

water depth (44 m), it is clear that the concentration profiles follow the vertical distribution given by Eq. (2-204). The Rousean distribution has also been found to work well for the analysis of sediment transport in vegetated channels (Lopez and García 1998). In this particular case, the eddy diffusivity is enhanced by the presence of the vegetation, resulting in vertical sediment concentration distributions that are slightly more uniform than those predicted by the Rousean formulation.

Although strictly speaking the credit for the above relation should go to Hunter Rouse, Kennedy (1983) argued that Eq. (2-204) should be named the Rouse-Vanoni-Ippen equation for suspended sediment distribution, because all of these researchers contributed either directly or indirectly to its development and subsequent testing. The seminal idea of using the logarithmic flow velocity distribution and the Prandtl analogy to estimate the eddy diffusivity was suggested independently to both Hunter Rouse and Arthur Ippen by Professor Theodore von Karman at the California Institute of Technology. Rouse used the Karman-Prandtl logarithmic velocity distribution that led to the development of the classic relation that now bears his name, while Ippen used the velocity distribution proposed earlier by Krey instead of the Karman-Prandtl relation. Thus, the Rousean formulation predicts sediment concentration relative to a near-bed concentration  $\bar{c}_b$ , which has to be estimated as a function of flow parameters and sediment characteristics, as will be shown below.

Starting with his PhD dissertation completed at Caltech in 1940, Vito Vanoni spent a substantial amount of effort studying open-channel suspensions, in particular the predictions made by the Rousean formulation both in the laboratory (Fig. 2-51) and in the field (Fig. 2-52). By the time *ASCE Manual 54* was first published, the Rouse-Vanoni-Ippen formulation had already reached prominence and since then it has become one of the most important milestones in the field of sediment transport (Vanoni 1984).

**2.9.5.1 Modification of the Rousean Formulation to Include Flow Stratification Effects** River flows carrying suspended sediment are self-stratifying. As illustrated in Fig. 2-51, the Rousean profile predicts a concentration of suspended sediment that decreases with increasing elevation above the bed. It follows that the density of the water-sediment mixture also decreases with increasing elevation above the bed. This stable stratification inhibits turbulent mixing of both flow momentum and sediment mass in the vertical. The result is a modification of the vertical distributions of both streamwise momentum and suspended sediment concentration. More specifically, stratification effects lead to a streamwise velocity profile that increases more rapidly in the vertical than the logarithmic profile, and a suspended sediment profile that decreases more rapidly in the vertical than the Rousean profile.

Starting with his seminal contribution to the subject of sediment transport by currents and waves in continental

shelves (Smith 1977), J. Dungan Smith has been a tireless advocate of the importance of self-stratification by flows with suspended sediment. Smith and McLean (1977a), Smith and McLean (1977b), Gelfenbaum and Smith (1986), McLean (1990), and McLean (1992) offer quantitative formulations of stratification effects based on simple algebraic closures. The kinematic eddy diffusivity  $D_d$  given in Eq. (2-200) is now denoted as  $D_{do}$ , where the subscript “o” denotes the absence of stratification effects. The value of  $D_d$  in the presence of stratification effects is given as

$$D_d = D_{do} F_{strat} (RI_g) \quad (2-205a)$$

$$D_{do} = \kappa u_* z \left( 1 - \frac{z}{H} \right) \quad (2-205b)$$

$$RI_g = \frac{-Rg \frac{d\bar{c}}{dz}}{\left( \frac{d\bar{u}}{dz} \right)^2} \quad (2-205c)$$

Here  $RI_g$  denotes a gradient Richardson number and  $F_{strat}$  is a function that decreases with increasing gradient Richardson number, thus capturing the effect of damping of the turbulence due to flow stratification. Smith and McLean (1977) offer the following form for the function  $F_{strat}$ :

$$F_{strat} (RI_g) = 1 - 4.7 RI_g \quad (2-206)$$

Note that  $F_{strat}$  equals unity for a gradient Richardson number of zero (no stratification effects) and decreases to zero as  $RI_g$  increases to a value of 0.21, at which turbulent mixing is extinguished.

Smith and McLean (1977a) approximate the equation of streamwise momentum balance for the case of equilibrium flow in a wide channel Eq. (2-199) to the form

$$D_d \frac{d\bar{u}}{dz} = u_*^2 \left( 1 - \frac{z}{H} \right) \quad (2-207)$$

An appropriate near-bed boundary condition on Eq. (2-207) at  $z = b$  is obtained by matching the velocity profile to the logarithmic law (Eq. 2.17a) there:

$$\frac{\bar{u}}{u_*} \Big|_{z=b} = \frac{1}{\kappa} \ln \left( 30 \frac{b}{k_c} \right) \quad (2-208)$$

Here  $k_c$  is the composite roughness length accounting for both grain resistance and form-induced drag introduced

earlier. The corresponding boundary condition on Eq. (2-194a) is

$$-D_d \frac{d\bar{c}}{dz} \Big|_b = v_s E_s \quad (2-209)$$

Solving Eqs. (2-194a) and (2-207) subject to the boundary conditions (2-209) and (2-208) and the relations (2-205a), (2-205b), and (2-205c) results in the forms

$$\bar{c} = E_s \exp \int_b^z \left[ - \frac{v_s}{\kappa u_* z \left( 1 - \frac{z}{H} \right) F_{strat} (RI_g)} dz \right] \quad (2-210)$$

and

$$\bar{u} = \frac{u_*}{\kappa} \left[ \ln \left( \frac{b}{z_o} \right) + \int_b^z \frac{1}{z F_{st} (RI_g)} dz \right] \quad (2-211)$$

These two equations do not constitute an explicit solution for the concentration and velocity profiles, because  $RI_g$  is a function of the concentration gradient  $d\bar{c}/dz$  in accordance with Eq. (2-205c). In the limit, as  $RI_g \rightarrow 0$ , however, Eq. (2-210) converges to the Rousean solution of Eq. (2-204) and Eq. (2-211) converges to the logarithmic profile of Eq. (2-195). These two unstratified profiles can be used as base forms for an iterative solution of Eqs. (2-210) and (2-211).

The first step in this iterative process can be illustrated as follows. Let  $\bar{c}_o(z)$  denote the Rousean solution for the profile of suspended sediment concentration and let  $\bar{u}_o$  denote the logarithmic profile of streamwise velocity. The first iteration, including the effect of stratification yields the forms  $\bar{c}_1(z)$  and  $\bar{u}_1(z)$ , where

$$\bar{c}_1 = E_s \exp \int_b^z \left[ - \frac{v_s}{\kappa u_* z \left( 1 - \frac{z}{H} \right) \left[ 1 + 4.7 \frac{Rg \frac{d\bar{c}_o}{dz}}{\left( \frac{d\bar{u}_o}{dz} \right)^2} \right]} dz \right] \quad (2-212)$$

$$\bar{u}_1 = \frac{u_*}{\kappa} \left\{ \ln \left[ \frac{b}{z_o} \right] + \int_b^z \frac{1}{z \left[ 1 + 4.7 \frac{Rg \frac{d\bar{c}_o}{dz}}{\left( \frac{d\bar{u}_o}{dz} \right)^2} \right]} dz \right\} \quad (2-213)$$

A sample calculation illustrates the procedure. The following values are used:  $R = 1.65$ ,  $v_s = 0.748$  mm/s ( $D = 0.1$  mm for  $\nu = 1 \times 10^{-6}$  m<sup>2</sup>/s),  $H = 2$  m,  $k_c = 5$  mm,  $u_* = 0.02$  m/s,  $b = 0.05 H$ , and  $E_s = \bar{c}_b = 0.0001$ . Fourteen iterations are needed to converge to a solution based on a convergence criterion of less than 0.1 % of error. The Rousean and stratification-modified profiles of suspended sediment concentration are shown in Fig. 2-53(a). The logarithmic and stratification-modified profiles of streamwise velocity are shown in Fig. 2-53(b).

Recently, Wright and Parker (2004) have shown that sediment-induced stratification effects are important in large, low-gradient, sand-bed streams. Using an approach similar to the one presented here, they have estimated velocity profiles for the Red and the Atchafalaya Rivers, showing the difference between clear-water and stratified flow velocity profiles as shown in Figure 2-54.

Other approaches in the literature to account for the effect of sediment-induced stratification on velocity profiles not mentioned earlier include the work of Itakura and Kishi (1980), Adams and Weatherly (1981), Coleman (1981), and Soulsby and Wainright (1987). With the exception of Coleman (1981) who also used the Richardson number to quantify the effect of stratification, the rest of the formulations have made an analogy with stratified atmospheric flows, introducing the so-called Monin-Obukhov length into their analyses.

### 2.9.6 Vertically Averaged Concentrations: Suspended Load

Often times it is useful to know the average concentration in the water column. Assuming that a value of near-bed elevation  $b$  is selected, Eq. (2-204) can be used to evaluate a depth-averaged volume suspended sediment concentration  $\bar{C}$ , defined by

$$\bar{C} = \frac{1}{H} \int_b^H \bar{c}(z) dz \quad (2-214)$$

Using  $\delta = \frac{z}{H}$  and  $\delta_b = \frac{b}{H}$ , where  $b$  denotes a location just above the bed, Eq. (2-214) can be expressed as:

$$\bar{C} = \bar{c}_b J_1 = \bar{c}_b \int_{\delta_b}^1 \left[ \frac{(1-\delta)/\delta}{(1-\delta_b)/\delta_b} \right]^{Z_R} d\delta \quad (2-215)$$

Einstein (1950) proposed a relation for the depth-averaged sediment concentration as

**Fig. 2-53.** (a) Concentration profiles and (b) streamwise velocity profiles without and with stratification.

**Fig. 2-54.** Velocity profiles for Red and Atchafalaya Rivers with and without stratification effects (Wright and Parker 2004).

$$\bar{C} = \bar{c}_b \frac{\delta_b}{0.216} I_1 \quad (2-216)$$

Here,  $I_1$  is given in graphical form by Fig. 2-55(a). It follows from Eqs. (2-215) and (2-216) that

$$J_1 = \frac{\delta_b}{0.216} I_1 = \int_{\delta_b}^1 \left[ \frac{(1-\delta)/\delta}{(1-\delta_b)/\delta_b} \right]^{Z_R} d\delta \quad (2-217)$$

The streamwise suspended load  $q_s$  was seen in Eq. (2-85) to be given by the relation

$$q_s = \int_b^H \bar{c}_b \bar{u} dz \quad (2-218)$$

Reducing with the aid of Eqs. (2-195) and (2-204), it is found that Eq. (2-218) can be expressed as (García 1999)

$$q_s = \frac{1}{\kappa} \bar{c}_b u_* H \left[ J_1 \ln \left( 30 \frac{H}{k_c} \right) + J_2 \right] \quad (2-219)$$

This equation indicates that to compute the rate of volumetric suspended sediment transport per unit width under

uniform, equilibrium flow conditions, it is necessary to know the near-bed concentration  $\bar{c}_b$ , the total friction velocity  $u_* = \sqrt{(\tau_{bs} + \tau_{bf})/\rho}$ , the flow depth  $H$ , the value of the composite roughness which can be computed from Eq. (2-168b) as  $k_c = 11H \exp \left\{ -\frac{\kappa U}{u_*} \right\}$ , and the values of

the integral parameters  $J_1$  and  $J_2$ . Assuming that the flow discharge per unit  $q_w$  width is known, the mean flow velocity can be estimated as  $U = q_w / H$ .

$J_1$  is defined above and  $J_2$  is given by

$$J_2 = \int_{\delta_b}^1 \left[ \frac{(1-\delta)/\delta}{(1-\delta_b)/\delta_b} \right]^{Z_R} \ln(\delta) d\delta \quad (2-220a)$$

Again, Einstein (1950) stated another relation for this integral as

$$J_2 = \frac{\delta_b}{0.216} I_2 \quad (2-220b)$$

where  $-I_2$  is also given in tabular form by Fig. 2-55(b).

There have been a number of attempts at finding analytical expressions to estimate the integrals, first presented by Einstein (1950), and shown graphically in Figures 2-55a and

Fig. 2-55. Einstein integrals (a)  $I_1$  and (b)  $-I_2$ .

**Table 2-5 Coefficients from Regression Analysis for (a)  $J_1$  and (b)  $J_2$**

2-55b (e.g., Nakato 1984; Guo and Wood 1995; Guo and Julien 2004). Recently, Abad and García (2006) have proposed an approach that should be of practical use because it is easy to implement in computational models.

With the help of series analysis and appropriate software, Abad and García (2006) obtained expressions for  $J_1$  and  $J_2$  that are well approximated by the following regression-analysis equations:

$$J_1 = \frac{1}{c_0 + c_1 Z_R + c_2 Z_R^2 + c_3 Z_R^3 + c_4 Z_R^4 + c_5 Z_R^5 + c_6 Z_R^6} \quad (2-221a)$$

and

$$J_2 = \frac{-1}{c_0 + c_1 Z_R + c_2 Z_R^2 + c_3 Z_R^3 + c_4 Z_R^4 + c_5 Z_R^5 + c_6 Z_R^6} \quad (2-221b)$$

All the coefficients in Eqs. (2-221a) and (2-221b) are functions of the parameter  $\delta_b = b/H = z_b/H$  where the near-bed concentration  $c_b^-$  is evaluated. The values of such coefficients for both equations are presented in Tables 5a and 5b.

It is apparent from Eq. (2-219) that further progress is predicated on a method for evaluating the near-bed reference concentration  $\bar{c}_b$ , or equivalently (for the case of equilibrium suspensions) the sediment entrainment rate  $E_s$  (García and Parker 1991; Zyserman and Fredsøe 1994). Such a relation is necessary to model transport of suspended sediment in non-equilibrium situations (Celik and Rodi 1988; Alonso and Mendoza 1992; Admiraal and García 2000).

### 2.9.7 Functions for Sediment Entrainment or Equilibrium Near-Bed Sediment Concentration

A number of relations are available in the literature for estimating the entrainment rate of sediment into suspension  $E_s$  (and thus the reference concentration  $\bar{c}_b$  for the equilibrium

case). Table 2-6 summarizes most of the available relations. It includes the formulations proposed by Einstein (1950); Engelund and Fredsøe (1976); Smith and McLean (1977a), Itakura and Kishi (1980), van Rijn (1984), Engelund and Fredsøe (1982); Celik and Rodi (1984), Akiyama and Fukushima (1986), García and Parker (1991), Zyserman and Fredsøe (1994), and Cao (1999). García and Parker (1991) performed a detailed comparison of eight such relations against data. The relations were checked against a carefully selected set of data pertaining to equilibrium suspensions of uniform sand. In such case, it is possible to measure  $\bar{c}_b$  directly at some near-bed elevation  $z = b$ , and to equate the result to  $E_s$  according to Eq. (2-192).

The data consisted of some 64 sets from 10 different sources, all pertaining to laboratory suspensions of uniform sand with a submerged specific gravity  $R = (\rho_s - \rho) / \rho$  near 1.65. Information about the bed forms was typically not sufficient to allow for a partition of boundary shear stress in accordance with Nelson and Smith (1989). As a result, the shear stress due to skin friction alone  $\tau_{bs}$ , and the associated shear velocity due to skin friction  $u_{*s}$ , given by

$$\tau_{bs} = \rho u_{*s}^2 \quad (2-222a)$$

were computed with Eq. (2-156) with the following relation for roughness height  $k_s$

$$k_s = 2D_{50} \quad (2-222b)$$

The data covered the following ranges:

$$E_s: \quad 0.0002 \text{ to } 0.06$$

$$u_{*s}/v_s: \quad 0.70 \text{ to } 7.50$$

$$H/D: \quad 240 \text{ to } 2400$$

$$R_{ep} \quad 3.50 \text{ to } 37.00$$

The range of values of  $R_{ep} = (\sqrt{gRDD}/v)$  corresponds to a grain size range from 0.09 mm to 0.44 mm. Except for

**Table 2-6 Existing Relations to Estimate Sediment Entrainment or Near-Bed Concentration Under Equilibrium Conditions**

Author	Formula	Parameters	Reference height
Einstein (1950)	$\bar{c}_b = \frac{q_*}{23.2(\tau_s^*)^{0.5}}$		$b = 2D_s$
Engelund and Fredsøe (1976; 1982)	$\bar{c}_b = \frac{0.65}{(1 + \lambda_b^{-1})^3}$	$\lambda_b = \left[ \frac{\tau_s^* - 0.06 - \frac{\beta p \pi}{6}}{0.027(R+1)\tau_s^*} \right]^{0.5}; p = \left[ 1 + \left( \frac{\beta \pi}{\tau_s^* - 0.06} \right)^4 \right]^{-0.25}; \beta = 1.0$	$b = 2D_s$
Smith and McLean (1977)	$\bar{c}_b = \frac{0.65\gamma_o T}{1 + \gamma_o T}$	$T = \frac{\tau_s^* - \tau_c^*}{\tau_c^*}; \gamma_o = 2.4 \cdot 10^{-3}$	$b = \alpha_o (\tau_s^* - \tau_c^*) D_s + k_s$ $\alpha_o = 26.3$
Itakura and Kishi (1980)	$\bar{c}_b = k_1 \left( k_2 \frac{u_*}{v_s} \frac{\Omega}{\tau^*} - 1 \right)$	$\Omega = \frac{\tau^*}{k_3} \left( k_4 + \left[ \frac{\exp(-A_o^2)}{\int_{A_o}^{\infty} \exp(-\xi^2) d\xi} \right] \right) - 1; A_o = \frac{k_3}{\tau^*} - k_4;$ $k_1 = 0.008; k_2 = 0.14; k_3 = 0.143; k_4 = 2.0; v_s = \text{fall velocity}$	$b = 0.05H$
Van Rijn (1984)	$\bar{c}_b = 0.015 \frac{D_s}{b} \frac{T^{1.5}}{D_*^{0.3}}$	$D_* = D_s \left( \frac{gR}{v^2} \right)^{1/3}; \Delta_b \text{ is the mean dune height}$	$b = \frac{\Delta_b}{2}$ if $\Delta_b$ known else $b = k_s, b_{\min} = 0.01H$
Celik and Rodi (1984)	$\bar{c}_b = \frac{k_o C_m}{I}$	$C_m = 0.034 \left[ 1 - \left( \frac{k_s}{H} \right)^{0.06} \right] \frac{u_*^2}{gRH} \frac{U_m}{v_s}; I = \int_{0.05}^1 \left( \frac{1-\eta}{\eta} \cdot \frac{\eta_b}{1-\eta_b} \right)^{v_s/0.4u_*} d\eta;$ $h = z/H; h_b = 0.05; k_o = 1.13$	$b = 0.05H$
Akiyama and Fukushima (1986)	$E_s = 0; Z < Z_c$ $E_s = 3 \cdot 10^{-12} Z^{10} \left( 1 - \frac{Z_c}{Z} \right); Z_c < Z < Z_m$ $E_s = 0.3; Z > Z_m$	$Z = \frac{u_*}{v_s} R_p^{0.5}; Z_c = 5; Z_m = 13.2$	$b = 0.05H$
García and Parker (1991)	$E_s = \frac{AZ_u^5}{1 + \frac{A}{0.3} Z_u^5}$	$Z_u = \frac{u_{*s}}{v_s} R_p^n; u_{*s} = \frac{g^{0.5}}{C'} U_m; C' = 18 \cdot \log \left( \frac{12R_b}{3D_s} \right); n = 0.6; A = 1.3 \cdot 10^{-7}$	$b = 0.05H$
Zyserman and Fredsøe (1994)	$\bar{c}_b = \frac{0.331(\tau_s^* - 0.045)^{1.75}}{1 + \frac{0.331}{0.46}(\tau_s^* - 0.045)^{1.75}}$	$\tau_s^* = \frac{(u_{*s})^2}{RgD_s}$	$b = 2D_s$

the somewhat small values of  $H/D$ , the values cover a range that includes typical field sand-bed streams. Three of the relations for  $E_s$  (or  $\bar{c}_b$  at equilibrium) performed particularly well and are presented here. The first of these presented is the relation of García and Parker (1991). The reference level is taken to be 5 % of the depth; that is,

$$\frac{b}{H} = \delta_b = 0.05 \quad (2-223)$$

The relation takes the form

$$E_s = \frac{A Z_u^5}{\left(1 + \frac{A}{0.3} Z_u^5\right)} \quad (2-224a)$$

where

$$A = 1.3 \times 10^{-7} \quad (2-224b)$$

$$Z_u = \frac{u_*^*}{v_s} R_{ep}^{0.6} \quad (2-224c)$$

García and Parker (1993) have found that for fine-grained, non-cohesive sediments, Eq. (2-224a) performs well, provided that the similarity variable given by Eq. (2-224c) is modified to

$$Z_u = 0.708 \frac{u_*^*}{v_s} R_{ep}^{0.6} \text{ for } R_{ep} < 3.5 \quad (2-225)$$

A plot of the García-Parker entrainment function, including data from open-channel flows as well as turbidity currents, is shown in Fig. 2-56. The equation has been used to assess the impact of navigation on sediment resuspension in the Mississippi River basin (García et al. 1999; Admiraal et al. 2000) as well as the inception of channels in submarine fans (Imran et al., 1998). Of all the formulations in the literature, this equation is one of the few that has been generalized to handle sediment mixtures. This generalization of the formula is shown in Eq. (3-143a) of Chapter 3. Because the equation was developed with data from small-sized to medium-sized sand-bed streams, Wright and Parker (2004; 2005b) have found that it needs to be slightly modified for the case of large, low-slope sand-bed rivers. This modification of the formula is shown in Eq. (3-143e) of Chapter 3.

Another relation that has been found to perform well is that of van Rijn (1984b). This relation takes the form,

$$\bar{c}_b = 0.015 \frac{D \left( \tau_s^* / \tau_c^* - 1 \right)^{1.5}}{b D_*^{0.3}} \quad (2-226)$$

Here  $D_* = D(gR / v^2)^{1/3}$  and  $\tau_s^*$  denotes the Shields stress due to skin friction. Van Rijn computes  $\tau_{bs}$  from relations

Fig. 2-56. Sediment entrainment function of García and Parker (1991, 1993).

that are similar to Eqs. (2-155) and (2-156). Van Rijn's relations are

$$C_{fs} = \frac{1}{\kappa} \ln \left( 12 \frac{H}{k_s} \right)^{-2} \quad (2-227)$$

where for uniform material  $k_s = 3D$ . In this equation, the reference level  $b = 1/2\Delta$ , where  $\Delta$  = bed form height or  $b = k_s$  when the bed form height is not known. Note that in Eq. (2-227), the total depth  $H$  is used, in contrast to Eq. (2-156) where  $H_s$  is used. Van Rijn's formulation has been used extensively in numerical models of suspended sediment transport and bed morphology (e.g., Duan et al. 2001; Zeng et al. 2006). Its application for two-dimensional and three-dimensional sediment transport modeling is illustrated in Chapter 15.

A third relation that performs well is that of Smith and McLean (1977). Its origin can be traced back to the early work of Yalin (1963) on bed load transport and was first proposed by Smith (1977). It can be expressed as

$$\bar{c}_b = 0.65 \frac{\gamma_o (\tau_s^* / \tau_c^* - 1)}{1 + \gamma_o (\tau_s^* / \tau_c^* - 1)} \quad (2-228a)$$

where

$$\gamma_o = 0.0024 \quad (2-228b)$$

The value  $b$  at which  $\bar{c}_b$  is to be evaluated is given by the relation below:

$$b = 26.3 \left( \tau_s^* / \tau_c^* - 1 \right) D + k_s \quad (2-228c)$$

Here  $k_s$  denotes the equivalent roughness height (i.e., Nikuradse's roughness) for a fixed bed. The Smith-McLean formulation is used extensively in benthic boundary layer flows and oceanic sedimentation (e.g., Wiberg et al. 1994; Hill and McCave 2001).

After the comparative analysis of different entrainment formulations by García and Parker (1991), Zyserman and Fredsøe (1994) proposed an empirical relation using the Fort Collins experimental data. It reads

$$\bar{c}_b = \frac{0.331 (\tau_s^* - \tau_c^*)^{1.75}}{1 + 0.72 (\tau_s^* - \tau_c^*)^{1.75}} \quad (2-229)$$

In this formulation the near-bed equilibrium concentration  $\bar{c}_b$  is assigned to a reference level  $b = 2D_{50}$ . Even though this relation was developed with laboratory data, it has been used to estimate near-bed sediment concentration in coastal sediment transport (e.g., Soulsby 1997).

## 2.9.8 Example of Depth-Discharge and Sediment Load Computation

Consider the example stream of Section 2.8.2. For this stream,  $S = 0.0004$  and  $D = 0.35$  mm (uniform material). At bankfull flow, the stream width is 75 m. For flows below bankfull, the following sample relation is assumed (Parker and Peterson 1980):

$$\frac{B}{B_{bf}} = \left( \frac{Q}{Q_{bf}} \right)^{0.1}$$

A more precise relation can be worked out for any cross section using measured cross-sectional profiles in a stream. Here the subscript  $bf$  denotes bank-full. Assume that the stream is wide enough to equate the hydraulic radius  $R_h$  with the cross-sectionally averaged depth  $H$ .

1. Compute depth-discharge relations for flows up to bank-full (lower regime only) using the Engelund-Hansen method. Plot  $H$  versus  $Q$ . Use the results of the Engelund-Hansen method to compute values of  $\tau_s^*$  as well.
2. Use the values of  $\tau_s^*$  to compute the bed load discharge  $Q_b = q_b B$  using the Ashida-Michiue formulation (Eq. 2-94). For each value of  $H$  and  $U$ , back-calculate the composite roughness  $k_c$ . Then compute the suspended load  $Q_s = q_s B$  from the Einstein formulation and the relation for  $E_s$  due to García and Parker. Plot  $Q_b$ ,  $Q_s$ , and  $Q_T = Q_b + Q_s$  as functions of water discharge  $Q$ .

For example, compute the flow depth, bed load discharge, and suspended load discharge as a function of flow discharge for a stream with the following properties:

$$S = 0.0004$$

$$D_s = 0.35 \text{ mm} = 3.5 \times 10^{-4} \text{ m}$$

$$R = 1.65$$

$$B = 75 \text{ m at bankfull}$$

$$H = 2.9 \text{ m at bankfull}$$

The calculations are performed for flows up to bank-full. For flows below bank-full, the following relation is used to calculate the stream width:

$$(i) \quad \frac{B}{B_{bf}} = \left( \frac{Q}{Q_{bf}} \right)^{0.1} = \left( \frac{U H B}{Q_{bf}} \right)^{0.1}$$

where the subscript  $bf$  indicates bankfull values. Solving for the stream width  $B$  yields:

$$(ii) \quad B = \left[ B_{bf} \left( \frac{U H}{Q_{bf}} \right)^{0.1} \right]^{1/0.9}$$

The methods used to determine  $Q$ ,  $Q_b$ ,  $Q_s$ , and  $Q_{bf}$  are described below. A computer program can be written or a spreadsheet can be used to perform the necessary calculations. All computations and results are summarized in Table 2-7.

**2.9.8.1 Depth-Discharge Calculations** The depth-discharge relation is computed using the Engelund-Hansen method. The calculations are performed by assuming a value for  $H_s$  (the flow depth that would be expected in the absence of bedforms), and then calculating the actual flow depth ( $H$ ) and the flow discharge ( $Q$ ).  $H_s$  is varied between 0.22 m and the bank-full value of 2.9 m. The first step in calculating the depth-discharge relation is to compute the resistance coefficient due to skin drag ( $C_{fs}$ ) from  $H_s$ :

**Table 2-7    Computation of Depth-Discharge Relation and Total Sediment Load**

Hs (m)	U				H		Width B (m)	Discharge Q (m³/s)	$q_b^*$	$q_b$ (m²/s)	$Q_b$ (m³/s)	$k_c$ (m)	$Z_u$	$E_s$	$u^*$ (m/s)	Rouse#		$J_1$	$J_2$	$q_s$ (m²/s)	$Q_s$ (m³/s)	$Q_t$ (m³/s)

$$(iii) \quad C_{fs} = \left[ \frac{1}{\kappa} \ln \left( 11 \frac{H_s}{k_s} \right) \right]^{-2}$$

where  $\kappa$  is the von Karman constant (0.4) and  $k_s$  is given by

$$(iv) \quad k_s = 2.5 D_s = 2.5 (3.5 \times 10^{-4}) = 8.75 \times 10^{-4} m$$

The depth-averaged flow velocity ( $U$ ) can be found from  $C_{fs}$  and  $H_s$

$$(v) \quad U = \sqrt{\frac{g H_s S}{C_{fs}}}$$

The Shields stress due to skin friction ( $\tau_s^*$ ) is given by

$$(vi) \quad \tau_s^* = \frac{\tau_{bs}}{\rho g R D_s} = \frac{H_s S}{R D_s}$$

According to Engelund-Hansen, the total Shields stress for the lower regime can be found from the following relation:

$$(vii) \quad \tau^* = \sqrt{\frac{\tau_s^* - 6}{0.4}}$$

The flow depth can be calculated from the total Shields stress as follows:

$$(viii) \quad H = \frac{\tau^* R D_s}{S}$$

Finally, the discharge can be calculated from the results of Eqs. (v) and (viii):

$$(ix) \quad Q = U H B$$

where  $B$  must be adjusted according to Eq. (ii) for flows less than bankfull. A plot of the depth-discharge relation is shown in Fig. 2-57(a).

**2.9.8.2 Bed Load Discharge Calculations** The dimensionless bed load transport rate ( $q^*$ ) is found from the Ashida-Michiue formulation:

$$(x) \quad q^* = 17(\tau_s^* - \tau_c^*) [(\tau_s^*)^{0.5} - (\tau_c^*)^{0.5}]$$

where  $\tau_s^*$  is calculated in Eq. (vi) and  $\tau_c^*$  is taken to be 0.05. The bed load transport rate per unit width  $q_b$  is given by

$$(xi) \quad q_b = q^* \sqrt{g R D_s} D_s$$

Therefore, the bedload transport rate (in  $m^3/s$ ) is given by

$$(xii) \quad Q_b = q_b B$$

Again,  $B$  must be adjusted according to Eq. (ii) for flows less than bank-full.

**2.9.8.3 Sediment Load Discharge Calculations** The Einstein formulation is used to compute the suspended load transport rate per unit width  $q_s$ ,

$$(xiii) \quad q_s = \frac{1}{\kappa} \bar{c}_b u_* H \left[ J_1 \ln \left( 30 \frac{H}{k_c} \right) + J_2 \right]$$

where

$$(xiv) \quad u_* = \sqrt{g H S}$$

If the suspension is assumed to be at equilibrium,  $\bar{c}_b = E_s$ . The dimensionless rate of entrainment ( $E_s$ ) is calculated with the relation of García and Parker (1991),

$$(xv) \quad E_s = \frac{A Z_u^5}{\left( 1 + \frac{A}{0.3} Z_u^5 \right)}$$

where  $A$  is equal to  $1.3 \times 10^{-7}$  and

$$(xvi) \quad Z_u = \frac{u_{*s}}{v_s} R_{ep}^{0.6}$$

$$(xvii) \quad u_{*s} = \sqrt{g H_s S}$$

$$(xviii) \quad R_{ep} = \frac{\sqrt{R g D_s D_s}}{v}$$

Notice that for the entrainment formulation, the shear velocity associated with skin friction  $u_{*s}$  has to be used. The temperature is assumed to be about 20°C; therefore, the kinematic viscosity  $\nu$  is about  $10^{-6} m^2/s$ . An iterative method, or Eq. (2-47a), is used to calculate the terminal fall velocity of the sediment particles  $v_s$ , which is found to be  $5.596 \times 10^{-2} m/s$ . The composite roughness ( $k_c$ ) is calculated according to the following relation:

$$(xix) \quad k_c = 11 H \exp \left\{ - \frac{\kappa U}{u_*} \right\}$$

The Einstein integral parameters  $J_1$  and  $J_2$  are found for  $\delta_b = 0.05$  with the help of Equations (2-221a) and (2-221b).

The suspended load transport rate per unit width calculated according to Eq. (xiii) is used to compute the suspended load transport rate suspended load per unit width  $q_s$ , so that the total suspended load can be obtained (in  $m^3/s$ ) with

$$(xx) \quad Q_s = q_s B$$

For flows less than bankfull flow, the channel width  $B$  must be adjusted according to Eq. (ii).

**2.9.8.4 Determination of Bank-Full Flow Discharge ( $Q_{bf}$ )** The flow discharge at bankfull ( $Q_{bf}$ ) is determined by assuming that up to bank-full flow, lower regime conditions exist. The bank-full flow depth for this stream is assumed to

be 2.9 m. Then for bank-full flow, the total shear stress  $\tau^*$  is given by

$$(xxi) \quad \tau^* = \frac{HS}{RD_s} = \frac{2.9 \cdot 0.0004}{1.65 \cdot 3.5 \times 10^{-4}} = 2.01$$

From Engelund and Hansen,

$$(xxii) \quad \tau_s^* = 0.06 + 0.4(\tau^*)^2 = 0.06 + 0.4(2.01)^2 = 1.67$$

$$(xxiii) \quad H_s = \frac{\tau_s^* RD_s}{S} = \frac{1.67 \times 1.65 \times (3.5 \times 10^{-4})}{0.0004} = 2.42 \text{ m}$$

$$(xxiv) \quad C_{fs} = \left[ \frac{1}{\kappa} \ln \left( 11 \frac{H_s}{k_s} \right) \right]^{-2}$$

$$= \left[ \frac{1}{0.4} \ln \left( 11 \frac{2.42}{8.75 \times 10^{-4}} \right) \right]^{-2} = 1.5 \times 10^{-3}$$

$$(xxv) \quad U = \sqrt{\frac{g H_s S}{C_{fs}}}$$

$$= \sqrt{\frac{9.81 \times 2.42 \times 0.0004}{1.5 \times 10^{-3}}} = 2.51 \text{ m/s}$$

$$(xxvi) \quad Q_b = UHB = 2.51 \times 2.9 \times 75 = 546.35 \text{ m}^3/\text{s}$$

A plot of  $Q_b$ ,  $Q_s$ , and  $Q_T = Q_b + Q_s$  as functions of water discharge is shown in Fig. 2-57(b). For flows up to 100 m<sup>3</sup>/s, the bed load discharge is larger than the suspended load discharge. As the flow discharge increases, the suspended load becomes much larger than the bed load all the way up to bank-full flow conditions.

Notice also that the composite roughness  $k_c$  (grain-friction plus form drag) first increases with flow discharge for low flows, but from then on it decreases monotonically as the bedforms begin to be washed out by the flow. For bank-full conditions, the bedforms have a small effect on flow resistance in this particular example.

**Fig. 2-57.** (a) flow discharge rating curve, and (b) sediment discharge rating curves for bed load, suspended load and total load.

**Fig. 2-57.** (a) flow discharge rating curve, and (b) sediment discharge rating curves for bed load, suspended load and total load. (*Continued*)

## 2.10 DIMENSIONLESS RELATIONS FOR TOTAL BED-MATERIAL LOAD IN SAND-BED STREAMS

### 2.10.1 Form of the Relations

In the analysis presented in previous sections, the guiding principle has been the development of mechanistically accurate models of the bed load and suspended load components of bed-material load. The total bed-material load is then computed as the sum of the two. That is, where  $q_b$  denotes the volume bed load transport rate per unit width, and  $q_s$  denotes the volume suspended load transport rate per unit width (bed material only), the total volume transport rate of bed material per unit width  $q_t$  is given by

$$q_t = q_b + q_s \quad (2-229)$$

Another, simpler approach is to ignore the details of the physics of the problem, and instead use empirical techniques such as regression analysis to correlate dimensionless parameters involving  $q_t$  to dimensionless flow parameters inferred to be of importance for sediment transport. This can be implemented in the strict sense only for equilibrium or quasi-equilibrium flows, i.e., near-normal flow conditions. The resulting relations are no better than the choice of dimensionless parameters to be correlated. They are also less versatile than physically based relations, because their application to non-steady, nonuniform flow fields is not obvious. On the other hand, they have the advantage of being relatively simple to use and of having been calibrated to sets of both laboratory and field data often deemed to be trustworthy.

Here six such relations are presented, those due to Engelund and Hansen (1967); Ackers and White (1973); Yang (1973); Brownlie (1981b); Karim and Kennedy (1981; 1990); and Molinas and Wu (2001).

They apply only to sand-bed streams with relatively uniform bed sediment. The Engelund and Hansen relation together with the relations of Brownlie and Karim and Kennedy, are the most complete ones, as each is presented as a pair of relations for total load and hydraulic resistance. Ackers and White (1973), Yang (1973), and Molinas and Wu (2001) are presented as relations for total load only. In most cases, it will also be necessary for the user to specify a relation for hydraulic resistance in order to perform actual calculations. Computations for one-dimensional river modeling using the Ackers-White, Engelund-Hansen, and Yang transport relations are presented in Chapter 14.

As stated earlier, the importance of using transport and hydraulic resistance relations as pairs cannot be overemphasized (e.g., Parker and Anderson 1977). Consider, for example, the simplest generalization beyond the assumption of normal flow, the case of quasi-steady, gradually varied one-dimensional flow. The governing equations for a wide rectangular channel with flow in the streamwise  $x$  direction, can be written as (Chow 1959)

$$\frac{d}{dx} \left( \frac{V^2}{2g} + H \right) = S - S_f \quad (2-230a)$$

$$q_w = UH \quad (2-230b)$$

Here the friction slope  $S_f$  is given as

$$S_f = \frac{\tau_b}{\rho g H} = C_f \frac{U^2}{g H} \quad (2-231)$$

A slightly more general form for non-rectangular channels is

$$\frac{d}{dx} \left( \frac{1}{2} \frac{Q^2}{g A^2} + \xi_b \right) = S - S_f \quad (2-232a)$$

$$Q = U A \quad (2-232b)$$

where

$A$  = channel cross-sectional area,  
And the friction slope  $S_f$  is given as

$$S_f = \frac{\tau_b}{\rho g R_h} = C_f \frac{U^2}{g R_h} \quad (2-233)$$

In the above equations,  $R_h$  denotes the hydraulic radius and  $\xi_b$  denotes the water surface elevation above the deepest point in the channel, as shown in Fig. 2-58.

Note that in the case of normal flow, the momentum equations reduce to  $S_f = S$ , or  $\tau_b = \rho g H S$  for the wide rectangular case and  $\tau_b = \rho g R_h S$  for the non-rectangular, natural case. In the case of gradually varied flow, however,  $S_f \neq S$ , in which case the bed slope  $S$  cannot be used as a basis for calculating sediment transport. The appropriate choice is  $S_f$ , so that from Eq. (2-233), for example,

$$\tau_b = \rho g R_h S_f \quad (2-234)$$

It should be apparent for the case of gradually varying flow, then, that the friction slope necessary to perform sediment

transport calculations must be obtained from a predictor of hydraulic resistance. Cholley and Cunge (1979) demonstrate a useful approach to estimate friction slopes for unsteady flow computations (i.e., head losses) using two hydraulic resistance predictors developed for steady, normal flow conditions (i.e., Einstein-Barbarossa and Engelund-Hansen). Chapter 14 also presents relevant information on how the friction slope is estimated for one-dimensional computational modeling.

A few parameters are introduced here. Let  $Q$  denote the total water discharge, and  $Q_{st}$  the total volume of bed-material sediment discharge. Furthermore, let  $B_a$  denote the active width of the river over which bed material is free to move as described in Fig. 2-58. In general,  $B_a$  is usually somewhat less than water surface width  $B$  due to the common tendency for the banks to be cohesive, vegetated, or both.

It follows then that

$$Q = B q_w \quad (2-235a)$$

$$Q_{st} = B_a q_t \quad (2-235b)$$

One dimensionless form for dimensionless total bed material transport per unit width is  $q_t^*$  where

$$q_t^* = \frac{q_t}{\sqrt{R g D D}} \quad (2-236)$$

where

$D$  = grain size usually equated to  $D_{50}$ .

Another commonly used measure is concentration by weight in parts per million, here called  $C_s$ . This can be given as

$$C_s = 10^6 \frac{\rho_s Q_{st}}{\rho Q + \rho_s Q_{st}} \quad (2-237)$$

Fig. 2-58. Definition diagram for channel parameters.

## 2.10.2 The Engelund-Hansen Relation

**2.10.2.1 Sediment Transport** This relation is one of the simplest to use for sediment transport, and also one of the most accurate. It was determined from a rather small set of laboratory data (Guy et al. 1966), but performs quite well as a field predictor as well. It takes the form

$$C_f q_t^* = 0.05 (\tau^*)^{5/2} \quad (2-238)$$

where

$C_f$  = total resistance coefficient (skin friction plus form drag); and

$\tau^*$  = total (skin friction plus form drag) Shields stress based on the size  $D_{50}$ .

**2.10.2.2 Hydraulic Resistance** The hydraulic resistance relation of Engelund and Hansen has already been introduced above. It must be written in several parts. The key relation for skin friction is

$$C_{fs}^{-1/2} = \frac{U}{\sqrt{g R_{hs} S}} = 2.5 \ln \left( 11 \frac{R_{hs}}{k_s} \right) \quad (2-239a)$$

where

$$k_s = 2 \text{ to } 2.5 D_{50}$$

Here,  $R_{hs}$  denotes the hydraulic radius due to skin friction, which often can be approximated by  $H_s$ . The relation for form drag can be written in the form

$$\tau_s^* = f(\tau^*) \quad (2-239b)$$

where for the lower regime

$$\tau_s^* = 0.06 + 0.4 (\tau^*)^2 \quad (2-239c)$$

and for the upper regime

$$\tau_s^* = \begin{cases} \tau^* & ; \tau^* < 1 \\ \left[ 0.298 + 0.702 - (\tau^*)^{-1.8} \right]^{-(1/1.8)} & ; \tau^* > 1 \end{cases} \quad (2-239d)$$

An approximate condition for the transition between the lower and upper regimes is given by

$$\tau_s^* = 0.55 \quad (2-239e)$$

The Engelund-Hansen relation has been found to be a good predictor of both laboratory and field data in spite of its simplicity.

## 2.10.2.3 Computational Procedure for Normal Flow

The water discharge  $Q$ , slope  $S$ , and grain size  $D_{50}$  must be known. In addition, channel geometry must be known, so that  $B$ ,  $B_a$ ,  $A$ ,  $H$ ,  $P$ , and  $R_h$  are all known functions of stage (water surface elevation)  $\xi$ . The procedure is best outlined assuming that  $R_{hs}$  is known and  $Q$  is to be calculated, rather than vice versa. For any given value of  $R_{hs}$  (or  $H_s$ ),  $U$  can be computed from Eq. (2-239a). Noting that  $\tau_s^* = R_{hs} S / (R D_{50})$  and  $\tau^* = R_h S / (R D_{50})$ ,  $\tau^*$ , and thus,  $R_h$  can be computed from Eqs. (2-239b-e). The plot of  $R_h$  versus water surface elevation  $\xi$  is used to determine  $\xi_b$ , which is then used to determine  $B$ ,  $B_a$ ,  $H$ ,  $A$ ,  $P$ , etc. Discharge  $Q$  is then given by  $Q = UBH$ . In an actual implementation, this process is reversed ( $Q$  is given and  $R_{hs}$ , etc., is computed). This requires an iterative technique; Newton-Raphson is not difficult to implement (e.g., Parker 2005).

Once the calculation of hydraulic resistance is complete, it is possible to proceed with the computation of total bed material load  $Q_{st}$ . The friction coefficient  $C_f$  is given by  $(g R_{hs} S) / U^2$ . Placing the known values of  $C_f$  and  $\tau^*$  into (2-238),  $q_t^*$ , and thus,  $q_t$  can be computed. It follows that  $Q_{st} = q_t B_a$ .

## 2.10.2.4 Computational Procedure for Gradually Varied Flow

To implement the method for gradually varied flow, it is necessary to recast the above formulation into an algorithm for friction slope  $S_f$ , which replaces  $S$  everywhere in the formulation of Eqs. (2-239a) to (2-239e). The formulation is then solved in conjunction with Eqs. (2-230a) and (2-230b) or Eqs. (2-232a) and (2-232b) to determine the appropriate backwater curve. Once  $C_f$  and  $\tau_b$  are known everywhere, the sediment transport rate can be calculated from Eq. (2-238). Computations for gradually-varied flow with the Engelund-Hansen relations are presented in Chapter 14.

## 2.10.3 The Brownlie Relation

**2.10.3.1 Sediment Transport** The Brownlie relations are based on regressions of over 1000 experimental and field data points. For normal or quasi-normal flow, the transport relation takes the form

$$C_s = 7115 c_f (F_g - F_{go})^{1.978} S^{0.6601} \left( \frac{R_h}{D_{50}} \right)^{-0.3301} \quad (2-240a)$$

where

$$F_g = \frac{U}{\sqrt{R g D_{50}}} \quad (2-240b)$$

$$F_{go} = 4.596 (\tau_c^*)^{0.5293} S^{-0.1045} \sigma_g^{-0.1606} \quad (2-240c)$$

$$\tau_c^* = 0.22Y + 0.06 \cdot 10^{-7.7Y} \quad (2-240d)$$

$$Y = R_{ep}^{-0.6} \quad (2-240e)$$

In Eq. (2-240a),  $c_f = 1$  for laboratory flumes and 1.268 for field channels. The parameters  $\tau_c^*$  and  $R_{ep}$  are the ones previously introduced in this chapter.

**2.10.3.2 Hydraulic Resistance** The Brownlie relations for hydraulic resistance were determined by regression from the same set of data used to determine the relation for sediment transport. The relation for lower regime flow is

$$\frac{R_h}{D_{50}} S = 0.3724 (\tilde{q})^{0.6539} S^{0.09188} \sigma_g^{0.1050} \quad (2-241a)$$

The corresponding relation for upper regime flow is

$$\frac{R_h}{D_{50}} S = 0.2836 (\tilde{q})^{0.6248} S^{0.08750} \sigma_g^{0.08013} \quad (2-241b)$$

In these relations,

$$\tilde{q} = \frac{q_w}{\sqrt{g D_{50} D_{50}}} \quad (2-241c)$$

The distinction between lower and upper regime is made as follows (see Fig. 2-44). For  $S > 0.006$ , the flow is assumed always to be in the upper regime. For  $S < 0.006$ , the largest value of  $F_g$  at which the lower regime can be maintained is taken to be

$$F_g = 0.8 F'_g \quad (2-241d)$$

And the smallest value of  $F_g$  for which upper regime can be maintained is taken to be

$$F_g = 1.25 F'_g \quad (2-241e)$$

In the above relations

$$F'_g = 1.74 S^{-1/3} \quad (2-241f)$$

### 2.10.3.3 Computational Procedure for Normal Flow

It is necessary to know  $Q$ ,  $S$ ,  $D_{50}$ ,  $\sigma_g$ , and cross-sectional geometry as a function of stage. The computation is explicit, although trial and error may be required in order to determine the flow regime. Hydraulic radius is computed from Eq. (2-241a) or Eq. (2-241b), and the result can be substituted

into Eq. (2-240a) in order to determine the concentration  $C_s$  in parts per million by weight. The transport rate  $Q_{st}$  is then computed from Eq. (2-237).

**2.10.3.4 Computation for Gradually Varied Flow** The Brownlie relation is not presented in a form that obviously allows extension to gradually varied flow. The most unambiguous procedure, however, is to replace  $S$  with  $S_f$  in the resistance relation and to couple it with a backwater calculation to determine  $S_f$ . The friction slope is then substituted into Eq. (2-240a) in place of the bed slope in order to determine the sediment transport rate.

### 2.10.4 The Ackers-White Relation

Based on Bagnold's stream power concept, Ackers and White (1973) applied dimensional analysis to express the mobility and transport rate of sediment in terms of dimensionless parameters. Several years later a corresponding relation for hydraulic resistance was also presented (White et al. 1980; 1982). Only the sediment load equation is presented here. It takes the form

$$C_s = 10^6 c \frac{\rho_s}{\rho} \frac{D_{50}}{R_h} \left( \frac{U}{u_*} \right)^n \left( \frac{F_{gr}}{A_{aw}} - 1 \right)^m \quad (2-242a)$$

where the so-called Ackers-White mobility number is given by

$$F_{gr} = \frac{u_*^n u_*'^{1-n}}{\sqrt{R g D_{50}}} \quad (2-242b)$$

$$u_*' = \frac{U}{\sqrt{32} \log \left( 10 \frac{R_h}{D_{50}} \right)} \quad (2-242c)$$

The parameters  $n$ ,  $m$ ,  $c$ , and  $A_{aw}$  were determined with best-fits of laboratory data, as functions of a dimensionless grain size  $D_{gr}$ , where

$$D_{gr} = R_{ep}^{2/3} \quad (2-242d)$$

in the following fashion. If  $D_{gr} > 60$ , then

$$n = 0 \quad (2-242e)$$

$$m = 1.5 \quad (2-242f)$$

$$A_{aw} = 0.17 \quad (2-242g)$$

$$c = 0.025 \quad (2-242h)$$

If  $1 < D_{gr} < 60$ , then

$$n = 1 - 0.56 \log(D_{gr}); \quad m = \frac{9.66}{D_{gr}} + 1.34 \quad (2-242i)$$

$$m = \frac{9.66}{D_{gr}} + 1.34 \quad (2-242j)$$

$$A_{aw} = \frac{0.23}{\sqrt{D_{gr}}} + 0.14 \quad (2-242k)$$

$$\log(c) = 2.86 \log(D_{gr}) - [\log(D_{gr})]^2 - 3.53 \quad (2-242l)$$

Note that all logarithms here are base 10;  $u_*$  retains its previously introduced meaning as shear velocity.

The procedure for the computation of sediment transport rate using Ackers and White's approach can be summarized as follows:

1. Determine the value of  $D_{gr}$  with Eq. (2-242d) from known values of  $D$ ,  $R = (\rho_s - \rho) / \rho$ , and kinematic viscosity  $\nu$ .
2. Determine the value of  $n$ ,  $A_{aw}$ ,  $m$ , and  $c$  corresponding to the value of  $D_{gr}$  from Eqs. (2-242e) to (2-242l).
3. Determine the total sediment concentration  $C_s$  by weight in parts per million (ppm) with Eq. (2-242a).
4. Determine the total sediment transport rate  $Q_{st}$  with Eq. (2-237) and a known value of flow discharge  $Q$ .

Computations for gradually-varied flow in a river with the Ackers-White relations are presented in Chapter 14. Brownlie (1981a) found that the Ackers-White sediment load relation predicted laboratory observations quite well but field observations were underestimated. In 1990, HR Wallingford adjusted the coefficients in the Ackers-White relation, because the original formula predicted transport rates which were too large for fine sediments ( $D_{50} < 0.2$  mm). More recently, Niño et al. (2002) has found that the Ackers-White relation provides a good predictor for coarse sand and gravel transport in the rivers of Chile, and used this relation to predict longitudinal grain-size variation. The Ackers-White formulation is extended for application to sediment mixtures in Chapter 3.

### 2.10.5 The Yang Relation

To determine total sediment concentration, Yang (1973) also used dimensional analysis and the fundamental concept of unit stream power given by the product of mean flow

velocity and channel slope. Coefficients in Yang's equation were determined by a multiple regression analysis of laboratory flume data. The relation takes the form

$$\log(C_s) = a_1 + a_2 \log\left(\frac{US}{v_s} - \frac{U_c S}{v_s}\right) \quad (2-243a)$$

where

$$a_1 = 5.435 - 0.286 \log\left(\frac{v_s D_{50}}{\nu}\right) - 0.457 \log\left(\frac{u_*}{v_s}\right) \quad (2-243b)$$

$$a_2 = 1.799 - 0.409 \log\left(\frac{v_s D_{50}}{\nu}\right) - 0.314 \log\left(\frac{u_*}{v_s}\right) \quad (2-243c)$$

and  $U_c$  denotes a critical mean flow velocity for initiation of motion given by

$$\frac{U_c}{v_s} = \begin{cases} 2.05 & \text{if } \frac{u_* D_{50}}{\nu} > 70 \\ \frac{2.5}{\log\left(\frac{u_* D_{50}}{\nu}\right) - 0.06} & \text{if } 1.2 < \frac{u_* D_{50}}{\nu} < 70 \end{cases} \quad (2-243d)$$

Note that the logarithms are all base 10, and that,  $v_s$  retains its previous meaning as fall velocity. Computations using Yang's approach for gradually-varied flow are presented in Chapter 14.

Yang and Molinas (1982) compared the Yang's formula with 1093 laboratory data and 166 river data, yielding a value of 95% of the predicted transport rates within a factor of 2 of measured transport rates. Large-scale river data were not included in this comparison. Recently, Yang and Simoes (2005) have used Yang's unit stream power approach (Yang 1979; Yang et al. 1996) to predict total bed-material load as well as wash load in the Yellow River, China.

### 2.10.6 The Karim-Kennedy Relation

The Karim and Kennedy (1981, 1990) methodology for depth-discharge predictors described previously in Section 2.8.3.5 also includes a total sediment discharge formula obtained from nonlinear regression using a database of 339

river flows and 608 flume flows. The uncoupled sediment load and resistance relations they obtained are given by

$$\begin{aligned} \log \frac{q_t}{\sqrt{gRD_{50}^3}} = & -2.279 + 2.972 \log \left[ \frac{U}{\sqrt{gRD_{50}}} \right] \\ & + 1.060 \log \left[ \frac{U}{\sqrt{gRD_{50}}} \right] \log \left[ \frac{u_* - u_{*c}}{\sqrt{gRD_{50}}} \right] \\ & + 0.299 \log \left( \frac{H}{D_{50}} \right) \log \left[ \frac{u_* - u_{*c}}{\sqrt{gRD_{50}}} \right] \end{aligned} \quad (2-244a)$$

and

$$\frac{U}{\sqrt{gRD_{50}}} = 2.822 \left[ \frac{q_w}{\sqrt{gRD_{50}}} \right]^{0.376} S^{0.310} \quad (2-244b)$$

in which

$q_t$  = total volumetric sediment discharge per unit width.

The rest of the variables have been defined above. Equation (2-244b) can be used for flows well above incipient sediment motion. If it is necessary to take into account the bed configuration changes, Eq. (2-244b) should be replaced with Eq. (2-183d).

More recently, Karim (1998) proposed a simpler power relation for the sediment transport equation using the same data sets employed in the Karim-Kennedy analysis, with the results given by

$$\frac{q_t}{\sqrt{gRD_{50}^3}} = 0.00139 \left[ \frac{U}{\sqrt{gRD_{50}}} \right]^{2.97} \left[ \frac{u_*}{v_s} \right]^{1.47} \quad (2-244c)$$

Both relations yield approximately the same results but Eq. (2-244c) would be easier to implement than the original Eq. (2-244a). Karim (1998) applied his equation to laboratory and field data having non-uniform sediments by dividing the sediment into size fractions. More on this application can be found on Chapter 3.

### 2.10.7 The Molinas-Wu Relation

This empirical relation is based on Velikanov's gravitational power theory, which assumes that the power available in flowing water is equal to the sum of the power required to overcome flow resistance and the power required to keep sediment in suspension against gravitational forces. In fact, this is equivalent to the simplified energy balance presented

earlier (Eq. 2-72a) for the discussion of wash load and bed-material load. The formulation proposed by Celik and Rodi (1984) to estimate sediment transport capacity (see Table 2-6) is also based on Velikanov's theory. Molinas and Wu (2001) argued that the predictors of Engelund-Hansen, Ackers and White, and Yang have been developed with flume experiments representative of shallow flows and cannot be applied to large rivers having deep-flow conditions. Average depths vary between 12 and 68 m in the Amazon River, and between 3 and 22 m in the Mississippi River (Posada 1995). These flow depths are much larger than those commonly found in laboratory experiments ( $< 1$  m). At the same time, under laboratory conditions Reynolds numbers are much smaller, Froude numbers are larger, and water surface (energy) slopes are steeper than those observed in large natural rivers. Motivated by the need for having a total bed-material load predictor for application to large sand-bed rivers, they used stream power and energy considerations together with data from large rivers (e.g., Amazon, Atchafalaya, Mississippi, Red River), to obtain an empirical fit for the total bed-material load concentration (Eq. 2-237) in ppm,

$$C_s = \frac{1430(0.86 + \sqrt{\Psi})\Psi^{1.5}}{0.016 + \Psi} \quad (2-245a)$$

where

$\Psi$  = stream power, which is defined by

$$\Psi = \frac{U^3}{g R H v_{s50} \left[ \log_{10} \left( \frac{H}{D_{50}} \right) \right]^2} \quad (2-245b)$$

Where

- $U$  = mean flow velocity;
- $g$  = acceleration of gravity,
- $H$  = flow depth,
- $v_{s50}$  = fall velocity for sediment size  $D_{50}$ ; and
- $R$  = submerged specific gravity of sediment.

Most parameters in this empirical relation can be measured and/or estimated in the field, making it a useful formulation for practical use in large sand-bed rivers. One advantage of this approximation is that the energy slope ( $S$ ) does not have to be measured directly, which is always a challenge in large alluvial rivers. On the other hand, since Molinas and Wu (2001) do not mention how the wash load was separated from the bed-material load and the same large river data were used both to develop and to test their formulation, Eq. (2-245) might overestimate bed-material load concentrations when applied to other large rivers not included in the calibration. More testing of this formulation with independent data

sets is needed. Such data should be forthcoming given the new technologies that are now available for flow and sediment measurements in large rivers.

### 2.10.8 Other Relations for Total Bed-Material Load

Several other total sand-discharge formulae can be found in the literature, including those of Shen and Hung (1972), Kikkawa and Ishikawa (1978), Ranga-Raju et al. (1981), van Rijn (1984), and Pacheco-Ceballos (1989; 1992) among others. A more complete review and evaluation and ranking of various relations can be found in Alonso (1980), Brownlie (1981), Yang and Molinas (1982), Gomez and Church (1989), Yang and Wan (1991), Maza-Alvarez and García-Flores (1996), Yang (1996), and Bravo-Espinosa et al. (2003), and Yang (2005).

In general, sediment transport predictors should be applied within the range of flow conditions and sediment characteristics for which they were developed (Williams and Julien 1989). Of paramount importance is to realize that sediment transport and flow resistance relations should be specified in pairs (Parker and Anderson 1977). The most reliable predictors for sediment load and flow resistance will continue to rely on direct observations in the field. Some guidance regarding the estimation of sediment discharge in the field can be found in Appendix D.

## 2.11 MORPHODYNAMICS OF RIVERS AND TURBIDITY CURRENTS

### 2.11.1 Introduction

Turbidity currents are bottom currents of water laden with suspended sediment that move downslope in otherwise still bodies of water (García 1992). Turbidity currents are very similar to river flows, except for one important difference. In the case of a river, gravity pulls the water downslope, and the water drags the sediment with it. In the case of turbidity current in a body of still water, there would be no flow if there were no suspended sediment. Gravity acts to pull the suspended sediment in the bottom water downslope, and the sediment then drags the water with it. Turbidity currents occur in lakes, reservoirs, and the ocean. They provide major mechanisms for moving sediment into deep water.

Knowledge about sediment transport by turbidity currents was limited when *ASCE Manual 54* was first published. Manual 54 cited frequent observations of turbidity currents in Lake Mead induced by the high sediment loads of the Colorado River, suggesting that these flows could play an important role in lake and reservoir sedimentation (Vanoni 2006, p.166). In China, the impact of turbidity currents on reservoir sedimentation has long been recognized and attempts have been made to use the transport capacity of these underflows to preserve storage capacity (Fan and Morris 1992a, 1992b). One of the first attempts at modeling turbidity in reservoirs with a simple one-dimensional

approach, including their venting to prevent siltation, was made by Fan (1986). A few years later, Sloff (1994) used the method of characteristics to model turbidity currents in reservoirs, but did not address the morphodynamics of reservoir sedimentation. More recently, De Cesare et al. (2001) also indicated that turbidity currents have played an important role in the siltation of many Swiss reservoirs. Thus, the main reason for introducing turbidity currents in this section is to motivate a succeeding section on the modeling of lake and reservoir sedimentation. No attempt is made here to provide a detailed discussion of either turbidity currents or reservoir sedimentation. The latter issue is addressed in more detail in Chapter 12. Rather, the goal here is to guide the reader in understanding the processes involved in the morphodynamics of lake and reservoir sedimentation.

### 2.11.2 Equations Governing the Morphodynamics of Rivers

Rivers evolve over time in accordance with the interaction between the flow and sediment-transport fields over an erodible bed (which changes the bed) and the changing morphology of the bed (which changes the flow and sediment-transport fields). This co-evolution is termed “morphodynamics” (Parker and García 2006). It is useful to introduce the relations governing the morphodynamics of turbidity currents in analogy to the morphodynamics of one-dimensional flow in a river of constant width. The parameters  $h$ ,  $U$  and  $\eta$  denote flow depth, depth-averaged flow velocity, and bed elevation, respectively. Depth-averaged flow velocity is defined as

$$Uh = \int_0^h \bar{u} dz \quad (2-246)$$

where

$z$  = upward normal coordinate with its origin at the bed;  
and

$\bar{u}$  = local streamwise flow velocity averaged over turbulence at  $z$ .

Under appropriate simplifying assumptions, the one-dimensional St. Venant shallow-water equations take the form

$$\frac{\partial h}{\partial t} + \frac{\partial Uh}{\partial x} = 0 \quad (2-247a)$$

$$\frac{\partial Uh}{\partial t} + \frac{\partial U^2 h}{\partial x} = -gh \frac{\partial h}{\partial x} + ghS - C_f U^2 \quad (2-247b)$$

where

$t$  = time;

$x$  = boundary-attached (bed-attached) streamwise coordinate;

$g$  = gravitational acceleration;  
 $\rho$  = water density;  
 $S$  = bed slope, given as

$$S = -\frac{\partial \eta}{\partial x} \quad (2-248a)$$

and

$C_f$  = bed friction coefficient such that the bed shear stress  $\tau_b$  is given as

$$\tau_b = \rho C_f U^2 \quad (2-248b)$$

Here Eq. (2-247a) describes water-mass conservation and Eq. (2-247b) describes water-momentum conservation.

The river is assumed to carry a dilute suspension of sediment. Let the depth-flux averaged volume concentration  $C$  of suspended sediment be given by the relation

$$q_s = UCh = \int_0^h \bar{u} \bar{c} dz \quad (2-249)$$

where  $\bar{c} \ll 1$  is the local volume suspended-sediment concentration averaged over turbulence at elevation  $z$ , and  $q_s$  denotes the volume transport rate per unit width of suspended sediment. An approximate form for depth-averaged conservation of suspended sediment is as follows:

$$\frac{\partial Ch}{\partial t} + \frac{\partial UCh}{\partial x} = v_s (E_s - \bar{c}_b) \quad (2-250)$$

where

$v_s$  = sediment fall velocity;  
 $E_s$  = dimensionless rate of entrainment of bed sediment into suspension; and  
 $\bar{c}_b$  = near-bed value of  $\bar{c}$ ,

all of which were introduced earlier in this chapter. The Exner equation of conservation of bed sediment presented earlier takes the form

$$(1 - \lambda_p) \frac{\partial \eta}{\partial t} = -\frac{\partial q_b}{\partial x} + v_s (\bar{c}_b - E_s) \quad (2-251)$$

where  $q_b$  denotes the volume bedload transport rate per unit width and  $\lambda_p$  denotes the bed porosity.

Equations (2-247a), (2-247b), (2-250), and (2-251) are the basic equations describing the one-dimensional morphodynamics of rivers. The equations need to be closed by specifying relations for (1) volume bed load transport  $q_b$ ,

(2) dimensionless rate of entrainment of bed sediment into suspension  $E_s$ , and (3) near-bed suspended-sediment concentration  $\bar{c}_b$ . Numerous relations for  $q_b$  and  $E_s$  have been introduced in this chapter. In addition, if the flow and suspension do not deviate too strongly from equilibrium (i.e., logarithmic and Rousean profiles), the following approximate relation for  $\bar{c}_b$  is obtained from Eqs. (2-195), (2-204), and (2-249):

$$\bar{c}_b = r_o C \quad (2-252a)$$

$$r_o = \frac{\ln \left( 11 \frac{h}{k_c} \right)}{\int_{\zeta_b}^1 \left[ \frac{(1-\zeta)/\zeta}{(1-\zeta_b)/\zeta_b} \right]^{Z_R} \ln \left( 30 \frac{h}{k_c} \zeta \right) d\zeta} \quad (2-252b)$$

$$Z_R = \frac{v_s}{\kappa u_*} \quad (2-252c)$$

$$\zeta = \frac{z}{h} \quad (2-252d)$$

where  $\zeta_b \ll 1$  is a near-bed parameter. When  $\xi_b = b/h = 0.05$ , which is the commonly used value for this parameter, the shape factor  $r_o$  can be estimated with a simple fit to the Rousean profile (Parker et al. 1987)

$$r_o = 1 + 31.5 \left( \frac{u_*}{v_s} \right)^{-1.46} \quad (2-252e)$$

Thus, Eqs. (2-250) and (2-251) take the respective forms

$$\frac{\partial Ch}{\partial t} + \frac{\partial UCh}{\partial x} = v_s (E_s - r_o C) \quad (2-253)$$

$$(1 - \lambda_p) \frac{\partial \eta}{\partial t} = -\frac{\partial q_b}{\partial x} + v_s (r_o C - E_s) \quad (2-254)$$

Alternatively, between Eqs. (2-249), (2-250), and (2-251) it is found that

$$(1 - \lambda_p) \frac{\partial \eta}{\partial t} + \frac{\partial Ch}{\partial t} = -\frac{\partial q_b}{\partial x} - \frac{\partial q_s}{\partial x} \quad (2-255a)$$

For the case of a dilute suspension ( $C \ll 1$ ), the amount of sediment stored in suspension can be neglected compared to

the amount of sediment stored in the bed, so that the above equation accurately approximates to

$$(1 - \lambda_p) \frac{\partial \eta}{\partial t} = - \frac{\partial q_b}{\partial x} - \frac{\partial q_s}{\partial x} = - \frac{\partial q_t}{\partial x} \quad (2-255b)$$

Where  $q_t$  denotes the total volume bed-material load per unit width. The formulation of Eq. (2-255b) can be implemented by assuming an appropriate relation for the volume bed-load transport rate per unit width  $q_b$ , and estimating the volume suspended-load transport rate per unit width  $q_s$  for disequilibrium flow by the means of the local application of a formulation for equilibrium flow (based on, e.g., a logarithmic velocity profile and the Rousean profile for suspended sediment).

In point of fact the forms for Eqs. (2-247) and (2-251) are only approximate. The more general forms of Eq. (2-247) and (2-251) are, respectively,

$$\frac{\partial U h}{\partial t} + \frac{\partial \alpha_1 U^2 h}{\partial x} = - g h \frac{\partial h}{\partial x} + g h S - C_f U^2 \quad (2-256a)$$

where

$$\alpha_1 = \int_0^1 \left( \frac{\bar{u}}{U} \right)^2 d\zeta \quad (2-256b)$$

and

$$\frac{\partial \alpha_2 C h}{\partial t} + \frac{\partial U C h}{\partial x} = v_s (E_s - r_o C) \quad (2-257a)$$

where

$$\alpha_2 = \int_0^1 \frac{\bar{c}}{C} d\zeta = \frac{\left( \int_0^1 \bar{u} d\zeta \right) \left( \int_0^1 \bar{c} d\zeta \right)}{\left( \int_0^1 \bar{u} \bar{c} d\zeta \right)} \quad (2-257b)$$

where  $\zeta$  is given by Eq. (2-252d). Here  $\alpha_1$  and  $\alpha_2$  are dimensionless shape factors governing the velocity and concentration profiles. Were  $\bar{u}$  and  $\bar{c}$  constant in the vertical, both shape factors would be equal to unity (i.e., top-hat approximation). They are often approximated to unity for simplicity.

### 2.11.3 Equations Governing the Morphodynamics of Turbidity Currents

A turbidity current is illustrated in Fig. 2-59. Let  $x$  denote a boundary-attached (bed-attached) streamwise coordinate

Fig. 2-59. Definition diagram for turbidity current.

and  $z$  denote an upward vertical coordinate from the bed. Just as in the case of rivers, the streamwise flow velocity  $\bar{u}$  and volume concentration of suspended sediment  $\bar{c}$ , both averaged over turbulence, show notable variation in the  $z$  direction. Note, however, that because a turbidity current is a bottom flow, it can be expected that both  $\bar{u}$  and  $\bar{c}$  become vanishingly small as  $z \rightarrow \infty$ , where here “ $\infty$ ” is shorthand for “high above the bottom current.”

The turbidity current flows because it is laden with sediment, which renders it heavier than the ambient water above. Let  $\rho$  denote the density of water and  $\rho_s$  denote the density of sediment. The density  $\rho_t(z)$  of the turbidity current at level  $z$  is thus given as

$$\rho_t = \rho(1 - \bar{c}) + \rho_s \bar{c} = \rho(1 + R\bar{c}) \quad (2-255)$$

where

$$R = \frac{\rho_s}{\rho} - 1 \quad (2-256)$$

denotes the “submerged specific gravity” of the sediment, taking the value 1.65 for quartz. The turbidity current is driven downslope due to gravity acting on the density excess of the turbidity current relative to the ambient water. The fractional density excess is given as

$$\frac{\rho_t - \rho}{\rho} = R\bar{c} \quad (2-257)$$

Here the case of dilute turbidity currents is considered, so that  $\bar{c} \ll 1$  and thus  $R\bar{c} \ll 1$ .

One-dimensional layer-averaged equations governing the flow of turbidity currents can be derived in analogy to the St. Venant equations of shallow water flow in rivers. The suspended sediment that drives the turbidity current is characterized here in terms of a single fall velocity  $v_s$ . Layer thickness  $h$  and layer-averaged flow velocity  $U$  and volume concentration of suspended sediment  $C$  are defined in terms of the following three moments (e.g., Ellison and Turner 1959):

$$Uh = \int_0^\infty \bar{u} dz \quad (2-258a)$$

$$U^2h = \int_0^\infty \bar{u}^2 dz \quad (2-258b)$$

$$UCh = \int_0^\infty \bar{u} \bar{c} dz \quad (2-258c)$$

Note that Eqs. (2-258a) and (2-258c) for turbidity currents are almost identical in form to the corresponding Eqs. (2-245) and (2-249) used to define the layer-averaged (more precisely depth-averaged) quantities  $U$  and  $C$  in a river. The only difference is that the upper limit  $y = h$  in a river is replaced with  $y = \infty$  in a turbidity current. That is, turbidity currents have no "layer thickness" in the precise sense of the word. The extra relation of Eq. (2-258b) specifies a momentum-based equivalent layer thickness  $h$ .

A complete derivation of the one-dimensional flow equations for turbidity currents are given in Parker et al. (1986). The one-dimensional equations contain a number of dimensionless shape factors analogous to  $\alpha_1$  and  $\alpha_2$  of Eqs. (2-256b) and (2-257b), all of which take the value unity for the special case of the velocity and concentration profiles

$$\frac{\bar{u}}{U} = \frac{\bar{c}}{C} = \begin{cases} 1 & ; 0 < z \leq h \\ 0 & ; z > h \end{cases} \quad (2-259)$$

Parker et al. (1987) and García (1993, 1994) have evaluated these shape factors for experimental turbidity currents. Because the values so determined do not deviate strongly from unity, values of unity are assumed below as well.

The one-dimensional layer-averaged equation of conservation of water mass takes the form

$$\frac{\partial h}{\partial t} + \frac{\partial Uh}{\partial x} = e_w U \quad (2-260)$$

where

$e_w$  = coefficient of entrainment of ambient (sediment-free) water from above into the turbidity current.

The one-dimensional layer-averaged equation of conservation of streamwise flow momentum is

$$\frac{\partial Uh}{\partial t} + \frac{\partial U^2h}{\partial x} = -\frac{1}{2}g \frac{\partial Ch^2}{\partial x} + gRChS - C_f U^2 \quad (2-261)$$

The one-dimensional layer-averaged equations for conservation of suspended and bed sediment are given by the same forms as for a river, that is, Eqs. (2-250) and (2-251), respectively.

The governing equations of turbidity currents are thus seen to be very similar to those governing flow and sediment transport in a river. There is, however, one important difference. A river that carries no suspended sediment continues to flow, because the pull of gravity acts directly on the water. This effect is embodied in the term  $ghS$  in Eq. (2-247). So gravity pulls the water downhill, and the water pulls the sediment with it. In the case of a turbidity current, the corresponding downslope impelling term in Eq. (2-261) is  $gRChS$ . If the concentration of suspended sediment  $C$  drops to zero, the downslope impelling force also drops to zero, and the current must eventually die. In a turbidity current, then, gravity pulls the sediment downslope, and the sediment drags the water with it. In a river, the dynamics of the flow is essentially decoupled from the dynamics of suspended sediment. In a turbidity current, the two are intimately linked (García 1992).

Equations (2-260) and (2-261), along with Eqs. (2-250) and (2-251), can be closed with functional relations for  $E_s$ ,  $q_b$  and  $r_o$  that are similar to those used for rivers. In addition, however, an equation for the entrainment coefficient of ambient water  $e_w$  must be specified. Parker et al. (1987) suggest the following functional form

$$e_w = \frac{0.075}{(1 + 718 \times Ri^{2.4})^{0.5}} \quad (2-262)$$

where  $Ri$  denotes the bulk Richardson number, given as

$$Ri = \frac{RgCh}{U^2} \quad (2-263)$$

The bulk Richardson number is related to the densimetric Froude number  $Fr_d$  as

$$Fr_d = \frac{U}{\sqrt{gRCh}} = Ri^{-1/2} \quad (2-264)$$

A turbidity current is supercritical if  $Fr_d > 1$  ( $Ri < 1$ ) and subcritical if  $Fr_d < 1$  ( $Ri > 1$ ). (In fact the precise borderline between subcritical and supercritical flow depends upon the shape factors discussed above, but a value of unity is generally an acceptable approximation.) Supercritical turbidity currents

tend to entrain ambient water from above, in analogy to the tendency of supercritical open channel flows to entrain air on spillways. In accordance with Eq. (2-262), highly subcritical turbidity currents tend to entrain little ambient water (García 1994). More material on water entrainment by underflows, including the role played by bottom slope and roughness, can be found in Fernandez and Imberger (2006).

## 2.12 MORPHODYNAMICS OF LAKE AND RESERVOIR SEDIMENTATION

The following material is intended to provide a brief summary of the morphodynamics of sedimentation in lakes and reservoirs. More detail on reservoir sedimentation is given in Chapter 12.

### 2.12.1 Introduction: Topset, Foreset, and Bottomset of Delta

As a river enters the slack water of a lake or reservoir, the flow decelerates and its sediment drops out. The result is the formation of a delta (Fig. 2-60). The coarser sediment (typically sand and/or gravel) deposits fluviially to form an aggrading topset and deposits by avalanching to form a prograding foreset. The finer sediment (typically mud, i.e., silt and clay) deposits in deeper water to form a bottomset (e.g., Morris and Fan 1997).

Fig. 2-60. Definition diagram for a fluvial delta.

These characteristic features are seen for the case of Lake Mead in Fig. 2-61 (Grover and Howard 1938; Smith et al. 1954). The figure shows the history of reservoir sedimentation from the closing of the dam in 1936 to 1948. The topset, foreset, and bottomset deposits are clearly visible in the figure. It is of interest to note that the maximum slope of the foreset is less than  $1^\circ$ . An inset in Fig. 2-61 is expanded in Fig. 2-62. This inset shows that the topset and foreset are predominantly composed of sand, and the bottomset is predominantly composed of mud (silt and clay). The foreset-bottomset interface clearly defines a moving boundary. This feature is exploited in the modeling described here.

Fig. 2-61. Formation of fluvial delta in Lake Mead, USA. Adapted from Smith et al. (1954).

**Fig. 2-62.** Inset of Fig. 2-61 showing the moving boundary between the muddy bottomset and the sandy topset-foreset.

The bottomset can be emplaced in three ways. If the sediment-laden river water is lighter than the lake water, a muddy surface plume extends out into the lake from the delta front. Mud gradually rains out of this plume and deposits to form the bottomset, as shown in Fig. 2-63a. Lakes are often stratified, however, so that the surface water is warmer and lighter than the water at a depth. If the sediment-laden river water has a density that is intermediate between that of the surface and bottom water in the lake, the muddy plume partially plunges to form an interflow, as shown in Fig. 2-63b. During floods, when rivers are likely to carry their highest concentrations of mud as wash load, the river water is often sufficiently dense to plunge to the bottom of the reservoir and form a turbidity current, as shown in Fig. 2-63c (Bell 1942; Fan and Morris 1992a).

### 2.12.2 Fluvial Deposition of Topset and Foreset

A simple one-dimensional morphodynamic model of delta topset and foreset evolution is first considered. A river of constant width flows into a lake of the same width and infinite streamwise extent. The water surface elevation  $\xi_o$  in the lake is held constant. The river transports sand as bed-material load; this sand is approximated with a single grain size  $D_s$ . The hydrograph of the river is approximated in the following way; for a constant fraction  $I_f$  of the year the river is in flood, carrying a constant floodwater discharge per unit width  $q_w$ . Otherwise, the river is assumed to be morphodynamically inactive. During floods sand enters the river at  $x = 0$  at volume rate per unit width  $q_{ft}$ , where the subscript  $t$  denotes total bed material load and  $f$  denotes flood. The porosity of the sandy bed deposit is denoted as  $\lambda_{ps}$ , where  $s$  denotes sand. Since the flood flow is assumed to be steady, Eqs. (2-246) and (2-247) can be reduced to the backwater equation

$$\frac{\partial h_f}{\partial x} = \frac{-\frac{\partial \eta_f}{\partial x} - C_{ff} Fr^2}{1 - Fr^2} \quad (2-265a)$$

**Fig. 2-63.** Illustration of the formation of a muddy surface plume (a), a muddy interflow (b), and a muddy bottom turbidity current (c).

$$Fr^2 = \frac{q_w^2}{gh_f^3} \quad (2-265b)$$

In this backwater equation,

$h_f$  and  $\eta_f$  = flow depth and bed elevation in a fluvial zone that includes the topset and foreset regions but excludes the bottomset;

$Fr$  = Froude number of the fluvial flow; and

$C_{ff}$  = bed friction coefficient in the fluvial region.

The boundary condition on this equation is expressed in terms of the flow depth at a point  $x = s_{\text{stand}}$  where standing water elevation  $\xi_o$  is maintained. Let  $\eta_f(x, t)$  denote the bed elevation at any point  $x$  and time  $t$ . The boundary condition is then

$$h_f(x, t) \Big|_{x=s_{stand}} = \xi_o - \eta_f(x, t) \Big|_{x=s_{stand}} \quad (2-265c)$$

The flow is assumed to be everywhere subcritical ( $Fr < 1$ ), so that Eq. (2-265a) is integrated in the upstream (negative  $x$ ) direction from  $x = s_{stand}$ . The solution of Eq. (2-265a) subject to Eq. (2-265c) constitutes the standard backwater formulation; in a consideration of reservoir sedimentation the backwater curve of interest is the M1 curve (Chow 1959).

The Shields number  $\tau^*$  of the fluvial flow is given as

$$\tau^* = \frac{\tau_b}{\rho R_s g D_s} = \frac{C_f q_w^2}{R_s g D_s h_f^2} \quad (2-266)$$

where  $R_s$  denotes the submerged specific gravity for the sand. In all following calculations, the total volume bed material load per unit width of the river  $q_t$  is estimated using the relation of Engelund and Hansen (1967) introduced earlier in the chapter,

$$q_t^* = \frac{q_t}{\sqrt{R_s g D_s D_s}} = \frac{0.05}{C_{ff}} (\tau^*)^{5/2} \quad (2-267)$$

Here the friction coefficient  $C_{ff}$  is assumed to be a specified constant for simplicity. At any given time  $t$ , then, the total volume bed material transport rate per unit width of sand  $q_t(x, t)$  can be computed by (1) solving Eq. (2-265a) subject to Eq. (2-265c) to determine  $h_f(x, t)$  over a known bed  $\eta_f(x, t)$ , and then (2) using Eqs. (2-266) and (2-267) to determine  $q_t(x, t)$ .

The bed evolution or morphodynamics driven by the backwater of the lake is computed from the Exner equation of sediment continuity. Modifying Eq. (2-255b) for the fluvial region so as to account for the fact that the river is morphologically active only  $I_f$  fraction of the time, it is seen that

$$(1 - \lambda_{ps}) \frac{\partial \eta_f}{\partial t} = -I_f \frac{\partial q_t}{\partial x} \quad (2-268)$$

The boundary condition on Eq. (2-268) is a specified feed rate of sand, here taken to be constant;

$$q_t \Big|_{x=0} = q_{tf} \quad (2-269)$$

The initial condition on the problem is here simplified to a bed with constant slope  $S_{base}$  and a bed elevation  $\eta_f = 0$  at  $x = s_{stand}$ .

The problem defined by Eqs. (2-265) to (2-269) has been solved numerically by many authors, e.g., Hotchkiss and Parker (1991). Here techniques outlined in Parker (2005) are used to solve the problem. A predictor-corrector method is used to solve the backwater equation over the bed at any given time, and the Euler step method is used to compute the bed elevation at a later time from the above Exner formulation. The input parameters are given as those of Case A of Table 2-8. The size  $D_s$  of the sand is seen there to be 0.4 mm, or 400  $\mu\text{m}$ .

The results of a computer simulation of Case A for a simulated run time  $t_{run}$  of 30 years are shown in Fig. 2-64. The

Fig. 2-64. Simulation of formation of sandy topset and foreset in a lake using a shock-capturing formulation and the input of Case A of Table 2.7.

method is fundamentally shock-capturing (the delta front being the shock); a delta forms of its own accord, steepens, and progrades downstream. The topset and foreset are clearly visible in Fig. 2-64. There is no bottomset because mud has not been included in the formulation. Although this formulation clearly captures the mechanism of formation and progradation of the delta topset and foreset, it does not correctly describe foreset slope. In a shock-capturing method, the slope of the foreset is entirely dependent on the spatial step length.

Once the delta has formed, it becomes possible to change the formulation to a shock-fitting formulation, in which the foreset has a prescribed slope of avalanching  $S_a$  that can be selected based on physical considerations. Swenson et al. (2000) have developed such a formulation. The delta is defined in terms of a topset-foreset break and a foreset-basement break, as shown in Fig. 2-65. The foreset progrades over a subaqueous basement of prescribed morphology. The distance from the sediment feed point at  $x = 0$  to the topset-foreset break is denoted as  $s_s(t)$  (the subscript s being shorthand for shoreline),

and the corresponding distance to the foreset-bottomset break is denoted as  $s_b(t)$ . Both these parameters define boundaries that move as the delta evolves. Likewise, the bed elevation at the topset-foreset break is defined as  $\eta_s(t)$ , and the bed elevation at the foreset-basement break is defined as  $\eta_b(t)$ .

In a shock-fitting formulation, delta progradation is described in terms of a shock condition determined by integrating the Exner equation (2-268) from the topset-foreset break to the foreset-bottomset break, under the condition of constant foreset slope  $S_a$ . Kostic and Parker (2003a) generalized the work of Swenson et al. (2000) to obtain the condition

$$\dot{s}_s = \frac{1}{(S_a - S_s)} \left[ \frac{I_f q_t|_{x=s_s}}{(1 - \lambda_{ps})(s_b - s_s)} - \frac{\partial \eta_f}{\partial t} \Big|_{x=s_s} \right] \quad (2-270)$$

In this relation  $\dot{s}_s$  denotes the speed of migration of the topset-foreset break, and

$$S_s = - \frac{\partial \eta_f}{\partial x} \Big|_{x=s_s} \quad (2-271)$$

i.e., the slope of the topset at the topset-foreset breaks. Eq. (2-270) indicates that the foreset progrades at a speed that is commensurate with the rate of delivery of bed-material load (sand in the simulations reported here) to the topset-foreset break.

The shock condition of Eq. (2-270) is augmented with an elevation continuity condition at the foreset-basement break, which reduces to the following condition; where  $\dot{s}_b$  denotes the speed of migration of the foreset-basement break,

$$(S_a - S_b)\dot{s}_b = (S_a - S_s)\dot{s}_s + \frac{\partial \eta_f}{\partial t} \Big|_{x=s_s} \quad (2-272)$$

In the above relation  $S_b$  denotes the slope of the subaqueous basement at the foreset-basement break.

**Fig. 2-65.** Definition diagram for a moving-boundary shock-fitting formulation of delta topset-foreset evolution.

The problem is conveniently solved numerically in terms of moving boundary coordinates, according to which

$$\hat{x}_f = \frac{x}{s_s(t)} \quad (2-273a)$$

$$\hat{t}_f = t \quad (2-273b)$$

That is, Eqs. (2-265) and (2-268) are transformed according to Eqs. (2-273a) and (2-273b) and solved in conjunction with Eqs. (2-270) and (2-272). The transformed problem is stated here in terms of the backwater formulation,

$$\frac{1}{s_s} \frac{\partial h_f}{\partial \hat{x}_f} = \frac{-\frac{1}{s_s} \frac{\partial \eta_f}{\partial \hat{x}_f} - C_{ff} \frac{q_w^2}{gh_f^3}}{1 - \frac{q_w^2}{gh_f^3}} \quad (2-274a)$$

$$h_f|_{\hat{x}_f=1} = \xi_o - \eta_f(1, \hat{t}) \quad (2-274b)$$

the Exner equation of sediment continuity,

$$(1 - \lambda_{ps}) \left[ \left( \frac{\partial \eta_f}{\partial \hat{t}_f} - \frac{\dot{s}_s}{s_s} \hat{x} \frac{\partial \eta_f}{\partial \hat{x}_f} \right) \right] = -\frac{1}{s_s} I_f \frac{\partial q_t}{\partial \hat{x}_f} \quad (2-275)$$

the shock condition for foreset progradation,

$$\dot{s}_s = \frac{1}{S_a} \left[ \frac{I_f q_t(1, \hat{t}_f)}{(s_b - s_s)(1 - \lambda_{ps})} - \frac{\partial \eta_f}{\partial \hat{t}_f} \right]_{\hat{x}_f=1} \quad (2-276)$$

and the continuity condition at the foreset-basement break,

$$\dot{s}_b = \dot{s}_s + \frac{1}{S_a} \frac{\partial \eta_f}{\partial \hat{t}_f} \bigg|_{\hat{x}_f=1} \quad (2-277)$$

Details are given in Kostic and Parker (2003a; 2003b). The calculation is implemented here as Case B, the input parameters for which are given in Table 2-8. Case B is chosen to be very close to Case A. Case B requires initial values  $s_{sl}$ ,  $\eta_{sl}$  and  $\eta_{bl}$  for  $s_s$ ,  $\eta_s$  and  $\eta_b$ , respectively, as well as an initial fluvial bed slope  $S_{ff}$ . These values have been estimated from the output of Case A at  $t = 15$  years. Basement slope  $S_{base}$  is the same in Case B as that of Case A; because it is constant,  $S_b$  in Eq. (2-272) is always equal to  $S_{base}$ . The foreset avalanche slope  $S_a$  has been set equal to 0.05, i.e., 2.86°.

The results of 600 years of simulation of Case B are shown in Fig. 2-66. Progradation forces the evolution of a topset with an upward-concave long profile, i.e., one for which slope declines in the streamwise direction. After 600 years the delta front has prograded well over 150 km. It should be noted that the progradation predicted by a one-dimensional model is considerably exaggerated as compared to nature. This is because in a one-dimensional model the

**Fig. 2.66.** Simulation of progradation of sandy topset and foreset in a lake using a shock-fitting formulation and the input of Case B of Table 2-7.

only place for the topset sediment to deposit is in the channel, whereas in nature sediment deposits on the surface of a much wider fan-delta over which the river channel avulses. The two-dimensional case is considered below.

### 2.12.3 Plunging of a Muddy Turbidity Current

Up to now the muddy bottomset has been excluded from the formulation. Sand- and gravel-bed rivers often carry copious amounts of mud (sand and silt) as wash load, i.e., material that is carried in suspension but constitutes only a negligible fraction of the bed sediment. An example is the Colorado River, USA (Smith et al. 1954). Because the mud does not deposit in the bed of the river, it may be neglected in a first model of the evolution of the topset and foreset.

As seen in Figs. 2-63, however, when river meets the standing water of a lake or reservoir, the sand is left behind on the topset-foreset and the remaining muddy water continues as a surface plume, interflow, or bottom turbidity current. The case considered here is the one for which the muddy water is sufficiently dense to plunge and form a bottom turbidity current.

When muddy river water is denser than lake water at every level of the lake, the river water plunges somewhere above the foreset to create the bottom turbidity current schematized in Fig. 2-67. A number of relations are available to predict plunging of muddy water in a lake; these are reviewed in Parker and Toniolo (2007). Here the treatment of Parker and Toniolo (2007) is offered as a sample.

The analysis is applied to muddy water flowing into a lake with no ambient stratification. The flow near the plunge point is illustrated in Fig. 2-68. Except for the mud, the river water is assumed to have the same density as the sediment-free lake water. The flow velocity, depth, and volume mud concentration in the river water just upstream of the plunge point are denoted as  $U_p$ ,  $h_p$  and  $C_{mp}$ , respectively; the corresponding flow velocity, layer thickness and volume mud concentration in the turbidity current just downstream of the plunge point are denoted as  $U_d$ ,  $h_d$  and  $C_{md}$ , respectively. The

Fig. 2-67. Definition diagram illustrating plunging.

submerged specific gravity of the mud is denoted as  $R_m$ . As the river flow plunges, it invariably draws into it some ambient water from the lake. The velocity at which this ambient water enters the muddy flow is denoted as  $U_a$ .

The coefficient of mixing of ambient water into the muddy flow,  $\gamma$ , is defined as

$$\gamma = \frac{U_a(h_p - h_d)}{U_p h_p} \quad (2-278)$$

A value  $\gamma > 0$  is required for the muddy flow to plunge. The flow discharge per unit width just downstream of plunging is related to that just upstream of plunging as

$$U_d h_d = U_p h_p (1 + \gamma) = q_w (1 + \gamma) \quad (2-279)$$

The depth ratio  $\phi$  and the densimetric Froude numbers  $Fr_{dp}$  and  $Fr_{dd}$  just upstream and downstream of the plunge point are defined as

$$\phi = \frac{h_d}{h_p} \quad (2-280a)$$

$$Fr_{dp}^2 = \frac{U_p^2}{R_m C_{mp} g h_p} = \frac{q_w^2}{R_m C_{mp} g h_p^3} \quad (2-280b)$$

$$Fr_{dd}^2 = \frac{U_d^2}{R_m C_{md} g h_d} \quad (2-280c)$$

Parker and Toniolo (2007) obtain the following relations for these parameters:

$$Fr_{dd}^2 = Fr_{dp}^2 \frac{(1 + \gamma)^3}{\phi^3} \quad (2-281)$$

Fig. 2-68. Detailed illustration of flow near the plunge point with definitions.

$$Fr_{dp}^2 = \frac{1}{2\gamma^2}(1-\phi)^3 \quad (2-282)$$

$$\frac{1}{\gamma^2}(1-\phi)^3 - \frac{1}{\gamma^2} \frac{(1-\phi)^3}{\phi} (1+\gamma)^2 - (1-\phi)^2 + 1 - \frac{\phi^2}{(1+\gamma)} = 0 \quad (2-283)$$

Once the mixing coefficient  $\gamma$  is specified, these equations allow the determination of the plunge point and the flow below it. Let  $q_{mf}$  denote the volume feed rate of mud per unit width. Because the mud does not settle out upstream of the plunge point, the volume concentration of mud,  $C_{mp}$ , just upstream of the plunge point (and, indeed, everywhere upstream of the plunge point) is given from the relation

$$q_{mf} = q_w C_{mp} \quad (2-284)$$

The ratio  $\phi = h_d/h_p$  is obtained from Eq. (2-283). Once this value is known,  $h_p$  is computed from Eqs. (2-282) and (2-280b) and  $h_d$  is further computed from this value and the previously computed value of  $\phi$ . The value of  $U_d$  is then computed from Eq. (2-279), and the value of  $C_{md}$  is computed from  $U_d$ ,  $h_d$ , and Eqs. (2-280c) and (2-281).

Plunging occurs at the point of the foreset where the fluvial depth  $h_f$  becomes equal to the value  $h_p$  predicted from the above relations. It can be verified from these relations that a necessary condition for plunging is a mixing coefficient  $\gamma > 0.14$ . Under such conditions, the river flow just upstream of the plunge point is subcritical in the sense of the densimetric Froude number, i.e.,  $Fr_{dp} < 1$ , and the turbidity current just downstream of the plunge point is supercritical, i.e.,  $Fr_{dd} > 1$ .

#### 2.12.4 Linked One-Dimensional Model of Topset, Foreset and Bottomset Evolution

As noted above, Eqs. (2-260), (2-261), (2-253), and (2-254) describe, respectively, flow mass balance, momentum balance, suspended-sediment mass balance, and conservation of bed sediment for the case of a turbidity current. Here the following assumptions are made to simplify the problem.

- The turbidity current is assumed to be steady and driven by the steady inflow from the river.
- The turbidity current is assumed to be flowing over a bed that is sufficiently steep to render it everywhere supercritical in the densimetric sense.
- The turbidity current is purely depositional, so the term  $E_s$  in Eqs. (2-253) and (2-254) can be neglected.
- The turbidity current is allowed to run out infinitely in the streamwise direction.
- Bed load transport is neglected.

Under these assumptions, Eqs. (2-253), (2-260) and (2-261) can be reduced to the forms

$$\frac{\partial h_t}{\partial x} = \frac{Ri \frac{\partial \eta_t}{\partial x} + e_w \left( 2 - \frac{1}{2} Ri \right) + C_{ft} - \frac{1}{2} Ri r_o \frac{v_{sm}}{U_t}}{1 - Ri} \quad (2-285a)$$

$$\frac{\partial U_t}{\partial x} = \frac{Ri \frac{\partial \eta_t}{\partial x} - e_w \left( 1 + \frac{1}{2} Ri \right) - C_{ft} + \frac{1}{2} Ri r_o \frac{v_{sm}}{U_t}}{1 - Ri} \frac{U_t}{h_t} \quad (2-285b)$$

$$\frac{\partial q_m}{\partial x} = -r_o \frac{v_{sm}}{U_t} \frac{q_m}{h_t} \quad (2-285c)$$

Where

$\eta_t$  = elevation of the bed below the turbidity current;

$h_t$  = layer thickness of the turbidity current;

$U_t$  = layer-averaged velocity of the turbidity current; and

$q_m$  = volume discharge of mud per unit width of the turbidity current, related to the layer-flux averaged mud concentration  $C_t$  as

$$q_m = U_t h_t C_t \quad (2-286)$$

In addition,  $v_{sm}$  denotes the fall velocity of the mud and  $C_{ft}$  denotes the coefficient of bed resistance of the turbidity current, here approximated as constant. Finally, the Richardson number  $Ri$  is given from Eqs. (2-263) and (2-286) as

$$Ri = \frac{R_m g C_t h_t}{U_t^2} = \frac{R_m g q_m}{U_t^3} \quad (2-287)$$

The assumption of supercritical flows implies that  $Ri < 1$  everywhere. This assumption allows Eqs. (2-285a), (2-285b), and (2-285c) to be integrated downstream from the plunge point. Let  $x = s_p$  denote the position of the plunge point. The boundary conditions on (2-285a), (2-285b), and (2-285c) are then

$$h_t|_{x=s_p} = h_d \quad (2-288a)$$

$$U_t|_{x=s_p} = U_d \quad (2-288b)$$

$$q_m|_{x=s_p} = U_d h_d C_{md} \quad (2-288c)$$

where  $h_d$ ,  $U_d$  and  $C_{md}$  are obtained from the calculation of plunging.

Once the flow over the bed is solved, the morphodynamic evolution of the lake bed is solved from Eq. (2-251) subject to these assumptions, which reduce it to the form

$$(1 - \lambda_{pm}) \frac{\partial \eta_t}{\partial t} = -I_f r_o \frac{v_{sm}}{U_t} \frac{q_m}{h_t} \quad (2-289)$$

where  $\lambda_{pm}$  denotes the porosity of the mud deposit. The solution of Eqs. (2-285a), (2-285b), and (2-285c) subject to Eqs. (2-288a), (2-288b), and (2-288c) for the flow over the bed, and Eq. (2-289) for the bed evolution describes the evolution of a bottomset emplaced by a purely depositional one-dimensional muddy turbidity current.

Kostic and Parker (2003a, 2003b) have devised a moving-boundary formulation that dynamically links the moving-boundary model of the topset-foreset evolution described in Section 2.12.2 with the model of the bottomset evolution described in this section. All the equations describing topset-foreset evolution remain the same except for Eq. (2-272) describing the evolution of the foreset-basement break. In a linked model the foreset-basement break is replaced with a foreset-bottomset break located at  $x = s_b$ , as described in Fig. 2-66. The modified relation is

$$(S_a - S_b) \dot{s}_b = (S_a - S_s) \dot{s}_s + \left. \frac{\partial \eta_f}{\partial t} \right|_{s_s} - \left. \frac{\partial \eta_t}{\partial t} \right|_{s_s} \quad (2-290)$$

where  $S_b$  is now given as the slope of the bottomset at the foreset-bottomset break:

$$S_b = - \left. \frac{\partial \eta_t}{\partial x} \right|_{x=s_b} \quad (2-291)$$

The moving boundary formulation for topset/foreset evolution remains the same as that of Section 2.12.2, except for Eq. (2-277), which takes the amended form

$$\dot{s}_b = \dot{s}_s + \frac{1}{S_a} \left( \left. \frac{\partial \eta_f}{\partial \hat{t}_f} \right|_{\hat{x}_f=1} - \left. \frac{\partial \eta_t}{\partial \hat{t}_t} \right|_{\hat{x}_t=0} \right) \quad (2-292)$$

where the moving boundary coordinates for the bottomset region are given as

$$\hat{t}_t = t \quad \hat{s}_t = \frac{x - s_b}{s_{max} - s_b} \quad (2-293)$$

and  $x = s_{max}$  denotes the downstream limit of the range on which the calculation is to be performed.

Sample calculations of the coevolution of the sandy topset-foreset and muddy bottomset of a one-dimensional delta are presented as Case C, which has three subcases Ca, Cb, and Cc, corresponding to mud size  $D_m = 10, 15$ , and  $25 \mu\text{m}$ , respectively. The relevant modeling parameters are given in Table 2-8; for these cases  $S_{base}$  corresponds to the slope of the antecedent subaqueous bed over which the turbidity current deposits mud. Fall velocities  $v_{sm}$  have been computed using the values of  $R_m$  and  $D_m$  listed in Table 2-8, the kinematic viscosity  $\nu$  of water at  $20^\circ\text{C}$  and the relation of Dietrich (1982) presented in Eq. (2-47a). Water entrainment has been computed using Eq. (2-262). The coefficient  $r_o$  has been set equal to 2 (García 1994). The plunging formulation used in the computation is a highly simplified version that is less rigorous than the one presented in the previous section. It serves, however, to illustrate the morphodynamics of coevolution. In the calculation the turbidity current runs a short distance down the foreset from the plunge point before debouching onto the bottomset. It is assumed that the foreset is too steep to allow for the deposition of mud. Mud deposition commences at the foreset-bottomset break.

The results of the calculations for Cases Ca, Cb and Cc are presented in Fig. (2-69). In Case Ca with  $10\text{-}\mu\text{m}$  material, the bottomset is quite thin due to the small fall velocity of the mud. (The bottomset extends far beyond the point  $s_{max} = 30,000 \text{ m}$  in Cases Ca, Cb, and Cc.) Progradation of the foreset simply pushes the bottomset lakeward. In Case Cb with  $15\text{-}\mu\text{m}$  material the foreset and bottomset are seen to interact; progradation of the foreset pushes the bottomset lakeward, and aggradation of the bottomset reduces the elevation drop of the foreset. The interaction is seen to be even stronger for the  $25\text{-}\mu\text{m}$  material of Case Cc. Note that as the mud becomes coarser it falls out more rapidly from the turbidity current, so that deposition on the bottomset becomes more proximal to the foreset.

Figure 2-69(c) in particular bears a remarkable resemblance to the delta of Lake Mead shown in Fig. 2-61. In both images the interface between the sand and mud (foreset-bottomset break) is first seen to move upward and lakeward, and then to move downward and lakeward.

The restriction to supercritical flow means that the backwater formulation of Eqs. (2-285a), (2-285b), and (2-285c) for the turbidity (actually a frontwater formulation, because supercritical flow dictates integration in the downstream direction) can only be implemented on relatively high subaqueous bed slopes. On lower slopes the turbidity current undergoes a hydraulic jump to subcritical flow (García 1993). The problem can still be solved, but steady forms of Eqs. (2-285a), (2-285b), and (2-285c) must be replaced by their corresponding unsteady forms, even when the incoming flow is constant. The unsteady forms of the equations allow automatic shock capturing of any hydraulic jump. Kostic and Parker (2003a, 2003b) have implemented such calculations using a moving-boundary formulation that adds an extra moving boundary. In addition to the moving boundaries of the topset-foreset and foreset-bottomset breaks, the model also captures the

migration of the front of the turbidity current until such time as it exits the calculational domain. Tracking the front propagation constitutes a challenging problem (e.g., Choi and García 1995, 2001). Finally, a quasi-steady state turbidity current is achieved in a relatively short amount of time when the inflow conditions are steady.

### 2.12.5 Linked Quasi-Two-Dimensional Model of Topset, Foreset and Bottomset Evolution

Most real deltas at the upstream end of lakes are fan-deltas. That is, they spread out in the transverse direction. Fig. 2-70 shows an example of such a fan-delta: the Eau Claire River flowing into Lake Altoona, a reservoir in Wisconsin. As the river channel on a fan-delta aggrades, it migrates and avulses to fill the available surface of the fan-delta as it progrades. That is, it fills the area of the fan rather than the area of the channel in Fig. 2-71. Since the river fills a much wider area than just the bed of the channel itself, the rate of delta progradation is greatly slowed compared to the one-dimensional case.

The two-dimensional morphodynamics of a fan-delta can be approximated using a one-dimensional model in the following way. The river on the fan is assumed to have an effective constant width  $B_c$  for transporting sediment. In the long-term average, however, the sediment is assumed to be

deposited across the entire fan by gradual channel shift and avulsion. Here an axially symmetric fan with angle  $\theta_f$  is considered, as illustrated in Fig. 2-71. A radial coordinate  $r$  is defined from the apex of the fan. The equations governing flow in the channel remain unchanged from the one-dimensional formulation (except for the transformation from  $x$  to radial coordinate  $r$ ).

The radial width  $B_f$  is given as

$$B_f = \theta_f r \quad (2-294)$$

The appropriate form of the Exner equation of sediment conservation for the topset and foreset is

$$(1 - \lambda_{ps})B_f \frac{\partial \eta_f}{\partial t} = -I_f B_c \frac{\partial q_t}{\partial r} \quad (2-295a)$$

or rearranging,

$$(1 - \lambda_{ps}) \frac{\partial \eta_f}{\partial t} = -I_f \frac{B_c}{B_f} \frac{\partial q_t}{\partial r} \quad (2-295b)$$

**Fig. 2-69.** Simulation of coevolution of a sandy topset-foreset and a muddy bottomset foreset in a lake using a shock-fitting formulation and the input of Cases Ca(a),Cb(b), and Cc(c) of Table 2-8. The mud has a size of (a)10  $\mu\text{m}$ , (b) 15  $\mu\text{m}$ , and (c) 25  $\mu\text{m}$ .

(b)

(c)

**Fig. 2-69.** Simulation of coevolution of a sandy topset-foreset and a muddy bottomset foreset in a lake using a shock-fitting formulation and the input of Cases Ca(a), Cb(b), and Cc(c) of Table 2-8. The mud has a size of (a)  $10 \mu\text{m}$ , (b)  $15 \mu\text{m}$ , and (c)  $25 \mu\text{m}$ . (Continued)

As the fan progrades the ratio  $B_c/B_f$  must become small in accordance with Eq. (2-294). The result is a greatly suppressed rate of delta progradation and aggradation as compared to a purely one-dimensional formulation in which all the topset sand deposits within the channel.

As illustrated in Fig. 2-71, the topset-foreset break is located at  $r = s_s(t)$  and the foreset-bottomset break is located at  $r = s_b(t)$ ; both define moving boundaries. The shock condition at the foreset now takes the form

$$\frac{1}{2}(s_b^2 - s_s^2)\theta_f \left[ \frac{\partial \eta_f}{\partial t} \right]_{s_s} + (S_a - S_s)\dot{s}_s = \frac{I_f B_c q_t|_{r=s_s}}{(1 - \lambda_{ps})} \quad (2-296)$$

**Fig. 2-70.** Fan-delta of the Eau Claire River as it flowed into Lake Altoona, a reservoir in Wisconsin, in 1988.

**Fig. 2-71.** Definition diagram for a two-dimensional fan-delta.

where

$$S_s = - \frac{\partial \eta_f}{\partial r} \bigg|_{r=s_s} \quad (2-297)$$

The continuity condition at the foreset-bottomset break remains unaltered from the one-dimensional case (except for the transformation  $x \rightarrow r$ ).

The turbidity current is assumed to spread out axially at angle  $\theta_t$ . It is assumed to have an upstream width equal to that of the effective river channel, as described in Fig. 2-71. Let  $r_t$  denote the position of the virtual origin of the wedge of the turbidity current with angle  $\theta_t$  in Fig. 2-71. The governing equations of a steady, axially symmetric, purely depositional turbidity current can be reduced to the forms

$$\frac{dh_t}{d\tilde{r}} = \frac{Ri \frac{\partial \eta_t}{\partial \tilde{r}} Ri + e_w \left( 2 - \frac{1}{2} Ri \right) + C_{ft} - \frac{h_t}{\tilde{r}} \left( 1 - \frac{1}{2} Ri \right) - \frac{1}{2} Ri r_o \frac{v_{sm}}{U_t}}{1 - Ri} \quad (2-298a)$$

$$\frac{dU_t}{d\tilde{r}} = \frac{Ri \frac{\partial \eta_t}{\partial \tilde{r}} - e_w \left( 1 + \frac{1}{2} Ri \right) - C_{ft} + \frac{1}{2} Ri \frac{h_t}{\tilde{r}} + \frac{1}{2} Ri r_o \frac{v_{sm}}{U_t} \frac{U_t}{h_t}}{1 - Ri} \quad (2-298b)$$

$$\frac{dq_m}{d\tilde{r}} = - \frac{q_m}{\tilde{r}} - r_o \frac{v_{sm}}{U_t} \frac{q_m}{h_t} \quad (2-298c)$$

where

$$\tilde{r} = r - r_t \quad (2-299)$$

The turbidity current is assumed to migrate across the subaqueous fan, filling it in a manner analogous to that of a subaerial fan-delta. That is, the turbidity current deposits over an area that is much larger than that of the turbidity current itself at any given time. The appropriate form of the Exner equation of sediment continuity becomes

$$(1 - \lambda_{pm})\theta_f r \frac{\partial \eta_t}{\partial t} = r_o \frac{v_{sm}}{U_t} \frac{q_m}{h_t} \theta_t (r - r_t) \quad (2-300)$$

This quasi-two-dimensional formulation can be cast into a moving-boundary framework and solved in a manner that is completely analogous to the one-dimensional case. The input parameters for the calculation are shown as Case D in Table 2-8. As in all previous cases, the sand size  $D_s$  is 0.4 mm (400  $\mu$ m); the mud size is 10  $\mu$ m. The fan angle  $\theta_f$  is taken to be 90° and the angle of spread of the turbidity current  $\theta_t$  is taken to be 10°.

**Fig. 2-72.** Simulation of coevolution of a sandy topset-foreset and a muddy bottomset foreset in a lake using a quasi-2D shock-fitting formulation and the input of Case D of Table 2-8. The mud has a size of  $10\ \mu\text{m}$ .

The results of the quasi-two-dimensional calculation of Case D are shown in Fig. 2-72. The analogous one-dimensional case is that of Case Cc. It is seen that after 3000 years the quasi-two-dimensional fan-delta has prograded out much less than in the corresponding one-dimensional case over 45 years. The effect of the two-dimensional geometry in limiting the rate of progradation is clearly apparent.

#### 2.12.6 Formation of a Muddy Pond in a Reservoir: Detrainment and Sediment Trap Efficiency

In the calculations presented in the previous two sections the turbidity current has been allowed to run out infinitely in the streamwise direction. In a reservoir, however, a sustained turbidity current eventually hits the dam and reflects off it.

**Fig. 2-73.** Process by which a muddy pond is set up in a reservoir.

**Fig. 2-74.** Quasi-steady flow in a reservoir after the establishment of an internal hydraulic jump and a muddy pond.

**Fig. 2-75.** Diagram illustrating the gradual decline in trap efficiency of a reservoir as the level of the muddy interface gradually rises above an outlet.

This creates an upstream-migrating bore that eventually stabilizes upstream as an internal hydraulic jump (García and Parker 1989; García 1993). The result is the formation of a deep, slow-moving muddy pond downstream of the hydraulic jump (Lamb et al. 2006). The setup process is illustrated in Fig. 2-73, and the resulting quasi-steady flow after setup of the muddy pond is illustrated in Fig. 2-74.

The muddy pond is a zone containing a nearly stagnant turbidity current, for which the densimetric Froude number  $Fr_d$  satisfies the condition

$$Fr_d \ll 1 \quad (2-301)$$

It is subject to a phenomenon which Toniolo (2002) and Lamb et al. (2004) have called “water detrainment.” In the absence of incoming flow from upstream, the interface between the muddy pond and the clear water above would gradually migrate downward at a rate equal to the fall velocity  $v_{sm}$  of the mud. Thus muddy water is converted to clear water at a detrainment discharge equal to  $v_{sm} A$ , where  $A$  is equal to the surface area of the interface. When muddy water is constantly being replaced from upstream as it passes through the hydraulic jump, however, the elevation of the muddy pond

can stabilize well below the water surface of the reservoir, while water continues to detrain at the discharge  $v_{sm} A$ .

Initially the interface of the muddy pond may stabilize at a level that is below any outlet, as shown in Fig. 2-75. In such a case the trap efficiency of the reservoir is 100 %. As the foreset progrades and the bottomset aggrades, however, the interface should rise in time, so that mud is washed out of a reservoir outlet. This process is illustrated in Fig. 2-75. The result is a trap efficiency that gradually drops below 100 percent.

Toniolo et al. (2007) have developed a moving boundary numerical model to describe the coevolution of a sandy topset-foreset and a muddy bottomset, in which a dam forces the formation of a muddy pond. The model is one-dimensional, but it could easily be adapted to a quasi-twodimensional configuration. The model requires a fully unsteady treatment of the flow in order to capture the hydraulic jump (e.g., Choi and García1995). Once its position is stabilized, however, a quasi-steady flow is maintained in the presence of slow delta progradation and bottomset. Again, the turbidity current is treated as purely depositional.

The equations governing flow mass and momentum conservation and conservation of suspended sediment must be adapted to include water detrainment from a stagnant, muddy pond for which  $Fr_d \ll 1$ . The forms of these relations used in the analysis are

**Fig. 2-76.** Simulation of coevolution of a sandy topset-foreset and a muddy bottomset foreset in a reservoir using a one-dimensional shock-fitting formulation and the input of Case E of Fig. 2-77. Prediction of reservoir trap efficiency for Case E of Table 2-8. The mud has a size of 50  $\mu\text{m}$ . Note the presence of the internal hydraulic jump and the muddy pond.

$$\frac{\partial h_t}{\partial t} + \frac{\partial U_t h_t}{\partial x} = (1 - \delta) e_w U_t - \delta v_{sm} \quad (2-302a)$$

$$\begin{aligned} \frac{\partial U_t h_t}{\partial t} + \frac{\partial U_t^2 h_t}{\partial x} + \delta U_t v_{sm} \\ = -\frac{1}{2} R_m g \frac{\partial C_t h_t^2}{\partial x} + R_m g C_t h_t S - C_{ft} U_t^2 \end{aligned} \quad (2-302b)$$

$$\frac{\partial C_t h_t}{\partial t} + \frac{\partial U_t C_t h_t}{\partial x} = -\delta r_o v_{sm} C_t \quad (2-302c)$$

Here the parameter  $\delta$  is set equal to 1 in the muddy pond, but is set equal to 0 elsewhere. The details of the moving-boundary analysis can be found in Toniolo et al. (2007). The treatment uses the plunging formulation of Parker and Toniolo (2007) with a value of  $\gamma$  of 1.3.

Toniolo et al. (2007) have applied the model at field scale. The parameters are given as Case E of Table 2-8. Note that  $r_o$  is set equal to 1 in the analysis, because the hydraulic jump should render the ponded zone well-mixed up, to the interface with the clear water above. The distance  $s_{max}$  from the origin to the wall of the dam is 6000 m. The flow intermittency  $I_f$  has been set equal to unity. This means that the 90 days of calculation time corresponds to 90 days of continuous flood, which might translate to, e.g., 2 to 10 years of real time.

The results of the calculation are shown in Fig. 2-76. Note that the bottomset deposit in the ponded zone is of nearly uniform thickness. This feature is driven by the ponding itself. In performing the calculation, water was vented from the reservoir at an elevation that was 38 m below the level of the water surface. As shown in Fig. 2-77, the trap efficiency was initially 100 percent because the settling interface was below the outlet. Reservoir sedimentation caused the level of the interface to rise in time, however, leading to a gradual reduction in trap

**Fig. 2-77.** Prediction of reservoir trap efficiency for Case E of Table 2-8.

efficiency. It should be pointed out that all the sediment escaping the model reservoir was mud, not sand.

Venting of turbidity currents through bottom outlets to prevent reservoir sedimentation has been considered around the world, particularly in China where the sediment loads of rivers are extremely large (e.g., Bruk 1985; Fan and Morris 1992b). For instance, the effectiveness of bottom outlets to discharge sediment-laden water will be greatly influenced by the characteristics of turbidity currents reaching the dam where they are placed (Toniolo and Schultz 2005). The location and frequency of operation of bottom outlets will also be influenced by sediment-laden underflows. The approach presented here, which is based on the dynamics of plunging turbidity currents, provides a way to assess how effective and useful different technologies might be for extending the life of reservoirs.

## 2.12.7 Remarks in Closing

The analyses of lake and reservoir sedimentation presented here are highly simplified. They should, however, serve to illustrate the main processes by which sedimentation occurs. They also should provide guidelines for the numerical prediction of lake and reservoir sedimentation as well as the operation of reservoirs to reduce sediment deposition by open-channel flows and turbidity currents. A more practical analysis of reservoir sedimentation is given in Chapter 12. One-dimensional modeling of sedimentation processes in rivers is addressed in Chapter 14, while two-dimensional and three-dimensional sediment transport models are covered in Chapter 15. Turbulence models for sediment-laden flows are considered in Chapter 16, while numerical modeling of sediment transport associated with dam removal is presented in Chapter 22.

## CHAPTER 3

# *Transport of Gravel and Sediment Mixtures*

*Gary Parker*

### 3.1 FLUVIAL PHENOMENA ASSOCIATED WITH SEDIMENT MIXTURES

When *ASCE Manual No. 54*, “Sedimentation Engineering,” was first published in 1975, the subject of the transport and sorting of heterogeneous sediments with wide grain-size distributions was still in its infancy. This was particularly true in the case of bed-load transport. At the time, the method of Einstein (1950) was one of the few available that were capable of computing the entire grain-size distribution of particles in bed-load transport. However, this capability had not been extensively tested against either laboratory or field data. Since that time there has been a steady increase in research on the subject of the selective (or nonselective) transport of sediment mixtures. A brief attempt to summarize this research in a useful form is provided in this chapter.

A river that is supplied with a wide range of grain sizes has the opportunity to sort them. Although the grain-size distribution found on river beds is never uniform, the range of sizes tends to be particularly broad in the case of rivers

with beds that consist of mixtures of gravel and sand. These streams are termed “gravel-bed streams” if the mean or median size of the bed material is in the gravel range; otherwise they are termed “sand-bed streams.” The river can sort its gravel and sand in the streamwise, lateral, and vertical directions, resulting in each case in a characteristic morphology. Summaries of these morphologies are given in Whiting (1996) and Powell (1998); Parker (1992) provides a mechanistic basis for their study.

Sorting phenomena range from very small scale to very large scale. In many gravel-bed rivers, the bed is vertically stratified, with a coarse armor layer on the surface. This coarse layer limits the supply of fine material from the subsurface to the bed load at high flow. Some gravel-bed streams, however, show no vertical stratification. An example of each type of stream is shown in Fig. 3-1, which illustrates the difference between a perennial stream with low sediment supply and moderate floods (left) and an ephemeral stream with a high sediment supply and violent floods (right).

**Fig. 3-1.** Contrasts in surface armoring between (a) the River Wharfe, UK, a perennial stream with a low sediment supply (left) and (b) the Nahal Yatir, Israel, an ephemeral stream with a high rate of sediment supply (right). Images courtesy of J. Laronne and I. Reid; see also Powell (1998).

If the flow is of sufficient strength, bed forms such as dunes can form in gravel-bed streams (Dinehart 1992). Dunes are the most common bed form in sand-bed streams. Depending on the strength of the flow, the parent grain-size distribution can interact with the bed forms to induce strong vertical and streamwise sorting, with coarser material accumulating preferentially in dune troughs. This is illustrated in Fig. 3-2. Note that the transition from lower-regime plane bed to dunes, which is illustrated in Fig. 2-28, thus engenders a reversal of vertical sorting, with a coarse layer at the top of the bed in the former case and near the base of the dunes in the latter case.

Under conditions of weak transport, the dunes devolve into bed-load sheets, which are rhythmic waves expressing downstream variation predominantly in terms of alternating zones of fine and coarse sediment rather than elevation variation (Fig. 3-3). Both dunes and bed-load sheets result in

**Fig. 3-2.** Sediment sorting in the presence of a dune field. Flow was from top to bottom. Image courtesy A. Blom.

**Fig. 3-3.** Pulsations associated with experimental bedload sheets composed of a mixture of sand and gravel. (a) Alternating arrangement of three bed states. (b) Fluctuation in gravel transport rate. (c) Fluctuation in sand transport rate. From Iseya and Ikeda (1987), with permission of Blackwell Publishing.

**Fig. 3-4.** View of the Ooi River, Japan, showing sorting of gravel and sand on bars. From Ikeda (2001), with permission of Hiroshi Ikeda. The direction of flow is from the bottom to the top of the image.

a bed-load transport that strongly pulsates in terms of both total rate and characteristic grain size.

Bars and bends that form in rivers interact with sediment to produce sorting morphologies at a larger scale. Figure 3-4 shows a mildly sinuous reach of the Ooi River, Japan. It is readily apparent that bar heads tend to be coarser, whereas bar tails tend to be finer. Similar patterns can be observed in the bars of braided streams.

At sufficiently steep slopes, bars give way to pool-riffle sequences, which are barlike undulations in bed elevation and grain size that, for the most part, are expressed in the streamwise rather than the lateral direction. As opposed to dunes and some bars, pool-riffle patterns usually show little tendency to migrate downstream. At even steeper slopes, which support flow that is supercritical in the Froude sense during floods, the bed devolves into a well-defined step-pool pattern. Each step is defined by what can be described as a boulder jam, as seen in Fig. 3-5; the pools between steps contain much finer material.

**Fig. 3-5.** Step-pool topography in the Hi Yamizu River, Japan. Image courtesy K. Hasegawa.

A lake or reservoir interrupts the downstream transport of sediment. As a result, the riverbed often aggrades upstream of the dam and degrades downstream. Figure 3-6 shows the aggradational deposit upstream of a sediment retention dam on the North Fork Toutle River, Washington. Over the 10 km upstream of the dam, the characteristic bed-sediment size shows a pronounced pattern of downstream fining, declining from about 7.4 to 0.4 mm. This downstream fining appears to be abetted by the tendency of the bed to devolve into local patches or lanes of finer and coarser sediment. Figure 3-7 illustrates two such patches on the North Fork Toutle River. An extreme limiting case of such local segregation is the formation of roughness “streaks,” “stripes,” or “ribbons,” which consist of vertical lanes of alternating coarse and fine material, with a high transport rate of the latter relative to the former. These streaks are shown in Fig. 3-8.

Downstream of a dam, on the other hand, the bed often both degrades and coarsens in response to the cutoff of sediment, eventually forming static or nearly static armor that inhibits further bed erosion. An image of the static armor downstream of the Lewiston Dam on the Trinity River, California is shown in Fig. 3-9. The static armor is partially covered by mobile, pea-sized gravel from a tributary entering downstream of the dam.

Sorting appears at the largest scale in terms of the tendency for characteristic grain size to become finer over tens or hundreds of kilometers. This large-scale downstream fining is typically associated with a long profile of the river that is concave upward. A famous example, the Kinu River, Japan, is shown in Fig. 3-10. This river displays not only downstream fining, but also a relatively abrupt transition from gravel bed to sand bed. Strong downstream fining is

**Fig. 3-6.** View of sedimentation upstream of a sediment retention dam on the North Fork Toutle River, Wash. Flow is from bottom to top. From Seal and Paola (1995). (Copyright 1995 American Geophysical Union. Reproduced by permission of American Geophysical Union.)

**Fig. 3-7.** Sorted sediment patches on the North Fork Toutle River, Wash.: (a) coarse patch on fine sediment; (b) fine patch on coarse sediment. From Paola and Seal (1995). (Copyright 1995 American Geophysical Union. Reproduced by permission of American Geophysical Union.)

observed along the gravel-bed reach, and weaker downstream fining along the sand-bed reach.

Abrupt gravel-sand transitions are quite common in the field and are associated with the tendency for grain sizes in the range of pea gravel to be relatively scarce in rivers. This tendency is common, but by no means universal. An example of this tendency is shown in Fig. 3-11, which shows bed-material grain-size distributions of 174 river reaches in Alberta, Canada (Shaw and Kellerhals 1982). Note that the sand-bed streams (i.e., median size in the sand range) contain very little gravel. The gravel-bed streams (i.e., median size in the gravel range) often contain a substantial amount of sand, but very little material between 1 and 8 mm.

Transient sorting can be induced by a pulse of sediment introduced into a river from a debris flow or landslide. An example illustrating a landslide that flowed into and blocked the Navarro River, California is shown in Fig. 3-12. Such inflows often contain copious amounts of material that is much finer than the ambient bed material. They can also contain some material that

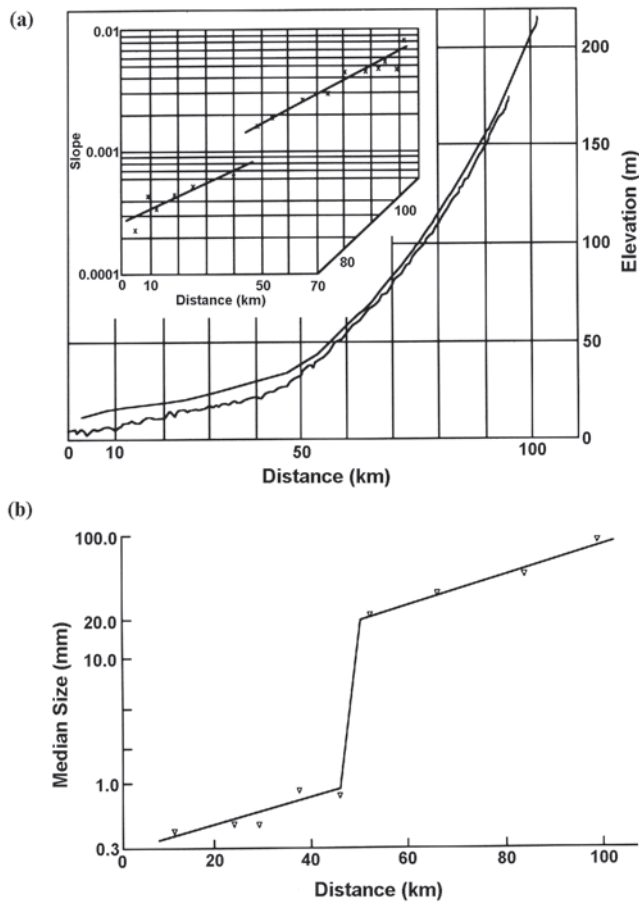

**Fig. 3-8.** Streaks of sorted sediment in (a) a laboratory flume (from Günter, 1971; courtesy A. Günter) and (b) a river (image courtesy T. Tsujimoto).

**Fig. 3-9.** Coarse static armor (dark grains) with a partial coverage of finer, mobile sediment (light grains) on the bed of the Trinity River, Calif. The coarse grains are rendered immobile by the presence of the Lewiston Dam upstream. (a) View of the river. (b) Closeup of the bed. Images courtesy Peter Wilcock.

**Fig. 3-10.** (a) Long profile and (b) downstream change in grain size of the Kinu River, Japan, illustrating downstream fining and a gravel-sand transition. Redrafted from an original in Yatsu (1955). (Copyright 1955 American Geophysical Union. Reproduced by permission of American Geophysical Union.)

is much coarser than the ambient bed material. Grain size sorting plays a key role in the process by which rivers digest such sediment inputs.

Most sediment sorting in rivers is accomplished by the differential transport of different sizes. In the case of heavy minerals (placers), however, increased specific gravity replaces increased size in this role. The issue is of some interest with regard to the extraction of placer gold from rivers. That finer grains are more mobile than coarser grains of the same specific density may appear to be intuitively obvious. However, this is usually but not always the case.

In addition to selective transport, rivers have the opportunity to create finer grains from coarser grains. This is sometimes accomplished by shattering of grains, but is more commonly associated with gradual abrasion and rounding of stones, yielding silt and some sand as a result. Abrasion can thus be a contributor to downstream fining. Figure 3.13 illustrates the effect of abrasion in gradually rounding grains downstream from their source.

**Fig. 3-11.** Grain size distributions of 174 samples of bed sediment from rivers in Alberta, Canada. From Shaw and Kellerhals (1982).

**Fig. 3-13.** Four sediment samples from the Ok Tedi River system, Papua New Guinea: (a) 1 km downstream of the Southern Dumps of the Ok Tedi Mine, after passage over a high waterfall, in the Harvey Creek debris flow fan as it enters the Ok Mani; (b) 8 km downstream, at the fluvial fan of the Ok Mani where it enters the Ok Tedi; (c) 27 km downstream on the Ok Tedi near the junction with the Ok Menga; and (d) 90 km downstream on the Ok Tedi at Ningerum Flats. Note that the grains become progressively rounder as the distance from the source increases.

The main focus of this chapter is on transport of mixed sizes and concomitant sorting in bed-load-dominated rivers. In the field, this usually refers to gravel-bed rivers. Some (typically small) sand-bed streams, such as Muddy Creek (Dietrich and Whiting 1999) also satisfy this criterion. Near the end of the chapter, however, suspension-dominated rivers, i.e., most sand-bed streams, are considered as well.

### 3.2 ENGINEERING RELEVANCE

Various aspects of grain sorting are relevant to river engineering design, habitat maintenance, and restoration of river ecosystems. First and foremost among these is gravel extraction, or mining from rivers for concrete aggregate and other construction purposes. The word “gravel” is used loosely with

regard to gravel mining and includes sand as well. The mining of fluvial gravels is particularly common in the western part of the United States. Gravel mining without appropriate constraints can lead to severe bed degradation downstream, with resulting failure of bridges and exposure of buried pipelines (Galay 1983). The Mad River, California, has been heavily utilized for gravel extraction. The effect on bed elevation at the bridge piers where Highway 101 crosses the river is readily apparent in Fig. 3-14. Gravel extraction was taking place on the day the photo was taken. Engineering models of the erosion, transport, and deposition of heterogeneous gravels have an important role to play in determining how much gravel can be safely extracted without adverse effects.

A common practice in many western rivers is "bar scalping," by which high-quality material is locally stripped from the surface of bars. This is done on the supposition that the river will eventually replace the mined gravel with material of similar competence. Anadromous fish such as salmon, however, are rather particular about the gravels in which they choose to build redds (egg nests) (Reiser 1998). If the

**Fig. 3-14.** Evidence of channel degradation on the Mad River, California under the Highway 101 bridge.

bed material is too coarse the fish cannot excavate a redd. If the bed is too fine, and in particular if it contains too much sand and silt, the fish will avoid it, instinctively knowing that eggs will be suffocated and poisoned by the inability of groundwater flow to carry away excreta. The Ooi river of Fig. 3-4 might be a good candidate for bar scalping in the United States, but in Japan, gravel extraction from most rivers has been banned in order to control bed degradation. The degradation of Japan's rivers is not only a product of gravel mining in previous times, but also a result of intensive sediment control works (e.g., sabou dams) in the upstream reaches of Japanese rivers that have dramatically reduced the sediment supply.

Spawning grounds can also be damaged or destroyed by agriculture or forestry. Road building for forest harvesting, if not done properly, can cause massive inputs of sand and finer material to a stream that is intrinsically gravel-bed. This finer material is usually transient, being washed downstream by successive floods. If the bed happens to be buried in fines, however, just before spawning, fish recruitment can drop drastically (e.g., Reiser 1998).

The installation of a dam on a river typically blocks the downstream delivery of all but the finest sediment, creating a pattern of bed aggradation upstream. The dam raises base level (i.e., the downstream water surface elevation to which the river upstream must adjust), forcing upstream-migrating deposition. This deposition is most intense near the delta at the upstream end of the reservoir. As a result, the effect is to intensify the upward concavity of the long profile of the bed upstream of the dam. The more sharply declining bed slope intensifies selective transport of fine material, setting up strong local downstream fining. This is what has taken place in the reservoir of the North Fork Toutle River, Washington, as illustrated in Fig. 3-6.

Downstream fining has a beneficial effect in terms of engineering that should be taken into consideration in designing dams. Aggradation induced by dams can require the leveeing of towns upstream of the dam. Sorting, however, tends to concentrate the aggradation toward the downstream end of the reach in question. Indeed, Leopold et al. (1964) observed that upstream aggradation driven by a dam never extends infinitely far upstream, no matter how much time has passed. Part of the reason for this is the tendency for the main stem and tributaries farther upstream in the drainage basin to absorb the effect of the dam. Sediment sizes that deposit in the backwater zone of the dam can be carried without deposition by the steeper main stem and tributaries upstream.

An extreme case of this tendency for sorting to damp upstream effects is often seen in gravel-bed streams, many of which carry loads of sand far in excess of the corresponding loads of gravel. However, the bed surface consists largely of gravel, with sand partially or completely filling the interstices. Analogously to the mud washload of sand-bed rivers, this sand load on a gravel-bed stream is called "throughput

load” if it interacts only passively with the bed (i.e., simply filling the pores of a gravel deposit). Sand can be carried as throughput load over a gravel bed when the rate of sand input necessary to drown the bed in sand is higher than the prevailing sand input. In gravel-bed rivers, the disparity between the two becomes increasingly large with increasing bed slope. The threshold for major sand deposition is crossed as bed slope declines. As a result, the sandy deposit caused by a dam migrates upstream only until the stream becomes sufficiently steep to prevent it from covering the bed completely.

The dam in Fig. 3-6 was installed as a debris-control measure in the wake of the Mount St. Helens eruption in 1980. Such dams play an important role in disaster mitigation. In Fig. 3-6 the dam is nearly full. Understanding the process of filling requires an understanding of the transport of sediment mixtures.

The cutoff of sediment at a dam often induces bed degradation, as the river mines itself to replace the lost load. Bed degradation rarely continues unabated. Even small amounts of coarse, erosion-resistant material in the substrate tend to concentrate on the bed surface as the bed degrades, eventually limiting the process through the formation of static armor. Figure 3-15 gives an example of the time evolution of bed armoring of the Colorado River downstream of Hoover Dam (Williams and Wolman 1984).

It would be a mistake, however, to believe that the installation of a dam universally causes bed degradation downstream. As illustrated in Fig. 2-29, bank-full flows in gravel-bed rivers often correspond to conditions that do not much exceed those needed to mobilize the gravel. When dams are operated for flood control, cutting off the flood

peaks needed to mobilize the gravel can cause a river to lose most of its capacity to move gravel. As a result, downstream of the first tributary the riverbed aggrades, as the sediment from the tributaries reaches a main stem that is no longer competent to transport it. This process has been documented in the Peace River, Canada, downstream of the W. A. C. Bennett Dam (Kellerhals and Gill 1973).

The Trinity River, California, downstream of the Lewiston Dam, provides a type example of the downstream effects of a dam (Kondolf and Wilcock 1996). This dam not only cuts off the sediment, but also maintains a constant flow that is well below bank-full flow. From the dam to the first major tributary downstream, not only is the gravel not replenished, but also the lack of the flows necessary to mobilize it has allowed the interstices of the gravel to become filled with debris that is not cleaned out by floods (Fig. 3-9). This lack of renewal not only degrades the gravel bars as a spawning habitat, but also leads to general decline in the ecological productivity of the system. The first tributary brings in a substantial quantity of corn-sized grains of weathered granite that partially fill the pores of the gravel and further degrade habitat. Loss of flood flows has also caused channel narrowing, which is associated with the encroachment of alders as well as humans, the latter being lulled by the lack of flood flows. The renewal of such a stream requires at the least controlled flood releases from the dam. How much and how long must be determined at least partially in terms of the mobility of the various sizes of sediment in the bed (Wilcock et al. 1996).

Dam removal has become quite popular in recent years, the main motivating factors being habitat improvement and stream restoration. Lack of understanding of the transport mechanics of heterogeneous sediments has often led to complete excavation of the deposit behind dams, even when the sediment is uncontaminated. The techniques necessary to evaluate the fate of both coarse and fine sediments released from a dam, and thus whether or not removal is necessary, are available, but have not usually been put into practice. Fortunately, however, a description of one version of the technology is provided as Chapter 23 of this manual. Developments in the area of river restoration can be found in Hay (1998) and Hotchkiss and Glade (2000).

Disposal of mine waste into a river can lead to massive bed aggradation. This aggradation is almost invariably associated with a pattern of downstream fining. The Ok Tedi copper/gold mine in Papua New Guinea is a case in point (Parker et al. 1996; Dietrich et al. 1999). Throughout much of the latter 1990s the mine disposed of some 40 Mtn/year of waste rock and 30 Mtn/year of tailings into a river system characterized by a steep gravel-bed reach with a fairly sharp transition to a sand-bed reach (Fig. 3-16). The extreme overloading of the system has caused massive channel and floodplain deposition, as well as major modification in the pattern of downstream fining. Input sizes range from boul-

Aggradation of bed sediment has exacerbated both flooding and the overbank deposition of fine sediment, resulting in the loss of riparian forest.

ders to silt. The coarse material contains several mineral types, some of which are highly subject to abrasion. The effect of wear on the coarser grains is illustrated in Fig. 3-13; the degree of overloading makes it highly likely that all grains in the image originated from the mine. Any numerical model designed to track the fate of the sediment, the evolution of the river profile, and the design of countermeasures must account for downstream fining, abrasion of several rock types, and overbank deposition of finer material. Cui and Parker (1999) describe such a model. Part of the model was adapted to study the effects of dam removal (Appendix A, this volume).

These examples represent a subset of the engineering problems requiring a description of the selective transport of heterogeneous sediments. Other examples include woody debris in rivers, flow augmentation by diversion, the effect of extreme floods, the fate of contaminated sediments from mines and industrial sites, avulsion on alluvial fans, and the competence of riprap placed on or in an alluvial bed to resist scour.

### 3.3 GRAIN-SIZE DISTRIBUTIONS

#### 3.3.1 Definitions and Continuous Formulation

The sedimentological phi ( $\phi$ ) scale introduced in Chapter 2 has the disadvantage that grain size decreases as the value of  $\phi$  increases. With this in mind, the alternative  $\psi$  scale is introduced (Parker and Andrews 1985); where  $D$  denotes grain size in mm,

$$\psi = \frac{\ln(D)}{\ln(2)} \quad (3-1a)$$

$$D = 2^\psi \quad (3-1b)$$

Thus  $\psi = -\phi$ . Let  $p(\psi)$  denote the probability density by weight of a sample associated with size  $\psi$ , and let  $p_f(\psi)$  denote the associated probability distribution. Then by definition,

$$\int_{-\infty}^{\infty} p(\psi) d\psi = 1 \quad (3-2a)$$

$$p_f(\psi) = \int_{-\infty}^{\psi} p(\psi) d\psi \quad (3-2b)$$

Thus  $p_f(\psi)$  denotes the fraction of the sample that is finer than size  $\psi$ . Let  $x$  denote some percentage, say 50%, and let  $\psi_x$  denote the grain size on the  $\psi$  scale such that  $x\%$  of the sample is finer. It then follows that

$$p_f(\psi_x) = \frac{x}{100} \quad (3-3)$$

The corresponding grain size in mm  $D_x$  is given from (3-1b) as

$$D_x = 2^{\psi_x} \quad (3-4)$$

A value of  $x = 50$  yields the median grain size  $D_{50}$ ; the value  $x = 90$  yields the value  $D_{90}$  such that 90% of the sample is finer, a value commonly used in the computation of the roughness associated with skin friction (grain roughness).

The arithmetic mean  $\psi_m$  and arithmetic standard deviation  $\sigma_m$  of the grain-size distribution are given as

$$\psi_m = \int \psi p(\psi) d\psi \quad (3-5a)$$

$$\sigma^2 = \int (\psi - \psi_m)^2 p(\psi) d\psi \quad (3-5b)$$

The corresponding geometric mean  $D_g$  and geometric standard deviation  $\sigma_g$  are then given as

$$D_g = 2^{\psi_m} \quad (3-6a)$$

$$\sigma_g = 2^\sigma \quad (3-6b)$$

Sediment samples with values of  $\sigma_g$  in excess of 1.6 are said to be poorly sorted (Chapter 5, this volume). Poorly sorted sediment provides grist for the mill of the river as it sorts it spatially over the planform and in the vertical.

A grain-size distribution is said to be unimodal if the density  $p(\psi)$  displays a single peak and bimodal if it displays two peaks. The grain-size densities and distributions associated with unimodal and bimodal distributions are illustrated in Figs. 3-17a and 3-17b. When Fig. 3-11 is compared with Figs. 3-17a and 3-17b, it is seen that the sediment samples from the sand-bed streams of the former diagram, those for which  $D_{50}$  is in the sand size range, are unimodal, and those from the gravel-bed streams of the former diagram, those for which  $D_{50}$  is in the gravel range, are bimodal, with peaks in the sand and gravel range and a paucity in the pea gravel range (2–8 mm). It is not accurate to say that the sediment in all sand-bed streams is unimodal and the sediment in all gravel-bed streams is bimodal, but this general tendency is observed.

The simplest realistic analytical form for the probability density and distribution of grain sizes is the lognormal form (normal distribution of the logarithm of grain size),

$$p(\psi) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{(\psi - \psi_m)^2}{2\sigma^2}\right) \quad (3-7a)$$

$$p_f(\psi) = \frac{1}{\sqrt{2\pi}\sigma} \int_{-\infty}^{\psi} \exp\left(-\frac{(\psi' - \psi_m)^2}{2\sigma^2}\right) d\psi' \quad (3-7b)$$

Equation (3-7a) describes a symmetric, unimodal probability density that often provides a reasonable fit for samples from sand-bed streams, but rarely does so in the case of gravel-bed streams. (The size densities of gravel-bed streams with a bimodal mix of sand and gravel can sometimes be approximated as weighted sums of two lognormal densities.)

In the case of a sediment sample that is lognormally distributed, it can be shown that the mean size  $\psi_m$  and the standard deviation  $\sigma$  are given by the relations

$$\psi_m = \frac{1}{2}(\psi_{84} + \psi_{16}) \quad (3-8a)$$

$$\sigma = \frac{1}{2}(\psi_{84} - \psi_{16}) \quad (3-8b)$$

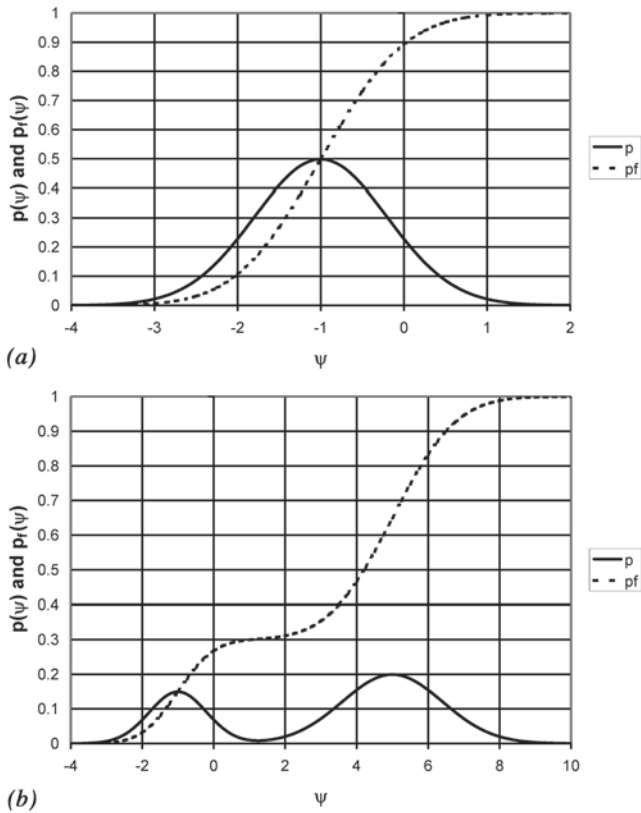

The corresponding geometric mean and geometric standard deviation are

$$D_g = \sqrt{D_{84} D_{16}} \quad (3-9a)$$

$$\sigma_g = \sqrt{\frac{D_{84}}{D_{16}}} \quad (3-9b)$$

It should be emphasized, however, that Eqs. (3-9a) and (3-9b) are not generally accurate when the distribution cannot be approximated as lognormal, in which case  $D_g$  and  $\sigma_g$  must be computed from Eqs. (3-5) and (3-6).

The necessity of using a logarithmic scale to treat the grain-size distributions of poorly sorted river sediments cannot be overemphasized. Consider a size distribution that is half sand (0.0625–2 mm) and half gravel (2–64 mm), uniformly distributed over all sizes. A plot of the distribution versus the logarithmic scale  $\psi$  (equivalent to a logarithmic scale for  $D$ ) is given in Fig. 3-17c; the corresponding plot

**Fig. 3-17.** (a) Diagram illustrating the probability density and distribution functions of a unimodal sediment sample. (b) Diagram illustrating the probability density and distribution functions of a bimodal sediment sample. (c) Plot of probability distribution function for a sand-gravel mix with constant content density as percent finer versus logarithmic grain size  $\psi$ . (d) Plot of the same probability distribution function versus  $D$  in mm on a linear scale.

using a linear scale for  $D$  is given in Fig. 3-17d. Figure 3-17c clearly reflects the fact that half of the sample is sand and half is gravel, whereas in the case of Fig. 3-17d the sand is squeezed into a tiny range on the left-hand side of the graph. The use of statistics based on  $D$  rather than any logarithmic scale for  $D$  (such as  $\psi$ ) implies the computation of an arithmetic mean grain size  $D_m$ , given as

$$D_m = \int D p(D) dD \quad (3-10)$$

rather than the geometric mean grain size  $D_g$  given from Eqs. (3-5a) and (3-6a). In the case of the distribution of Figs. 3.17c and 3.17d, the two differ substantially;  $D_g$  is equal to 2 mm, reflecting the fact that the sample is half sand and half gravel, whereas  $D_m$  is 9.25 mm, reflecting a strong bias toward the coarse material.

These comments notwithstanding, at least three bed-load transport relations for mixtures discussed in Section 3.7, proposed by Ashida and Michiue (1972), Tsujimoto (1991);

1999), and Hunziker and Jaeggi (2002), define and use  $D_m$  rather than  $D_g$ .

### 3.3.2 Discretization of the Grain-Size Distribution

Although grain-size density and distribution are continuous concepts, they must be discretized in order to handle data from rivers. Let the size range within which a sediment sample has content be divided into  $n$  intervals bounded by  $n + 1$  grain sizes  $\psi_i$ ,  $i = 1, \dots, n + 1$ . The following definitions are made: for  $i = 1, \dots, n$  ordered in increasing size,

$$\bar{\psi}_i = \frac{1}{2}(\psi_i + \psi_{i+1}) \quad (3-11a)$$

$$p_i = p_f(\psi_{i+1}) - p_f(\psi_i) \quad (3-11b)$$

$$\Delta\psi_i = \psi_{i+1} - \psi_i \quad (3-11c)$$

Note that by definition

$$\sum_{i=1}^n p_i = 1 \quad (3-12a)$$

The discretized versions of Eqs. (3-5a), (3-5b), and (3-10) are then

$$\psi_m = \sum_{i=1}^n \bar{\psi}_i p_i \quad (3-12b)$$

$$\sigma^2 = \sum_{i=1}^n (\bar{\psi}_i - \psi_m)^2 p_i \quad (3-12c)$$

$$D_m = \sum_{i=1}^n D_i p_i \quad (3-12d)$$

The following notations are used to characterize sediment size distributions. Gravel-bed rivers often show some degree of armoring (coarsening) of the sediment at the surface of the bed compared to the substrate below, so it is useful to distinguish between the two. The fractions in the surface layer of the bed are denoted as  $F_i$ ; the median size, geometric mean size, arithmetic standard deviation, geometric standard deviation, and arithmetic mean size of the surface sediment are denoted as  $D_{50}$ ,  $D_g$ ,  $\sigma$ ,  $\sigma_g$ , and  $D_m$ , respectively. The fractions within the substrate at elevation  $z$  are denoted as  $f_i(z)$ . The fractions averaged over a relatively thick layer of substrate just below the surface layer are denoted as  $\bar{f}_i$ ; the corresponding median size, geometric mean size, arithmetic standard deviation, geometric standard deviation, and arithmetic mean size of the substrate sediment are denoted as  $D_{u50}$ ,  $D_{ug}$ ,  $\sigma_u$ ,  $\sigma_{ug}$ , and  $D_{um}$ , respectively. The fractions in the bed-load transport are denoted as  $f_{bi}$ .

### 3.3.3 Sampling of Bed Sediments

The subject of the sampling of riverbed sediments is treated in depth in Chapter 5 of this volume, as well as by Bunte and Abt (2001), and so only a short summary is given here. There are

two basic types of sediment samples in the field. The first of these is the bulk sample, in which a large amount of sediment is removed in bulk from the bed. Church et al. (1987) provide rigorous criteria for accurate sampling. They indicate that each bulk sample should be sufficiently large so that the largest stone in the sample is not more than 1% of the total sample weight. They also provide guidelines for the areal distribution of bulk samples. A careful areal distribution of samples is often necessary because wherever the sediment is poorly sorted, the distribution itself is likely to vary from place to place.

The second kind of sample is the Wolman point count sample. Such a sample can be obtained by defining a grid on the bed and sampling the particles at each node of the grid (Wolman 1954). Alternatively, the bed can be paced according to a conceptual grid, and 100 or more grains exposed on the surface may be sampled randomly near, e.g., the toe of one's shoe (preferably with one's eyes shut). Such a sample is biased toward the coarse grains in two ways. First, the method is usually appropriate only for gravel-sized grains; it is very difficult to pick up single sand grains. Second, even the grains that are sampled are systematically biased toward coarser sizes if analyzed in terms of percent finer by weight, as demonstrated in Kellerhals and Bray (1971).

Kellerhals and Bray (1971) have suggested a simple equivalency by which a Wolman sample analyzed in terms of percent finer by number of grains is a good approximation to a bulk sample of the same parent material analyzed by weight. This approximate conversion has generally stood the test of time with only minor modifications; see Chapter 5 of this volume, Diplas and Sutherland (1988), and Fripp and Diplas (1993) for more details. The equivalency only holds, however, when the bulk sample has been truncated to exclude sizes that are too small to sample by means of the Wolman technique.

Useful variations on these two techniques have been proposed. In the freeze-core technique, a hollow rod is pounded into the bed and liquid carbon dioxide is introduced into the rod. The evaporation of the carbon dioxide causes the sediment adjacent to the rod to freeze to it. The sample is obtained by hoisting the rod out. Freeze-core sampling has the advantage of obtaining a sample with minimal disturbance. It is, however, biased toward the coarser sizes around the edge of the sample. Rood and Church (1994) describe a modified freeze-core technique based on a frozen barrel that helps overcome this disadvantage.

A second technique may be called the Klingeman surface sample (Klingeman et al. 1979). In this case a circle is placed over the bed surface. The circle should have a radius that is at least 10 times that of the largest stone exposed on the surface. This stone is then removed, and all the sediment is removed to the deepest level exposed by the stone. This method has the advantage of sampling not only the coarse grains on the bed surface, but also the finer grains, including sand, that would be exposed by the removal of the coarse grains. In addition, Klingeman samples can be obtained in deep gravel-bed rivers by using a cylindrical "cookie cutter" with a serrated bottom that can

be worked into the bed by divers. The stilling of the flow in the cylinder helps prevent the loss of the finer part of the sample as divers collect it.

In general the Wolman surface sample best serves to characterize the grain roughness offered by the bed surface, whereas the Klingeman surface sample best characterizes the material immediately available for transport under flow conditions sufficient to mobilize the larger surface grains. As a result, Klingeman samples are often used to characterize the grain-size distribution of the active layer, i.e., the bed layer that exchanges directly with the bed load, in gravel-bed streams.

### 3.4 DIMENSIONLESS BANK-FULL RELATIONS FOR GRAVEL-BED AND SAND-BED STREAMS

Alluvial rivers can be broadly divided into two types: sand-bed streams, for which surface median size  $D_{50}$  falls in the range 0.0625–2 mm, and gravel-bed streams, for which  $2 < D_{50} < 256$  mm. Here cobbles and gravel are grouped together for simplicity. The dividing line between the two is not arbitrary; streams with a characteristic size between 2 and 16 mm (pea gravel) are relatively rare. This is illustrated here using two sets of data. One set pertains to 78 river reaches in Alberta, Canada described in Kellerhals et al. (1972). The other set is a combination of two sets pertaining to a total of 115 reaches in the Japanese archipelago (Yamamoto 1994; Fujita et al. 1998; K. Fujita kindly provided the full data set). In Fig. 3-18 the number of river reaches in each set with a characteristic grain size falling within each specified grain size range is plotted. The two sets are not completely comparable; whereas (surface)  $D_{50}$  is used in the Alberta data, the Japanese data are based on size  $D_{\text{bulk60}}$ , where the subscript “bulk” denotes bulk. The difference between the two is likely to be appreciable only for gravel-bed streams, for which surface median size  $D_{50}$  can

**Fig. 3-18.** Plot of number of reaches for which characteristic grain size is within the specified grain size range for streams in Alberta, Canada and Japan.

be more than twice the substrate median size  $D_{u50}$ , and thus substantially larger than  $D_{\text{bulk60}}$ .

In the case of the Alberta streams the division between sand-bed and gravel-bed streams is complete; there are no streams in the set with values of  $D_{50}$  between 1 and 16 mm. In the case of the Japanese streams every size range is represented, but there is a clear paucity of streams with  $D_{\text{bulk60}}$  between 2 and 16 mm, with the smallest number of reaches in the range from 4 to 8 mm.

Modeling of the transport of sediment mixtures in rivers requires some feel for how the rivers behave. Alluvial rivers tend to construct their channel geometries and floodplains in consistent ways. This geometry can be characterized in terms of bank-full characteristics, where bank-full conditions are attained when the river is just beginning to spill out of its channel and onto its floodplain. Bank-full conditions can be most easily defined in terms of a rating curve of stage  $\xi$  (water surface elevation) versus flow discharge  $Q$ . When the flow is confined within the channel, stage increases relatively rapidly with discharge. As stage increases, the water spills out onto the floodplain, so that even substantial increases in discharge beyond bank-full discharge  $Q_{bf}$  yield much smaller increases in stage. A plot of  $\xi$  versus  $Q$  allows the determination of  $Q_{bf}$  as shown in Fig. 3-19.

At any given point along the river an average down-channel bed slope  $S$  can be defined. Once bank-full discharge  $Q_{bf}$  is identified the bank-full channel width  $B_{bf}$  and average depth  $H_{bf}$  can be determined from cross-sectional shape. Bank-full flow velocity  $U_{bf}$  is given from continuity as

$$U_{bf} = \frac{Q_{bf}}{B_{bf} H_{bf}} \quad (3-13)$$

**Fig. 3-19.** Diagram illustrating the definition of bank-full discharge in terms of the stage-discharge ( $\xi$ - $Q$ ) relation.

A characteristic bank-full boundary shear stress  $\tau_{bbf}$  and shear velocity  $u_{*bf}$  can be estimated from the depth-slope product rule for normal (steady, uniform) flow in open channels:

$$\tau_{bbf} = \rho g H_{bf} S \quad (3-14a)$$

$$u_{*bf} = \sqrt{\frac{\tau_{bbf}}{\rho}} = \sqrt{g H_{bf} S} \quad (3-14b)$$

where

$\rho$  = density of water.

It is useful to define two dimensionless friction coefficients,  $C_{fbf}$  and  $Cz_{bf}$ , as

$$C_{fbf} = \frac{\tau_{bbf}}{\rho U_{bf}^2} = \frac{g H_{bf} S}{U_{bf}^2} \quad (3-15a)$$

$$Cz_{bf} = \frac{U_{bf}}{u_{*bf}} = C_{fbf}^{-1/2} \quad (3-15b)$$

The friction coefficient  $C_{fbf}$  is of the standard form used in the study of fluid mechanics and is precisely equal to the corresponding D'arcy-Weisbach friction coefficient divided by 8. The parameter  $Cz_{bf}$  may be called a dimensionless Chezy resistance coefficient, because between Eqs. (3-14b) and (3-15b) it is found that

$$U_{bf} = Cz_{bf} \sqrt{g H_{bf} S} \quad (3-16)$$

which is a form of the Chezy relation for flow velocity.

The friction coefficients  $C_{fbf}$  and  $Cz_{bf}$  are examples of dimensionless numbers. In the study of natural phenomena a dimensional number such as bank-full depth may vary greatly from site to site, whereas an appropriately defined dimensionless counterpart can allow the extraction of more universal characteristics. Alluvial rivers are no exception in this regard.

In order to implement a dimensionless characterization of the bank-full characteristics of alluvial streams, the following dimensionless parameters are defined:

$$\hat{Q} = \frac{Q_{bf}}{\sqrt{g D_{50}} D_{50}^2} \quad (3-17a)$$

$$\hat{B} = \frac{B_{bf}}{D_{50}} \quad (3-17b)$$

$$\hat{H} = \frac{H_{bf}}{D_{50}} \quad (3-17c)$$

$$Fr_{bf} = \frac{U_{bf}}{\sqrt{g H_{bf}}} \quad (3-17d)$$

$$\tau_{bf50}^* = \frac{\tau_{bbf}}{\rho R g D_{50}} \quad (3-17e)$$

$$R_{p50} = \frac{\sqrt{R g D_{50}} D_{50}}{v} \quad (3-17f)$$

$$R = \frac{\rho_s}{\rho} - 1 \quad (3-17g)$$

where

$\rho_s$  = density of the sediment.

That is,

$\hat{Q}$  = dimensionless bank-full discharge;

$\hat{B}$  = dimensionless bank-full width;

$\hat{H}$  = dimensionless bank-full depth;

$Fr_{bf}$  = dimensionless bank-full Froude number;

$\tau_{bf50}^*$  = bank-full Shields number; and

$R_{p50}$  = a version of the particle Reynolds number introduced in Chapter 2, but here based on the surface median size  $D_{50}$ .

Note that between Eqs. (3-14a), (3-16), (3-17d), and (3-17e) it is found that

$$C_{fbf} = Fr_{bf}^{-2} S \quad (3-18a)$$

$$Cz_{bf} = \frac{Fr_{bf}}{\sqrt{S}} \quad (3-18b)$$

$$\tau_{bf50}^* = \frac{H_{bf} S}{R D_{50}} \quad (3-18c)$$

Two simple limiting cases are considered in order to characterize alluvial rivers in a simple but clear way. One case consists of alluvial sand-bed streams ( $0.0625 \text{ mm} < D_{50} < 2 \text{ mm}$ ) that are further restricted to have values of  $D_{50}$  not larger than 0.5 mm. Such streams are usually suspension-dominated in terms of how the riverbed interacts with the sediment it carries. Another limiting case consists of alluvial gravel-bed streams with  $D_{50} > 25 \text{ mm}$ . (Here cobble-bed streams are included in the classification of gravel-bed streams for simplicity.) Such streams are almost invariably bed-load-dominated in terms of the interaction between riverbed and sediment load. Most sand-bed streams transport much more mud (silt and clay) than sand, and many gravel-bed streams transport much more sand than gravel, but in both cases the finer fraction often interacts only weakly with the bed.

The restriction to these two limiting cases in terms of grain size does not mean that streams with values of  $D_{50}$  between 0.5 and 25 mm do not exist; their existence is demonstrated in Fig. 3-18. Rather, the difference between the two limiting cases helps characterize the difference between bed-load-dominated and suspension-dominated rivers.

The database for the relations presented here pertains to (1) three sets of gravel-bed streams, one from Alberta, Canada, one from Wales, U.K., and one from Idaho, and (2) a set of both single-channel and multiple-channel sand-bed

**Fig. 3-20.** Dimensionless bank-full depth  $\hat{H}$  versus dimensionless bank-full discharge  $\hat{Q}$ .

streams from various locations. The three sets for gravel-bed streams are given in Parker et al. (2003). The sand-bed set was extracted from the much larger database of Church and Rood (1983).

Figure 3-20 shows  $\hat{H}$  versus  $\hat{Q}$ . The gravel-bed and sand-bed streams each form coherent and very similar trends for depth. The following regressions are obtained:

$$\hat{H} = \begin{cases} 0.368 \hat{Q}^{0.405}, & \text{gravel-bed} \\ 3.01 \hat{Q}^{0.321}, & \text{sand-bed} \end{cases} \quad (3-19)$$

In Fig. 3-21  $\hat{B}$  is plotted versus  $\hat{Q}$ . Again each data set defines a coherent trend, but there is somewhat greater discrimination between the sand-bed and gravel-bed cases for width. The regressions are

$$\hat{B} = \begin{cases} 4.87 \hat{Q}^{0.461}, & \text{gravel-bed} \\ 0.274 \hat{Q}^{0.565}, & \text{sand-bed} \end{cases} \quad (3-20)$$

**Fig. 3-21.** Dimensionless bank-full width  $\hat{B}$  versus dimensionless bank-full discharge  $\hat{Q}$ .

**Fig. 3-22.** Channel bed slope  $S$  versus dimensionless bank-full discharge  $\hat{Q}$ .

In Fig. 3-22  $S$  is plotted against  $\hat{Q}$ . Here the scatter is much larger and the discrimination between sand-bed and gravel-bed streams stronger. There is a reason for the scatter in slope. Rivers can construct their own cross-sectional geometry in relatively short geomorphic time. Changing the slope of the long profile of a river requires much more time, however. The characteristic time scale is so large that it can be on the order of the tectonism (uplift or subsidence) that ultimately drives landscape evolution. As a result, there is a general trend for  $S$  to decrease with  $\hat{Q}$ , but not a precise one. The regression relations are

$$S = \begin{cases} 0.0976 \hat{Q}^{-0.341}, & \text{gravel-bed} \\ 6.42 \hat{Q}^{-0.397}, & \text{sand-bed} \end{cases} \quad (3-21)$$

Figure 3-23 shows bank-full Shields stress  $\tau_{bf50}^*$  versus  $\hat{Q}$ . Again, there is strong discrimination between sand-bed and gravel-bed streams, but little variation with  $\hat{Q}$ . The trends can be reasonably approximated in terms of average values of  $\tau_{bf50}^*$ :

$$\tau_{bf50}^* \approx \begin{cases} 0.049, & \text{gravel-bed} \\ 1.86, & \text{sand-bed} \end{cases} \quad (3-22)$$

**Fig. 3-23.** Dimensionless Shields stress  $\tau_{bf50}^*$  based on bank-full flow and  $D_{50}$  versus dimensionless bank-full discharge  $\hat{Q}$ .

Figure 3-23 shows a considerable amount of scatter. There are at least two reasons for this. The fine component of the load (mud in the case of sand-bed streams and sand in the case of gravel-bed streams) either may not be present in the bed (sand-bed streams) or may interact only passively with the bed (sand simply filling the pores of gravel-bed streams). This finer material is available, however, to build up the floodplain. As a result, bank-full depth  $H_{bf}$  in particular can vary in ways that are not captured by the use of a single bed-surface median size  $D_{50}$ . In addition, some gravel-bed streams contain relict gravel on their beds that was emplaced during a regime of higher flows. In such streams finer gravel may move over the bed without completely covering the relict material. As a result the median size  $D_{50}$  may be too large to reflect the present mobility of the stream. These caveats notwithstanding, the estimates of Eq. (3-22) are useful for characterizing the two limiting cases. A bank-full Shields stress on the order of 1.86, the average value for the sand-bed streams in Fig. 3-23, describes a suspension-dominated river, whereas a bank-full Shields stress on the order of 0.049, the average value for the gravel-bed streams in Fig. 3-23, describes a bed-load-dominated system, as illustrated in Figs. 2-28 and 2-29.

Figure 3-24 shows a plot of  $\tau_{bf50}^*$  versus  $S$ . Again the sand-bed and gravel-bed streams plot in different regimes, but in each case  $\tau_{bf50}^*$  shows some tendency to increase with increasing slope  $S$ .

Figure 3-25 shows the dimensionless Chezy number  $Cz_{bf}$  versus  $S$ . Except for one outlier the values of  $Cz_{bf}$  range between 4 and 26, and  $Cz_{bf}$  decreases noticeably with increasing  $S$ . There is little discrimination between sand-bed streams and gravel-bed streams in terms of the trend, but values for sand-bed streams, which range from 9 to 26 excluding one outlier, are generally somewhat higher than those for gravel-bed streams, which range from 4 to 19 excluding one outlier. Thus sand-bed streams tend to have somewhat lower

**Fig. 3-24.** Dimensionless Shields stress  $\tau_{bf50}^*$  based on bank-full flow and  $D_{50}$  versus channel bed slope  $S$ .

**Fig. 3-25.** Dimensionless Chezy friction coefficient  $Cz_{bf}$  versus channel bed slope  $S$ .

**Fig. 3-26.** Dimensionless Chezy friction coefficient  $Cz_{bf}$  versus dimensionless depth  $\hat{H}$ .

bank-full friction coefficients  $C_{bf}$  than gravel-bed streams (0.0015–0.012 versus 0.003–0.06). Figure 3-26 shows  $Cz_{bf}$  plotted against  $\hat{H}$ . The scatter is large, and the two types plot in very different regions. The fact that the values of  $Cz_{bf}$  are not greatly different between the two cases, even with vastly different values of  $\hat{H}$ , indicates that grain roughness, which is often dominant for gravel-bed streams, may be relatively unimportant in most sand-bed streams, with bed forms taking over its role.

Figure 3-27 shows a plot of  $Fr_{bf}$  versus  $S$ . With the exception of one point, all the bank-full flows are in the Froude-subcritical regime. This does not mean that supercritical flow does not occur in rivers. However, it tends to be restricted to floods in very steep rivers with step-pool topography, a class of stream that is not represented in Figure 3-27. Within the scatter of the data, the two stream types define a common trend, but with sand-bed streams usually having lower bank-full Froude numbers. More specifically, sand-bed streams have values of  $Fr_{bf}$  ranging from 0.14 to 0.58 and gravel-bed

**Fig. 3-27.** Froude number at bank-full flow,  $Fr_{bf}$ , versus channel bed slope  $S$ .

streams have values ranging from 0.24 to 0.93 (excluding one supercritical outlier).

Figure 3-28 shows the bank-full width:depth ratio (aspect ratio)  $B_b/H_{bf}$  versus bed slope  $S$ . In general the aspect ratio tends to be between 10 and 100, with the sand-bed streams tending toward somewhat larger values than the gravel-bed streams.

Figure 3-29 shows the bank-full Shields number  $\tau_{bf50}^*$  against particle Reynolds number  $Re_{p50}$ , which is a surrogate for grain size  $D_{50}$ . Slightly different versions of the diagram were presented as Figs. 2-28 and 2-29, where the basis for the various regimes was explained. The only essential difference between the two figures is that Brownlie's (1981) relation for the onset of motion is used in Fig. 2-26, whereas a modified version, in which the predicted critical Shields number is halved, is used in Fig. 3-29 (and also Fig. 3-30). (This modified relation is presented and explained below in Section 3.7.1.) The strong tendency for the size  $D_{50}$  to move

**Fig. 3-28.** Bank-full width-depth ratio  $B/H$  versus channel bed slope  $S$ .

**Fig. 3-29.** Dimensionless Shields stress based on bank-full flow  $\tau_{bf50}^*$  versus particle Reynolds  $Re_{p50}$  number based on  $D_{50}$ . Also included is a point from Sagehen Creek, Calif.

as bed load in gravel-bed streams and as suspended load in sand-bed streams is clear. In addition, at bank-full stage the Shields numbers of sand-bed rivers are typically about 50 times the critical Shields stress at the threshold of motion, whereas the corresponding value for the gravel-bed streams is only about 1.6. These differences provide the basis for the exposition of grain-size-specific sediment transport relations for heterogeneous sediment that follows. Also included in Fig. 3-29 is a single point for Sagehen Creek, California (Andrews and Erman 1986). Sagehen Creek is explained in more detail in Section 3.11.3.

Figure 3-30 addresses the issue of streams with values of  $D_{50}$  between 0.5 and 25 mm. The added data are from the two sets of Japanese streams described above in regard to Figure 3-18. As noted above,  $D_{bulk60}$  rather than surface median size  $D_{50}$  was used to characterize the bed material of the Japanese streams. In addition, self-formed bank-full discharge is not as clearly defined in the heavily engineered

**Fig. 3-30.** Extended version of Fig. 3-29 including data from Japanese streams and the empirical regime relation of Yamamoto (1994).

Japanese streams as in streams in other parts of the world, and as a result mean annual peak flood flow was used as the basis for the computation of Shields stress in the diagram. This notwithstanding, the plot shows a concentration of sand-bed and gravel-bed streams within and adjacent to the two limiting cases described here, along with a lesser but still substantial number of transitional streams. The solid line in the figure is due to Yamamoto (1994). It should be remembered that such transitional streams are not unique to Japan; see Kleinhans (2002) for a description of such streams in Europe.

A final discriminator between sand-bed and gravel-bed streams is embodied in Fig. 2-14. It is seen in that figure that gravel-bed rivers tend to have grain-size distributions that are substantially wider than those for sand-bed streams. This fact, combined with the fact that in Fig. 3-29 the gravel-bed streams tend to cluster close to the threshold condition under bank-full conditions, whereas the sand-bed streams plot well above it, renders grain sorting of heterogeneous sediment rather more intense in gravel-bed streams than in sand-bed streams. The difference is, of course, relative; sand-bed rivers also sort their sediment.

### 3.5 THE ACTIVE LAYER CONCEPT

#### 3.5.1 The Role of Fluctuations in Bed Elevation during Sediment Transport

Transport of bed-material load in a river is always accompanied by fluctuations in bed elevation. Fluctuations occur on a variety of scales, including the scour and fill of river bends, pool riffles, and bank-attached bars through a flood hydrograph, as well as the migration of free bars, dunes, and ripples and their interaction. On the finest scale, even in the absence of clearly defined bed forms, bed elevation fluctuations are observed on the scale of the surface size  $D_{90}$  of the bed material. That is, coarse clusters form and break up, the removal of a coarse grain creates a hole in which finer grains are captured, coarse grains are buried by local scour of the finer grains around them, etc. Fluctuations in bed elevation are typically linked to fluctuations in the rate of sediment transport. In the case of dunes in a bed-load-dominated regime, for example, the probability density of bed load fluctuations can often be accurately estimated from the probability density of bed elevation through consideration of bed form migration (Hamamori 1962; Hubbell 1987; Ribberink 1987; Kuhnle and Southard 1988; Gomez et al. 1989).

These bed fluctuations are an interesting feature of the transport of uniform or well-sorted sediments, but are essential to understanding the transport of sediment mixtures. If the possibility of leaching of fine grains through bed sediment by groundwater flow is neglected for the sake of argument, in order for a grain in the bed to be entrained into motion it must be exposed at least momentarily at the bed surface. The

**Fig. 3-31.** Definition diagram showing (a) the spatial variation of bed elevation at a given time or temporal variation of bed elevation at a given location; (b) the probability density of bed elevation; (c) the probability of entrainment per unit time of a grain as a function of elevation in the bed; and (d) the approximation to (c) embodied in the active layer approximation.

higher the elevation of the grain, the higher is the probability per unit time that it is entrained. Deeply buried grains have minimal probability of entrainment because the probability that the bed will locally be at that elevation must decline with depth. Figure 3-31 schematizes the instantaneous bed profile (curve a), the associated probability density of bed elevation (curve b), and the probability per unit time of entrainment of a grain as a function of elevation (curve c).

The simplest reasonable approximation of curve c is as a step function, according to which the probability of erosion of a grain per unit time is a constant value in an “exchange,” “active,” or “surface” layer of thickness  $L_a$  near the bed surface and is vanishing below this layer. That is, all the bed fluctuations are assumed to be concentrated in a well-mixed layer of finite thickness  $L_a$ . This approximation, which is shown as curve d in Fig. 3-31, is the essence of the active-layer formulation of the Exner equation for the conservation of bed sediment mass for mixtures. It was first introduced in a landmark paper by Hirano (1971) and is outlined in Section 3.5.2. The extension to continuous variation in the vertical direction is briefly introduced in Section 3.15.2.

#### 3.5.2 The Formulation of Hirano

Consider the bed of Fig. 3-32. Let the fractions  $p_i$  in the size distribution (as defined in section 2.3.5) in the active or surface layer be denoted as  $F_i$ ; here it is assumed that the fractions have been averaged over fluctuations. Note that  $F_i$  might be functions of time  $t$ , streamwise coordinate  $s$ , and transverse coordinate  $n$ , but may not be functions of the upward normal coordinate  $z$ , because the surface layer is assumed to be perfectly mixed by the fluctuations. The size fractions in the substrate are denoted as  $f_i$ , where in general  $f_i$  can be functions of  $s$ ,  $n$ , and  $z$ , thus defining the stratigraphy of the deposit, but cannot be functions of  $t$  because they are assumed to be below the level of bed fluctuations.

Now consider one-dimensional transport of bed load in the  $s$  direction. Let  $q_i$  denote the volume rate of bed-load transport of sediment in the  $i$ th grain size range per unit width

Fig. 3-32. Definition diagram for the active layer concept.

normal to the flow. In the case of 1D bed-load transport of sediment mixtures, Eq. (2.88b) without sediment suspension generalizes to

$$(1 - \lambda_p) \left[ f_{li} \frac{\partial \eta_b}{\partial t} + \frac{\partial}{\partial t} (L_a F_i) \right] = - \frac{\partial q_i}{\partial s} \quad (3-23)$$

In this relation  $f_{li}$  denotes the size fractions of the material exchanged between the surface layer and the substrate as the bed aggrades or degrades. In addition,  $\eta_b$  denotes the elevation of the bottom of the surface layer, so that bed elevation  $\eta$  is given as

$$\eta = \eta_b + L_a \quad (3-24)$$

Note that  $\eta$  and  $\eta_b$  correspond to averages over bed elevation fluctuations. Equation (3-23) may be summed over all grain sizes, yielding in conjunction with Eq. (3-24) the following relation:

$$(1 - \lambda_p) \frac{\partial \eta}{\partial t} = - \frac{\partial q_T}{\partial s} \quad (3-25)$$

where

$$q_T = \sum_{i=1}^n q_i \quad (3-26)$$

These four equations yield the following relation for the time evolution of the active layer:

$$(1 - \lambda_p) \left[ \frac{\partial}{\partial t} (L_a F_i) - f_{li} \frac{\partial L_a}{\partial t} \right] = - \left( \frac{\partial q_i}{\partial s} - f_{li} \frac{\partial q_T}{\partial s} \right) \quad (3-27)$$

Denoting the fractions in the bed load as  $f_{bi}$ , it is seen from Eq. (3-26) that

$$f_{bi} = \frac{q_i}{\sum_{i=1}^n q_i} \quad (3-28)$$

A full derivation of Eq. (3-23) and the associated forms (3-25) and (3-27) can be found in Parker and Sutherland (1990) and Parker et al. (2000). Once appropriate forms for  $q_i$ ,  $L_a$ , and  $f_{li}$  are specified, Eq. (3-25) can be used to compute the time change in bed elevation due to net deposition or erosion, and Eq. (3-27) can be used to compute the time change in the composition in the surface layer of the bed.

### 3.5.3 Active Layer Thickness and Interfacial Exchange Fractions

There is a degree of arbitrariness in the specification of the active surface-layer thickness  $L_a$ . In the absence of bed forms,  $L_a$  can be thought to scale with a characteristic large size of the surface such as  $D_{90}$  or  $D_\sigma$ , where  $D_\sigma$  is defined as

$$D_\sigma = D_g \sigma_g \quad (3-29)$$

Note that  $D_\sigma$  corresponds to  $D_{84}$  for a lognormal distribution. Thus,

$$L_a = n_a D_{90} \quad (3-30)$$

where

$n_a$  = an order-one parameter that requires calibration in the absence of a probability distribution of bed fluctuations.

The Klingeman sampling method discussed previously implicitly assumes that  $n_a$  is unity. When bed forms such as dunes and bars are present, and when the time scales of interest are large enough for the bed above the troughs to be thoroughly mixed by these bed forms,  $L_a$  must scale with bed form height. In the case of meander bends,  $L_a$  must scale with some measure of the amplitude of scour and fill, and the time scales must be restricted to those larger than one corresponding to the passage of enough floods to completely rework the sediment within this amplitude. A compendium of expressions for  $L_a$  used by various researchers in numerical models of bed elevation variation and sorting due to the transport of mixtures can be found in Kelsey (1996).

The interfacial exchange fractions  $f_{li}$  describe the mean size distribution of the sediment that is exchanged between the surface layer and the substrate as the bed aggrades or degrades. When the bed degrades, substrate is transferred to the active layer, so that

$$f_{li} = f_i(z) \Big|_{z=\eta_b} \quad \text{for} \quad \frac{\partial \eta_b}{\partial t} < 0 \quad (3-31)$$

In the original formulation of Hirano (1971), surface material was transferred to the substrate during bed aggradation. Subsequent research has suggested that the material transferred is a weighted mixture of bed load and surface material, so that

$$f_{fi} = aF_i + (1-a)f_{bi} \quad \text{for} \quad \frac{\partial \eta_b}{\partial t} > 0 \quad (3-32)$$

This form was first suggested by Hoey and Ferguson (1994); Toro-Escobar et al. (1996) used a set of large-scale experiments on downstream fining of gravel-sand mixtures to evaluate  $a$  for at least one case.

### 3.5.4 Further Generalizations and Alternate Formulations

Equation (3-23) is easily generalized to include (1) channel width variation in a 1D formulation, (2) transverse as well as streamwise variation in a 2D formulation, (3) suspended sediment, as well as bed-load sediment, and (4) abrasion. All these cases are discussed later in this chapter. Abrasion may be included in a variety of ways. Here it is assumed that the product of abrasion is silt or fine sand that then moves as throughput load. As a result, abrasion is assumed to represent a net loss of bed material. Where  $A_i$  denotes the net loss per unit time per unit bed area of clast volume in the  $i$ th grain size range due to abrasion, Eq. (3-23) generalizes to

$$(1 - \lambda_p) \left[ f_{fi} \frac{\partial \eta_b}{\partial t} + \frac{\partial}{\partial t} (L_a F_i) \right] = -\frac{\partial q_i}{\partial s} - A_i \quad (3-33)$$

The issue of abrasion will be treated in more detail in Section 3.9.

Use of Eq. (3-23) or some close variant thereof has increasingly become standard in implementation of the active-layer formulation. Some researchers, however, have used ad hoc formulations that are similar in nature but cannot be expressed in the compact analytical formulation given above. Examples of these ad hoc formulations can be found in Borah et al. (1982); Park and Jain (1987); Copeland and Thomas (1992); and Belleudy and SOGREAH (2000). In many such treatments the active layer is implemented only to the extent necessary to describe the evolution of a static armor as the sediment supply is cut off.

As will be shown in Section 3.11, Eq. (3-27) can be used to describe the evolution of bed armoring. When the supply of sediment to a river with a mix of sediment sizes is cut off, the bed coarsens to eventually form a static armor, i.e., a surface layer containing material so coarse that it can no longer be removed and the bed can no longer degrade. The same formulation can also be used to describe mobile armor, in which case a coarse surface layer is maintained even when all sizes are mobile. It will be demonstrated that there is a smooth progression from the unarmored state to mobile armor and then to static armor as river stage decreases.

As can be seen by comparing cases c and d in Fig. 3-31, the active-layer formulation is the simplest formulation capable of describing the change in bed composition due to the selective transport of sediment mixtures. Recently progress has been made by Parker et al. (2000) in moving from the

simplified case d to the real case c. This work is described briefly in Section 3.15.

### 3.5.5 Entrainment Formulation

Before the close of this section, an alternative active-layer formulation of the Exner equation for sediment conservation of mixtures deserves mention. Bed-load particles typically roll, slide, or saltate intermittently without being substantially supported by turbulence. Einstein (1950) introduced the concepts of a pickup rate and a step length for bed-load particles. Tsujimoto and Motohashi (1990) and Tsujimoto (1991; 1999) have pursued these concepts. Here the pickup rate is described in terms of a bed-load volume entrainment rate per unit time per unit bed area for the  $i$ th grain size range  $E_{bi}$ . The probability density for a grain in size range  $i$  moving a distance  $s$  in one step is denoted as  $P_{si}(s)$ . The mean step length  $L_{si}$  for the  $i$ th grain size range is thus given as

$$L_{si} = \int_0^\infty s P_{si}(s) ds \quad (3-34)$$

The volume rate of deposition of particles in the  $i$ th size range from the bed load per unit time per unit bed area is given as  $D_{bi}$ , where

$$D_{bi} = \int_0^\infty E_{bi}(s-s') P_{si}(s') ds' \quad (3-35)$$

The entrainment form of Eq. (3-23) is thus

$$\begin{aligned} (1 - \lambda_p) \left[ f_{fi} \frac{\partial \eta_b}{\partial t} + \frac{\partial}{\partial t} (L_a F_i) \right] \\ = D_{bi} - E_{bi} = \int_0^\infty E_{bi}(s-s') P_{si}(s') ds' - E_{bi} \end{aligned} \quad (3-36)$$

The bed-load transport rate  $q_i$  can be computed as

$$q_i = \int_0^\infty E_{bi}(s-s') \int_{s'}^\infty P_{si}(s'') ds'' ds' \quad (3-37)$$

With a little algebra it can be demonstrated from Eqs. (3-35) and (3-37) that

$$D_{bi} - E_{bi} = -\frac{\partial q_i}{\partial x} \quad (3-38)$$

establishing the equivalency between Eqs. (3-23) and (3-36).

This equivalency applies, however, only to the treatment of sediment conservation. In the transport formulation of Eq. (3-23) it is necessary to specify  $q_i$  as a function of the flow and surface-layer characteristics; in the entrainment formulation of Eq. (3-36) it is necessary to specify  $E_{bi}$  and  $P_{si}$  as functions of the flow and surface-layer characteristics. On small time and length scales the predictions of the two methods may be different. On scales that are large compared to the step length and associated step time, the predictions will

be nearly the same if the bed load and entrainment formulations are related by Eq. (3-37).

This model can be simplified by assuming the step length  $L_{si}$  to be specified deterministically rather than in terms of a probability function. The versions of Eqs. (3-35), (3-36), and (3-37) simplified in this manner are, respectively,

$$D_{bi} = E_{bi}(s - L_{si}) \quad (3-39)$$

$$(1 - \lambda_p) \left[ f_{ti} \frac{\partial \eta_b}{\partial t} + \frac{\partial}{\partial t} (L_a F_i) \right] = D_{bi} - E_{bi} \quad (3-40)$$

$$q_i = \int_0^{L_{si}} E_{bi}(s - s') ds' \quad (3-41)$$

### 3.6 GENERAL FORMULATION FOR BED-LOAD TRANSPORT OF MIXTURES

#### 3.6.1 Surface-Based Formulation

If material within a given size range is not present in the bed surface then it cannot be entrained into the bed load. To account for this it is appropriate to define a volume bed-load transport rate  $q_{Ui}$  per unit time, per unit width, and per unit fraction content in the surface layer and a corresponding bed-load entrainment rate  $E_{Ubi}$  such that

$$q_{Ui} = \frac{q_i}{F_i} \quad (3-42a)$$

$$E_{Ubi} = \frac{E_{bi}}{F_i} \quad (3-42b)$$

Thus, for example, even if a given model predicts that  $q_{Ui} > 0$ , implying that the flow is competent to move material in the  $i$ th grain size range, if  $F_i = 0$  then that size range is unavailable for participation in bed-load transport. The model thus must predict a value of  $q_i$  of zero. Such a treatment defines a surface-based formulation for bed-load transport. A substrate-based formulation will also be defined subsequently.

#### 3.6.2 Dimensional Analysis for Bed-Load Transport of Mixtures

In general the unit bed-load transport rate  $q_{Ui}$  can be expected to be a function of not more than two hydraulic parameters, here denoted as  $X_1$  and  $X_2$ , and also of water density  $\rho$ , sediment material density  $\rho_s$ , water viscosity  $\nu$ , gravitational acceleration  $g$ , grain sizes  $D_i$ , and other parameters based on the first, second, third, ... moments of the surface grain-size distribution, here denoted as  $m_1, m_2, m_3, \dots$  (Parker and Anderson, 1977). Thus

$$q_{Ui} = \frac{q_i}{F_i} = fn(X_1, X_2, \rho_s, \rho, \nu, g, D_i, m_1, m_2, m_3, \dots) \quad (3-43)$$

Here the moment series is truncated at the second moment,  $m_1$  is equated with the surface size  $D_g$  (based on the first

moment of  $F_i$ ), and  $m_2$  is equated with the surface arithmetic standard deviation  $\sigma$  (the square root of the second moment of  $F_i$ ). In a theory with the highest local accuracy  $X_1$  and  $X_2$  must be parameters that are most closely tied to bed load. In a formulation to be applied to locally quasi-equilibrium flows at a macroscopic scale, however, the precise choice of these parameters is less critical. They can be chosen from, e.g., depth-averaged flow velocity  $U$ , flow depth  $H$ , water discharge per unit width  $q_w$ , bed or energy slope  $S$ , or boundary shear stress  $\tau_b$ . Customarily one of the hydraulic parameters plays a primary role in sediment transport and the other one (or other ones) plays a secondary role. Here it is assumed that  $X_1$  is the primary hydraulic parameter. In addition, many researchers have used  $D_{50}$  rather than  $D_g$  as the parameter of choice for characteristic surface grain size.

Some researchers, e.g., Einstein (1950), have included more than two hydraulic parameters in their formulation of Eq. (3-43). For the case of locally quasi-equilibrium transport, however, the constraints of fluid mass and momentum balance, as well as a formulation for hydraulic resistance, allow the ultimate elimination of the extra hydraulic parameters.

Equation (3-43), truncated at the second moment, constitutes a relation between 10 dimensioned parameters. The principles of dimensional analysis allow the reduction of this relation to an equivalent dimensionless one involving 7 parameters. From the definitions

$$R = \frac{\rho_s}{\rho} - 1 \quad (3-44a)$$

$$q_i^* = \frac{q_i}{F_i \sqrt{RgD_i D_g}} \quad (3-44b)$$

$$R_{pg} = \frac{\sqrt{RgD_g D_g}}{\nu} \quad (3-44c)$$

Equation (3-43) can be recast as

$$q_i^* = T_b \left( \hat{X}_1, \hat{X}_2, \frac{D_i}{D_g}, \sigma, R_{pg}, R \right) \quad (3-45a)$$

In this relation  $T_b$  denotes a dimensionless bed-load transport function,  $\hat{X}_1$  and  $\hat{X}_2$  are dimensionless versions of  $X_1$  and  $X_2$ ,  $q_i^*$  denotes a grain-size-specific Einstein number,  $R$  denotes the submerged specific gravity of the sediment (nearly 1.65 for the most common natural sediments in rivers), and  $R_{pg}$  denotes an explicit particle Reynolds number. Note that  $\hat{X}_2$  may contain the parameter  $D_i$  and thus be grain-size-specific.

Many but not all researchers have assumed the existence of a critical or threshold value of the primary dimensionless hydraulic parameter  $\hat{X}_{1c}$ , which may in turn depend on  $D_i/D_g$ ,  $\sigma$ ,  $R_{pg}$ , and  $R$ , below which sediment transport vanishes. In this way (3-45a) is amended to

$$q_i^* = T_b \left( \hat{X}_1, \hat{X}_2, \frac{D_i}{D_g}, \sigma, R_{pg}, R \right) \quad (3-45b)$$

Nearly all dimensionless formulations for the bed-load transport of sediment mixtures can be cast into the form of Eq. (3-45) (but sometimes with extra dimensionless hydraulic parameters). Researchers such as Fernandez Luque and van Beek (1976) have studied bed-load transport rates for a variety of values of  $R$  and found no discernible independent effect as long as  $R$  is incorporated into the primary dimensionless hydraulic parameter (e.g. Shields number). As a result it is dropped here. Although there are many possible choices for  $\hat{X}_1$  and  $\hat{X}_2$ , for the sake of illustration  $\hat{X}_2$  is dropped and  $\hat{X}_1$  is set equal to a Shields number  $\tau_{si}^*$  based on the shear stress associated with skin friction  $\tau_{bs}$  and grain size  $D_i$ ;

$$\tau_{si}^* = \frac{\tau_{bs}}{\rho R g D_i} = \frac{u_{*s}^2}{R g D_i} \quad (3-46)$$

where

$$u_{*s} = \sqrt{\frac{\tau_{bs}}{\rho}} \quad (3-47)$$

denotes the shear velocity associated with skin friction. The (partial) justification for the use of the Shields stress is that it has become the standard primary dimensionless hydraulic parameter in many recent bed load formulations. The (partial) justification for dropping the second dimensionless hydraulic parameter is that the removal of the form drag from the boundary shear stress used in Eq. (3-46) eliminates other parameters that would enter into the bed-load transport relation through the relation for hydraulic resistance. (See Chapter 2 for a discussion of these relations and the decomposition of boundary shear stress into skin friction and form drag components.) With these assumptions Eq. (3-45a) becomes

$$q_i^* = T_b \left( \tau_{si}^*, \frac{D_i}{D_g}, \sigma, R_{pg} \right) \quad (3-48)$$

The flow is hydraulically rough during events that transport gravel in gravel-bed streams and many laboratory flumes. For such flows the particle Reynolds number  $R_{pg}$  can be dropped. In the case of flow in sand-bed streams, however, it generally cannot be dropped. The reader should also be reminded that  $D_g$  can be replaced with  $D_{50}$  in the above formulation with no loss of generality.

A form equivalent to Eq. (3-48) can be obtained by dividing both sides of the equation by  $(\tau_{si}^*)^{3/2}$ , in which case it reduces to

$$W_i^* = \hat{T}_b \left( \tau_{si}^*, \frac{D_i}{D_g}, \sigma, R_{pg} \right) \quad (3-49)$$

where

$$W_i^* = \frac{R g q_i}{F_i u_{*s}^3} = \frac{q_i^*}{(\tau_{si}^*)^{3/2}} \quad (3-50a)$$

$$\hat{T}_b = \frac{T_b}{(\tau_{si}^*)^{3/2}} \quad (3-50b)$$

The advantage of Eq. (3-49) is that it places all the effect of variation of grain sizes  $D_i$  and  $D_g$  on the right-hand side of the equation, simplifying the job of identifying selective transport.

### 3.6.3 Critical or Reference Condition for the Onset of Significant Transport

Equations (3-48) and (3-49) provides a basis for studying not only bed-load transport itself, but also the beginning of transport of sediment mixtures. Before proceeding with this, however, one must wrestle with the meaning of “beginning of transport.” In Chapter 2, the transport relation of Eq. (2-95) of Meyer-Peter and Müller (1948) contains a critical condition for the onset of bed-load transport, whereas the Einstein (1950) relation of Eq. (2-96) does not. This raises the question of whether there really is a threshold condition for the onset of motion.

The answer is yes and no. Fortunately, however, this answer is not as complicated as one might think. In a classical set of experiments, Paintal (1971) ran flows over an erodible bed under conditions that were well below established critical conditions for the onset of bed-load transport. After weeks or months of patient waiting, some sediment was invariably collected at the downstream end of the flume. In addition, these data could be organized into a sensible transport relation of the following form at very low transport rates:

$$q^* = 6.5 \times 10^{18} (\tau^*)^{16} \quad (3-51a)$$

$$W^* = 6.5 \times 10^{18} (\tau^*)^{14.5} \quad (3-51b)$$

where  $\tau^*$  and  $q^*$  are defined in Eqs. (2.56) and (2.91) and  $W^*$  is obtained by dividing  $q^*$  by  $(\tau^*)^{3/2}$ . The implication is that there is no “absolute” threshold of motion in the statistical sense.

This notwithstanding, Paintal’s work allows the definition of an “effective” threshold of motion, below which the sediment transport rate is so low that the resulting morphodynamic change of the bed is negligible over most or all time periods of interest. The definition is made meaningful by the high exponent in Eq. (3-51), which guarantees that in the regime of very low bed-load transport rates, large changes in  $q^*$  lead to only small changes in  $\tau^*$ . Both the absolute and effective approaches are pursued here in order to better summarize the available data.

In the absolute approach,  $q_i^*$  is set equal to zero in Eq. (3-48) or  $W_i^*$  is set equal to zero in Eq. (3-49), resulting in the following relation for the critical Shields stress  $\tau_{sci}^*$  for the  $i$ th grain size:

$$\tau_{sci}^* = F_c \left( \frac{D_i}{D_g}, \sigma, R_{pg} \right) \quad (3-52)$$

(Here the subscript “sci” denotes “skin, critical,  $i$ th grain size”). In the “effective” approach, flow conditions are determined for a very low but measurable reference value of bed-load transport. Parker et al. (1982a), for example, suggested the reference dimensionless transport rate

$$W_r^* = 0.002 \quad (3-53)$$

based on field data from Oak Creek, Oregon. Setting  $W_i^*$  equal to  $W_r^*$  in Eq. (3-49) and solving for the associated reference Shields stress  $\tau_{ssri}^*$  it is found that

$$\tau_{ssri}^* = F_r \left( \frac{D_i}{D_g}, W_r^*, \sigma, R_{pg} \right) \quad (3-54)$$

(Here the subscript “ssri” denotes “skin, surface-based, reference,  $i$ th grain size.”) Equations (3-52) and (3-54) are very similar. The latter equation has the advantage of referring to a small but measurable transport rate. It is very hard to measure zero sediment transport rate accurately. Based on the high exponent in Eq. (3-51b) of Paintal (1971), it can be expected that the values of  $\tau_{ssri}^*$  depend only weakly on the choice of  $W_r^*$  as long as it is sufficiently small.

Equation (3-52) or (3-54) can be further reduced by evaluating it for  $D_i = D_g$  and dividing the result into the original equation, yielding the respective forms

$$\frac{\tau_{sci}^*}{\tau_{scg}^*} = \frac{F_c \left( \frac{D_i}{D_g}, \sigma, R_{pg} \right)}{F_c (1, \sigma, R_{pg})} \quad (3-55a)$$

$$\frac{\tau_{ssri}^*}{\tau_{ssrg}^*} = \frac{F_r \left( \frac{D_i}{D_g}, \sigma, R_{pg} \right)}{F_r (1, \sigma, R_{pg})} \quad (3-55b)$$

(The parameter  $W_r^*$  is suppressed in Eq. (3-55b) because in any given formulation its value must be specified and held constant subsequently.) It is commonly assumed that the critical or reference Shields stress  $\tau_{scg}^*$  or  $\tau_{ssrg}^*$  (or equivalent forms using the surface size  $D_{50}$  instead of  $D_g$ ) depends only on  $R_{pg}$ , and the ratios on the left-hand sides of Eqs. (3-55a) and (3-55b) depend only on  $D_i/D_g$  (or  $D_i/D_{50}$ ):

$$\frac{\tau_{sci}^*}{\tau_{scg}^* (R_{pg})} = F_{hc} \left( \frac{D_i}{D_g} \right) \quad (3-56a)$$

$$\frac{\tau_{ssri}^*}{\tau_{ssrg}^* (R_{pg})} = F_{hr} \left( \frac{D_i}{D_g} \right) \quad (3-56b)$$

where the functions  $F_{hc}$  and  $F_{hr}$  differ from those in Eqs. (3-55a) and (3-55b).

### 3.6.4 Similarity Hypothesis

The bed-load transport rate  $q_i^*$  in Eq. (3-48) or alternatively  $W_i^*$  in Eq. (3-49) is assumed to be a function of, among other parameters, the ratio  $D_i/D_g$ . The shape of the bed-load curve defined as  $q_i^*$  versus  $\tau_{si}^*$ , or alternatively  $W_i^*$  versus  $\tau_{si}^*$ , may thus differ from grain size to grain size in a mixture. It may be, however, that the curve for each value of  $D_i/D_g$  can be collapsed into a single curve, greatly simplifying the analysis. Similarity analysis can be used to test this hypothesis.

Here a similarity analysis is pursued in the context of Eq. (3-49) as an example. In Figs. 3.33(a and c)  $W_i^*$  is plotted against  $\tau_{si}^*$  for  $n = 5$  values of  $D_i/D_g$  based on two sets of synthetic data. The solid lines shown in the figures can be taken to be fits to data points. A standard value  $W_r^*$  of 0.002 used to define the reference parameters  $\tau_{ssri}^*$  in accordance with Eq. (3-54). The ratio  $W_i^*/W_r^*$  is then plotted against  $\tau_{si}^*/\tau_{ssri}^*$ , so defining a total of  $n$  curves, one for each value of  $i$ . Note that by definition every curve passes through the point  $(W_i^*/W_r^*, \tau_{si}^*/\tau_{ssri}^*) = (1, 1)$ . If the curves in fact coincide for all values of  $\tau_{si}^*/\tau_{ssri}^*$  and every value of  $i$ , a similarity collapse is realized according to which

$$\frac{W_i^*}{W_r^*} = G_{sim} \left( \frac{\tau_{si}^*}{\tau_{ssri}^*} \right) \quad (3-57)$$

where

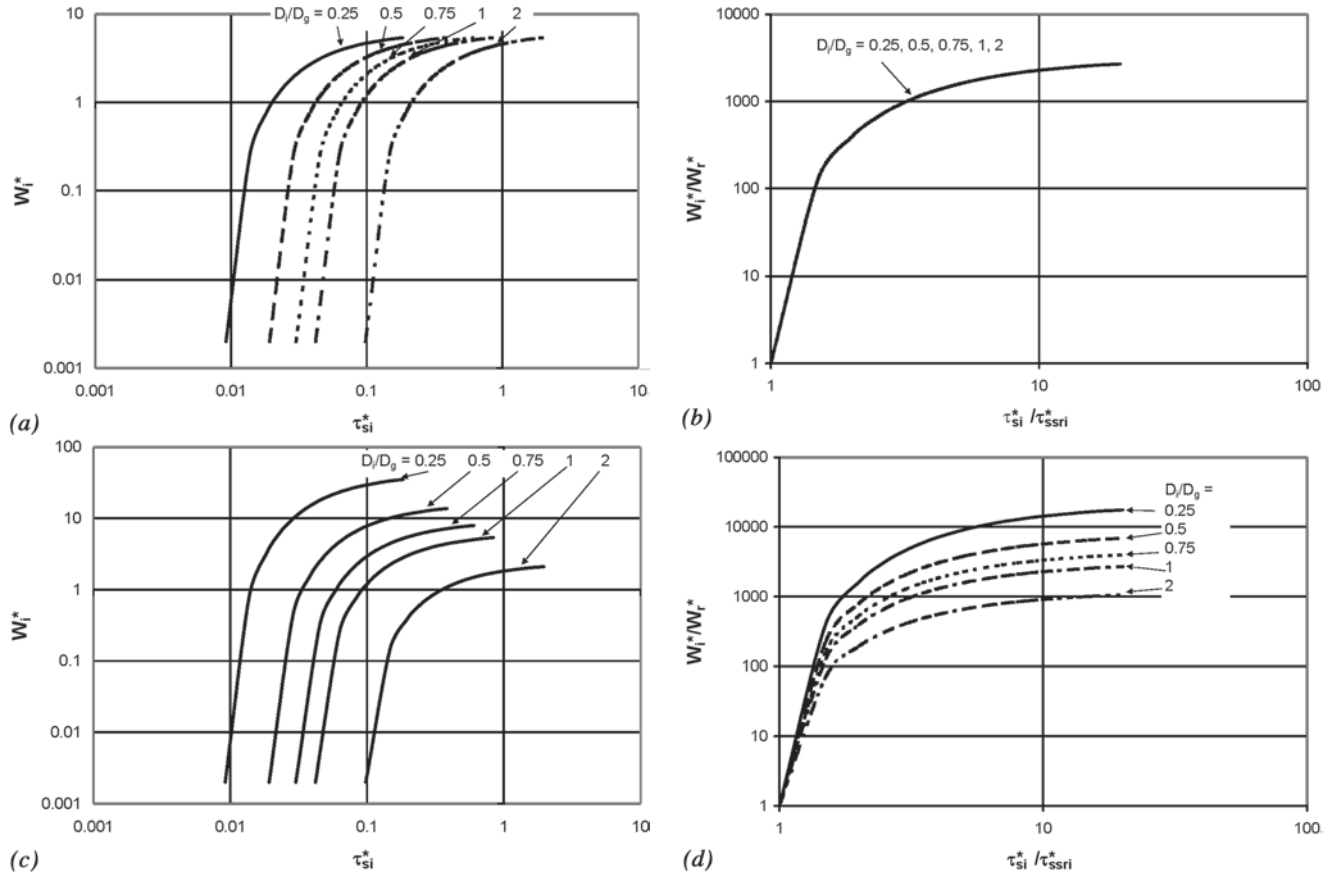

$G_{sim}$  = a similarity collapse function that is independent of grain size.

The synthetic data of Fig. 3-33a do in fact yield the similarity collapse of Fig. 3-33b. The synthetic data of Fig. 3-33c, however, do not collapse into a single line, as shown in Fig. 3-33d.

Figures 3.33(a and b) thus show a case for which a similarity collapse to a common function is realized; Figs. 3.33(c and d) show one for which it is not realized. Even in the event that similarity is realized, the parameters  $D_i/D_g$ ,  $\sigma$ , and  $R_{pg}$  do not necessarily become unimportant; rather, it follows that  $\tau_{ssri}^*$  itself may be a function of these parameters. A further similarity collapse, if successful, allows this relation to be reduced to the form

$$\frac{\tau_{ssri}^*}{\tau_{ssrg}^* (R_{pg}, \sigma)} = F_{hr} \left( \frac{D_i}{D_g} \right) \quad (3-58)$$

i.e., a hiding function similar to Eq. (3-56b).

**Fig. 3-33.** Plots illustrating the use of similarity. (a) Plot of  $W_i^*$  versus  $\tau_{si}^*$  for a case for which similarity collapse is realized. (b) Similarity plot of the data of the figure to the left which results in a perfect collapse. (c) Plot of  $W_i^*$  versus  $\tau_{si}^*$  for a case for which similarity collapse is not realized. (d) Similarity plot of the data of the figure to the left does not results in a collapse.

Parker et al. (1982a), Parker and Klingeman (1982), Parker (1990a), Wilcock and McArdeil (1993), Wilcock (1997a), and Wilcock and Crowe (2003) have pursued approximate similarity collapses of the above type based on both surface and substrate. They have invariably found that a better approximation to a collapse of the data is realized using the parameter  $W_i^*$  than  $q_{bi}^*$ , largely because  $W_i^*$  does not contain grain size  $D_i$  in its definition by Eq. (3-50a).

### 3.6.5 Hiding Functions

Equations (3-55), (3-56), and (3-58) may be termed hiding functions. The reason for this relates to the seminal work of Egiazaroff (1965), who derived a relation of this form from consideration of the forces acting on exposed grains on a bed containing a mixture of grain sizes. In Egiazaroff's simple but cogent model, larger grains are harder to move because they are heavier. Larger grains, on the other hand, are easier to move because they tend to protrude more into the flow, thus feeling a higher drag. (Hence the term "hiding," in that the finer grains are sheltered from the full

brunt of the flow by the protrusion of the coarser grains.) The net result of these two effects is a modest bias toward lesser mobility for coarser grains. The reduced mobility of coarser grains in a mixture turns out, then, to be much more subdued than would be expected based on weight alone. Egiazaroff's version of (3-56), along with others, is introduced in Section 3.7.

The dimensioned values of the critical (reference) boundary shear stresses based on skin friction (and surface content in the case of reference values),  $\tau_{bsci}$  and  $\tau_{bscg}$  ( $\tau_{bssri}$  and  $\tau_{bssrg}$ ), associated with sizes  $D_i$  and  $D_g$ , respectively, are given from the relations

$$\tau_{bsci} = \rho Rg D_i \tau_{sci}^* \quad (3-59a)$$

$$\tau_{bscg} = \rho Rg D_g \tau_{scg}^* \quad (3-59b)$$

$$\tau_{bssri} = \rho Rg D_i \tau_{ssri}^* \quad (3-59c)$$

$$\tau_{bssrg} = \rho Rg D_g \tau_{ssrg}^* \quad (3-59d)$$

Between Eqs. (3-56) and (3-59) it is found that

$$\frac{\tau_{bsci}^*}{\tau_{bscg}^*} = F_{rhc} \left( \frac{D_i}{D_g} \right) \equiv \frac{D_i}{D_g} F_{hc} \left( \frac{D_i}{D_g} \right) \quad (3-60a)$$

$$\frac{\tau_{bssri}^*}{\tau_{bssrg}^*} = F_{rhr} \left( \frac{D_i}{D_g} \right) \equiv \frac{D_i}{D_g} F_{hr} \left( \frac{D_i}{D_g} \right) \quad (3-60b)$$

These equations may be termed reduced hiding functions.

### 3.6.6 Size-Independence and Equal-Threshold Limiting Cases

Two limiting cases are of interest here. In one limit  $F_{hc}$  (or  $F_{hr}$ ) is equal to unity, in which case Eqs. (3-56a), (3-56b), (3-60a), and (3-60b) devolve to

$$\frac{\tau_{sci}^*}{\tau_{scg}^* (R_{pg})} = 1 \quad (3-61a)$$

$$\frac{\tau_{ssri}^*}{\tau_{ssrg}^* (R_{pg})} = 1 \quad (3-61b)$$

$$\frac{\tau_{bsci}^*}{\tau_{bscg}^*} = \frac{D_i}{D_g} \quad (3-61c)$$

$$\frac{\tau_{bssri}^*}{\tau_{bssrg}^*} = \frac{D_i}{D_g} \quad (3-61d)$$

This case corresponds to the absence of hiding. Each grain has a critical (reference) Shields stress that is the same, regardless of size. A grain of given size  $D$  within a mixture has exactly the same mobility that it would have if the bed were composed entirely of size  $D$ . Thus each grain acts independent of its neighbors of differing size. The dimensioned critical (reference) shear stress needed to move a grain of size  $D$  within a mixture increases linearly with size  $D$ . If this size-independence (hiding-free) scenario were to hold, the initiation of (significant) transport of sediment mixtures would be highly selective based on grain size.

In the second limiting case  $F_{hc}$  ( $F_{hr}$ ) is equated to  $(D_i/D_g)^{-1}$ , in which case Eqs. (3-56a), (3-56b), (3-60a), and (3-60b) devolve to

$$\frac{\tau_{sci}^*}{\tau_{scg}^* (R_{pg})} = \left( \frac{D_i}{D_g} \right)^{-1} \quad (3-62a)$$

$$\frac{\tau_{ssri}^*}{\tau_{ssrg}^* (R_{pg})} = \left( \frac{D_i}{D_g} \right)^{-1} \quad (3-62b)$$

$$\frac{\tau_{bsci}^*}{\tau_{bscg}^*} = 1 \quad (3-62c)$$

$$\frac{\tau_{bssri}^*}{\tau_{bssrg}^*} = 1 \quad (3-62d)$$

In this limiting case the effect of the mixture has been to equalize the threshold for (significant) motion, so that all grains are mobilized at the same absolute boundary shear stress.

In the next chapter it will be shown that sediment mixtures behave somewhere in between the size-independence and equal-threshold scenarios, but are biased more toward the latter than the former.

### 3.6.7 Substrate-Based Formulation

A surface-based formulation is necessary to develop a local predictor of bed-load transport. Gross overall predictions can be made, however, using a substrate-based formulation. Let  $\bar{f}_i$  denote the volume fraction of material in the  $i$ th grain size range averaged over a relatively thick layer of substrate, proceeding downward from the surface-substrate interface. The substrate-based forms corresponding to Eqs. (3-44b), (3-48), (3-49), (3-50a), (3-56), and (3-60) are

$$q_{ui}^* = \frac{q_i}{\bar{f}_i \sqrt{RgD_i} D_i} \quad (3-63)$$

$$q_{ui}^* = T_{ub} \left( \tau_{si}^*, \frac{D_i}{D_{ug}}, \sigma_u, R_{pug} \right) \quad (3-64)$$

$$W_{ui}^* = \hat{T}_{ub} \left( \tau_{si}^*, \frac{D_i}{D_{ug}}, \sigma_u, R_{pug} \right) \quad (3-65)$$

$$W_{ui}^* = \frac{Rgq_i}{\bar{f}_i u_{*s}^3} \quad (3-66)$$

$$\frac{\tau_{suci}^*}{\tau_{sug}^* (R_{pug})} = F_{uhc} \left( \frac{D_i}{D_{ug}} \right) \quad (3-67a)$$

$$\frac{\tau_{suri}^*}{\tau_{surg}^* (R_{pug})} = F_{uhr} \left( \frac{D_i}{D_{ug}} \right) \quad (3-67b)$$

$$\frac{\tau_{bsuci}^*}{\tau_{bsug}^*} = F_{urhc} \left( \frac{D_i}{D_{ug}} \right) \equiv \frac{D_i}{D_{ug}} F_{uhc} \left( \frac{D_i}{D_{ug}} \right) \quad (3-68a)$$

$$\frac{\tau_{bsuri}^*}{\tau_{bsurg}^*} = F_{urhr} \left( \frac{D_i}{D_{ug}} \right) \equiv \frac{D_i}{D_{ug}} F_{uhr} \left( \frac{D_i}{D_{ug}} \right) \quad (3-68b)$$

where the subscript “ $u$ ” everywhere denotes “under,” i.e., substrate (as “ $s$ ” has already been used for surface), and the parameter  $R_{pug}$  is obtained from Eq. (3-44c) with the transformation  $D_g \rightarrow D_{ug}$ , where  $D_{ug}$  ( $D_{u50}$ ) refers to substrate values based on  $\bar{f}_i$ . It is useful to remind the reader that  $D_g$  ( $D_{50}$ ) refers to surface mean (median) sizes based on  $F_i$ . The same limiting cases of grain-independent and equal-threshold behavior can be defined based on a substrate formulation with the use of Eqs. (3-67) and (3-68).

### 3.6.8 Surface-Based Formulation for Entrainment

A parallel development is possible for the entrainment formulation. Here the case of deterministic step lengths  $L_{si}$  in a surface-based formulation is considered for simplicity. In analogy to Eq. (3-44b), the dimensionless entrainment rate  $E_i^*$  and step length  $L_{si}^*$  are defined as

$$E_i^* = \frac{E_i}{\sqrt{RgD_i}} \quad (3-69a)$$

$$L_{si}^* = \frac{L_{si}}{D_i} \quad (3-69b)$$

The analogs of Eq. (3-48) are

$$E_i^* = T_{be} \left( \tau_{si}^*, \frac{D_i}{D_g}, \sigma, R_{pg} \right) \quad (3-70a)$$

$$L_{si}^* = T_{bl} \left( \tau_{si}^*, \frac{D_i}{D_g}, \sigma, R_{pg} \right) \quad (3-70b)$$

Equation (3-70a) can be used to develop threshold (reference) conditions for the onset of (significant) entrainment into bed load that are analogous to Eqs. (3-56) and (3-60).

## 3.7 RELATIONS FOR HIDING AND BED-LOAD TRANSPORT IN MIXTURES

### 3.7.1 Relations for Threshold of Motion and Hiding

The classical relation for the threshold of motion of uniform sediment is that of Shields (1936). In terms of the notation presented above, the relation predicts the critical Shields stress  $\tau_{scg}^*$  (or  $\tau_{sc50}^*$ ) as a function of explicit particle Reynolds number  $R_{pg}$  or  $R_{p50}$ . Brownlie (1981) fitted a convenient analytical function to this curve. In general, however, the Shields curve tends to overpredict the critical Shields stress. For example, in the limit of hydraulically rough flows ( $R_{pg} \rightarrow \infty$ ) the predicted value of  $\tau_{scg}^*$  is near 0.06. This criterion incorrectly indicates, however, that most gravel-bed streams would be unable to move a surface mean or median size particle even at bank-full flow, as demonstrated below. Neill (1968) has suggested a revised value of 0.03, which appears to have stood the test of time (e.g., in the case of Oak Creek, Ore., as analyzed by Milhous 1973 and Parker and Klingeman 1982 and in the case of the Nahal Eshtemoa, Israel as analyzed by Powell et al. 2001). By adjusting the Brownlie relation by multiplying the right-hand side by one-half to obtain this limit, the following curve is obtained:

$$\tau_{scg}^* = \frac{1}{2} \left[ 0.22 R_{pg}^{-0.6} + 0.06 \cdot 10^{(-7.7 R_{pg}^{-0.6})} \right] \quad (3-71)$$

The appropriate grain size to use in Eq. (3-71) is a surface value  $D_g$  or  $D_{50}$ . In the case of field gravel-bed rivers in particular, the bed tends to be armored at low flow, so that the

corresponding substrate  $D_{ug}$  or  $D_{u50}$  can usually be expected to be below the corresponding surface value, by a multiplicative factor ranging from 0.25 to 1 (e.g., Dietrich et al. 1989). As a result the value of  $\tau_{scg}^*$  based on  $D_{ug}$  tends to be higher than  $\tau_{scg}^*$  by a factor of 1 to 4.

Buffington and Montgomery (1997) conducted a review of eight decades of incipient motion data, with special reference to gravel-bed rivers. Their database includes both experimental and field data. Their analysis was done in terms of  $D_{50}$  rather than  $D_g$ . They went to some effort to ensure the removal of form drag from most of the estimates of shear stress used in their treatment. In addition, they performed a service to the community in publishing their entire data set. They found that the data generally followed the overall shape of the Shields curve. Equation (3-71) forms an approximate lower bound for the data for  $R_{pg} > 100$  ( $D_g > 0.85$  mm for  $R = 1.65$  and  $\nu = 1 \times 10^{-6}$  m<sup>2</sup>/s). A subset of their database is compared with Eq. (3-71) in Fig. 3-34. Also included in the figure are (a) the original form of the Brownlie fit to the Shields curve and (b) points based on bank-full flow and surface  $D_{50}$  (measured at low flow) for the three sets of gravel-bed streams introduced in Section 3.3. Most (but not all) of these streams can be expected to be competent to move the surface  $D_{50}$  size at bank-full flow.

The large scatter in Fig. 3-34 is a problem, as noted by Buffington and Montgomery (1997). This notwithstanding, Eq. (3-71) would appear to be an appropriate estimator of at least a lower bound on  $\tau_{scg}^*$  or the corresponding  $\tau_{sc50}^*$  based on  $D_{50}$  in streams with values of  $D_g$  or  $D_{50}$  in excess of 1 mm. The original form the Brownlie fit to the Shields curve is seen to overpredict the critical Shields stress for the great majority of the data from Buffington and Montgomery (1997), and to render most of the gravel-bed streams in these data incapable of transporting their mean or median surface size at bank-full flow.

**Fig. 3-34.** Plot of critical Shields stress versus particle Reynolds number showing the following lines and points: (a) the Brownlie (1981) fit to the original Shields (1936) curve, (b) the modified Brownlie fit of Eq. (3-71), (c) the data of Buffington and Montgomery (1997), and (d) the gravel-bed rivers of Fig. 3-29.

Several researchers have presented derivations of the Shields diagram from basic principles. In the case of uniform sediment, the work of Ikeda (1982) and Wiberg and Smith (1987) stands out. The latter work also provides an extension to sediment mixtures, and thus implicitly determines a hiding function similar to that of Egiazaroff (1965).

The first researcher to suggest a form for a hiding function for sediment mixtures was Einstein (1950). This work is remarkable in that it provides a complete, physically based implementation of the dimensional analysis presented above. Unfortunately the work was so far ahead of its time that few data were available to test the hiding function. Further analysis (e.g., Misri et al. 1984) has shown that the Einstein hiding function is a poor approximation of the data.

The first hiding function that was found to be a reasonable approximation of at least some data for heterogeneous sediments was the surface-based relation of Egiazaroff (1965). Egiazaroff provides a simplified derivation from basic principles that includes the effect of both increasing grain weight in reducing mobility and increasing protrusion of larger grains in increasing mobility within a mixture:

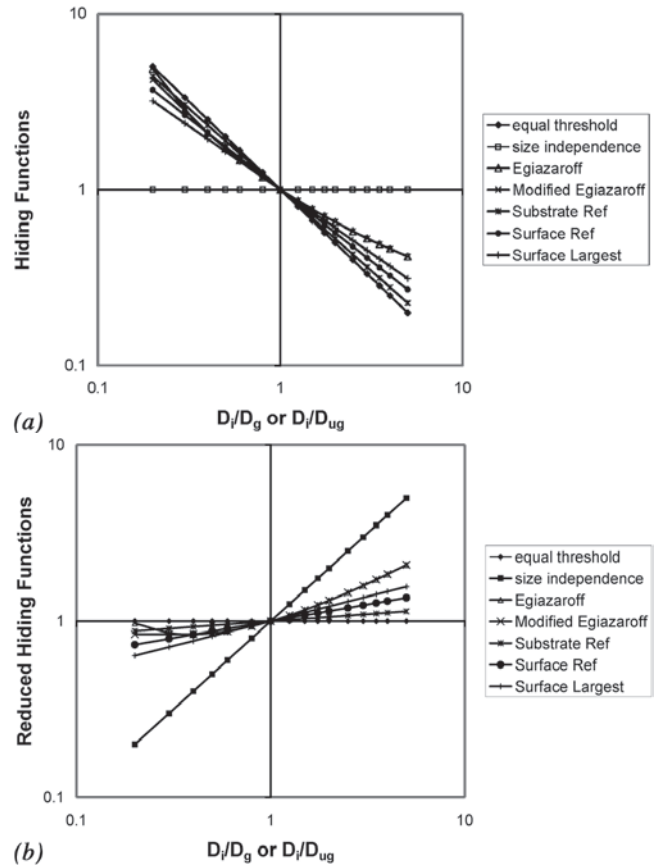

$$\frac{\tau_{sci}^*}{\tau_{scg}^*} = F_{hc} \left( \frac{D_i}{D_g} \right) = \left[ \frac{\log(19)}{\log \left( 19 \frac{D_i}{D_g} \right)} \right]^2 \quad (3-72a)$$

$$\frac{\tau_{bsci}}{\tau_{bscg}} = F_{rhc} \left( \frac{D_i}{D_g} \right) = \frac{D_i}{D_g} \left[ \frac{\log(19)}{\log \left( 19 \frac{D_i}{D_g} \right)} \right]^2 \quad (3-72b)$$

(In point of fact Egiazaroff used  $D_m$ , defined by Eq. (3-10), rather than  $D_g$ , perpetuating a misconception that has continued to this day, that  $D_m$  rather than  $D_g$  is the appropriate size with which to characterize sediment mixtures.) The Egiazaroff hiding function is illustrated in Fig. 3-35a, along with the limiting cases of size-independence (no hiding) and equal-threshold. The corresponding reduced hiding function is shown in Fig. 3-35b, along with the limiting cases.

Figure 3-35b is of particular interest. The Egiazaroff hiding function clearly plots between the cases of size-independence and equal-threshold. It is clearly closer, however, to the latter case, indicating that the structure of sediment mixtures works in the direction of equalizing the threshold shear stress required for the motion of all grains. This equalization cannot extend, however, all the way to very coarse, rare grains, and as a result the largest deviation from equal threshold is for the coarsest grains in a mix.

Ashida and Michiue (1972) noted one curious feature in Fig. 3-35b: sizes such that  $D_i/D_g < 0.04$  become progressively harder to move with decreasing grain size. With this in mind, they suggested the following ad hoc modification:

**Fig. 3-35.** Plots of (a) hiding function obtained from Egiazaroff relation, the modified Egiazaroff relation, the condition of size-independence, the condition of equal-threshold, and the power relations of Eqs. (3-74a,b) using  $\gamma_{subref} = 0.81$ ,  $\gamma_{surfref} = 0.90$ , and  $\gamma_{surfarg} = 0.72$ ; and (b) reduced hiding functions corresponding to (a).

$$\frac{\tau_{sci}^*}{\tau_{scg}^*} = F_{hc} \left( \frac{D_i}{D_g} \right) = 0.843 \left( \frac{D_i}{D_g} \right)^{-1} \quad \text{for } \frac{D_i}{D_g} \leq 0.4 \quad (3-73a)$$

$$\frac{\tau_{bsci}}{\tau_{bscg}} = F_{rhc} \left( \frac{D_i}{D_g} \right) = 0.843 \quad \text{for } \frac{D_i}{D_g} \leq 0.4 \quad (3-73b)$$

Many subsequent researchers have used this modified form.

Parker et al. (1982a) and Parker and Klingeman (1982) introduced the concept of power relations for hiding functions. In particular, they deduced the following surface-based forms for reference (rather than critical) conditions using  $D_{50}$ :

$$\frac{\tau_{ssri}^*}{\tau_{ssr50}^*} = F_{hr} \left( \frac{D_i}{D_{50}} \right) = \left( \frac{D_i}{D_{50}} \right)^{-\gamma} \quad (3-74a)$$

$$\frac{\tau_{bssri}}{\tau_{bssr50}} = F_{hrh} \left( \frac{D_i}{D_{50}} \right) = \left( \frac{D_i}{D_{50}} \right)^{1-\gamma} \quad (3-74b)$$

**Table 3-1. Values of  $\gamma$  Measured for Various Gravel-Bed Streams**

Stream	Authors	$D_{50}$	$\gamma$
Surface-based reference method			
Oak Creek, Oregon	Parker (1990a)	54	0.90
Allt Dubhaig, Scotland	Ashworth and Ferguson (1989)	50	0.65
Goodwin Creek, Mississippi	Kuhnle (1992)	11.7	0.81
Allt Dubhaig, Scotland	Wathen et al. (1995)	21	0.90
Sunwapta River, Canada	Ashworth et al. (1992)	24	0.79
<i>Averaged surface-based reference</i>			0.81

Sunwapta River, Canada	Ashworth et al. (1992)	21	0.69
<i>Averaged surface-based largest grain</i>			0.72

as well as corresponding substrate-based forms. Here a value of  $\gamma$  of 0 corresponds to size-independence and a value of 1 corresponds to equal-threshold conditions.

Parker et al. (1982a) found a substrate-based value of  $\gamma$  of 0.982 for Oak Creek, Oregon, very near equal-threshold conditions. Parker (1990a) deduced a surface-based value for the same stream of 0.905. Parker and Klingeman (1982) interpreted the difference between these two numbers in terms of mobile-bed armor, as discussed in Section 3.10.

Values of  $\gamma$  have been investigated in a number of rivers and laboratory flumes. Buffington and Montgomery (1997) and Powell (1998) provide summaries of these relations. Computations have proceeded using the reference concentration method, in which measured bed load data are used to interpolate or extrapolate values of reference Shields stress, and also by determining the coarsest grain captured in a bed-load sample for a given flow. Discussion of the difference between the two methods can be found in Komar (1987); Wilcock (1988); and Shih and Komar (1990). The reported values of  $\gamma$  are summarized for field streams in Table 3-1.

Table 3-1 can be summarized as follows. Substrate-based values of  $\gamma$  based on the reference method average to  $\gamma_{\text{subref}} = 0.90$ , and are closest to the equal-threshold condition. Surface-based values based on the reference method average to  $\gamma_{\text{surfref}} = 0.81$ , and surface-based values using the method of largest clast average to  $\gamma_{\text{surflarg}} = 0.72$ . The resulting hiding functions are shown in Fig. 3-34. In all cases the trend is far more toward equal-threshold conditions than size-independence conditions. In all cases, however, there is

at least a residual tendency toward selecting the finer sizes in mobilizing sediment mixtures. Surface-based values of the exponent  $\gamma$  are smaller than substrate-based values.

As pointed out previously, a simple power form for the hiding function cannot in general be correct. In particular, both the hiding function and the reduced hiding function can be expected to be concave upward. On one hand rare, large clasts must be difficult to move, causing the hiding function to curve upward as relative grain size increases. On the other hand the influence of grain size on mobility can be expected to diminish as relative grain size decreases, causing the hiding function to curve upward with decreasing grain size. The hiding functions of Egiazaroff (1965) and Proffitt and Sutherland (1983) have this property; in the former case it can be readily seen in Figs. 3-35a and 3-35b. Misri et al. (1984) have demonstrated the same behavior for their experimental data. Wilcock and Southard (1988) demonstrated it for their own data, as well as the experimental data of Day (1980) and Parker et al. (1982b) and the field data for Oak Creek due to Milhous (1973). The hiding function of Wilcock and Crowe (2003) also shows this property, as is discussed in Section 3.7.10.

### 3.7.2 Calculation of Boundary Shear Stress and Other Flow Parameters

Bed-load transport is driven by the hydraulics of flow. As noted in Section 3.6.2, at least one hydraulic parameter, such as boundary shear stress  $\tau_b$  or depth-averaged flow

velocity  $U$ , invariably appears in bed-load transport relations. Boundary shear stress is often quantified in terms of shear velocity  $u_*$ , where

$$u_* = \sqrt{\frac{\tau_b}{\rho}} \quad (3-75a)$$

Depth or cross-sectionally averaged flow velocity  $U$  is related to shear velocity in terms of a dimensionless friction coefficient  $C_f$  or an equivalent dimensionless Chezy coefficient  $Cz$ , where

$$Cz = \frac{U}{u_*} \quad (3-75b)$$

$$C_f = \frac{\tau_b}{\rho U^2} = Cz^{-2} \quad (3-75c)$$

Forms for these parameters were introduced for bank-full flow as Eqs. (3-15a) and (3-15b) in Section 3.4.

The boundary shear stress acting on the bed of a river can be a mixture of skin friction  $\tau_{bs}$  and form drag  $\tau_{bf}$ , as discussed in Chapter 2. In the case of flow over a hydraulic rough granular bed in the absence of form drag friction relations of the following type are often used:

$$Cz = 2.5 \ln \left( 11 \frac{H}{k_s} \right) \quad (3-75d)$$

$$Cz = 8.1 \left( \frac{H}{k_s} \right)^{1/6} \quad (3-75e)$$

where

$H$  = flow depth; and  
 $k_s$  = roughness height.

Equations (3-75d) and (3-75e) are similar; the former is a logarithmic form due to Keulegan (1938) and the latter is a Manning-Strickler form due to Parker (1991a). Many variations on these forms can be found in the literature. Roughness height  $k_s$  is often related to surface size  $D_{90}$  as follows:

$$k_s = n_k D_{90} \quad (3-75f)$$

where  $n_k$  has been estimated to range between 2 and 3.5 for granular beds (Kamphuis, 1974; Hey, 1979).

Many predictive relations for bed-load transport require boundary shear stress as an input parameter. The simplest formulation for calculating boundary shear stress, or shear velocity is based on the assumption of 1D normal (steady, uniform equilibrium) flow in a wide rectangular channel:

$$\tau_b = \rho g H S \quad (3-76a)$$

$$u_* = \sqrt{g H S} \quad (3-76b)$$

where

$H$  = flow depth; and  
 $S$  = bed slope.

Where flow velocity is required for a sediment transport calculation, it can then be computed from Eqs. (3-75) and (3-76).

Two questions arise at this point. Is form drag negligible in gravel-bed rivers? Can the flow field be accurately computed from the assumption of 1D normal flow? The latter query is approached first. Many gravel-bed rivers are small and steep, with very flashy hydrographs. For such streams Eq. (3-76) may be inadequate to model boundary shear stress. The next level of complication is the use of the 1D shallow-water St. Venant equations to predict the flow field. The 1D equations of momentum balance take the form

$$\frac{\partial H}{\partial t} + \frac{\partial UH}{\partial s} = 0 \quad (3-76c)$$

$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial s} = -g \frac{\partial H}{\partial s} + gS - \frac{C_f U^2}{H} \quad (3-76d)$$

These equations, coupled with the resistance formulations of Eqs. (3-75d) or (3-75e), allow the computation of  $\tau_b$  or  $u_*$ ,  $U$ ,  $H$ , and other hydraulic parameters that might serve as inputs to sediment transport equations as functions of streamwise distance  $s$  and time  $t$ . In some cases Eqs. (3-76c) and (3-76d) can be simplified to their backwater forms by neglecting the time derivatives. In other cases even a 1D unsteady, non-uniform approach may be insufficient, and the local input parameters to a sediment transport equation may require estimation with a 2D model. A case in point is a resolution of the 2D sediment transport field in a river bend. The issue is discussed in more detail in Section 3.13.2.

As for the former question, form drag in sand-bed streams is of sufficient importance to merit extensive attention, as seen in Chapter 2. A number of methods are available to extract only the term  $\tau_{bs}$  due to skin friction from the total boundary shear stress  $\tau_s$  for such streams.

As noted in Section 3.6.2, it is explicitly or implicitly assumed in most shear-stress-based formulations of bed-load transport that only the portion of the shear stress due to skin friction actually drives sediment transport, so that  $\tau_{bs}$  rather than  $\tau_b$  should appear as input to the computation. The problem with gravel-bed streams, however, is that once obvious effects such as debris jams and major channel irregularities have been discounted, the residual form drag due to, e.g., bars has only been poorly quantified to date. Parker and Peterson (1980) have argued that form drag associated with bars in gravel-bed rivers is negligible at flows high enough to transport significant gravel loads. Hey (1989) has argued otherwise, and Millar (1999) has presented further evidence suggesting that form drag can be significant in some gravel-bed streams. A generally

validated predictive method allowing boundary shear stress decomposition into skin friction and form drag, however, is not yet available.

The reader is thus offered two caveats concerning the transport relations presented below.

- Although the indicated input parameter in the text is  $\tau_{bs}^*$ , in point of fact the user will most often have to equate this to  $\tau_b$  because the information for shear stress decomposition is lacking.
- In addition, much of the data analysis used to estimate boundary shear stress and other parameters in developing the relations presented below is based on the assumption of normal flow, which in fact may not be an accurate approximation to the actual flows in question. This is particularly true of the field data.

The scatter seen between the predictions of the various relations must be viewed in light of these two sources of error.

### 3.7.3 Relation of Einstein

Considerations of dimensional analysis yielded bed-load transport relations of the type of Eqs. (3-48) and (3-49). The conversion of these forms into predictive relations has typically required the folding of parameters together by means of an explicit or implicit similarity hypothesis. Einstein (1950) was the first to execute such an analysis for the bed-load transport of mixtures. The relation cannot be considered appropriate for the purposes of calculation due to the gross inaccuracies in the hiding function. As a result the relation is not covered in detail here. (The form for a single grain size is given in Chapter 2.) This notwithstanding, subsequent researchers have owed a debt to Einstein for pointing the path toward the progress that has been realized to date.

### 3.7.4 Relation of Ashida and Michiue

The relation of Ashida and Michiue (1972) was the first bed-load transport relation for mixtures with a thorough test against data. The data pertained exclusively to experiments. Although the authors did not specify their relation as surface-based because the concept did not exist at the time, it is here treated as such.

In Eq. (3-48) the parameters  $R_{pg}$  and  $\sigma$  are dropped,  $D_m$  is used rather than  $D_g$  (so that  $g \rightarrow m$  in the subscripts), and the dependence on  $D_i^g/D_m$  is folded into a hiding relation for critical stress. The relation thus takes the form

$$q_i^* = 17(\tau_{si}^* - \tau_{sci}^*) \left( \sqrt{\tau_{si}^*} - \sqrt{\tau_{sci}^*} \right) \quad (3-77a)$$

where

$$\frac{\tau_{sci}^*}{\tau_{scm}^*} = F_{hc} \left( \frac{D_i}{D_m} \right) = \begin{cases} 0.843 \left( \frac{D_i}{D_m} \right)^{-1} & \text{for } \frac{D_i}{D_m} \leq 0.4 \\ \left[ \frac{\log(19)}{\log \left( 19 \frac{D_i}{D_m} \right)} \right]^2 & \text{for } \frac{D_i}{D_m} > 0.4 \end{cases} \quad (3-77b)$$

i.e., the modified Egiazaroff relation. Note that in the above relation  $D_m$  denotes a mean surface grain size calculated in accordance with the arithmetic rule of Eq. (3-10) rather than the geometric rule of Eqs. (3-5a) and (3-6a). This treatment of grain statistics appears to be a legacy of Egiazaroff (1965), who likely did not perceive clearly the difference between  $D_g$  and  $D_m$ . Ashida and Michiue recommend the following value for  $\tau_{scm}^*$ :

$$\tau_{scm}^* = 0.05 \quad (3-77c)$$

Shear stress is based on skin friction. Ashida and Michiue provide their own method for removing form drag. The database used to develop the relation consists mostly of experiments with a sand bed, but experiments using pea gravel were also a significant component. The relation, however, is difficult to apply to many natural gravel-bed streams due to the high value of  $\tau_{scm}^*$ . In particular, the average value of the bank-full Shields stress  $\tau_{bf50}^*$  based on surface median size in the gravel-bed streams of Fig. 3-23 is only 0.049.

Calculations with the relation of Ashida and Michiue proceed as follows. The grain sizes and fractions ( $D_i, F_i$ ) of the surface layer, the submerged specific gravity of the sediment  $R$ , and the shear velocity associated with skin friction  $u_{*s}$  must be specified. The surface mean grain size  $D_m$  is computed with Eq. (3-12d) (in which  $p_i \rightarrow F_i$ ), the Shields numbers  $\tau_{si}^*$  are computed with Eqs. (3-46) and (3-47), and the critical Shields numbers  $\tau_{sci}^*$  are computed from Eqs. (3-77b,c). The Einstein numbers  $q_i^*$  are then computed from Eq. (3-77a), and the volume transport rates per unit width  $q_i$  from Eq. (3-44b). The total bed-load transport rate per unit width  $q_T$  and fraction bed load in the  $i$ th grain size range  $f_{bi}$  are then computed from Eqs. (3-26) and (3-28).

### 3.7.5 Substrate-Based Relation of Parker, Klingeman, and McLean and Derivative Formulations

The substrate-based relation of Parker et al. (1982a) is based solely on field data, mostly from Oak Creek (Milhous, 1973), but also from the Elbow River, Canada (Hollingshead, 1971), and several other streams. The shear stresses were computed from depth-slope products, and it was assumed that form drag for gravel-transporting flows was negligible. This assumption was made based on visual observation of the channel of Oak Creek at low flow, which is not particularly

sinuous and contains only very subdued bars. In retrospect, however, the assumption may not be entirely accurate. The relations are developed with the aid of an approximate substrate-based similarity collapse similar to the one introduced in Section 3.6.4.

The relation applies only to gravel transport. A bulk sample of substrate in a relatively thick layer immediately below the surface layer is used to characterize the fractions  $\bar{f}_i$ . All sand must be extracted out of the substrate size distribution, and the resulting gravel distribution renormalized so that  $\bar{f}_i$  sums to unity before applying the relation.

The relevant characteristic grain size in the relation is substrate median size  $D_{u50}$ . It does not contain a critical shear stress, but rather uses a reference value  $W_r^*$  of 0.002 in order to determine reference Shields stresses  $\tau_{suri}^*$ . The hiding relation was found to be

$$\frac{\tau_{suri}^*}{\tau_{sur50}^*} = F_{uhr} \left( \frac{D_i}{D_{ug}} \right) = \left( \frac{D_i}{D_{ug}} \right)^{-0.98} \quad (3-78a)$$

where

$$\tau_{sur50}^* = 0.0876 \quad (3-78b)$$

The transport relation is obtained from an approximate similarity collapse of the data. Thus  $R_{pg}$  and  $\sigma$  are dropped from Eq. (3-65), and the parameter  $D_i/D_{u50}$  is folded into the reference Shields stresses, resulting in the relation

$$W_{ui}^* = \frac{Rgq_i}{\bar{f}_i u_{*s}^3} = G_u(\phi) \quad (3-78c)$$

$$\phi = \frac{\tau_{si}^*}{\tau_{suri}^*} \quad (3-78d)$$

where

$$G_u(\phi) = \begin{cases} 0.0025 \exp[14.2(\phi - 1) - 9.28(\phi - 1)^2] & \text{for } 0.95 < \phi < 1.65 \\ 11.2 \left( 1 - \frac{0.822}{\phi} \right)^{4.5} & \text{for } \phi > 1.65 \end{cases} \quad (3-78e)$$

The alternative for  $\phi > 1.65$  in Eq. (3-78e) is based on the Parker (1978b) approximation of the Einstein (1950) relation for uniform sediment.

Calculations with the above relation proceed as follows. The grain sizes and fractions ( $D_i, \bar{f}_i$ ) of the substrate layer, the submerged specific gravity of the sediment  $R$ , and the shear velocity associated with skin friction  $u_{*s}$  must be specified. The substrate median grain size  $D_{u50}$  is computed from by interpolation from the fractions finer. The Shields numbers  $\tau_{si}^*$  are computed with Eqs. (3-46) and (3-47), and the reference Shields numbers  $\tau_{suri}^*$  are computed from Eqs. (3-78a) and (3-78b). The values of  $W_{ui}^*$  and  $q_i$  are then

obtained from Eqs. (3-78c) to (3-78e). The total bed-load transport rate per unit width  $q_T$  and fraction bed load in the  $i$ th grain size range  $f_{bi}$  are then computed from Eqs. (3-26) and (3-28).

Equations (3-78a) and (3-78b) engender a remarkable simplification that merits note. By replacing the exponent  $-0.98$  in Eq. (3-78a) with  $-1$ , corresponding to the equal-threshold condition, and substituting into Eq. (3-78c), it is found that grain size  $D_i$  exactly cancels out, resulting in the relation

$$\phi = \frac{\tau_{si}^*}{\tau_{suri}^*} = \frac{\tau_{si}^*}{\tau_{sur50}^*} \quad (3-78f)$$

$$\tau_{sur50}^* = \frac{\tau_{bs}}{\rho R g D_{u50}} \quad (3-78g)$$

As a result, (3-78c) becomes

$$q_i = \bar{f}_i \frac{u_{*s}^3}{Rg} G_u \left( \frac{\tau_{sur50}^*}{\tau_{suri}^*} \right) \quad (3-78h)$$

Because  $G_u$  has been rendered independent of  $D_i$ , it is quickly verified from Eqs. (3-28) and (3-78h) that

$$f_{bi} = \bar{f}_i \quad (3-78i)$$

That is, all sizes in the substrate are represented in the same proportion in the bed load. This defines an extreme case of substrate-based equal mobility.

Parker et al. (1982a) went on to demonstrate that perfect substrate-based equal mobility is not in fact satisfied because the similarity collapse of Eq. (3-78c) is not perfect. Lower flood flows are biased toward finer gravel, and higher flood flows are biased toward coarser gravel. This notwithstanding, substrate-based equal mobility is approximately satisfied in terms of the annual yield of gravel.

Parker et al. (1982a) extended their treatment to include deviation from perfect similarity. The resulting substrate-based transport relation contains three gravel size ranges and correctly predicts the tendency for median bed-load gravel size to increase with increasing stage. Parker and Klingeman (1982) extended this three-size treatment to a surface-based model. Diplas (1987) further refined the work with a detailed analysis of deviation from similarity, resulting in a model that can clearly define the degree of transport selectivity in Oak Creek. Bakke et al. (1999) have used the basic model of Parker and Klingeman (1982) to develop a modified predictor allowing for efficient site-specific calibration.

### 3.7.6 Surface-Based Relation of Parker

A substrate-based bed-load transport relation can be used for gross predictions of sediment transport. In a local sense, however, it is surface material that directly exchanges sediment with the bed load. As a result, it is not obvious how to

implement the active-layer formulation of Section 3.5 with a substrate-based bed-load formulation. This renders numerical modeling of bed-level variation and sorting difficult. In addition, it will be demonstrated in Section 3.11 that the grain-size distribution of the surface layer may vary dynamically with flow conditions.

With this in mind, Parker (1990a) reanalyzed the Oak Creek data to determine a surface-based bed-load transport formula. Again, all sand must be excluded from the surface grain-size distribution and the fractions  $F_i$  renormalized to sum to unity before applying the model. The reasons for the exclusion of sand are that (1) during flood flows capable of moving the gravel the sand may be suspended and carried as throughput load, with little interaction with the bed other than a passive filling of gravel pores, and (2) many rivers (although not Oak Creek) are strongly bimodal, with a paucity of pea gravel, thus defining a natural cutoff size for gravel. The model takes the form

$$W_i^* = \frac{Rgq_i}{F_i u_{*s}^3} = 0.00218G(\phi) \quad (3-79a)$$

where

$$\phi = \omega \phi_{sgo} \left( \frac{D_i}{D_g} \right)^{-0.0951} \quad (3-79b)$$

$$\phi_{sgo} = \frac{\tau_{sg}^*}{\tau_{ssrg}^*} \quad (3-79c)$$

$$\tau_{sg}^* = \frac{\tau_{bs}}{\rho RgD_g} \quad (3-79d)$$

$$\tau_{ssrg}^* = 0.0386 \quad (3-79e)$$

$$G(\phi) = \begin{cases} 5474 \left( 1 - \frac{0.853}{\phi} \right)^{4.5} & \text{for } \phi > 1.59 \\ \exp[14.2(\phi - 1) - 9.28(\phi - 1)^2] & \text{for } 1 \leq \phi \leq 1.59 \\ \phi^{14.2} & \text{for } \phi < 1 \end{cases} \quad (3-79f)$$

$$\omega = 1 + \frac{\sigma}{\sigma_o(\phi_{sgo})} [\omega_o(\phi_{sgo}) - 1] \quad (3-79g)$$

Finally the functions  $\sigma_o(\phi_{sgo})$  and  $\omega_o(\phi_{sgo})$  are specified in Fig. 3.36. Tables for these functions are given in Parker (1990b), along with a DOS implementation of the described method, ACRONYM1.

Observations of the state of the bed surface of Oak Creek during floods transporting bed load were not possible (Milhous 1973). As a result, the above equation is

Fig. 3.36. Plots of the functions  $\sigma_o(\phi_{sgo})$  and  $\omega_o(\phi_{sgo})$  for the Parker (1990a) relation.

not based on direct measurements of the composition of the surface layer during floods. Rather, the variation in  $F_i$  as a function of stage was inferred in the derivation of the relation. When applied to Oak Creek with a varying gravel bed-load transport rate and a constant gravel bed-load grain-size distribution, the model predicts a tendency for the surface layer to become finer with increasing stage, eventually approaching the composition of the substrate. That is, the model predicts that at very high stages the bed should be unarmored. This is exactly what is observed in some ephemeral streams subject to violent floods, such as the Nahal Eshtemoa (Powell et al. 2001). The issue is explored in more detail in Section 3.11.3. Some debate about this result remains, however, because in point of fact the gravel bed-load grain-size distribution becomes coarser with stage in Oak Creek.

Calculations with this relation proceed as follows. The grain sizes and fractions ( $D_i$ ,  $F_i$ ) of the surface layer (from which the sand has been excluded), submerged specific gravity of the sediment  $R$ , and shear velocity associated with skin friction  $u_{*s}$  must be specified. The surface geometric grain size  $D_g$  and arithmetic standard deviation  $\sigma$  are computed from Eqs. (3-6a) and (3-6b) with the transformation  $p_i \rightarrow F_i$ . The Shields number  $\tau_{sg}^*$  is computed with Eqs. (3-79d) and (3-47). The values of  $W_i^*$  and  $q_i$  are then obtained from Eq. (3-79a) with the aid of Eqs. (3-79b), (3-79c), (3-79e), (3-79f), and (3-79g). The total bed-load transport rate per unit width  $q_T$  and fractional bed load in the  $i$ th grain size range  $f_{bi}$  are then computed from Eqs. (3-26) and (3-28).

### 3.7.7 Surface-Based Entrainment Relation of Tsujimoto

In a bed-load entrainment model of the type specified in Eqs. (3-39) to (3-41) it is necessary to specify expressions for  $E_i$  and  $L_{si}$  along the lines of Eqs. (3-70a) and (3-70b). Tsujimoto

and Motohashi (1990) and Tsujimoto (1991; 1999) have developed such forms:

$$E_i^* = 0.02 \tau_{si}^* \left( 1 - 0.7 \frac{\tau_{sci}^*}{\tau_{si}^*} \right)^3 \quad (3-80a)$$

$$\left\{ \begin{array}{l} 0.843 \left( \frac{D_i}{D_m} \right)^{-1} \text{ for } \frac{D_i}{D_m} \leq 0.4 \end{array} \right. \quad (3-80b)$$

$$\frac{\tau_{sci}^*}{\tau_{scm}^*} = F_{hc} \left( \frac{D_i}{D_m} \right) = \left\{ \begin{array}{l} \frac{\log(19)}{\log \left( 19 \frac{D_i}{D_m} \right)} \text{ for } \frac{D_i}{D_m} > 0.4 \end{array} \right. \quad (3-80c)$$

$$\left\{ \begin{array}{l} L_{si}^* = L_{so}^* \end{array} \right. \quad (3-80d)$$

In these relations the arithmetic mean grain size  $D_m$  is specified by the arithmetic rule of Eq. (3-10) rather than the geometric rule of Eqs. (3-5a) and (3-6a). The hiding function is the same one as used by Ashida and Michiue (1972), i.e., the modified Egiazaroff (1965) relation. The critical Shields stress  $\tau_{scm}^*$  is in general a function of  $R_{pm}$  that appears to be specified in Nakagawa et al. (1982), but takes the value 0.05 in the limit of large  $R_{pm}$ , i.e., the same limit as in Ashida and Michiue (1972). In addition, Tsujimoto (1990) rather vaguely specifies  $L_{so}^*$  as “almost constant” among grain sizes and taking a value between 10 and 30, i.e., “smaller... than the value for uniform size material (80–250).”

In the case of bed-load transport that can be approximated as quasi-uniform at the scale of the step length, Eq. (3-41), the definitions of Eqs. (3-70a) and (3-70b) and the preceding relations yield the following expression for bed-load transport rate:

$$q_i^* = E_i^* L_{si}^* = 0.02 L_{so}^* \tau_{si}^* \left( 1 - 0.7 \frac{\tau_{sci}^*}{\tau_{si}^*} \right)^3 \quad (3-80e)$$

The main reason for including this relation is the illustration of a bed-load transport relation obtained from considerations of entrainment into bed load. The equation itself is not of sufficient generality to recommend it as a general method for calculating bed-load transport in gravel-bed streams.

### 3.7.8 Surface-Based Relation of Hunziker and Jaeggi

The surface-based relation of Hunziker and Jaeggi (2002) represents a generalization of the relation of Meyer-Peter and Müller (1948). It was developed in order to obtain a description of both static and mobile armoring in rivers. The experiments on mobile armoring reported in Suzuki and Kato (1991) and Suzuki and Hano (1992) were used to help develop and verify the model. The formulation is expressed as

$$q_i^* = 5 \left( \frac{D_i}{D_m} \right)^{-3/2} \left[ \left( \frac{D_i}{D_m} \right)^{-\alpha} (\tau_{sm}^* - \tau_{scm}^*) \right]^{1.5} \quad (3-81a)$$

$$\tau_{sm}^* = \frac{\tau_{bs}}{\rho R g D_m} \quad (3-81b)$$

$$\tau_{scm}^* = \tau_{scmo}^* \left( \frac{D_{um}}{D_m} \right)^{0.33} \quad (3-81c)$$

$$\tau_{scmo}^* = 0.05 \quad (3-81d)$$

$$\alpha = 0.011 (\tau_{sm}^*)^{-1.5} - 0.3 \quad (3-81e)$$

where

$D_m$  = mean surface size and

$D_{um}$  = substrate size,

computed from the arithmetic rule of Eq. (3-10) rather than the geometric rule of Eqs. (3-5a) and (3-6a).

Calculations with the relation of Hunziker and Jaeggi proceed as follows. The grain sizes and fractions ( $D_i, F_i, f_i$ ) of the surface and immediate substrate layers, submerged specific gravity of the sediment  $R$  and shear velocity associated with skin friction  $u_{*s}$  must be specified. The surface and substrate mean grain sizes  $D_m$  and  $D_{um}$  are computed from Eq. (3-12d) with the respective transformations  $p_i \rightarrow F_i$  and  $p_i \rightarrow f_i$ . The Shields number  $\tau_{sm}^*$  is computed with Eqs. (3-81b) and (3-47), and the Einstein numbers  $q_i^*$  are then computed from Eq. (3-81a) with the aid of Eqs. (3-81c) to (3-81e). The volume transport rates per unit width  $q_i$  are obtained from Eq. (3-44b). The total bed-load transport rate per unit width  $q_T$  and fraction bed load in the  $i$ th grain size range  $f_{bi}$  are then computed from Eqs. (3-26) and (3-28).

### 3.7.9 Two-Fraction Relation of Wilcock and Kenworthy

A unique set of experiments on the transport of sand-gravel mixtures in a recirculating flume (Wilcock et al. 2001) has allowed quantification of the interplay between the sand and gravel components of a mixture undergoing bed-load transport. The experiments, in which sand content in the bulk material varies from 6.2 to 34%, reveal a degree of interaction that was not foreseen by, e.g., Parker (1990a), in whose relation the sand is excluded from the surface grain-size distribution before the gravel bed-load transport is computed.

Consider a sediment mixture undergoing bed-load transport in, for example, a sediment feed flume. Now increase the feed rate of a range of the finest grain sizes undergoing bed-load transport without changing the feed rate of the coarser sizes. The increased feed of finer sizes has the effect of lowering  $D_{50}$ , and so increases the Shields stress  $\tau_{s50}^*$ , given as

$$\tau_{s50}^* = \frac{\tau_{sb}}{\rho R g D_{50}} \quad (3-82)$$

The result is increased mobility of all sizes. The model of Parker (1990a) can capture this effect when fine gravel is added, but it is unable to capture it when sand is added because the sand is explicitly excluded from the grain-size distribution.

Wilcock et al. (2001) have demonstrated that the addition of sand results in an effect that is stronger than that embodied in the increase of  $\tau_{s50}^*$  through decreased  $D_{50}$ . In particular, the addition of sand can dramatically lower the reference Shield stress for gravel. This effect was first described in Wilcock (1998a). (Recall that a reference Shields stress is a surrogate for critical Shields stress.)

Wilcock and Kenworthy (2002) captured this effect in terms of a two-fraction model such that grain size  $D_1$  characterizes the sand and size  $D_2$  characterizes the gravel. The model was developed with both the laboratory data reported in Wilcock et al. (2001) and field data from the East Fork River, Wyoming (Emmett et al. 1980); Goodwin Creek, Mississippi (Kuhnle 1992); Jacoby Creek, California (Lisle 1989); and Oak Creek, Oregon (Milhous 1973). Their model is presented in both surface-based and substrate-based forms. Only the surface-based form is presented here; the reader is referred to the original reference for the substrate-based form:

$$W_i^* = \frac{R g q_i}{F_i u_{*s}^3} = G(\phi) \quad (3-83a)$$

$$\phi = \frac{\tau_{si}^*}{\tau_{ssri}^*} = \frac{\tau_{bs}}{\tau_{bssri}} \quad (3-83b)$$

$$G = \begin{cases} 0.002\phi^{7.5} & \text{for } \phi < \phi' \\ A \left(1 - \frac{\chi}{\phi^{0.25}}\right)^{4.5} & \text{for } \phi \geq \phi' \end{cases} \quad (3-83c)$$

$$\tau_{ssri}^* = \tau_{ssri,\max}^* - \frac{\tau_{ssri,\max}^* - \tau_{ssri,\text{sand}}^*}{1 + \exp(-kF_1)} \quad (3-83d)$$

Recall here that  $i = 1$  corresponds to sand and  $i = 2$  corresponds to gravel; thus  $F_1$  and  $F_2$  correspond to the content of sand and gravel, respectively, in the surface layer. The form of  $G$  has a steep dependence on  $\phi$  for low stage, in the manner of Paintal (1971), and incorporates a modified form of the Parker (1978b) approximation to the Einstein (1950) relation for higher stage. In the above relations,

$$A = \begin{cases} 70, & \text{laboratory} \\ 115, & \text{field} \end{cases} \quad (3-83e)$$

$$\chi = \begin{cases} 0.908, & \text{laboratory} \\ 0.923, & \text{field} \end{cases} \quad (3-83f)$$

$$\phi' = \begin{cases} 1.19, & \text{laboratory} \\ 1.27, & \text{field} \end{cases} \quad (3-83g)$$

$$\tau_{ssr1,\max}^* = \tau_{ssr2,\max}^* \frac{D_2}{D_1} \quad (3-83h)$$

$$\tau_{ssr2,\max}^* = 0.061 \quad (3-83i)$$

$$\tau_{ssr1,\text{sand}}^* = 0.065 \quad (3-83j)$$

$$\tau_{ssr2,\text{sand}}^* = 0.011 \quad (3-83k)$$

$$k = 20 \quad (3-83l)$$

It is Eq. (3-83d) that plays the key role of increasing the mobility of gravel as sand content is increased.

Note that in Eqs. (3-83e) to (3-83g) the constants in the relations differ between laboratory and field. There is a reason why the same underlying sediment transport relation might be expressed somewhat differently in the field as compared to the laboratory, even though the underlying physics is identical. This issue is discussed in more detail in Section 3.7.16.

To apply the above formulation, it is necessary to specify the characteristic grain sizes  $D_1$  for the sand portion and  $D_2$  for the gravel portion of the surface layer, the fractions  $F_1$  and  $F_2$  of sand and gravel, respectively, in the surface layer, the submerged specific gravity of the sediment  $R$ , and shear the velocity associated with skin friction  $u_{*s}$ . The Shields numbers  $\tau_{si}^*$  are computed with Eqs. (3-46) and (3-47), and the parameters  $\tau_{ssri}^*$  are evaluated from Eq. (3-83d) with the aid of Eqs. (3-83e) to (3-83l). The parameters  $W_i^*$  and  $q_i$  are obtained from Eqs. (3-83a) to (3-83c). The total bed-load transport rate per unit width  $q_T$  and fraction bed load in the  $i$ th grain size range  $f_{bi}$  are then computed from Eqs. (3-26) and (3-28).

### 3.7.10 Surface-Based Relation of Wilcock and Crowe

The surface-based relation of Wilcock and Crowe (2003) generalizes the two-grain method of Wilcock and Kenworthy (2002) to an arbitrary number of grain size ranges of both gravel and sand. That is, not only is the sand not excluded from the method, but also it plays an important role in determining the gravel transport rate. A reference value  $W_r^*$  of 0.002 was used to determine the reference stresses. The relation can be stated as

$$W_i^* = \frac{R g q_i}{F_i u_{*s}^3} = G(\phi) \quad (3-84a)$$

$$G = \begin{cases} 0.002\phi^{7.5} & \text{for } \phi < 1.35 \\ 14 \left(1 - \frac{0.894}{\phi^{0.5}}\right)^{4.5} & \text{for } \phi \geq 1.35 \end{cases} \quad (3-84b)$$

$$\phi = \frac{\tau_{sg}^*}{\tau_{ssrg}^*} \left( \frac{D_i}{D_g} \right)^{-b} \quad (3-84c)$$

$$\tau_{ssrg}^* = 0.021 + 0.015 \exp(-14F_s) \quad (3-84d)$$

$$b = \frac{0.69}{1 + \exp(1.5 - D_i / D_g)} \quad (3-84e)$$

where  $\tau_{sg}^*$  is given by Eq. (3-79d) and  $F_s$  = fraction of surface layer material that is sand.

The essential role of sand is to depress the reference Shields stress  $\tau_{ssrg}^*$  via Eq. (3-84d). This in turn increases the mobility of all sizes, including gravel. The experiments of Wilcock et al. (2001), which were used to develop the above relation, clearly show that the addition of sand to a sand-gravel mix in a sediment-recirculating flume can increase the transport rate of gravel, in some cases substantially. Cui et al. (2003b) have confirmed this effect in an experimental study of sediment pulses in gravel-bed rivers using a sediment-feed flume.

The surface-based relation of Wilcock and Crowe (2003) has not yet been tested against field data. A notable aspect of the experiments used to develop the relation is the fact that the surface size distribution was measured immediately after a flow event, before substantial reworking could take place. In this sense, the relation is truly a surface-based relation. In point of fact the armor layer showed little variability in grain-size distribution with stage over the range of the experiments.

Calculations with this relation proceed as follows. The grain sizes and fractions ( $D_i$ ,  $F_i$ ) of the surface layer, the submerged specific gravity of the sediment  $R$ , and the shear velocity associated with skin friction  $u_{*s}$  must be specified. The surface geometric mean size  $D_g$  is computed from the fractions finer in the surface material and  $\tau_{sg}^*$  is evaluated from Eqs. (3-82) (but with  $D_{50} \rightarrow D_g$  therein) and (3-47). The fraction  $F_s$  of the surface material that is sand is computed from the fractions  $F_i$ . The values of  $W_i^*$  and  $q_i$  are then obtained from Eqs. (3-84a) with the aid of Eqs. (3-84b) to (3-84e). The total bed-load transport rate per unit width  $q_T$  and fraction bed load in the  $i$ th grain size range  $f_{bi}$  are then computed from Eqs. (3-26) and (3-28).

### 3.7.11 Relation of Wu, Wang, and Jia

The bed-load transport relation of Wu et al. (2000) was developed using data from one set of experiments using poorly sorted sand (Samaga et al. 1986), three sets of experiments using poorly sorted gravel (Liu 1986; Kuhnle 1993; Wilcock and McArdeil 1993), and five gravel-bed streams in the United States (Williams and Rosgen 1989). The model appears to be substrate-based, but the authors nowhere make a distinction between surface and substrate. The reference stress method was used to develop a hiding function. The relation can be expressed in the form

$$W_{ui}^* = \frac{Rgq_i}{\bar{f}_i u_{*s}^3} = 0.0053 \frac{1}{(\tau_{si}^*)^{3/2}} \left( \frac{\tau_{si}^*}{\tau_{suri}^*} - 1 \right)^{2.2} \quad (3-85a)$$

$$\tau_{suri}^* = \tau_{suro}^* \left( \frac{p_{ei}}{p_{hi}} \right)^{-0.6} \quad (3-85b)$$

$$\tau_{suro}^* = 0.03 \quad (3-85c)$$

$$p_{ei} = \sum_{j=1}^N \bar{f}_j \frac{D_i}{D_i + D_j} \quad (3-85d)$$

$$p_{hi} = \sum_{j=1}^N \bar{f}_j \frac{D_j}{D_i + D_j} \quad (3-85e)$$

The authors also suggested a framework for removing form drag from the boundary shear stress based on adjusted Manning's  $n$ , but they did not specify how to implement it.

Wu et al. attempted to verify their bed-load relation in two ways. First, they compared the predictions of their relation in the limiting case of uniform sediment against 1859 sets of data from the compendium of Brownlie (1981), obtaining excellent agreement. The paper does not state, however, how many of the data refer to gravel. Second, they compared predictions for mixtures against laboratory and field data, all of which pertain to sand-bed streams. Again, excellent agreement is reported. The method awaits an independent test against a field gravel-bed stream.

Calculations with this relation proceed as follows. The grain sizes and fractions ( $D_i$ ,  $\bar{f}_i$ ) of the substrate layer, the submerged specific gravity of the sediment  $R$ , and shear velocity associated with skin friction  $u_{*s}$  must be specified. The parameters  $p_{ei}$  and  $p_{hi}$  are computed from Eqs. (3-85d) and (3-85e). The values of  $\tau_{suri}^*$  are computed from Eqs. (3-85b) and (3-85c). The values of  $W_i^*$  and  $q_i$  are then obtained from Eq. (3-85a).

### 3.7.12 Relation of Powell, Reid, and Laronne

The bed-load relation of Powell et al. (2001, 2003) is solely based on field data from the Nahal Eshtemoa, an ephemeral stream in Israel subject to occasional violent floods. The streambed is virtually unarmored when the channel is dry. As a result it is not possible to use the data to discriminate between a surface-based and a substrate-based model. This notwithstanding, the model is treated as a surface-based formulation here.

The transport relation is based on the Parker (1978b) approximation to the Einstein (1950) relation. It is assumed that all material below 2 mm is removed and the grain-size distribution renormalized so that it sums to unity before application of the model, which takes the form

$$W_i^* = \frac{Rgq_i}{F_i u_{*s}^3} = 11.2 \left( 1 - \frac{1}{\phi} \right)^{4.5} \quad (3-86a)$$

$$\phi = \frac{\tau_{si}^*}{\tau_{sci}^*} \quad (3-86b)$$

$$\frac{\tau_{sci}^*}{\tau_{sc50}^*} = F_{hc} \left( \frac{D_i}{D_{50}} \right) = \left( \frac{D_i}{D_{50}} \right)^{-0.74} \quad (3-86c)$$

$$\tau_{sc50}^* = \frac{\tau_{bsc}}{\rho R g D_{50}} = 0.03 \quad (3-86d)$$

Equation (3-86b) can be reduced with Eq. (3-86c) to yield

$$\phi = \frac{\tau_{s50}^*}{\tau_{sc50}^*} \left( \frac{D_i}{D_{50}} \right)^{-0.26} \quad (3-86e)$$

Although the model was not verified with data under conditions of mobile-bed armoring, it appears to have all the characteristics necessary to predict it.

Calculations with the above relation proceed as follows. The grain sizes and fractions ( $D_i$ ,  $F_i$ ) of the surface layer (from which the sand has been excluded), the submerged specific gravity of the sediment  $R$ , and the shear velocity associated with skin friction  $u_{*s}$  must be specified. The surface median size  $D_{50}$  is computed from the fractions finer in the surface material. The Shields numbers  $\tau_{si}^*$  are computed with Eqs. (3-46) and (3-47). The values of  $W_i^*$  and  $q_i$  are then computed from Eq. (3-86a) with the aid of Eqs. (3-86b) to (3-86d). The total bed-load transport rate per unit width  $q_T$  and fraction bed load in the  $i$ th grain size range  $f_{bi}$  are then computed from Eqs. (3-26) and (3-28).

### 3.7.13 Relation of Ackers and White Extended with Proffitt and Sutherland's Hiding Function

The total bed-material load predictor of Ackers and White (1973) has already been introduced in Chapter 2. It is based on a characteristic grain size  $D$  of the bed material and is not designed to compute the grain-size distribution of the transported sediment. In point of fact very few of the data used to develop this relation were in the range of gravel-bed rivers. This notwithstanding, it has been found to be a good predictor of bed-material load in both the laboratory and the field (Brownlie 1981). Several efforts have been made to provide it with a hiding function that would allow generalization to sediment mixtures, including those of Day (1980); Ackers and White (1980); White and Day (1982); and Proffitt and Sutherland (1983). These reformulations were made with gravel-bed rivers specifically in mind. The hiding function due to Proffitt and Sutherland is presented here.

The reader is referred back to Eqs. (2-242a) to (2-242l). The original relation of Ackers and White can be written as

$$q^* = C \frac{U}{\sqrt{RgD}} \left( \frac{U}{u_*} \right)^n \left( \frac{F_{gr}}{A} - 1 \right)^m \quad (3-87a)$$

where the parameter  $F_{gr}$  is specified by Eq. (2-242b) and requires known values of  $u_*$ ,  $u_{*s}$ ,  $R$ , and  $D_{50}$  for its computation. In this form the Einstein number  $q^*$  is related to the transport parameter  $G_{gr}$  of the original relation as

$$G_{gr} = \left( \frac{U}{\sqrt{RgD}} \right)^{-1} \left( \frac{U}{u_*} \right)^{-n} q^* \quad (3-87b)$$

In Eq. (3-87a)  $F_{gr}$  is the primary dimensionless parameter driving sediment transport and  $A$  is the value of  $F_{gr}$  at the threshold of motion. These parameters are defined in Eqs. (2-242a-1); the parameter  $F_{gr}$  contains an exponent  $n$ . The parameters  $A$ ,  $C$ ,  $n$ , and  $m$  are all dependent on a dimensionless grain size  $D_{gr}$ , where in terms of the notation of this chapter

$$D_{gr} = R_{p50}^{2/3} = \left( \frac{\sqrt{RgD_{50}} D_{50}}{v} \right)^{2/3} \quad (3-87c)$$

The generalization to mixtures is here treated as surface-based; it proceeds as follows. Equation (3-87a) is amended to

$$q_{bmi}^* = C_i \frac{U}{\sqrt{RgD_i}} \left( \frac{U}{u_*} \right)^{n_i} \left( \frac{F_{gri}}{A_{ai}} - 1 \right)^{m_i} \quad (3-87d)$$

where

$$q_{bmi}^* = \frac{q_{bmi}}{F_i \sqrt{RgD_i} D_i} \quad (3-87e)$$

$$u_* = \sqrt{\frac{\tau_b}{\rho}} \quad (3-87f)$$

In these relations  $\tau_b$  denotes boundary shear stress at the bed,  $u_*$  denotes shear velocity (total values, not skin friction only), and  $q_{bmi}$  denotes the total volume bed-material transport rate (bed load plus bed-material suspended load) per unit width per unit time. The parameters  $F_{gri}$ ,  $A_{ai}$ ,  $C_i$ ,  $n_i$ , and  $m_i$  are all computed as in the original relation, but with the transformation  $D_{50} \rightarrow D_i$ . The adjusted value  $A_{ai}$  embodying the hiding function is given as

$$\frac{A_{ai}}{A_i} = \begin{cases} \frac{1}{1.3} \text{ for } \frac{D_i}{D_u} > 3.7 \\ \frac{1}{0.53 \log(D_i/D_u) + 1} \text{ for } 0.075 < \frac{D_i}{D_u} < 3.7 \\ \frac{1}{0.4} \text{ for } \frac{D_i}{D_u} < 0.075 \end{cases} \quad (3-87g)$$

In addition,  $D_u$  is computed from the relation

$$\frac{D_u}{D_{50}} = f_u(\tau_{50}^*) \quad (3-87h)$$

**Fig. 3-37.** Plot of  $D_u/D_{50}$  as a function of  $\tau_{50}^*$  for the hiding function of Proffitt and Sutherland (1983) as applied to the sediment transport relation of Ackers and White (1973). Reproduced with permission of the International Association for Hydraulic Research (IAHR).

where

$$\tau_{50}^* = \frac{\tau_b}{\sqrt{RgD_{50}}} \quad (3-87i)$$

The relation is given graphically in Fig. 3-37a.

The original relation of Ackers and White (1973) was developed using the same database as was used for the hydraulic resistance relation of White et al. (1980). It thus may be inferred that the relations should be used as a pair and that this also holds for the extension to mixtures.

In applying the above relation the grain sizes and surface layer fractions ( $D_p$ ,  $F_p$ ), the cross-sectionally averaged flow velocity  $U$ , the shear velocity  $u_*$ , the submerged specific gravity of the sediment  $R$ , and the kinematic viscosity of water  $\nu$  must be specified. The surface median size  $D_{50}$  is computed from the grain-size distribution of the surface layer, and  $\tau_{50}^*$  and  $D_u$  are computed from Eqs. (3-87f), (3-87h), and (3-87i). The parameters  $n_p$ ,  $m_p$ ,  $F_{gr}$ ,  $A_p$ , and  $C_i$  are all computed from the relations in Chapter 2, but with the transformation  $D_{50} \rightarrow D_p$ . The values of  $A_{ai}$  are computed from Eq. (3-87g). The values of  $q_{bmi}^*$  and  $q_{bmi}$  are then computed from Eqs. (3-87d) and (3-87e).

### 3.7.14 Other Bed-Load Transport Relations for Mixtures

The preceding relations represent only a sample of those available in the literature that describe the bed-load transport of sediment mixtures. Some others follow.

Proffitt and Sutherland (1983) generalized the Paintal (1971) transport relation to mixtures by developing a hiding relation, and used it to study the development of static armor. Misri et al. (1984) developed a new relation for bed-load transport of uniform material and generalized it to mixtures, using their own set of experimental data. The analysis clearly illustrates the failure of the Einstein (1950) hiding function. The only reason their relation is not presented in detail here is that the data used to develop the hiding function for mixtures are all restricted to the range of very coarse sand and

pea gravel. Samaga et al. (1986) extended and corrected the model of Misri et al. (1984), this time including data from several rivers.

The Yang (1973) total bed-material transport relation presented in Chapter 2 was developed for the prediction of sediment transport in sand-bed streams, and uses only a single sediment size. Yang (1984) extended this relation for gravel, again using only a single sediment size. Yang and Wan (1991) further extend these relations to allow grain-size specific calculations of bed-material transport of sediment mixtures, including gravel. These methods are summarized in Yang (1996).

Bridge and Bennett (1992) developed a Bagnold-type stream power formulation for the bed-load transport of mixtures. The model is notable in that it pays attention to differences in shape and density as well as size. Belleudy and SOGREAH (2000) adapted the bed-material load predictor of Engelund and Hansen (1967) to mixtures in order to study bed-load transport. Their treatment of hiding had not yet been published at the time of writing of this chapter. Kleinhans and van Rijn (2002) generalized the bed-load transport relations of Meyer-Peter and Müller (1948) and van Rijn (1984) to mixtures. The generalization incorporates a stochastic submodel in order to increase the accuracy of predictions near the threshold of motion. In addition to the hiding function of Egiazaroff (1965), the model also contains an empirical “hindrance” factor to account for the difficulty of movement of finer grains over and through a bed of coarser grains.

One relation that does not specifically pertain to mixtures merits mention here. Smart and Jaeggi (1983) and Smart (1984) have developed a bed-load transport relation specifically designed for channels with steep slopes, in excess of 3%. The data used to develop the relation were also used to show that the Meyer-Peter and Müller (1948) relation, for example, seriously underestimates the bed-load transport rate for such slopes. Their predictor yields only transport rates and not size distributions. This notwithstanding, many of the experiments used to develop it were performed with poorly sorted sediment. The issue of grain-size distribution is of interest because Solari and Parker (2000) have documented and explained a reversal in mobility, with coarse grains rendered more mobile than fine grains in a mixture, at slopes exceeding about 2%.

Carson and Griffiths (1987) summarize several bed-load transport formulations and apply them to gravel-bed streams in New Zealand. Useful data on gravel transport for several streams in that country are presented. The treatment does not, however, focus on grain-size specific transport.

### 3.7.15 Sample Applications of Bed-Load Relations

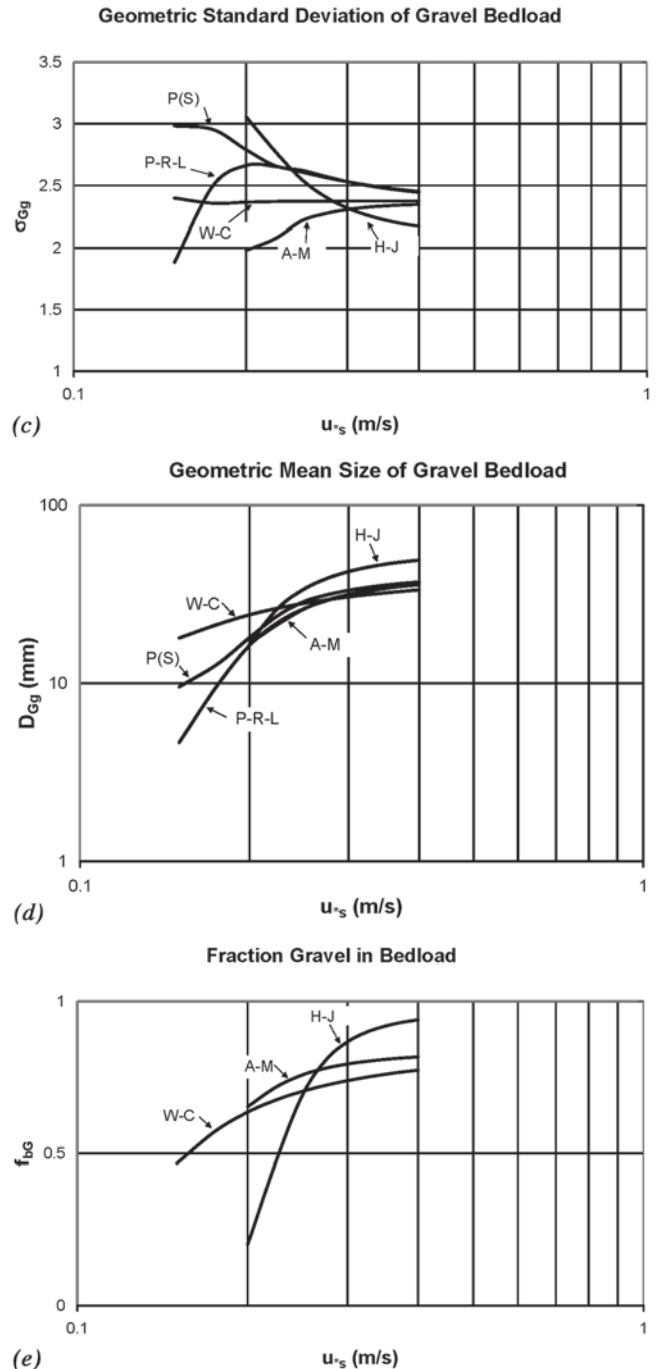

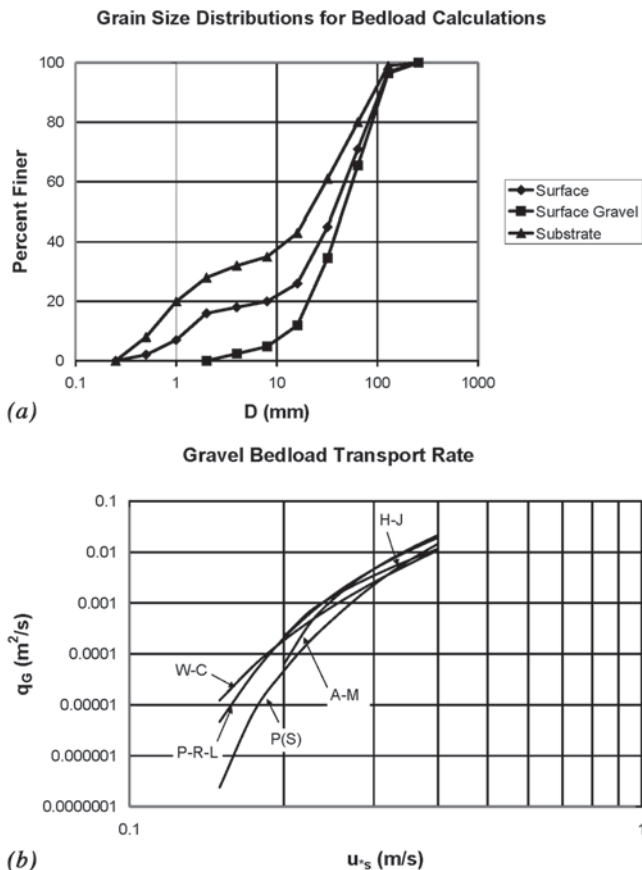

The results of sample calculations applied to a hypothetical gravel-bed river are presented here to illustrate the predictions of several of the relations presented above. The grain-size

distributions of the surface and substrate are presented in Figure 3-38a. The geometric mean size  $D_g$ , arithmetic mean size  $D_m$ , median size  $D_{50}$ , geometric standard deviation  $\sigma_g$ , and sand fraction  $F_s$  of the surface material are given by the respective values 22.3 mm, 46.0 mm, 36.6 mm, 4.93, and 0.16; the corresponding values for the substrate,  $D_{ug}$ ,  $D_{um}$ ,  $D_{u50}$ ,  $\sigma_{ug}$ , and  $F_{us}$ , are respectively 10.9 mm, 33.1 mm, 21.0 mm, 5.22, and 0.28. Also shown in Fig. 3-38a is the renormalized grain-size distribution of the surface with the sand removed, resulting in the respective values of  $D_g$ ,  $D_{50}$ , and  $\sigma_g$  of 40.7 mm, 45.3 mm, and 2.36.

Calculations are performed for the relations of Ashida and Michiue (1972); Parker (1990a); Powell et al. (2001); Hunziker and Jaeggi (2002); and Wilcock and Crowe (2003)—all of which are applied as surface-based relations. In applying the relations of Parker (1990a) and Powell et al. (2001) the sand has been excluded from the surface grain-size distribution, and only the bed-load transport rates of the gravel sizes are calculated. In the other cases, bed-load transport rates of sand are predicted as well.

The hydraulic parameter entering into the calculations is the boundary shear stress due to skin friction  $\tau_{bs}$ , or alternatively the shear velocity due to skin friction  $u_{*s}$  defined by Eq. (3-47). The range of values of  $u_{*s}$  considered is 0.15 to 0.40 m/s, corresponding to a range of Shields numbers  $\tau_{s50}^*$  based

**Fig. 3-38.** Predictions of bedload transport using the relations of Ashida and Michiue (1972) (A-M), Parker (1990a) (P(S)), Powell et al. (2001) (P-R-L), Hunziker and Jaeggi (2002) (H-J), and Wilcock and Crowe (2003) (W-C). (a) Grain-size distributions for bedload calculations, (b) total gravel bedload transport rate, (c) geometric mean size of gravel bedload, (d) gravel geometric standard deviation of gravel bedload, and (e) fraction of gravel in bedload (the rest being sand).

on surface median grain size of the surface material (sand included) of 0.038 to 0.270, where according to Eqs. (3-82) and (3-47)

$$\tau_{s50}^* = \frac{u_{*s}^2}{RgD_{50}} \quad (3-88)$$

Each model is used to compute (1) the total volume gravel bed-load transport rate per unit width  $q_G$  (summed over all gravel sizes; sand excluded), (2) the geometric mean size of the gravel portion of the bed load  $D_{Gg}$ , and (3) the geometric standard deviation of the gravel portion of the bed load  $\sigma_{Gg}$ . In addition, in all cases except the Parker (1990a) and Powell et al. (2001) relations, which exclude sand from the calculation, the fraction  $f_{bG}$  of the bed load consisting of gravel is computed.

The results are shown in Figs. 3-38(b–e). In Fig. 3-38b it is seen that the predictions for  $q_G$  fall well within an order of magnitude at all but the lowest shear velocities. The relations of Ashida and Michiue (1972) and Hunziker and Jaeggi (2002) predict vanishing transport rate for values of  $u_{*s}$  below a value between 0.175 and 0.20 m/s due to the presence of relatively high critical Shields numbers in the formulations. At the highest transport rates the difference between the predicted values of  $q_G$  is less than a factor of 2.

The predictions for  $D_{Gg}$  in Fig. 3-38c are also quite similar. In all cases the gravel bed load becomes coarser with increasing friction velocity, and the degree of coarsening levels off at the highest values of friction velocity. The relations of Hunziker and Jaeggi (2002) and Powell et al. (2001) show the strongest tendency for the gravel bed load to coarsen with friction velocity, and the relation of Wilcock and Crowe (2003) shows the least tendency. Figure 3-38d indicates that the predicted values of  $\sigma_{Gg}$  nearly all fall between 2 and 3, with a tendency for  $\sigma_{Gg}$  to decrease with increasing friction velocity through most or all of the calculated range of  $u_{*s}$  for all relations except Ashida and Michiue (1972).

The most variation among the predictions is in the relation between fraction of gravel in the bed load  $f_{bG}$  and shear velocity  $u_{*s}$  of Fig. 3-38e. This is likely because the tendency for sand in gravel-bed streams to go into suspension rather easily makes the prediction of the bed-load transport of sand rather inaccurate. Note in this regard that the fraction of sand in the bed load is given as  $1 - f_{bG}$ . This comment notwithstanding, for values of  $u_{*s}$  above 0.25 m/s the bed-load transport is predicted to be predominantly gravel for all four relations in the figure.

Some further discussion of Fig. 3-38b is warranted. It is encouraging to see that the predictions of the relations of Ashida and Michiue (1972), Hunziker and Jaeggi (2002), and Wilcock and Crowe (2003), all of which are based on laboratory data, are for the most part bracketed by the field-based relation of Powell et al. (2001) as an upper bound and the field-based relation of Parker (1990a) as a lower bound. This lends confidence to the concept of applying the

results of laboratory studies of gravel transport to field-scale rivers.

These comments notwithstanding, the predictions of the Parker (1990a) relation and that of Powell et al. (2001), both of which are based on field data, do show substantial differences. Some of the possible reasons for these differences, as well as avenues to reducing them in the future, are discussed in Section 3.7.18.

### 3.7.16 Topographic Variability, Patchiness, and Partial Transport

Rivers are not flumes; they are considerably more complex. Flumes are valuable tools for the study of sediment transport, but results based on flume data are not directly transferable to the field without accounting for the spatial and temporal variability characteristic of the field. A vivid example of this is provided by the bed-material load (bed load plus suspended load) predictor of Brownlie (1981). Brownlie found that his regression relation developed for laboratory data was modestly but consistently in discrepancy with his regression for field data. As a result the prediction for load is multiplied by a factor of 1.000 in applying the relation to flume data and a factor of 1.268 in applying the relation to the field.

The reason for this is not hard to decipher. The explanation provided here is adapted from the work of Paola and Seal (1995); Paola (1996); and Paola et al. (1999). Sediment transport predictors are invariably nonlinear in their primary driving parameter, e.g., Shields number. That is, a doubling of Shields number produces more than a doubling of the load. This effect is particularly strong at low transport rates.

To see this, consider a natural channel, with bars, bends, and other elements of channel complexity. Local skin friction can be expected to vary spatially according to some probability distribution. The same holds true for local mean grain size, and thus for the Shields number based on skin friction itself. The more complex the channel is, the higher will be the standard deviations of these fluctuations. In a nonlinear transport relation, zones of high Shields number will magnify the transport rate far more than zones of low Shields stress depress it. The result is to elevate the overall transport rate. In addition, if the transport relation is grain-size-specific and renders finer surface grains more mobile than coarser surface grains, the effect of nonlinearity can also act to bias the load toward the fine grains, especially in the case of relatively low boundary shear stress.

To see this, it is useful to begin with the case of uniform sediment. Consider a bed-load transport relation of the generic form

$$q = \sqrt{RgDD} \left[ \frac{\tau_{bs}}{\rho RgD} - \tau_{sc}^* \right]^{n_L} \quad (3-89a)$$

where

$$\tau_{sc}^* = \text{a critical Shields number}$$

and the exponent  $n_L$  is expected to be greater than unity. In most applications of flume-derived sediment transport relations to the field, the parameters actually put into the equation are the spatial averages, in this case  $\bar{\tau}_{bs}$  and  $\bar{D}$  (the spatial averaging in the case of grain size being performed on the  $\psi$  scale rather than directly on  $D$ ). Because of the nonlinear dependencies in Eqs. (3-89a) and (3-1b) the input of these averaged parameters does not yield  $\bar{q}$ . Instead,

$$\begin{aligned}\bar{q} &= \sqrt{Rg\bar{D}} \left[ \frac{\tau_{bs}}{\rho Rg\bar{D}} - \tau_{sc}^* \right]^{n_L} \\ &= C_{\text{comp}} \sqrt{Rg\bar{D}} \left[ \frac{\bar{\tau}_{bs}}{\rho Rg\bar{D}} - \tau_{sc}^* \right]^{n_L}\end{aligned}\quad (3-89b)$$

where the overbar denotes averaging over a reach containing morphologic complexity and

$C_{\text{comp}}$  = a dimensionless complexity coefficient.

Abbreviating the functional relation of Eq. (3-89b), the above relation can be summarized as

$$\bar{q} = C_{\text{comp}} q(\bar{\tau}_{bs}, \bar{D}) \quad (3-89c)$$

where

$q(x,y)$  = the functional relation; and  
 $C_{\text{comp}} > 1$  = a dimensionless parameter that amplifies the sediment load.

Paola and Seal (1995), Paola (1996), and Paola et al. (1999) describe a way to implement this calculation using probability densities for  $\tau_{bs}$  and  $D$ . They find that  $C$  takes the value of 1 in a straight flume with no bed forms and no local sorting. This value increases with increasing complexity, becoming as large as 3 to 4 in braided streams. The above analysis provides a conceptual explanation for the multiplicative factor 1.268 in the Brownlie (1981) relation; it is none other than the complexity coefficient  $C$ . The fact that it is not larger than 1.268 is likely related to the fact that sediment transport measurements in natural streams are usually taken along the straightest reaches with the least variation possible, e.g., in a straight reach rather than at the apex of a bend. Brownlie (1981) himself was cognizant of this nonlinear amplification effect and explained the factor in terms of it.

This framework receives further verification in terms of the flume experiments of Onishi et al. (1972). Onishi et al. studied sediment transport in two flumes, one straight and the other with meandering sidewalls, but with an average down-channel bed slope that was identical to that of the straight flume. For the same water discharge and sediment size, the sediment transport rate was measurably larger in the meandering flume.

Paola and Seal (1995) have extended this analysis to sediment mixtures. Consider a generic model transport relation of the form

$$q_i = \sqrt{RgD_i} D_i F_i \left[ \frac{\tau_{bs}}{\rho RgD_i} - \tau_{scg}^* \left( \frac{D_i}{D_g} \right)^{-m} \right]^{n_L} \quad (3-90a)$$

where it is again expected that  $n_L > 1$ . Note that the above equation represents a direct generalization of Eq. (3-89a) to mixtures, with the term containing the exponent  $m$  characterizing a hiding function. Again, the parameters actually input in field applications are usually the spatial averages  $\bar{\tau}_{bs}$ ,  $\bar{F}_i$ , and  $\bar{D}_g$ . Again,

$$\begin{aligned}\bar{q}_i &= \sqrt{Rg\bar{D}_i} \bar{D}_i \bar{F}_i \left[ \frac{\tau_{bs}}{\rho Rg\bar{D}_i} - \tau_{scg}^* \left( \frac{\bar{D}_i}{\bar{D}_g} \right)^{-m} \right]^{n_L} \\ &= C_{\text{comp},i} \sqrt{Rg\bar{D}_i} \bar{D}_i \bar{F}_i \left[ \frac{\bar{\tau}_{bs}}{\rho Rg\bar{D}_i} - \tau_{scg}^* \left( \frac{\bar{D}_i}{\bar{D}_g} \right)^{-m} \right]^{n_L}\end{aligned}\quad (3-90b)$$

This relation can be summarized as

$$\bar{q}_i = C_{\text{comp},i} q_i(\bar{\tau}_{bs}, \bar{D}_g, \bar{F}_i) \quad (3-90c)$$

where

$q_i(x,y,z)$  = functional relation for bed-load transport; and  
 $C_{\text{comp},i}$  = dimensionless grain-size-specific complexity coefficients.

Thus

$$\begin{aligned}\bar{q}_T &= \sum_{i=1}^n C_{\text{comp},i} q_i(\bar{\tau}_{bs}, \bar{D}_g, \bar{F}_i) > \sum_{i=1}^n q_i(\bar{\tau}_{bs}, \bar{D}_g, \bar{F}_i) \\ &= q_T(\bar{\tau}_{bs}, \bar{D}_g, \bar{F}_i)\end{aligned}\quad (3-90d)$$

so that the total bed-load transport is amplified. In addition, the morphologically averaged grain-size fractions  $\bar{f}_{bi}$  of the bed load differ from the ones that would be obtained using averaged parameters as input,

$$\bar{f}_{bi} = \frac{\bar{q}_i}{\bar{q}_T} \neq \frac{q_i(\bar{\tau}_{bs}, \bar{D}_g, \bar{F}_i)}{q_T(\bar{\tau}_{bs}, \bar{D}_g, \bar{F}_i)} \quad (3-90e)$$

and this bias is typically in the direction of a finer bed-load size distribution.

Paola and Seal (1995) found a notable enhancement of downstream fining in the North Fork Toutle River, Washington due to the presence of "patches" and "lanes" of sediment mixtures with differing mean sizes. Two of these patches are visible in Fig. 3-7. Paola (1996) outlines an algorithm for the adjustment of any sediment transport relation to account for channel complexity. To implement it, however, the probability distributions of spatial variation in boundary shear stress and grain-size distribution must be known, measured or inferred.

The two-grain relation of Wilcock and Kenworthy (2002) is reconsidered in this light. Recall that the bed-load transport rates in field streams used by them to develop their relation tended to be consistently higher than in the laboratory by a factor that varied with transport rate but was close to 1.64. This difference is most likely not an expression of a fundamental difference in the physics of field streams and laboratory flumes, but rather an expression of the fact that field streams are more complex than flumes.

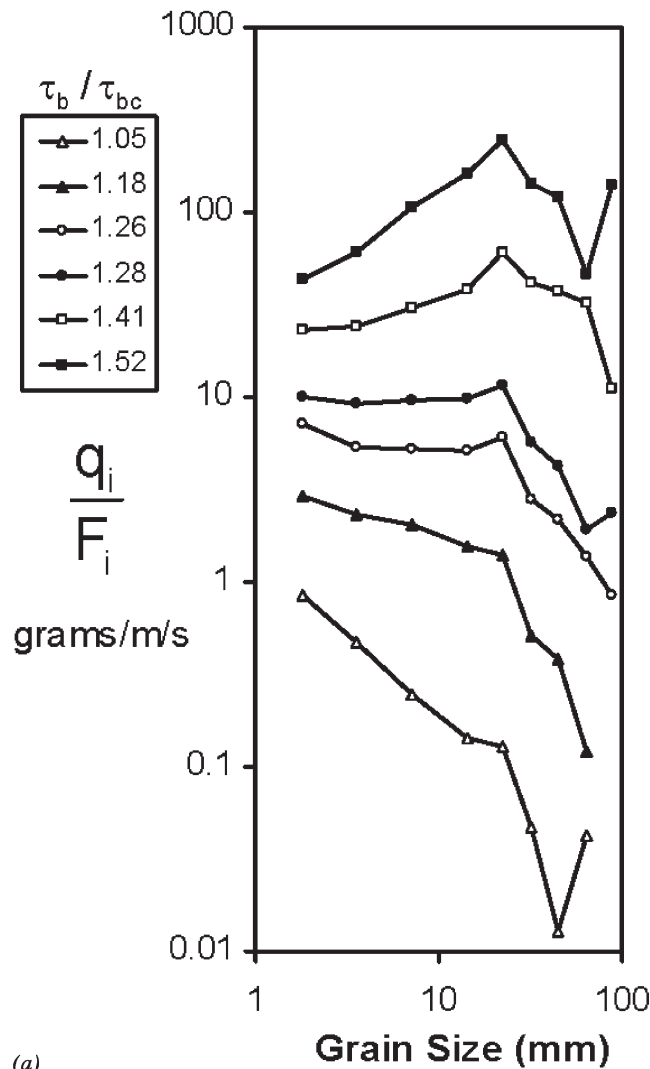

A second issue of particular interest for gravel-bed streams is partial transport. Partial transport may be defined as a condition in which a portion of the grains on the bed surface are actively transported, whereas the balance of the surface grains remain entirely immobile (Wilcock and McArde11 1993). A case of particular interest is when the immobile grains are coarser than a threshold size.

The following thought experiment illustrates one of the dilemmas of partial transport. A flume is supplied with a modest, constant feed of heterogeneous sediment and allowed to develop to a macroscopic mobile-bed equilib-

rium, here called case A. At this equilibrium all sizes fed in must exit the flume at the same macroscopic rate. Now cut off the supply of the very coarsest grains from the feed, and, if necessary, slightly increase the feed rate of the remaining load to prevent bed degradation. Because the bed does not degrade, some of the coarsest grains will remain at least partially exposed on the bed. These exposed grains must, however, attain a configuration (by partial burial, the formation of stone clusters, etc.) such as to eventually render them completely immobile. All the finer sizes continue to move through the system, resulting in case B.

Now the hydraulic conditions have barely changed, but in case A the largest stones are mobile, whereas in case B they are not. At present there is no sediment transport relation that contains enough physics to discriminate between the two cases.

In recent years, however, there has been an increasing interest in partial transport, resulting in a database that may help resolve this issue in the future (Wilcock and McArde11 1993, 1997; Hassan and Church 2000). Figure 3-39 illustrates three

**Fig. 3-39.** Plots of  $q_i/F_i$  versus  $D_i$  for (a) Oak Creek field data as presented by Wilcock (1997a); (b) experiments of Wilcock and McArdell (1997); and (c) Nahal Eshtemoa field data of Powell et al. (2001). (Copyright 1997, 2001 American Geophysical Union. Reproduced by permission of American Geophysical Union.)

plots of the ratio of unit bed-load transport rate  $q_i/F_i$  versus grain size  $D_i$ , one from Oak Creek, Oregon (from Wilcock 1997a); one for the experiments of Wilcock and McArdell (1997); and one from the Nahal Eshtemoa, Israel (Powell et al. 2001). Recalling that the fractions in the bed load  $f_{bi}$  are related to the fractional transport rates  $q_i$  according to Eq. (3-28), it is easily shown that if the ratio  $q_i/F_i$  is constant for all grain sizes  $D_i$  for a given flow, then

$$f_{bi} = F_i \quad (3-91)$$

so that the grain-size distribution of the bed load is identical to that of the bed surface. That is, a condition of perfect surface-based equal mobility prevails. A deviation from this constancy denotes size-selective transport. If  $q_i/F_i$  drops to zero for any grain size range, partial transport prevails.

Figure 3-39a from Oak Creek reveals partial transport with an absence of the coarsest grains in the bed load for

the lowest flow in the diagram, size-selective transport biased toward the finer grains at somewhat higher flows, and near-equal mobility, or rather a slight bias toward the coarser grains, at the highest flows, which transport the bulk of the sediment. Figure 3-39b reveals a much stronger tendency toward partial transport at the lower stages of the experiments of Wilcock and McArdell (1997) in a sediment-recirculating flume, with all sizes in motion and near-equal mobility only at the highest stage in the diagram. In the case of the Nahal Eshtemoa, Fig. 3-39c shows possible partial transport at the two lowest stages, size-selective transport at the two next-higher stages, and near-equal mobility at the seven highest stages.

The issue of partial transport becomes particularly important when the diversion of floodwater from a gravel-bed river is considered. The loss of floodwater may impose a perennial condition of partial transport, with the coarser grains no longer participating in the load. As a result, the bed may

no longer be reorganized and renewed by floods, and habitat may degrade, as in the case of the Trinity River below Lewiston Dam (Kondolf and Wilcock 1996).

### 3.7.17 Surface-Based versus Substrate-Based

A common objection to the use of surface-based formulations is that they require knowledge of the composition of the surface or active layer at any given time to compute the bed-load transport rate. The issue is important because the composition of the surface is free to respond to changes in the flow. Direct information on the composition of the surface is usually available, however, only at low flow, when the bed can be sampled. So it would appear that there is no obvious way to know what surface grain-size distribution to use in the model.

This dilemma is easily resolved. Surface-based models are designed to be implemented in a numerical simulation of the flow and sediment transport. The low-flow composition of the surface is input as an initial condition. The calculation proceeds by solving (1) the grain-size-specific Exner equation of sediment continuity, (2) a surface-based bed-load transport formula, and (3) an appropriate predictor of the flow, e.g., the St. Venant shallow-water equations through a flood hydrograph. In this way the composition of the surface layer is computed along with other parameters such as bed elevation, bed-load transport rate, and bed-load grain-size distribution at every time step of the calculation. The issue is described in more detail in Section 3.10.

In some cases, however, it may not be feasible to implement a full numerical calculation; one may simply wish to estimate the bed-load yield and grain-size distribution over one hydrograph or for a given flow duration curve. In such cases, a substrate-based formulation may be appropriate in that it requires a parameter, i.e., the grain-size distribution of the substrate, that can be measured at low flow and that is unlikely to change much in engineering time.

### 3.7.18 Comparison of Relations against Field Data: Future Developments

There have not been many comprehensive independent tests of predictive relations for bed-load transport of heterogeneous sediments against data, and in particular field data. Two attempts are outlined in Gomez and Church (1989) and van der Scheer et al. (2001). The results are not particularly encouraging. Gomez and Church state that "No formula performs consistently well." In the case of van der Scheer et al., various formulas were compared with three experimental sets, each using a mix of sand and pea gravel with well-developed dunes, as well as the data set due to Day (1980). The first three sets are likely to be outside the

range of applicability of most relations developed for heterogeneous gravel-bed streams. Not surprisingly, most of the relations performed poorly; the Ackers and White (1973) relation with the Proffitt and Sutherland (1983) hiding correction performed the best.

In Fig. 3-40 Reid et al. (1995) have plotted the Einstein number  $q_r^*$  based on total bed-load transport rate summed over all grain sizes and on  $D_{50}$  versus the Shields stress  $\tau_{50}^*$  based on average boundary shear stress and  $D_{50}$  for six rivers: Goodwin Creek, Mississippi, East Fork River, Wyoming, Oak Creek, Oregon, Nahal Yatir, Israel, Turkey Brook, England, UK, and Torlesse Stream, New Zealand. The parameter  $D_{50}$  was measured at low flow. The data from Oak Creek, Turkey Brook, and Nahal Yatir appear to collapse into a single curve. The data from the East Fork, Goodwin Creek, and Torlesse Stream are shifted to the right of this curve, and clearly do not collapse into a single curve. This same shift to the right can be seen in the data of Ashworth and Ferguson (1989) from three streams in Scotland and Norway. Reid et al. note that "Transport efficiency is shown to vary considerably for each stream and from one stream to another, suggesting that it may not be possible to incorporate it easily into bed-load equations in order to improve levels of prediction."

Their conclusion may be overly pessimistic. They themselves point out that Oak Creek, Turkey Brook, and the Nahal Yatir define a relatively consistent relation, a point amplified upon by Almedeij and Diplas (2003). This issue is explored in more detail in Section 3.10. In addition, Wilcock and Kenworthy (2002) have developed a consistent relation for Oak Creek, Goodwin Creek, and the East Fork River, having accounted for the effect of sand content in the bed. A proper accounting of the relevant physics is thus likely to bring most of the disparities into concordance before the next time this manual is revised. Considerations that might help bring about this concordance are given below.

1. As noted in Section 3.7.2, most transport relations for gravel-bed streams gloss over the issue of form drag (as opposed to sand-bed streams). Form drag may be more important than previously thought (Hey 1989; Millar 1999). Form drag associated with channel bars and bends may vary with channel width, slope, standard deviation of the parent sediment, etc. The presence of large, immobile colluvial boulders in streams may contribute to form drag. A form drag predictor for gravel-bed streams needs to be developed.
2. As described in Section 3.7.16, channels with the same mean morphological characteristics may transport sediment differently due to differing levels of complexity. The methodology discussed in that section needs to be implemented for more field streams.

**Fig. 3-40.** Dimensionless Einstein number based on total bedload transport rate  $q_T^*$  versus Shields stress  $\tau_{50}^*$  for six streams: Goodwin Creek, Miss.; East Fork River, Wyo.; Oak Creek, Ore.; Nahal Yatir, Israel; Turkey Brook, England, UK; and Torlesse Stream, New Zealand. From Reid et al. (1995). (Copyright 1995 American Geophysical Union. Reproduced by permission of American Geophysical Union.)

3. As noted in Section 3.7.16, gravel-bed streams with strong tendencies toward partial transport may behave differently from streams with only size-selective transport. Predictive methods specifically including partial transport need to be developed.
4. As illustrated by the relations of Wilcock and Kenworthy (2002) in Section 3.7.9 and Wilcock and Crowe (2003) in Section 3.7.10, variation in the sand content can in some cases dramatically affect the transport of gravel. The recent efforts to quantify this effect need to be redoubled.
5. If the composition of the surface layer changes with stage, the interaction of this variation with the bed-load transport may be intense. The few attempts to quantify this effect in the field (e.g., Andrews and Erman 1986) need to be augmented.
6. Finally, as noted in Section 3.7.2, the fluid mechanics used to calculate primary parameters controlling bed-load transport, such as boundary shear stress, is often much too primitive. In many cases boundary shear stress  $\tau_b$  is estimated from the simple depth-slope product rule for steady, uniform (normal) flow in a wide, rectangular channel:

$$\tau_b = \rho g H S \quad (3-92)$$

where

$S$  = mean bed slope; and

$H$  = mean depth.

The technology currently exists to perform the computations needed to obtain more precise measurements of boundary shear stress, including the effects of hydrograph variation, spatial variation, secondary flow, and convergences and divergences. This technology needs to be applied more consistently to the issue of bed-load transport in gravel-bed rivers.

### 3.8 FIELD DATA

Since *ASCE Manual No. 54*, "Sedimentation Engineering," was published in 1975, a major expansion of the database for the transport of heterogeneous sediments in rivers has taken place. This database serves two functions. First, it allows the engineer working on a problem with a particular stream to identify a similar stream for which the transport rate and grain-size distribution have been measured in order to determine appropriate countermeasures. Second, it is an essential key to future advances in predictive technology. With this in mind, a partial account of this database is provided in Table 3-2.

In addition to the streams of Table 3-2, a research group in Colorado centered around K. Bundt (Bundt et. al., 2004)

has collected a substantial set of data for bed-load transport in small gravel bed streams, mostly in Colorado. When this database becomes public, it should provide a most useful addition to the database represented by Table 3-2.

Wilcock (2001) has outlined a practical method for estimating sediment transport rates in gravel-bed streams. The importance of interaction between field-based and experimental research has been emphasized by Wilcock (2000). Kuhnle et al. (1989) and Kuhnle (1996) have pointed out the

need to consider systematic temporal variation in flow and sediment transport rates, an effect that is likely to be more important in the field than in the laboratory.

### 3.9 ABRASION

In addition to sorting their sediment through selective transport, rivers can also modify their grains through abrasion.

**Table 3-2 Streams for which gravel/sand transport rate and grain-size distribution have been measured:  $S$  denotes slope and  $D_{u50}$  denotes substrate or bulk median size**

\*Denotes surface rather than substrate size.

Gravels and sands that have been in a river for a sufficiently long time tend to be rounded as a consequence of abrasion. This effect is illustrated in Fig. 3-13.

As noted in Section 3.1, many rivers show a clear pattern of downstream fining of characteristic grain size. An example is given in Fig. 3-10. This decrease in characteristic grain size may be due to selective transport of finer grains, abrasion, a tendency for tributaries farther down in the drainage network to deliver finer sediment, or some other cause. To resolve this issue some understanding of fluvial abrasion is necessary.

The issue can be of considerable engineering importance. Large amounts of fresh, and in many cases relatively weak, sediment can enter river systems from natural or human-induced landslides (Fig. 3-12) or from the disposal of waste sediment from, e.g., a mine (Fig. 3-16). This sediment often consists of a mixture of lithologies, each of which has a different resistance to wear. In addition, the sediment may be highly fractured and thus far easier to abrade than material that has been in the river system for some time. In this sense one may think of the gravel in rivers at points far downstream of the source area as the very tough residual of an input that has had all the weaker members ground out of it. Thus if abrasion plays a significant role in the reorganization of inputs of fresh sediment, the gravel bed-load transport rates tens or hundreds of kilometers downstream from the source area may be considerably less than if abrasion had been neglected, because most of the gravel may be ground into sand and silt.

Mine waste in particular may contain such elements as copper, lead, and cadmium, which in bioavailable form can lead to serious damage to riparian ecosystems. One step in the process by which these elements become bioavailable is the grinding of the stones that contain them into silt. The large ratio of surface area to volume of silt-sized grains as compared to gravel facilitates the desorption of toxic elements into the water column. In addition, elevated concentrations of suspended silt in rivers can damage stream habitat by clogging fish gills, reducing visibility, and drowning near-bank and floodplain habitat in mud.

### 3.9.1 Quantification of Abrasion

The focus here is on the abrasion of gravel. The most common sand lithology in rivers, quartz, is highly resistant to abrasion, and the process by which sand grains become rounded is evidently a very slow one. Maunsell and Partners (1982) have demonstrated the very small tendency for sand to abrade as compared to gravel.

In most cases the process of breakdown of a single clast (stone) consists of an initial period during which it may shatter, followed by a much longer period during which it is gradually worn down by abrasion, producing silt and some sand as byproducts. There are several ways in which abrasion is accomplished.

1. In rivers in cold regions, in situ freeze-thaw processes can play a role in abrasion.
2. In meandering gravel-bed rivers with well-developed floodplains, channel migration can result in river gravels being stored under finer material in the floodplain for extended periods of time. This can result in the formation of a thin weathering rind. When the clast in question is re-introduced into the channel by migration or avulsion, the rind may be quickly shed, resulting in one-time abrasion of the clast (Bradley 1970).
3. As gravel clasts are carried downstream as bed load, frequent collisions with other clasts in the bed result in gradual wear, the main byproduct being silt (Shaw and Kellerhals 1982). The following exposition focuses on this type of abrasion.

Abrasion by gradual wear due to fluvial transport is quantified in terms of an abrasion coefficient. The abrasion coefficient, defined as the fractional volume loss (or equivalently mass loss) per unit distance traveled,  $\alpha_v$ , is

$$\alpha_v = -\frac{1}{V_p} \frac{dV_p}{ds} \quad (3-93a)$$

where

$V_p$  = particle volume; and  
 $s$  = distance of travel.

The corresponding coefficient based on grain size  $D$  is

$$\alpha_d = -\frac{1}{D} \frac{dD}{ds} \quad (3-93b)$$

Approximating grain shape as spherical, so that  $V_p \sim D^3$ , it is found that

$$\alpha_v = 3\alpha_d \quad (3-94)$$

Substituting Eq. (3-1) into Eq. (3-93b),

$$\frac{d\psi}{ds} = -\frac{\alpha_d}{\ln(2)} \quad (3-95)$$

For the case of an abrasion coefficient that varies with neither clast size nor downstream distance, Eqs. (3-94) and (3-95) can be solved to yield the results

$$D = D_u \exp(-\alpha_d s) \quad (3-96a)$$

$$\psi = \psi_u - \frac{\alpha_d}{\ln(2)} s \quad (3-96b)$$

where

$D_u, \psi_u$  = upstream values.

Equations (3-96a) and (3-96b) are alternate expressions of Sternberg's law for grain-size change in the downstream direction. The downstream variation in grain size in many rivers often approximates the exponential relation (3-96a), but this is no guarantee that abrasion is the cause. A very similar pattern of downstream fining can be driven mainly or exclusively by selective transport of finer grains, as discussed in Section 3.12.

It is in general very difficult to measure abrasion directly in the field. As a result, researchers have resorted to rotating tumbling mills such as the Los Angeles abrasion mill, concrete mixers, and circular flumes to quantify abrasion. The characteristics of the device are used to compute an equivalent distance traveled, and the resulting diminution in grain size is measured, allowing  $\alpha_d$  to be computed from Eq. (3-93b).

Summaries of abrasion coefficients from such tests are given by Shaw and Kellerhals (1982); Kodama (1994a); and Rice (1999). Figure 3-41 provides a summary of experimentally determined abrasion rates. It is seen that  $\alpha_d$  has been found to vary from about  $1 \times 10^{-5} \text{ km}^{-1}$  to above  $1 \times 10^{-1} \text{ km}^{-1}$ . The abrasion coefficient is partly a function of lithology, with quartz generally having a relatively low abrasion rate, limestone having a middling rate, and some mudstones having a very high rate. In addition, it can vary with grain size itself. Finally, Mikoš (1993; 1994; 1995) has documented a tendency for the abrasion rate to decrease with increasing distance of travel and for it to increase with increasing speed of a tumbling mill for the same travel distance.

In Fig. 3-41, the abrasion rates reported by Kodama (1994a) are in the range  $2 \times 10^{-3}$  to  $2 \times 10^{-1} \text{ km}^{-1}$  and are generally substantially higher than those reported in earlier studies. Kodama is of the opinion that the earlier studies did

not adequately replicate the violent grain-to-grain collisions during severe floods, and thus underestimated the abrasion rate. His experiments in a concrete mixer were designed to provide a better model of the process. The values reported by Mikoš (1995) are also higher than the earlier values, ranging from  $3 \times 10^{-3}$  to  $2 \times 10^{-2} \text{ km}^{-1}$ .

### 3.9.2 Application to Rivers

Equation (3-96a) can be used to define a "half-distance"  $L_{1/2}$  for abrasion over which grain size is reduced by half:

$$L_{1/2} = \frac{0.693}{\alpha_d} \quad (3-97)$$

For a value of  $\alpha_d$  of  $1 \times 10^{-5} \text{ km}^{-1}$   $L_{1/2}$  takes the value 69,300 km, and abrasion is likely to play a negligible role in the downstream change in grain size in a river. For a value of  $\alpha_d$  of  $1 \times 10^{-1} \text{ km}^{-1}$   $L_{1/2}$  takes the value 6.93 km, and abrasion is likely to play a dominant role in downstream fining.

The application of abrasion coefficients to rivers is rather more complicated than simply plotting grain size as a function of distance using Eq. (3-96). There are two reasons for this. Equation (3-96) does not account for grain-size variation due to selective transport. In addition, when a moving grain strikes a nonmoving grain on the bed, both can be expected to abrade, so that on the order of half of the abrasion is likely to be realized in situ.

To date there have not been many implementations of the abrasion term in the Exner equation of sediment continuity, Eq. (3-33). Parker (1991a; 1991b) has, however, proposed a form. This form is most easily expressed in terms of the continuous probability densities  $F(\psi)$ ,  $f_i(\psi)$ , and  $f_b(\psi)$  for surface material, interfacial exchange material, and bed-load material, respectively, rather than their discretized versions  $F_i$ ,  $F_{ir}$ , and  $f_{bi}$ . Let  $\alpha_d(\psi)$  define the abrasion coefficient, which is specifically allowed to be a function of grain size. Equation (3-33) takes the continuous form

$$(1 - \lambda_p) \left[ f_i \frac{\partial \eta_b}{\partial t} + \frac{\partial}{\partial t} (L_a F) \right] = - \frac{\partial q}{\partial s} - A \quad (3-98a)$$

where

$q(\psi)$  = density of bed-load transport rate such that total gravel bed-load transport rate  $q_T$  is given as

$$q_T = \int_1^\infty q(\psi) d\psi \quad (3-98b)$$

and  $A(\psi)$ , given by the relation

$$A = q_T \left[ 3\alpha_d f_b - \frac{1}{\ln(2)} \frac{\partial}{\partial \psi} (\alpha_d f_b) \right] + q_T \left[ \int_1^\infty \alpha_d(\psi') f_b(\psi') d\psi' \right] \left[ 3F_{ae} - \frac{1}{\ln(2)} \frac{\partial F_{ae}}{\partial \psi} \right] \quad (3-98c)$$

**Fig. 3-41.** Abrasion coefficients  $\alpha_d$  obtained from experiments by various researchers, as presented by Kodama (1994a), with permission of SEPM (Society for Sedimentary Geology).

denotes the density of the volume of material lost to abrasion per unit bed area per unit time, so that the total loss rate per unit area  $A_T$  is given as

$$A_T = \int_1^{\infty} A(\psi) d\psi \quad (3-98d)$$

In Eq. (3-98c) the parameter  $F_{ae}$  is defined as

$$F_{ae}(\psi) = \frac{F(\psi)2^{-0.5\psi}}{\int_1^{\infty} F(\psi)2^{-0.5\psi}} \quad (3-98e)$$

The lower limit of unity in the integral implies that only gravel is considered in the calculation; a value of  $\psi$  of 1 corresponds to a grain size  $D$  of 2 mm.

The first term on the right-hand side of Eq. (3-98c) denotes the abrasion density of bed-load particles, and the second term denotes the corresponding abrasion density of bed particles with which the bed-load particles collide. The derivative with respect to  $\psi$  in the same equation describes the flux of sediment through grain size space as grains are ground ever finer.

The discretized version of Eq. (3-98c) is

$$A_i = q_T \left[ 3\alpha_{d,i} f_{b,i} - \frac{1}{\ln(2)} \frac{(\alpha_{d,i+1} f_{b,i+1} - \alpha_{d,i} f_{b,i})}{\Delta\psi_i} \right] + q_T \left[ \sum_{j=1}^n \alpha_{d,j} f_{b,j} \right] \left[ 3F_{ae,i} - \frac{1}{\ln(2)} \frac{(F_{ae,i+1} - F_{ae,i})}{\Delta\psi_i} \right] \quad (3-98f)$$

$$F_{ae,i} = \frac{F_i D_i^{-1/2}}{\sum_{i=1}^n F_i D_i^{-1/2}} \quad (3-98g)$$

where  $\Delta\psi_i$  is given by Eq. (3-11c),  $\alpha_{d,i}$  denotes the abrasion coefficient for the  $i$ th grain size range, and  $f_{b,i}$  is synonymous with  $f_{b,i}$ . The total abrasion rate  $A_T$  is given as

$$A_T = A_{\text{silt}} + A_{\text{sand}} \quad (3-98h)$$

$$A_{\text{silt}} = 6q_T \sum_{i=1}^n (\alpha_{d,i} f_{b,i}) \quad (3-98i)$$

$$A_{\text{sand}} = \frac{q_T}{\Delta\psi_1 \ln(2)} \left[ \alpha_{d,1} f_{b,1} + \left( \sum_{j=1}^n \alpha_{d,j} f_{b,j} \right) F_{ae,1} \right] \quad (3-98j)$$

where

$A_{\text{silt}}$  and  $A_{\text{sand}}$  = associated volume rates of production per unit time per unit bed area of silt and sand, respectively.

In the case of crystalline rock it is common that very little sand is produced until the grain size reaches the range 5 to 10 mm. In many crystalline rocks the crystal size is on the order

of millimeters in size, and so the weak planes between crystals allow sudden shattering to sand-sized grains. This effect has been invoked as one possible explanation for the sharp gravel-sand transition evident in Fig. 3-10 (Yatsu 1955).

This formulation is implemented in Parker (1991b) and by the program ACRONYM4 in Parker (1990b). Parker (1991a) also provides a generalization to multiple lithologies. Results from an application to the disposal of mine waste in the Ok Tedi-Fly River system, Papua New Guinea are reported in Cui and Parker (1999).

### 3.10 NUMERICAL MODELING OF BED LEVEL VARIATION WITH SORTING

#### 3.10.1 Elements of a Numerical Model

The active-layer formulation of the grain-size-specific Exner equation of bed-load continuity combined with an appropriate grain-size-specific predictor for bed-load transport form the basis for the numerical modeling of the variation of bed level and grain-size distribution in bed-load-dominated rivers. To this must be added (1) an appropriate formulation of the fluid mechanics, usually realized through the St. Venant shallow water equations, and (2) an appropriate methodology for the computation of hydraulic resistance (including skin friction and form drag). The simple versions of the 1D shallow-water St. Venant equations given in Section 3.7.2 are here restated as

$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial s} = -g \frac{\partial H}{\partial s} - g \frac{\partial \eta}{\partial s} - g S_f \quad (3-99a)$$

$$\frac{\partial H}{\partial t} + \frac{\partial UH}{\partial s} = 0 \quad (3-99b)$$

where

$S_f$  = friction slope, given by

$$S_f = \frac{C_f U^2}{gH} = \frac{n_m^2 U^2}{k_{\text{nuisance}} H^{4/3}} \quad (3-99c)$$

In these relations  $U$  denotes cross-sectionally averaged flow velocity,  $H$  denotes cross-sectionally averaged flow depth (or hydraulic radius),  $C_f$  is the dimensionless friction coefficient defined in Section 3.7.2, i.e.,

$$C_f = \frac{\tau_b}{\rho U^2} = \frac{u_*^2}{U^2} = Cz^{-2} \quad (3-99d)$$

where

$Cz$  = dimensionless Chezy resistance coefficient;

$n_m$  = Manning's "n"; and

$k_{\text{nuisance}} = 1$  using the MKS implementation of the SI system and 1.49 for an FPS implementation of English units.

It is possible to simplify the St. Venant equations depending upon the type of flow under consideration. When the

channel is subject to a steady flow discharge, the classical quasi-steady approximation (de Vries 1965) generally allows the neglect of the time terms in Eqs. (3-99a,b), but retains them in the Exner equation of sediment continuity, i.e., Eq. (3-23) or Eq. (3-33). In field streams in general, and gravel-bed rivers in particular, however, the characteristic time of a hydrograph may be so short that it is necessary to retain the time terms. Any simplified model of flood wave propagation based on the St. Venant equations must be capable of resolving the time variation in boundary shear stress necessary for the computation of the time variation of sediment transport rate and size distribution.

In engineering applications to field rivers, both the Exner equation of sediment continuity and the St. Venant formulation must be modified. A minimal modification is outlined below.

### 3.10.2 Minimal Form for Field Application to Engineering Problems

Modifications to the forms of Eq. (3-23) or (3-33) and Eqs. (3-99a) and (3-99b) are required because (1) rivers rarely have constant widths, (2) they usually have floodplains, and (3) they usually have some degree of sinuosity. Here the sinuosity  $\Sigma_{\sin}$  is defined as the average along-channel distance  $s$  divided by the average along-valley distance  $s_v$  (Fig. 3-42); it commonly has a value between 1.0 and 2.5. The importance of the floodplain is as follows. Rivers transport the bulk of their sediment load during floods. Once river stage exceeds the bank-full stage, however, the water spreads out on the floodplain; further increases in stage increase water surface level very little. In the case of a vegetated floodplain, floodplain sediment is usually not mobilized, and a further increase in discharge does not result in substantially increased sediment transport. In the case of sufficiently sinuous channels, the sediment transport rate at above-bank-full stage can actually decline somewhat with increasing stage because the thread of high velocity no longer precisely follows the channel that

**Fig. 3-42.** Diagram defining in-channel and overbank flow in a river.

constitutes the source of bed-material load (Leopold 1994). The failure to include the damping effect of the floodplain in numerical modeling of variation in riverbed elevation can result in the spurious prediction of riverbed degradation during floods.

With this in mind, a down-valley coordinate  $s_v$  is defined in addition to the down-channel coordinate  $s$ . Averaged over several bends, the relation between these coordinates is

$$\frac{ds_v}{ds} = \frac{1}{\Sigma_{\sin}} \quad (3-100)$$

This definition limits the spatial resolution of the model; cross sections must be spaced by at least a bend or two. Channel width is denoted as  $B_c$ , which is here assumed to vary in the streamwise direction but not in time. The same holds true for floodplain width  $B_f$ , which here indicates the sum of the widths on both sides of the channel. In this simplest of implementations, the channel bed has elevation  $\eta$ , taken as constant across the cross section, and floodplain elevation  $\eta_f$  is similarly held constant across the floodplain (Fig. 3-41). Channel bank-full depth is denoted as  $H_{bf}$ , where

$$H_{bf} = \eta_f - \eta \quad (3-101)$$

For below-bank-full flow the St. Venant equations take the form

$$\frac{\partial U_c}{\partial t} + U_c \frac{\partial U_c}{\partial s} = -g \frac{\partial H_c}{\partial s} - g \frac{\partial \eta}{\partial s} - g S_{fc} \quad (3-102a)$$

$$B_c \frac{\partial H_c}{\partial t} + \frac{\partial B_c U_c H_c}{\partial s} = 0 \quad (3-102b)$$

where

subscript  $c$  = channel.

For overbank flow the formulation is modified to

$$\frac{\partial U_c}{\partial t} + U_c \frac{\partial U_c}{\partial s} = -g \frac{\partial (H_{bf} + H_f)}{\partial s} - g \frac{\partial \eta}{\partial s} - g S_{fc} \quad (3-102c)$$

$$\frac{\partial U_f}{\partial t} + \Sigma_{\sin} U_f \frac{\partial U_f}{\partial s} = -\Sigma_{\sin} g \frac{\partial H_f}{\partial s} - \Sigma_{\sin} g \frac{\partial \eta_f}{\partial s} - g S_{ff} \quad (3-102d)$$

$$\begin{aligned} & \frac{\partial}{\partial t} \left[ B_c (H_{bf} + H_f) + \left( \frac{B_f H_f}{\Sigma_{\sin}} \right) \right] \\ & + \frac{\partial}{\partial s} \left[ B_c (H_{bf} + H_f) U_c + B_f U_f H_f \right] = 0 \end{aligned} \quad (3-102e)$$

where

subscript  $f$  = floodplain,

so that, e.g.,

$S_{ff}$  = friction slope of the floodplain.

The corresponding form for the Exner equation of sediment continuity applied to sediment within the channel is

$$(1 - \lambda_p) B_{ca} \left[ f_{ti} \frac{\partial \eta_b}{\partial t} + \frac{\partial}{\partial t} (L_a F_i) \right] = - \frac{\partial B_{ca} q_i}{\partial s} - B_{ca} A_i \quad (3-103)$$

where the parameter  $\eta_b$  is defined in Fig. 3-32 and  $B_{ca}$  denotes a channel width adjusted to describe sediment transport, as described subsequently.

This formulation must be augmented with relations for hydraulic resistance. In the case of the floodplain, it usually suffices to prescribe a floodplain value  $n_f$  of Manning's  $n$  based on the calibration of backwater curves. In the case of the channel, the resistance relation should include at the very least the effect of roughness due skin friction and bed forms. The resistance relations in Chapter 2 are formulated in terms of bed slope  $S$  for the case of normal flow. In the case of flow that varies in time and space, the energy slope  $S_e$ , which may be defined as

$$S_e = \frac{\tau_b}{\rho g H} = - \frac{\partial \eta}{\partial s} - \frac{\partial H_c}{\partial s} - \frac{1}{g} \left( \frac{\partial U_c}{\partial t} + U_c \frac{\partial U_c}{\partial s} \right) \quad (3-104)$$

must be used instead. In the above relation,  $\tau_b$  refers to channel bed stress and  $H_c$  takes the value  $H_{bf} + H_f$  in the case of overbank flow. In addition, if the transport relation is based on skin friction  $\tau_{bs}$  rather than total bed friction  $\tau_b$ , the hydraulic resistance relation must allow for such a decomposition.

The adjusted width  $B_{ca}$  in the Exner equation (3-103) is in general a parameter that must be calibrated. It was seen in Section 3.7.16 that a complexity coefficient (or coefficients) must be introduced in order to account for the effects of channel complexity on sediment transport. One way to do this in a numerical model for a site-specific engineering application is to adjust the actual channel width  $B_c$  at each cross section.

This adjustment can be accomplished by the process of zeroing the model. Natural rivers typically (but not always) undergo change only at a morphologic time scale that is large compared to engineering time scales. When the actual channel widths  $B_c$  are input and the model is run under natural conditions for which only minor morphologic change is expected, it usually turns out that spurious, unacceptable amounts of aggradation or degradation occur at specific nodes. Zeroing consists of modifying  $B_c$  to the value  $B_{ca}$  at each cross section until such spurious bed level variation is reduced to an acceptable level. The model may be similarly zeroed by modest changes to the initial bed elevations. Without this process of zeroing the sediment transport and morphodynamic signals associated with engineering change such as flow diversion, dam removal, or sediment dumping from a mine often cannot be seen through the spurious signals, much less accurately predicted.

In the case of a gravel-bed river, when the river aggrades to the point of filling its channel it can spread out on the floodplain. Any vegetation may be buried or ripped out, resulting in the formation of a braid plain over which the channel wanders. In such a case it is useful to compute the

sediment transport within a channel of prescribed width and bank-full depth, but to spread the deposit out over the entire valley flat to as to simulate migration and avulsion. The form of the Exner equation for this case is

$$(1 - \lambda_p) B_v \left[ f_{ti} \frac{\partial \eta_b}{\partial t} + \frac{\partial}{\partial t} (L_a F_i) \right] = - \frac{\partial B_c q_i}{\partial s} - B_{ca} A_i \quad (3-105a)$$

$$B_v = B_c + B_f \quad (3-105b)$$

where

$B_v$  = width of the valley flat (including channel(s)).

It should be emphasized that this treatment represents the simplest possible physically realistic engineering formulation for a field river. It nevertheless excludes myriad other important features of rivers and river flow, including transverse variation in floodplain elevation, dynamic channel-floodplain interaction, and sorting due to 2D and 3D effects. One eventually reaches, however, a point of vanishing returns; the repeated addition of poorly constrained bells and whistles can degrade the predictive quality of a numerical model, in addition to making it difficult to use.

### 3.10.3 Examples of Numerical Models Using Grain-Size Distributions

Several numerical models of bed level variation with sorting are described below. No attempt is made to be comprehensive. Rather, the goal is to provide the engineer with a brief summary of what kinds of models were available at the time of writing.

Belleudy and SOGREAH (2000) describe the latest developments of the model SEDICOU. This model has been specifically designed to treat sediment mixtures. Earlier developments can be found in, e.g., Holly and Rahuel (1990). SEDICOU is a descendent of the model CARICHAR (Rahuel et al. 1989). Bezzola (1992) describes the application of the model MORMO to a flood in the Reuss River, Switzerland. Borah et al. (1982) present a numerical model designed for the study of the development of a static armor in rivers. The sediment transport equations used in the study are not grain-size-specific; this feature is considered in terms of an adjustment for "residual transport capacity." Copeland and Thomas (1992) describe the dynamic sorting and armor-ing algorithm in the U.S. Army Corps of Engineers TABS-1 model.

Cui et al. (1996) outline a model of grain sorting and aggradation verified against the experiments of Seal et al. (1997). This model is developed further in Cui and Parker (1997) for a shock-fitting of mobile gravel-sand transitions. Both models are descendants of ACRONYM 4 (Parker, 1990b). ACRONYM 4 was also adapted to study gravel transport, abrasion, and change in bed elevation in the OKGRAV models applied to mine waste disposal in Papua New Guinea

(Cui and Parker, 1999). Cui et al. (2003a; 2003b) develop the model further for the study of gravel pulses in rivers. See also Chapter 23 by Cui and Wilcox in this volume.

Hoey and Ferguson (1994) report on a model designed for and tested against downstream fining in the Allt Dubhaig, a river in Scotland, UK. Hoey and Ferguson (1997) use this model to study the controls on downstream fining. Ferguson et al. (2001) further develop this model and apply it to fluvial aggradation in the Vedder River, British Columbia, Canada. Van Niekerk et al. (1992) adapt the transport model of Bridge and Bennett (1992) to develop the numerical model MIDAS. Vogel et al. (1992) apply this model to the downstream sorting of heavy sediments such as placers in rivers. Robinson and Slingerland (1998) have expanded this work to the study of downstream sorting of bimodal sediment mixtures.

Armanini (1991/1992) defines the basis for a numerical model of mixed grain sizes that describes the evolution of various moments of the grain-size distribution, rather than that of the distribution itself.

### 3.11 STATIC AND MOBILE ARMORING: OBSERVATIONS, EXPERIMENTS, AND MODELING

The intense program of dam building in the United States and other countries in the period from 1920 to 1950 led to strong interest in the problem of static armor formation downstream of dams. The question of engineering relevance pertains to the elevation to which the bed would degrade downstream of a dam before coarsening sufficiently to stabilize and prevent further erosion. If this were not accounted for in designing the dam itself and the apron downstream of the spillway, the structure itself could be undermined.

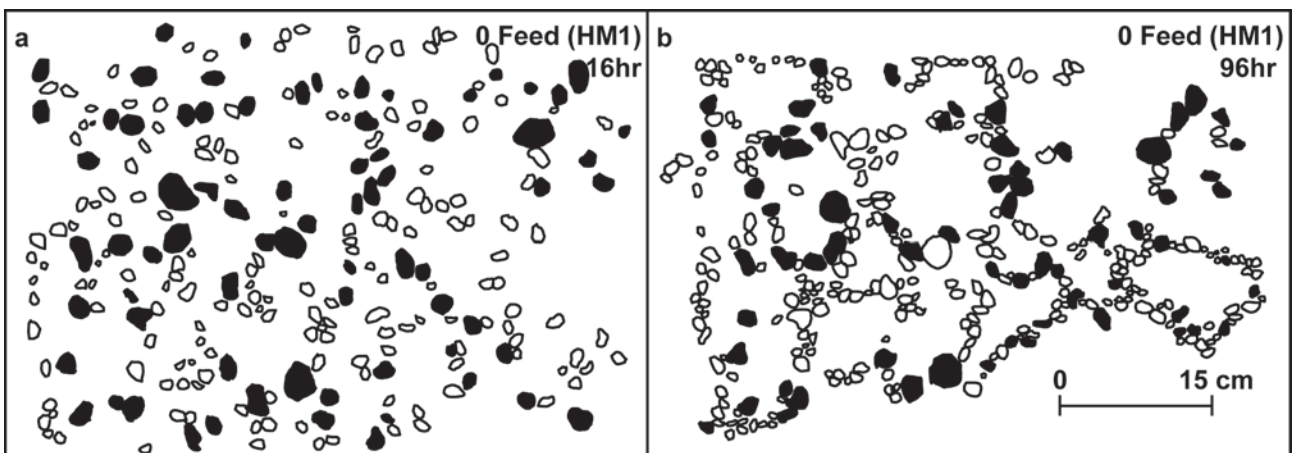

It is important to realize in this regard that sand-bed streams often have at least a trace of gravel, which can accumulate as the sand is carried downstream and eventually form a stable armor layer. The evolution of such armor is illustrated for the bed downstream of the Hoover Dam in Fig. 3-15.

#### 3.11.1 Static Armor

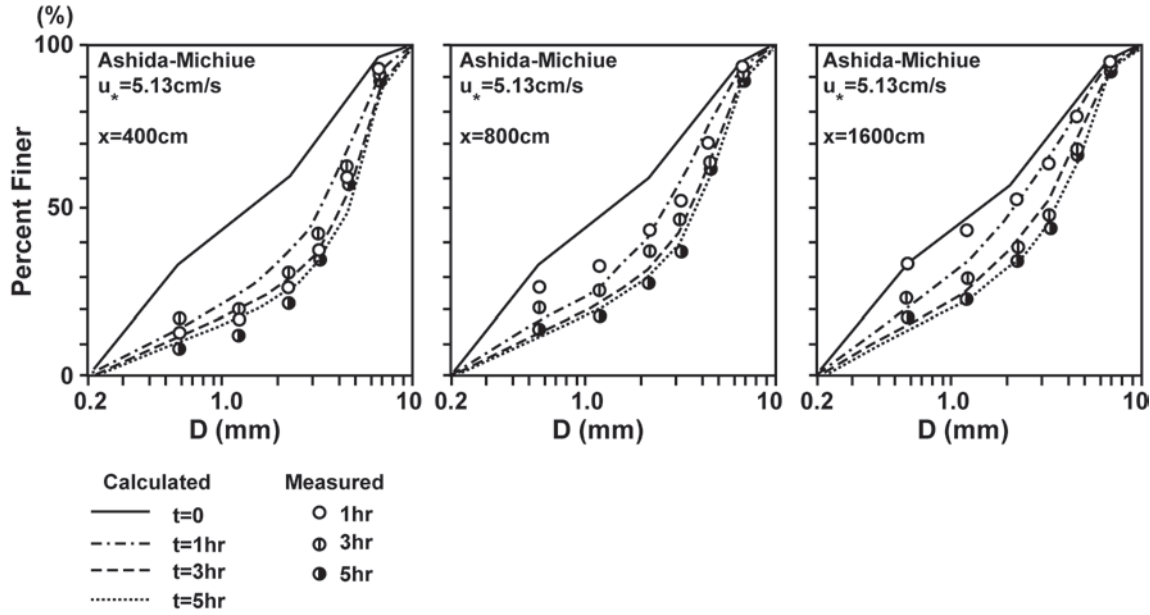

The topic of static armoring remains of strong interest today. Ashida and Michiue (1971), Hirano (1971), Proffitt (1980), Gomez (1983), Egashira and Ashida (1990), Tsujimoto and Motohashi (1990), Tait et al. (1992), Marion et al. (1997), Willetts et al. (1998), Church et al. (1998), and Hassan and Church (2000) have studied the phenomenon. In all cases the bed surface is found to coarsen to static armor as the sediment supply is cut off. Of recent interest is the tendency for the coarser grains to organize themselves into “clusters,” “rings,” and “stone cells” as the supply of gravel drops. Evidently armoring is associated not simply with the accumulation of coarser grains on the bed surface, but also with the organization of these grains into a pattern that increases the resistance to motion. An example of these structures is shown in Fig. 3-43.

Full numerical models of the evolution to static armor based on versions of the grain-size-specific Exner equation of sediment continuity, Eq. 3-23, have been implemented by many researchers, including Park and Jain (1987); Vogel et al. (1992); and Tsujimoto and Motohashi (1990). An example of such a calculation and its comparison against data is shown in Fig. 3-44.

Ashida and Michiue (1971) devised a way to compute static armor in a much simpler way. This method was corrected by Proffitt (1980) and Sutherland (1987). The case of

**Fig. 3-43.** Evolution of stone cells on the bed surface of a laboratory flume as the bed evolves in response to the cutoff of sediment supply, as observed by Hassan and Church (2000). Hassan and Church also document the presence of these cells in the case of equilibrium mobile-bed armor; the higher the sediment transport rate, the less developed are the cells. **Fig. 3-44.** Examples of comparisons of a numerical model of evolution to static armor versus experimental data from a laboratory flume, in which  $x$  denotes distance downstream; from Tsujimoto (1999). Copyright John Wiley & Sons Limited. Reproduced with permission.

late-stage degradation is considered. By this time the active layer  $L_a$  is assumed to have achieved a near-constant thickness. Assuming that the bed is degrading to a substrate with a spatially constant grain-size distribution with fractions  $\bar{f}_i$ , Eq. (3-23) may be rearranged with the aid of Eqs. (3-26) and (3-28) to yield

$$\frac{\partial F_i}{\partial t} = \frac{1}{L_a} \left[ (f_{bi} - \bar{f}_i) \frac{\partial \eta_b}{\partial t} - \frac{1}{1 - \lambda_p} q_T \frac{\partial f_{bi}}{\partial s} \right] \quad (3-106)$$

As degradation progresses the term  $\partial f_{bi} / \partial s$  can be expected to approach zero. Thus at a late stage Eq. (3-106) simplifies with Eq. (3-24) to

$$\frac{dF_i}{d(\eta/L_a)} = f_{bi} - \bar{f}_i \quad (3-107)$$

Insofar as the substrate fractions are given and the bed-load fractions can be computed from an appropriate sediment transport relation, the above equation can be solved iteratively until  $f_{bi}$  approaches  $\bar{f}_i$ , after which the bed will coarsen no more. Because the final state is the most important one to the engineer, Eq. (3-107) allows considerable simplification over a full model.

Parker and Sutherland (1990) proposed an even simpler method. Consider Fig. 3-45. The flume has a uniform substrate and is supplied with size fractions  $\bar{f}_i$ , constant water discharge, and constant total sediment feed rate  $q_T$  with constant size fractions  $f_{bi}$ . The flume is allowed to develop to a mobile-bed equilibrium. The experiment is then repeated, keeping the substrate and feed fractions constant but halving the total feed rate  $q_T$ . The water discharge is adjusted

from experiment to experiment to ensure that each reaches a mobile-bed equilibrium at the same bed slope  $S$  as the previous one. Static armor should be approached as  $q_T$  approaches zero.

The surface-based bed-load relation of Parker (1990a), Eqs. (3-79a) to (3-79g), is used here as an example. Equations (3-26) and (3-28) can be used to reduce these to

$$W_i^* = \frac{Rgq_T f_{bi}}{F_i u_{*s}^3} = G \left[ \omega \phi_{sgo} \left( \frac{D_i}{D_g} \right)^{-0.0951} \right] \quad (3-108a)$$

Solving for surface fractions  $F_i$ , it is found that

$$F_i = \frac{\frac{f_{bi}}{G \left[ \omega \phi_{sgo} \left( \frac{D_i}{D_g} \right)^{-0.0951} \right]}}{\sum_{i=1}^n \frac{f_{bi}}{G \left[ \omega \phi_{sgo} \left( \frac{D_i}{D_g} \right)^{-0.0951} \right]}} \quad (3-108b)$$

The static armor size distribution  $F_{ai}$  is then given as

$$F_{ai} = \lim_{q_T \rightarrow 0} F_i \quad (3-109)$$

This limit corresponds to extremely low transport rates, a range within which it is seen from Eq. (3-79f) that

$$G \left[ \omega \phi_{sgo} \left( \frac{D_i}{D_g} \right)^{-0.0951} \right] \rightarrow \left[ \omega \phi_{sgo} \left( \frac{D_i}{D_g} \right)^{-0.0951} \right]^{14.2} \quad (3-110)$$

**Fig. 3-45.** Conceptual diagram illustrating the evolution of static armor from equilibrium mobile-bed conditions as the sediment feed rate is repeatedly halved.

Substituting Eqs. (3-108b) and (3-110) into Eq. (3-109), the following very simple relation for static armor is obtained:

$$F_{ai} = \frac{\bar{f}_i D_i^{1.35}}{\sum_{i=1}^n \bar{f}_i D_i^{1.35}} \quad (3-111)$$

This predictor requires nothing more complicated than a hand calculator or spreadsheet to implement. Parker and Sutherland (1990) found that the agreement with five sets of data from experiments on armoring and one set from Oak Creek could be optimized by lowering the exponent in Eq. (3-111) from 1.35 to 1.12. The agreement holds across the entire grain-size distribution. Similar agreement was obtained with the Paintal (1971) bed-load transport model adapted for mixtures with the hiding function of Proffitt and Sutherland (1983). Any bed-load transport relation that satisfies a simple power law of the form of Eq. (3-51) at very low transport rates possesses such a simple limit for static armor.

### 3.11.2 Mobile Armor

The forms of Eqs. (3-108) and (3-109) raise another issue, however. In the thought experiment that was outlined previously, the grain-size distribution  $F_i$  of the surface layer cannot be expected to jump suddenly to the distribution for static armor  $F_{ai}$  as  $q_T$  is lowered; instead the change should be gradual. That is, under conditions of relatively low transport rate, even when all sizes participate in the bed load due to the constant grain-size distribution of the sediment feed, the bed surface should be coarser than the bed load. If the bed load material is the same material as that placed in the flume to make the substrate, then the bed surface should be coarser than the substrate as well. This state of an armored bed under equilibrium transport of all sizes may be called mobile armor.

Until the concept of mobile armor was introduced, it was often thought that the armor layer in gravel bed rivers present at low flow was suddenly broken up by an appropriate threshold discharge, leading to an unarmored state during active bed-load transport. The armor was thought to reform by downstream and vertical winnowing as the flow declined.

The existence of equilibrium mobile-bed armor was first demonstrated in a sediment feed flume by Parker et al. (1982b). Parker and Klingeman (1982) offered a simple explanation for it as follows. Consider a flume containing just two grain sizes, one coarse and one fine. The coarse and fine halves of the load are fed in at the same rate until a mobile-bed equilibrium is reached. The coarser grains are intrinsically less mobile than the finer grains, even after hiding effects are accounted for. But once equilibrium is reached both halves must be transported at exactly the same rate. The way the model river in the flume accomplishes this is by overrepresenting the coarse material on the bed surface, so

that the availability of coarse grains is increased, and that of fine grains decreased, until their effective mobility is equalized.

Parker and Toro-Escobar (2002) have termed this the weak form of the “equal mobility” hypothesis. Simply put, it says that no matter what the grain-size distribution of the sediment supply, in a stream that is locally in grade the bed surface must reorganize itself so that the coarse half of the feed moves through the system at the same rate as the fine half.

Mobile armor has been observed in laboratory sediment-feed flumes by Egashira and Ashida (1990); Tsujimoto and Motohashi (1990); Suzuki and Kato (1991); Suzuki and Hano (1992); and Hassan and Church (2000). Seal et al. (1997) documented the maintenance of a mobile armor under conditions of slow bed aggradation in a sediment feed flume. Parker et al. (2003) have documented the formation and maintenance of mobile-bed armor under conditions of a repeated full hydrograph designed to model field gravel-bed rivers.

Mobile armor has also been observed in sediment recirculating flumes. The most comprehensive documentation in this configuration is outlined in Wilcock and Kenworthy (2002), but see also Marion and Fraccarollo (1997). The expression of mobile-bed armor in a recirculating flume is somewhat different from that in a sediment feed flume, in which all sizes in the feed are forced to move at mobile-bed equilibrium. As a result, partial transport with little transport of the coarsest grains, even when  $D_{u50}$  is mobilized, is common. The reader is referred to Wilcock (2001b) for a discussion of the differences between the configurations.

### 3.11.3 The Variation of Mobile Armor with Bed-Load Transport Rate

Now it is of use to consider the limit of high transport rate. In the case of the relation of Parker (1990a), as  $q_T$  ( $\phi_{sgo}$ ) becomes large,  $G(\phi_{sgo})$  approaches the constant limit 5,474 in Eq. (3-77f). As a result, Eq. (3-108b) devolves to the result

$$F_i = f_{bi} \quad (3-112)$$

$q_T \rightarrow \infty$

That is, at high transport rates the grain-size distribution of the surface layer must approach that of the sediment supply. This same limit must be reached at high sediment transport rates for any sediment transport relation for which  $q_i^* \rightarrow (\tau_i^*)^{3/2}$  or equivalently  $W_i^* \rightarrow \text{const}$ . Relations satisfying this condition include those of Ashida and Michiue (1972); Hunziker and Jaeggi (2002); Wilcock and Crowe (2003); and Powell et al. (2001).

One may inquire whether or not mobile armor is observed in the field. It is difficult to sample a mobile gravel bed during a flood. This notwithstanding, Andrews and Erman (1986) report such a measurement. Sagehen Creek is a perennial stream in the Sierra Nevada of California. At low flow it

has a well-armored bed, with a value of (surface)  $D_{50}$  of 58 mm and a value of (substrate)  $D_{u50}$  of 30 mm. In addition, it has a well-defined self-constructed floodplain. The value of bank-full Shields stress  $\tau_{bf50}^*$ , defined in Eq. (3-17e), is about 0.059, so that the stream fits in the center of the gravel-bed rivers of Fig. 3-29, as is shown there. The creek typically floods during snowmelt season. In 1983 the river went over-bank during a snowmelt flood. Andrews and Erman sampled the surface layer both at low flow and near the flood peak, when particles as large as 86 mm were found to move. Mobile armor was found to be present during the flood, and the size distribution differed little from the static armor at low flow. The grain-size distribution of the surface was sampled both at low flow and twice during the flood event. The surface grain-size distribution at the peak of the flood had a median size of 46 mm. This value is somewhat finer than the low-flow value of 58 mm and considerably coarser than the substrate value of 30 mm. Evidently mobile armor was present during an event that (1) was above the bank-full stage and (2) mobilized grains larger than  $D_{50}$ . That is, the measured mobile armor had a median size that was coarser than that of the low-flow substrate but finer than that of the low-flow surface material.

The Nahal Yatir is a desert wadi in Israel (Reid et al. 1995). It is subject to rare, intense flash floods. The arrival of a flash flood in a similar adjacent stream, the Nahal Eshtemoa, is documented in Fig. 3-46. The floods subside so quickly that the bed has little time to reorganize itself. As a result, observations of the bed and substrate right after a flood more or less reflect the conditions at the flood peak. As can be seen in Fig. 3-1, the Nahal Yatir is essentially unarmored (Laronne et al. 1994). A substantial number of the data in Reid et al. (1995) on bed-load transport in the Nahal Yatir pertain to values of  $\tau_{50}^*$  (Shields stress based on surface  $D_{50}$ ) in the range 0.1 to 0.3, where in analogy to Eq. (3-18c)

$$\tau_{50}^* = \frac{HS}{RD_{50}} \quad (3-113)$$

These values are well above those reported for gravel-bed rivers in Fig. 3-29. This is because the Nahal Yatir is incised into tough loess and older alluvium that resist erosion.

A juxtaposition of the field measurements for Sagehen Creek and the Nahal Yatir suggests that the surface grain-size distribution changes systematically during floods. As  $\tau_{50}^*$  increases above a threshold for significant gravel motion of about 0.03, the ratio  $D_{50}/D_{u50}$  (surface median size to substrate median size), or alternatively the ratio  $D_g/D_{ug}$  (surface geometric mean size to substrate geometric mean size), should gradually decrease toward unity, at which point no discernible armor is present.

A simple calculation using ACRONYM2 (Parker 1990b) was implemented in an attempt to model this behavior. ACRONYM2 performs the calculation of Eq. (3-108b) using the Parker (1990a) relation. A reasonable approximation of the substrate size distribution of Sagehen Creek

**Fig. 3-46.** Flash flood in the ephemeral Nahal Eshtemoa, Israel: (a) arrival of the flood wave (looking upstream); and (b) passage of the flood wave (looking downstream). Images courtesy J. Laronne, I. Reid, M. Powell, and C. Garcia.

was constructed for this exercise. In the normalized form of  $\bar{f}_i$  versus  $D_i/D_{ug}$ , it also serves as a crude approximation of the substrate size distribution in the Nahal Yatir. This normalized size distribution was used to approximate the size fractions  $f_{bi}$  of the bed load during transport events in both streams. A range of values of total bed-load transport rate  $q_T$  were input into the program to simulate bed evolution as a function of transport rate. The results of the analysis are shown in Fig. 3-47.

Figure 3-47a shows the ratios  $D_{50}/D_{b50}$  and  $D_g/D_{bg}$  versus  $\tau_{50}^*$ . ACRONYM2 predicts that in the case of bank-full flow in Sagehen Creek ( $\tau_{50}^* = 0.059$ ), these ratios should decline only modestly from values at low flow. In the case of the Nahal Yatir, these ratios have dropped dramatically at a value of  $\tau_{50}^*$  of 0.1, and by the value 0.3 they are very close to unity. Figure 3-47b shows the size distribution of the bed load, that of the static armor, and that of the mobile armor at various values of  $\tau_{50}^*$ . The progressive approach of the surface grain-size distribution to that of the bed load as  $\tau_{50}^*$  increases is evident.

**Fig. 3-47.** (a) Predicted variation of the ratios  $D_g/D_{bg}$  and  $D_{50}/D_{b50}$  in  $\tau_{50}^*$ , along with a bank-full value of  $\tau_{50}^*$  for Sagehen Creek and two values of  $\tau_{50}^*$  for the Nahal Yatir that bracket most of the bedload data. (b) Assumed normalized grain-size distribution for bedload, along with predicted grain-size distributions for static armor and mobile armor at the values of  $\tau_{50}^*$  shown in the legend.

In the above formulation, it has been assumed that the size distribution of the bed load is always invariant and equal to that of the substrate, so that  $D_{b50}$  is equal to  $D_{u50}$  and  $D_{bg}$  is equal to  $D_{ug}$ . If this were true, Figs. 3-47a and 3-47b would imply that the mobile armor would become progressively finer as  $\tau_{50}^*$  increases, eventually approaching the grain-size distribution of the substrate in the limit of large  $\tau_{50}^*$ . That is, the armor would vanish for sufficiently high values of  $\tau_{50}^*$ . This is in fact what is observed in the Nahal Yatir.

The above results need to be qualified with the observation that the grain-size distribution of the bed load is typically not invariant with stage, but varies systematically so that  $D_{b50}$  and  $D_{bg}$  typically become coarser with increasing stage. This effect may tend to mute the approach of the surface grain-size distribution to that of the substrate as

stage becomes progressively higher. This notwithstanding, it seems reasonable to infer that (1) mobile armor is well developed in gravel-bed streams of the type shown in Fig. 3-29 even under bank-full conditions, but (2) mobile armor is either poorly developed or absent in gravel-bed streams that can sustain substantially larger Shields stresses and transport orders of magnitude more gravel, such as the Nahal Yatir.

A second look at Fig. 3-1 is instructive. Along with the unarmored Nahal Yatir, the well-armored River Wharfe is shown there. It can be inferred from the photographs, with some degree of reliability, that the gravel supply to the River Wharfe is much smaller than that to the Nahal Yatir. Dietrich et al. (1989) have quantified this concept in terms of a way to estimate the relative difference in gravel load between two streams based on the degree of armoring observed at low flow. The formulation may be used as a rough but accessible indicator of the gravel supply to the river.

### 3.11.4 The Hypothesis of Equal Mobility

A short discussion of the concept of “equal mobility” is in order. In addition to the weak form of Parker and Klingeman (1982), Parker et al. (1982a) advocated a “strong form” (Parker and Toro-Escobar, 2002), according to which the size distribution of the gravel bed load averaged over many floods should be close to that of the gravel portion of the substrate layer immediately below the surface layer. That is, as an approximation

$$\langle f_{bi} \rangle = \bar{f}_i \quad (3-114)$$

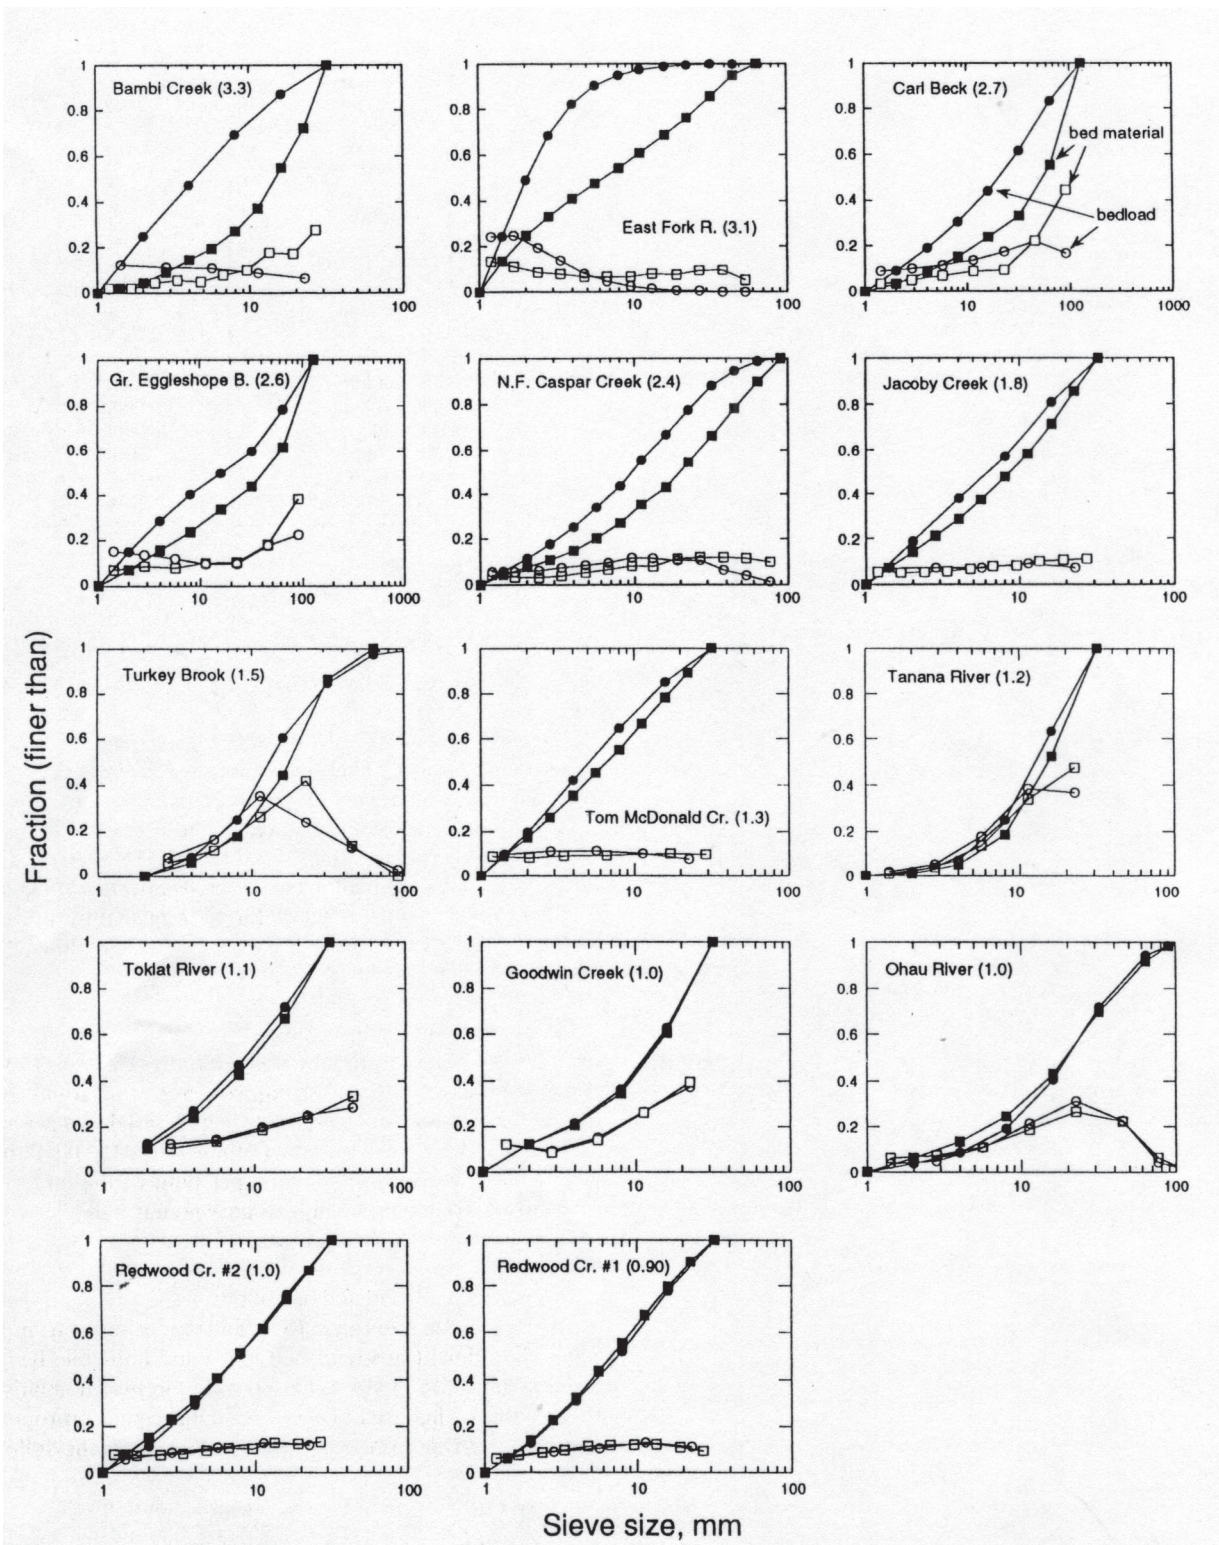

where the brackets denote values based on the size distribution of the mean annual gravel load. Lisle (1995) has performed a comprehensive test of this hypothesis. These results are shown in Fig. 3-48 in terms of  $\langle f_{bi} \rangle$  versus  $\bar{f}_i$ . All grain-size distributions have been truncated to remove material finer than 1 mm. Of the 14 stream reaches shown in the diagram, the strong form of equal mobility is rigorously or approximately satisfied in 8 cases, such that

$$1 < \frac{D_{u50}}{D_{b50}} < 1.5 \quad (3-115)$$

whereas in 6 cases it is not. The strongest discrepancy is in the East Fork River, which is not far upstream of a gravel-sand transition. In the other cases, Lisle associates the deviation from the strong form of equal mobility with low-order tributaries high up in a drainage basin. In addition, he suggests that the prominent formation of patches of fine gravel may contribute to the preferential transport of these sizes in such streams.

Church et al. (1991) provide a test of the hypothesis of equal mobility in fluvial sediment transport, with a focus on the sand fraction of the load.

**Fig. 3-48.** Normalized mean annual bedload (solid circles) and substrate (solid squares) grain-size distributions for 14 gravel-bed rivers studied by Lisle (1995). The grain-size distributions have been truncated at 1 mm. The hollow circles and squares pertain to fractions in each range. (Copyright 1995 American Geophysical Union. ### 3.12 DOWNSTREAM FINING: OBSERVATIONS, EXPERIMENTS, AND MODELING

#### 3.12.1 Abrasion or Selective Sorting?

Most but not all rivers are characterized by a concave-upward long profile, so that slope declines downstream. Many gravel-bed rivers with such a concave-upward profile also show a systematic tendency for the grain size of the bed material to become finer in the downstream direction. An example already discussed is the Kinu River, Japan, shown in Fig. 3-10. A second example, shown in Fig. 3-49, is the Red Deer River, Alberta, Canada (Shaw and Kellerhals 1982). The long profile is seen to be concave upward in Fig. 3-49a. The surface sizes  $D_{50}$  and  $D_{90}$  are seen in Fig. 3-49b to decline in the downstream direction over most of the 500 km of the gravel-bed reach, and then drop quickly to sand at a gravel-sand transition.

As noted previously, a downstream decrease in gravel size may be due to selective transport of the finer gravel, abrasion,

or some combination of the two. In the case of the Red Deer River, lithology provides a hint, as shown in Fig. 3-49c. The relative quantity of various rock types in the river gravels is seen to change systematically. In particular, the fraction of the bed that is limestone declines relative to quartz and granite, to the point of nearly vanishing content some 450 km downstream of the stream source. Shaw and Kellerhals (1982) present evidence to the effect that the limestone clasts in the river are more easily abraded than the granite clasts, and much more so than the quartz clasts. The implication is that the limestone is being ground out by abrasion, which thus may play an important or dominant role in the pattern of downstream fining.

Ferguson and Ashworth (1991) and Ferguson et al. (1996) provide another example of downstream fining that is very similar to that in the Red Deer River, yet very different from it. The Allt Dubhaig, Scotland, shows the same upward concave long profile and the same gravel-sand transition as the Red Deer (Fig. 3-50). Yet in this case the amount of fining

**Fig. 3-49.** Illustration of various aspects of downstream fining in the Red Deer River, Alta., Canada. (a) Long profile of the Red Deer River. (b) Downstream variation in  $D_{50}$  and  $D_{90}$  in the Red Deer River. (c) Downstream variation in three lithologies in the Red Deer River. From Shaw and Kellerhals (1982).

**Fig. 3-50.** Illustration of downstream fining in the Allt Dubhaig, Scotland, UK, showing the long profile of the river (top) and grain-size distributions of bulk surface samples taken at various points down the stream (bottom). Grain size distributions progress in order from the farthest upstream (left) to the farthest downstream (right). From Ferguson et al. (1996).

observed in the Red Deer River over hundreds of km is realized in the Allt Dubhaig over less than 4 km. In addition to the short distance, the durable nature of the rock types present in the river precludes an important role for abrasion. In this case, then, selective transport of the finer grains is the likely cause of the grain-size variation.

Kodama (1994a; 1994b) argues that the downstream fining observed in the Watarase River, Japan, is primarily caused by abrasion. He argues that abrasion rates determined in mills and flumes severely underestimate the violent collisions associated with floods in the Watarase River, which are associated with typhoons. He used a concrete mixer to better approximate conditions in the Watarase River.

One might infer from the above that in a country such as Britain, which is geologically old, heavily glaciated, and subject to a mild climatic regime, downstream fining might be wholly due to selective sorting, whereas in a geologically young, tectonically active country subject to violent storms such as Japan abrasion may tend to dominate. The picture is, however, not so simple. Seal and Paola (1995) observed rapid downstream fining over a 10-km reach upstream of a sediment retention dam on the North Fork Toutle River, Washington (Fig. 3-6). The sediment is largely derived from the Mount St. Helens eruption in 1980 and might be expected to abrade easily. Over the short distance of the deposit behind the dam, however, abrasion played a negligible role.

Gomez et al. (2001) have documented downstream fining over 90 km in the Waipaoa River, New Zealand. This example is of special interest because the median size of the

substrate in the gravel-bed reach is in the pea gravel range. Rice (1998; 1999) has documented a pattern of “punctuated” downstream fining in British Columbia, Canada, in which abrasion appears to play little role. That is, a pattern of downstream fining is set up by selective transport between major sediment sources, some of which can refresh the supply of coarse grains and interrupt the pattern of progressive downstream fining. These sources can include tributaries, glacial moraines, and bedrock cliff exposures.

Gravel-bed rivers undergoing downstream fining often but not always end in a rather abrupt transition to a sand-bed reach over a few km. Yatsu (1955) documented these transitions on many Japanese streams. Recently Sambrook Smith and Ferguson (1995) have documented such transitions on 18 streams in Canada, England, Japan, Papua New Guinea, Romania, and Scotland. The Waipaoa River discussed above also exhibits a gravel-sand transition. In most but not all cases the transition from gravel to sand is accompanied by a substantial drop in river bed slope. The reason for the transition is still a matter of debate, but it can often be ascribed to a bimodal grain-size distribution with a gap or paucity somewhere near the interface between sand and gravel sizes. Fujita et al. (1998) document both downstream fining and gravel-sand transitions on a variety of Japanese streams and present a conceptual model for the effect of engineering works on the location of the transition point.

Pizzuto (1995) has argued that downstream fining need be a consequence of neither abrasion nor downstream fining. Instead, it could be driven simply by a tendency for more distal tributaries to deliver finer sediment to the main stem of a river. His model emphasizes the importance of sediment provenance in considering the problem of downstream fining.

### 3.12.2 Laboratory Studies of Downstream Selective Sorting

Laboratory flumes are too short to allow modeling of downstream fining set up by abrasion, but they provide a useful venue for testing the process of selective sorting. An upward concave bed profile can usually be set up in a flume by forcing the bed to aggrade. The resulting downstream decrease in slope then ought to drive selective deposition of the coarser grains and transport of the finer grains. Curiously, however, one of the earliest documented studies of downstream sorting of heterogeneous sediments under aggradational conditions in the laboratory yielded the opposite result. Straub (1935) instead found a pattern of downstream coarsening caused by selective transport of the coarser grains. Kodama et al. (1992) specifically attempted to reproduce downstream fining in an aggrading channel and again obtained downstream coarsening. They describe this result as “quite contrary to common sense.”

Paola et al. (1992b) and Seal et al. (1997) finally succeeded in reproducing downstream fining in the laboratory. Their channel was 0.3 m wide and over 50 m long;

the sediment used in the study was a weakly bimodal mix of sand and gravel ranging from 0.125 to 90 mm. The sediment was fed in over an inerodible bed and allowed to prograde into standing water. The upward concave profile of gravel ended in a distinct gravel front, downstream of which only sand prevailed. The height of this front was controlled by the base level of the standing water. Toro-Escobar et al. (2000) repeated the experiments in a much wider channel, again obtaining unambiguous downstream fining driven by selective transport. The channel bed at the end of one of the experiments in Fig. 3-51 serves to illustrate the pattern of downstream fining. This set of experiments revealed that increased content of sand in the sediment feed caused more rapid downstream fining of the gravels, a result that might be explainable in terms of the model of gravel-sand transport of Wilcock and Crowe (2003; see also Wilcock 1998a; Wilcock et al., 2001).

The reason that downstream coarsening was obtained in some studies of aggrading deposits and downstream fining in others was identified by Solari and Parker (2000). They delineated a mobility reversal for bed slopes exceeding about 2%. For steeper slopes the direct effect of gravity acting to pivot out the larger exposed grains is enough to disturb the delicate balance between grain weight and grain protrusion that renders finer grains somewhat more mobile in a mixture at lower slopes. The experiments of Straub (1935) and Kodama et al. (1992) were above the threshold, whereas the experiments of Seal et al. (1997) and Toro-Escobar et al. (2000) were below the threshold.

Brummer and Montgomery (2003) have documented a similar tendency for downstream coarsening in field channels near their headwaters. More specifically, downstream coarsening was observed for drainage areas less than 10 km and bed slopes exceeding about 8%.

Such mobility reversal has been observed in other contexts. Everts (1973) reported on the phenomenon of overpassing, by which rare coarse grains can skim over a bed of much finer grains at relatively high speed. As opposed to slope-driven mobility reversal, overpassing appears to require a significant difference in size between the overriding coarse grains and the fine grains below.

Transitions similar to gravel-sand transitions have been modeled in the laboratory using density difference as a surrogate for size difference. In the experiments of Fujita et al. (1998) and Paola et al. (2001) the transition was produced in an aggrading model river containing (heavy) sand and (light) crushed coal.

**Fig. 3-51.** Illustration of downstream fining produced in a laboratory channel in Run 5 of Toro-Escobar et al. (2000). The channel width is 2.7 m. (a) The upstream 20 m of the deposit. (b) The downstream 20 m of the deposit. Flow was from top to bottom. (With permission from ASCE.)

### 3.12.3 The Role of Tectonics and Base Level Variation

There are two ways to approach the phenomenon of downstream fining. Either one can take the initial long profile of the river as given and calculate downstream change in grain size over it, or one can attempt to explain the shape of the long profile as well as the pattern of sorting.

The role of tectonics becomes important in the second case. The upward concave profile of a river is often set up as it flows from a zone of uplifting terrain to a zone of subsiding terrain. Indeed, rivers are attracted to zones of tectonic subsidence, as evidenced by the position of such major rivers as the Po and the Ganges. As a river migrates and avulses over the surface of such a zone, the accommodation space created by subsidence is gradually filled with sediment. Although the process occurs over geomorphic rather than engineering time, engineering activities such as the disposal of mine waste in rivers can interrupt this slow, quasi-equilibrium process and create major sedimentation problems. An inability to understand how a river establishes its long profile leads to an inability to predict the response of a river to such activities.

Not all rivers flow through depositional basins. Many of the streams on the west side of the northern Coast Range of California, such as the Mad River, shown in Fig. 3-14, are locked into place along synclines in an otherwise rapidly uplifting terrain. As a result, these streams show much less upward concavity in their profiles than rivers that flow into subsiding zones before reaching the sea. Before the advent of gravel mining, many of these rivers delivered gravel directly to the sea, with no gravel-sand transition. This balance, however, has been greatly altered by gravel mining.

Base level change can have a role analogous to tectonics. In particular, the 120m rise in eustatic sea level since the end of the last glaciation has created accommodation space for the storage of sediment within the coastal plain and estuaries. Fujita et al. (1998) associate sea level rise with an upstream migration of gravel-sand transitions in Japan. Paola (2000) provides a comprehensive summary of numerical models of basin stratigraphy that include the effects of tectonics and base level variation.

### 3.12.4 Numerical Models of Downstream Fining

Abrasion, subsidence, and delta progradation can all play a role in setting up the interaction between the long profile of a river and the heterogeneous bed sediment to produce downstream fining. In a numerical model, delta progradation can be handled with a migrating downstream boundary condition (e.g., Swenson et al. 2000; Kostic and Parker 2003). Abrasion and subsidence (or uplift), however, must be incorporated directly into the Exner equation of sediment continuity.

The subsidence rate  $\sigma_{\text{sub}}$  may be as high as a few millimeters per year depending upon setting. Negative subsidence corresponds to uplift. For the purpose of most engineering

models  $\sigma_{\text{sub}}$  can be taken as constant in time, but may vary in space. To account for subsidence, the Exner equation of sediment continuity, Eq. (3-33), must be modified to the form

$$(1 - \lambda_p) \left[ f_{ii} \left( \frac{\partial \eta_b}{\partial t} + \sigma_{\text{sub}} \right) + \frac{\partial}{\partial t} (L_a F_i) \right] = - \frac{\partial q_i}{\partial s} - A_i \quad (3-116)$$

It is easily shown that a constant speed of subsidence drives an upward concave long profile in the same way as an aggradational profile driven by a downstream dam the height of which is raised at a constant speed. That is, subsidence can set up conditions for downstream fining.

Rana et al. (1973) provide the first hint of a mechanistic formulation of downstream fining. The first full numerical model of downstream fining in a river was developed by Deigaard (1980) in the context of an engineering project on the sand-bed Niger River, Africa. This pioneering work was nevertheless rather primitive in nature, in that no hiding effects were included in the sediment transport relation. Paola et al. (1992a) developed a simple two-grain-size model of downstream fining as rivers fill subsiding depositional basins. One grain size is in the gravel range and the other is in the sand range. They used the Meyer-Peter and Müller (1948) transport equation and a constraint on bank-full Shields stress in rivers to reduce the Exner equation to diffusional form with the subsidence term acting as a sink. Both gravel and sand deposit out to balance subsidence, but the gravel does so at a higher rate. The gravel-sand transition occurs when the river runs out of gravel to carry. Paola and Seal (1995) developed a model capable of handling a full grain-size distribution and applied it to the deposit on the North Fork Toutle River, Washington shown in Fig. 3-6. They showed that the morphological complexity associated with local patches of sorted sediment acts to increase the rate of downstream fining, as described in Section 3.7.16.

Parker (1991a; 1991b) developed a numerical model, ACRONYM3, for the study of the effects of both aggradation and abrasion on downstream fining. Profile concavity was driven by the assumption of a wavelike progradational profile of constant form. The model was further developed along with ACRONYM4 for the purpose of predicting the response of the gravel-bed Ok Tedi, Papua New Guinea, to sediment supplied from a mine (Cui and Parker, 1999). Cui et al. (1996) and Cui and Parker (1997) tested the model against the downstream fining experiments of Seal et al. (1997). Parker and Cui (1998) and Cui and Parker (1998) went on to develop a numerical model of downstream fining in rivers with gravel-sand transitions the locations of which are stabilized by subsidence. In the case of bimodal sediments with a gap in the pea gravel range, they identified three ways to drive a transition: (1) the gravel runs out due to deposition upstream; (2) the gravel is ground out by abrasion; and (3) sand moving as throughput load eventually deposits on the bed as slope drops off and overwhelms the gravel. The model of Cui and Parker (1998) treats the throughput load of sand by filling the pores of the gravel to a

prescribed porosity as it aggrades, and passing the rest of the sand down to the gravel-sand transition.

Hoey and Ferguson (1994; 1997) developed a numerical model of downstream fining in the Allt Dubhaig, a stream in which neither abrasion nor subsidence appear to be playing a role. Rather, the fining is set up by the progradation of the river into a lake. In such cases the gravel-sand transition cannot stabilize; as long as gravel and sand are supplied to the river the transition must migrate downstream. The sediment supply is low in the case of the Allt Dubhaig, so that the transition migrates only slowly.

Robinson and Slingerland (1998) developed a numerical model for downstream fining in the case of bimodal sand-gravel mixtures. They applied it to the prediction of grain-size trends in a depositional foreland basin. The model is a descendant of MIDAS (van Niekerk et al. 1992).

### 3.13 MORPHODYNAMICS OF LOCAL PLANFORM SORTING

#### 3.13.1 Two-Dimensional Bed-Load Transport of Sediment Mixtures

Local sorting of bed-load sediment is often dominated by 2D effects, and thus must be described in terms of 2D formulations of bed-load transport of sediment mixtures. Such 2D relations for the case of uniform sediment with size  $D$  were presented in Section 2.6.11. Generalizations to mixtures are presented here.

Let

$$\vec{q}_i = (q_{i,s}, q_{i,n}) \quad (3-117a)$$

$$\vec{\tau}_{bs} = (\tau_{bs,s}, \tau_{bs,n}) \quad (3-117b)$$

denote the 2D vectors of volume bed-load transport per unit width in the  $i$ th grain size range and boundary shear stress due to skin friction, respectively. Parker and Andrews (1985) have generalized the linearized Ikeda-Parker formulation (Parker 1984) of Chapter 2 to the form

$$\vec{q}_i = |\vec{q}_i| \left[ \frac{\vec{\tau}_{bs}}{|\vec{\tau}_{bs}|} - \beta \left( \frac{\tau_{s,mag,i}^*}{\tau_{sci}^*} \right)^{-n_i} \vec{\nabla} \eta \right] \quad (3-118)$$

where

$\vec{\nabla} \eta$  = 2D vectorial gradient of bed elevation in the ( $s$ ,  $n$ ) directions,

$$\tau_{s,mag,i}^* = \frac{|\vec{\tau}_{bs}|}{\rho R g D_i} \quad (3-119a)$$

$$\beta = \frac{1 + r \mu_d}{\mu_d} \quad (3-119b)$$

$$n_i = \frac{1}{2} \quad (3-119c)$$

and values for  $\mu_d$  and  $r$  are given as Eqs. (2-112c) and (2-112d) in Chapter 2. In addition, the parameters  $\tau_{sci}^*$  are computed from the modified Egiazaroff hiding relation in the form of Eq. (3-73a). Under the condition  $q_{i,n}/q_{i,s} \gg 1$  Eq. (3-118) further linearizes to the form

$$|\vec{q}_i| = q_{i,s} \quad (3-120a)$$

$$q_{i,n} = q_{i,s} \left[ \frac{\tau_{bs,n}}{\tau_{bs,s}} - \beta \left( \frac{\tau_{si}^*}{\tau_{sci}^*} \right)^{-n_i} \right] \frac{\partial \eta}{\partial n} \quad (3-120b)$$

$$\tau_{si}^* = \frac{\tau_{bs}}{\rho R g D_i} \quad (3-120c)$$

Parker and Andrews (1985) evaluated the streamwise bed-load transport rates  $q_{si}$  in Eq. (3-120) using a generalization to mixtures of the Parker (1979) bed-load transport relations, also using the modified Egiazaroff hiding relations of Eqs. (3-72a) and (3-73a).

Recently Hasegawa et al. (2000) have similarly modified the 2D nonlinear bed-load transport relation of Kovacs and Parker (1994) to a 2D form for sediment mixtures. The linearized form of the relation is identical to that of Eq. (3-120) but

$$\beta = \sqrt{2} \quad (3-121)$$

and  $q_{i,s}$  is evaluated using the formulation of Ashida and Michiue (1972). Other relations for the 2D transport of bed-load mixtures can be found in Yamasaka et al. (1987) and Olesen (1987).

#### 3.13.2 Manifestations of Local Planform Sorting

As noted in Section 3.1, rivers may also sort sediment from bend to bend and from dune to dune. These local sorting processes are only discussed briefly here; the interested reader may refer to the references quoted.

The flow in river bends drives a characteristic pattern of sorting, with coarser material at the outside of the bend, and on the upstream side of the point bar on the inside of the bend. This pattern can be seen in Fig. 3-4. Bridge and Jarvis (1976) document bend sorting in the River South Esk, Scotland. Dietrich and Smith (1984) and Dietrich and Whiting (1989) document patterns of flow, topography, sediment transport, and sediment sorting in a reach of the meandering Muddy Creek, Wyoming. The latter study provides a complete set of data for testing numerical models.

The flow in river bends sets up a topography with strong transverse slopes. As bed load is transported downstream across such slopes, the coarser grains tend to preferentially move down the transverse slope. This process is one of several that play a fundamental role in driving sorting in bends.

To treat sediment transport and sorting in bends it is necessary to generalize Eq. (3-23) to the 2D form

$$(1 - \lambda_p) \left[ f_{ti} \frac{\partial \eta_b}{\partial t} + \frac{\partial}{\partial t} (L_a F_i) \right] = - \frac{\partial q_{i,s}}{\partial s} - \frac{\partial q_{i,n}}{\partial n} \quad (3-122)$$

The form of Eq. (3-122) in conjunction with a 2D bed-load transport formulation of the form of Eq. (3-120b) allows an intricate interplay between the depth-averaged flow in the  $s$  and  $n$  directions, the secondary flow set up by the bend, and sorting of bed-load grains through the bend. Analytical and numerical models of bend sorting using the above formulation have been presented by Ikeda et al. (1987), Ikeda (1989), and Seminara et al. (1997) for the case of a bend of constant curvature; Parker and Andrews (1985) and Ashida et al. (1991) studied sorting in a meandering channel.

Rivers that are constrained from meandering or braiding by artificial, inerodible banks often develop a pattern of alternate bars instead. Lisle et al. (1997) have performed an experimental study of alternate bars in a steep channel containing heterogeneous sediment. Lanzoni and Tubino (1999) have developed a stability model of alternate bars in rivers that not only predicts realistic sorting pattern, with coarser grains accumulating toward the bar crests, but also demonstrates that the grain-size distribution damps the growth of bar amplitude and reduces bar wavelength as well. A sorting model of the type of Eqs. (3-120b) and (3-122) is used to perform the analysis. Ashworth et al. (1991) describe sorting processes in braided streams. Predictive models for this case seem to be lacking.

Bed-load sheets are low sorting bed forms, the characteristics of which are shown in Fig. 3-3. They have been observed in the laboratory by Iseya and Ikeda (1987) and Kuhnle and Southard (1988) and in the field by Whiting et al. (1988). It has been argued that bed-load sheets are simply immature dunes. This may be true of some bed-load sheets, but Seminara et al. (1996) have used stability analysis to delineate a nearly pure sorting wave that can propagate without evolving into a dune. The basis for the analysis is the Exner equation of sediment continuity, Eq. (3-23), the Parker (1990a) surface-based bed-load transport relation, and a simplified  $k$ - $\epsilon$  turbulence closure for the flow field (Rodi 1993). The handling of the exchange fractions  $f_{li}$ , however, proves difficult in a stability analysis due to the discontinuity in treatment between aggradation and degradation inherent in Eqs. (3-31) and (3-32). This points out the need for an improved Exner relation for sediment conservation that does not have this feature. Progress toward such a model is discussed in Section 3.15. Tsujimoto (1991; 1999) has approached the same problem from the point of view of bed-load entrainment rather than bed-load transport.

Seminara (1998) provides an excellent summary of the application of stability analysis to study river morphodynamics, including sediment mixtures in as general and bed-load sheets in particular.

Tsujimoto (1991; 1999) and Colombini and Parker (1995) have developed stability theories to explain the longitudinal gravel-sand streaks of Fig. 3-8. Colombini and Parker (1995) found that at least some variation in

**Fig. 3-52.** Side view of step-pool topography formed in the laboratory. Image courtesy K. Hasegawa.

grain size is necessary to trigger the instability. The basis for their analysis is (1) the Exner equation of sediment continuity (3-23), (2) the Parker (1990a) formulation for bed-load transport, and (3) the Speziale (1987) turbulence closure for the flow. Tsujimoto posed the problem of longitudinal streaks in terms of bed-load entrainment rather than transport.

Whittaker and Jaeggi (1982) and Ashida et al. (1984) have explained the step-pool topography in steep streams shown in Fig. 3-5 in terms of antidunes. The boulders tend to collect at the crest of antidunes during rare floods, and then stabilize into resistant steps as they are reworked by declining flows. Grant et al. (1990) suggest that these floods may have a recurrence interval on the order of 50 years. Removal of the boulders can lead to wholesale destabilization of the channel (Ikeda, 2001). Tatsuzawa et al. (1999a; 1999b) have performed parallel laboratory and field studies to illustrate the grain sorting processes that give rise to and maintain step-pool bed forms. An example of one of their laboratory step-pool morphologies is given in Fig. 3-52.

Lisle et al. (1997) describe the fate of sudden sediment pulses in streams such as the landslide shown in Fig. 3-12. Sutherland et al. (2002), Cui et al. (2003a; 2003b), and Cui and Parker (in press) describe a numerical model of the disposition of pulses in rivers that includes both selective transport and abrasion. The basis of the model is Eq. (3-33) for sediment conservation (but modified for multiple lithologies), the St. Venant equations, and the Parker (1990a) formulation of bed-load transport. The model was tested in the laboratory and applied successfully to the landslide of Fig. 3-12 (Lisle et al. 1997; Lisle et al. 2001; Cui and Parker in press).

### 3.14 THE CASE OF SUSPENSION-DOMINATED SAND-BED RIVERS

#### 3.14.1 Sorting in Suspension-Dominated Streams

As was shown in Fig. 2-14 and Section 3.4, sand-bed streams tend to (1) be suspension-dominated and (2) contain sediment that is much more uniform than gravel-bed streams. This rule is not universal. Muddy Creek (Dietrich and Whiting, 1989), for example, is an example of a small, relatively steep sand-bed stream in which bed load and suspended load are both important. This observation notwithstanding, the larger the bank-full discharge and the lower the slope, the more likely a sand-bed stream is to be suspension-dominated.

Even though the bulk of the bed-material load might be carried in suspension, one must not dismiss out of hand the possibility that the bed load might do most of the sorting in such streams. To this end, consider as an example the bed load equation of Ashida and Michiue (1972), Eq. (3-77a). As the Shields number becomes large compared to the critical Shields number, the relation reduces to

$$\frac{q_i}{F_i \sqrt{RgD_i D_i}} = 17 \left( \frac{\tau_{bs}}{\rho RgD_i} \right)^{3/2} \quad (3-123a)$$

or reducing with Eq. (3-47),

$$\frac{q_i}{F_i} = \frac{17}{Rg} u_{*s}^3 \quad (3-123b)$$

That is,  $q_i/F_i$  becomes independent of grain size. This result and Eq. (3-28) allow the conclusion that at Shields stresses sufficiently high to allow the neglect of the critical Shields numbers  $\tau_{sci}^*$  in Eq. (3-77a) the bed-load size distribution becomes identical to that of the active layer, implying surface-based equal mobility and the absence of sorting.

The same result holds for the relations of Parker (1990a); Hunziker and Jaeggi (2002); Powell et al. (2001); and Wilcock and Kenworthy (2002), presented in Section 3.7. In all these relations, for large values of  $\tau_i^*$ , (1)  $q_i^*$  varies with  $(\tau_i^*)^{3/2}$  and (2) the critical or reference Shields number containing the hiding function drops out. The near-absence of armoring in the Nahal Yatir at Shields numbers based on surface  $D_{50}$  between 0.1 and 0.3, as illustrated in Section 3.11.3, argues for the validity of this conclusion. In sand-bed streams of the type shown in Fig. 3-29 the bank-full Shields number is on the order of 50 times the critical or reference value, with an average of 1.86. Even the assumption that as much as half of this is form drag does not change the conclusion that sorting due to bed load should be rather minor in suspension-dominated sandbed streams. Some bed-load sorting may be caused topographically in accordance with Eq. (3-120b), however.

Before continuing with the issue of sediment sorting in suspension-dominated sand-bed streams, however, it is important to note that there is a class of streams that are bed-load-dominated but have beds with significant quantities of

both sand and gravel and have median grain sizes falling in the range from coarse sand to fine gravel. These streams are seen in Fig. 3-30 as the Japanese streams that fall in between the sand-bed and gravel-bed clusters of Fig. 3-29. Kleinhans (2002) has described reaches of the Rhine, Allier, and Meuse Rivers of Europe that fall into this range (see Fig. 2-1 there, which has the same format as Figs. 3-30 and 3-31 here). Blom and Kleinhans (1999) and Kleinhans (2002) have modeled them experimentally, as have Wilcock et al. (2001). It is evident from Fig. 3-2 that bed forms such as dunes play a major role in vertical sorting in such streams. The relations proposed by Wilcock and Kenworthy (2002), described in Section 3.7.9, Wilcock and Crowe (2003), described in Section 3.7.10, and Kleinhans and van Rijn (2002), mentioned in Section 3.7.14, may be used to predict grain-size-specific bed-load transport in this type of river.

Sorting of suspended sediment arises from a mechanism rather different from that applying to bed load. In turbulent suspensions of sediment, the finer particles tend to ride higher in the water column. This biases them toward a zone of higher velocity and amplifies their downstream transport rate at the expense of the coarser grains. For the same reason finer particles are more likely to be carried overbank and deposited on the floodplain.

#### 3.14.2 Modified Rouse-Vanoni Approach for Grain-Size-Specific Suspended Load

The analysis of Chapter 2 is modified here for multiple grain sizes. Overbars denote averages over turbulence. Let  $\bar{c}_i(s, z, t)$  denote the volume concentration of suspended sediment of the  $i$ th grain size class at streamwise position  $s$ , normal distance above the bed  $z$ , and time  $t$ . The grain size ranges are chosen to exclude wash load, which is conventionally (but not necessarily accurately) equated with the sediment in transport in the silt and clay sizes ( $<0.0625$  mm). The total concentration of bed-material load in suspension is thus given as

$$\bar{c}_T = \sum_{i=1}^n \bar{c}_i \quad (3-124)$$

Equation (3-23) is generalized to

$$(1 - \lambda_p) \left[ f_{li} \frac{\partial n_b}{\partial t} + \frac{\partial}{\partial t} (L_a F_i) \right] = - \frac{\partial q_i}{\partial s} + v_{si} (\bar{c}_{bi} - E_{si}^*) \quad (3-125)$$

where

$$\bar{c}_{bi} = \bar{c}_i|_{z=z_b} \quad (3-126)$$

denotes a near-bed reference concentration at elevation  $z = z_b$  and  $v_{si}$  denotes the fall velocity of the  $i$ th grain size. In addition,  $E_{si}^*$  denotes a dimensionless rate of entrainment of sediment from the bed such that  $E_{si} = v_{si} E_{si}^*$  is the volume rate of entrainment of sediment from the  $i$ th grain size range per unit time per unit bed area, and  $v_{si} \bar{c}_{bi}$  denotes the deposition rate of the  $i$ th class per unit time per unit bed area.

In the case of an equilibrium suspension, entrainment into suspension balances deposition from it, so that

$$E_{si}^* = \bar{c}_{bi} \quad (3-127)$$

In general, however,  $\bar{c}_i$  must satisfy the advection-diffusion equation of conservation of suspended sediment. This is presented here in 2D form in the  $s$ - $z$  plane with  $z$  denoting the upward normal direction and the parameter  $D_d$  denoting the kinematic eddy diffusivity of suspended sediment, here approximated by the corresponding value for momentum:

$$\frac{\partial \bar{c}_i}{\partial t} + \bar{u} \frac{\partial \bar{c}_i}{\partial s} + (\bar{w} - v_{si}) \frac{\partial \bar{c}_i}{\partial z} = \frac{\partial}{\partial z} D_d \frac{\partial \bar{c}_i}{\partial z} \quad (3-128)$$

This equation is in turn coupled to the equations of streamwise momentum balance and continuity of the flow,

$$\frac{\partial \bar{u}}{\partial t} + \bar{u} \frac{\partial \bar{u}}{\partial s} + \bar{w} \frac{\partial \bar{u}}{\partial z} = -g \frac{\partial H}{\partial s} - g \frac{\partial \eta}{\partial s} + \frac{\partial}{\partial z} D_d \frac{\partial \bar{u}}{\partial z} \quad (3-129)$$

$$\frac{\partial \bar{u}}{\partial s} + \frac{\partial \bar{w}}{\partial z} = 0 \quad (3-130)$$

In Eqs. (3-128) and (3-129) the slender flow approximation has been used to (1) drop the streamwise turbulent diffusion terms, (2) drop the upward normal equation of momentum balance, and (3) approximate the pressure distribution as hydrostatic. The above three relations easily generalize to 3D flow.

The boundary conditions on Eq. (3-128) are

$$-D_d \frac{\partial \bar{c}_i}{\partial z} \Big|_{z_b} = v_{si} E_{si}^* \quad (3-131a)$$

$$\left( v_{si} \bar{c}_i + D_d \frac{\partial \bar{c}_i}{\partial z} \right) \Big|_{z=H} = 0 \quad (3-131b)$$

where

$E_{si}^*$  = a specified function of the flow.

The first of these specifies the near-bed rate of entrainment of sediment into suspension, and the second specifies the condition of vanishing upward normal sediment flux at the water surface. Equation (3-131a) is sometimes replaced with a concentration boundary condition, according to which

$$\bar{c}_{bi} = \bar{c}_i \Big|_{z=z_b} = \bar{c}_{bed,i} \quad (3-131c)$$

where

$\bar{c}_{bed,i}$  = a specified function of the flow.

In the case of equilibrium suspensions Eqs. (3-131a) and (3-131c) yield identical results in light of Eq. (3-127). In the case of disequilibrium suspensions Eq. (3-131a) is the preferred form, as outlined in, e.g., Parker (1978a). The boundary conditions on the flow are

$$\frac{\bar{u}}{u_*} \Big|_{z_b} = \frac{1}{\kappa} \ln \left( 30 \frac{z_b}{k_s} \right) \quad (3-132a)$$

$$D_d \frac{\partial \bar{u}}{\partial z} \Big|_H = 0 \quad (3-132b)$$

$$\bar{w} \Big|_{z_b} = 0 \quad (3-132c)$$

$$\left( \frac{\partial \bar{u}}{\partial t} + \bar{u} \frac{\partial \bar{u}}{\partial s} - \bar{w} \right) \Big|_H = 0 \quad (3-132d)$$

i.e., the streamwise flow velocity matches the logarithmic law near the bed, the water surface is free of shear stress, the normal velocity vanishes at the bed, and the kinematic boundary condition is satisfied at the water surface. In Eq. (3-132a)  $\kappa$  denotes the von Karman constant and  $k_s$  is the roughness height of the bed.

As described in Chapter 2, density stratification effects induced by suspended sediment can interact with the flow. The net effect is to increase the flow velocity and reduce the concentrations of suspended sediment. Wright and Parker (2004a, 2004b) have shown that this effect is particularly important in large, low-slope sand-bed rivers.

When the model of Smith and McLean (1977) outlined in Chapter 2 is extended to sediment mixtures, the turbulent eddy viscosity  $D_d$  is damped by a stratification effect mediated by the gradient Richardson number  $Ri_g$ :

$$D_d = D_{do} F_{\text{strat}}(Ri_g) \quad (3-133a)$$

$$Ri_g = \frac{-Rg \frac{\partial \bar{c}_r}{\partial z}}{\left( \frac{\partial \bar{u}}{\partial z} \right)^2} \quad (3-133b)$$

In this relation  $F_{\text{strat}}(Ri_g)$  is a specified function of the gradient Richardson number, which Smith and McLean (1977) equate to

$$F_{\text{strat}}(Ri_g) = 1 - 4.7 Ri_g \quad (3-133c)$$

Note that according to Eq. (3-133c) the turbulence should be completely damped out for a gradient Richardson number of 0.21, a value that is fully in accord with the more advanced turbulence closure scheme of Mellor and Yamada (1974).

Equations (3-128) to (3-130) can be solved subject to Eq. (3-131a) or Eq. (3-131c), Eq. (3-131b), Eqs. (3-132), the closure model of Eq. (2-200), and appropriate initial conditions to yield solutions for  $\bar{c}_i(s, z, t)$  and  $\bar{u}(s, z, t)$ . The depth-averaged flow velocity  $U$  and concentrations  $C_i$  and the bed material part of the volume suspended load per unit width per unit time  $q_{si}$  are then computed as

$$UH = \int_{z_b}^H \bar{u} dz \quad (3-134a)$$

$$q_{si} = UC_i H = \int_{z_b}^H \bar{u} \bar{c}_i dz \quad (3-134b)$$

Equation (3-128) can be depth-integrated subject to Eqs. (3-131a,b), yielding the relation

$$\frac{\partial C_i H}{\partial t} + \frac{\partial q_{si}}{\partial s} = v_{si} (\bar{c}_{bi} - E_{si}^*) \quad (3-135)$$

As long as the time rate of change of the volume of suspended sediment stored in the water column per unit bed area is small (as can be expected for nearly all fluvial suspensions), the first term on the left-hand side of Eq. (3-135) can be dropped, so that Eq. (3-125) reduces to

$$(1 - \lambda_p) \left[ f_{li} \frac{\partial \eta_b}{\partial t} + \frac{\partial}{\partial t} (L_a F_i) \right] = - \frac{\partial q_i}{\partial s} - \frac{\partial q_{si}}{\partial s} = - \frac{\partial q_{bmi}}{\partial s} \quad (3-136)$$

where

$q_{bmi}$  = volume bed-material load (bed load + bed-material suspended load) transport rate per unit time per unit width.

Let  $U_{ch}$ ,  $H_{ch}$ , and  $v_{sch}$  denote characteristic values for flow velocity, flow depth, and sediment fall velocity, respectively. The parameter  $(U_{ch}/v_{sch})H_{ch}$  defines an appropriate relaxation length for streamwise adjustment of the suspended sediment profile. When the length scale of interest for sorting due to suspension is smaller than this relaxation length the full 2D (or 3D) problem for the flow and suspended sediment profiles must be solved to determine the evolution of the bed elevation and sorting in accordance with Eq. (3-125). An example of this is the sorting of sediment over one bend or meander length of a suspension-dominated stream, in which case Eq. (3-125) must be amended to the 2D form

$$(1 - \lambda_p) \left[ f_{li} \frac{\partial \eta_b}{\partial t} + \frac{\partial}{\partial t} (L_a F_i) \right] = - \frac{\partial q_{si,s}}{\partial s} - \frac{\partial q_{si,n}}{\partial n} + v_{si} (\bar{c}_{bi} - E_{si}^*) \quad (3-137)$$

to include transverse effects. In this relation  $(q_{si,s}, q_{si,n})$  denotes the volume bed-load transport rate per unit width in the  $(s, n)$  directions.

When the length scale of interest is sufficiently long compared to the relaxation length, on the other hand, it suffices to obtain  $q_{si}$  from a quasi-equilibrium solution for suspension and flow and allow the bed to evolve and sort according to, e.g., in the case of a 1D formulation, Eq. (3-136). An example of such a problem is downstream fining in suspension-dominated sand-bed streams.

The case of an equilibrium or quasi-equilibrium suspension is considered next. As in Chapter 2, for simplicity the turbulent eddy diffusivity in the absence of stratification  $D_{do}$  is chosen to be the one that yields the logarithmic profile:

$$D_{do} = \kappa u_* z \left( 1 - \frac{z}{H} \right) \quad (3-138)$$

For this case Eqs. (3-128) to (3-132) can be solved to yield

$$\bar{c}_i = E_{si}^* \exp \int_{z_b}^z \left[ - \frac{v_{si}}{\kappa u_* z \left( 1 - \frac{z}{H} \right) F_{\text{strat}}(\text{Ri}_g)} dz \right] \quad (3-139a)$$

and

$$\bar{u} = \frac{u_*}{k} \left[ \ln \left( 30 \frac{z_b}{k_s} \right) + \int_{z_b}^z \frac{1}{z F_{\text{strat}}(\text{Ri}_g)} dz \right] \quad (3-139b)$$

These two equations do not in and of themselves constitute a solution to the problem, because  $\text{Ri}_g$  is a function of the concentration gradient  $\partial \bar{c}_i / \partial z$  as specified by Eq. (3-133b). They can, however, be solved readily enough iteratively, starting with the Rouse-Vanoni concentration profile (Rouse, 1939) and logarithmic velocity profile that would prevail in the absence of stratification. These are obtained by setting  $F_{\text{strat}}$  equal to unity in Eqs. (3-139a,b), yielding the respective forms

$$\bar{c}_i = E_{si}^* \left[ \frac{\left( 1 - \frac{z}{H} \right)}{\left( 1 - \frac{z_b}{H} \right)} \right]^{\frac{v_{si}}{\kappa u_*}} \quad (3-140a)$$

$$\bar{u} = \frac{u_*}{\kappa} \ln \left( 30 \frac{z}{k_s} \right) \quad (3-140b)$$

Once the solutions for  $\bar{c}_i$  and  $\bar{u}$  are obtained, the grain-size-specific transport rates  $q_{si}$  are evaluated as

$$q_{si} = \int_{z_b}^H \bar{u} \bar{c}_i dz \quad (3-141)$$

and bed evolution and sorting can be evaluated from Eq. (3-136).

### 3.14.3 Grain-Size-Specific Relations for Sediment Entrainment or Near-Bed Concentration

Few relations specifically designed for predicting the entrainment (bed concentration) of heterogeneous suspended sediment appear to be available. One of these is due to Garcia and Parker (1991). Along the lines of Section 3, the following general form is assumed:

$$\frac{E_{si}^*}{F_i} \equiv E_{si}^* = T_{se} \left( \frac{u_{*s}}{v_{si}}, \frac{D_i}{D_{50}}, \text{R}_{pi}, \sigma \right) \quad (3-142a)$$

$$\text{R}_{pi} = \frac{\sqrt{RgD_i D_i}}{v} \quad (3-142b)$$

Garcia and Parker (1991) used a similarity collapse of laboratory data, as well as field data from two small sand-bed streams, to obtain the following entrainment relation:

$$E_{si}^* = \frac{AZ_{ui}^5}{1 + \frac{A}{0.3} Z_{ui}^5} \quad (3-143a)$$

$$Z_{ui} = \lambda_m \frac{u_{*s}}{v_{si}} \text{R}_{pi}^{0.6} \left( \frac{D_i}{D_{50}} \right)^{0.2} \quad (3-143b)$$

$$\lambda_m = 1 - 0.298\sigma \quad (3-143c)$$

$$A = 1.3 \times 10^{-7} \quad (3-143d)$$

Recently Wright and Parker (2004b) found that this relationship, although reasonably accurate for small to medium sand-bed streams, overpredicts the entrainment rate for large sand-bed streams. They have modified the relation as follows:  $E_{si}^*$  is still given Eq. (3-143a), but  $Z_{ui}$  is now given by the relation

$$Z_{ui} = \lambda_m \left( \frac{u_{*s}}{v_{si}} R_{pi}^{0.6} \right) S^{0.08} \left( \frac{D_i}{D_{50}} \right)^{0.02} \quad (3-143e)$$

where

$$A = 7.8 \times 10^{-7} \quad (3-143f)$$

and  $S$  denotes bed slope. In Eq. (3-143e),  $\lambda_m$  is still given by Eq. (3-143c).

In either the original or amended Garcia-Parker relations the value  $z_b$  at which the entrainment rate is evaluated is specified as

$$z_b = 0.05H \quad (3-143g)$$

This value was chosen because data with which to develop the relation were available at this elevation. Once the concentration profile is determined it can be extrapolated downward to find values closer to the bed.

McLean (1991; 1992) formulates the problem in terms of a concentration boundary condition of the form of Eq. (3-131c) rather than the entrainment boundary condition of Eq. (3-131a). McLean presents the following relation for near-bed concentration. Let  $\bar{c}_{bT}$  denote the total near-bed concentration summed over all grain sizes. Recalling that  $f_{bi}$  denotes the fractions in the bed load, the computation for the near-bed concentrations  $\bar{c}_{bi}$  proceeds as follows:

$$\bar{c}_{bi} = f_{sbi} \bar{c}_{bT} \quad (3-144a)$$

where

$\bar{c}_{bT}$  = total near-bed concentration summed over all grain sizes;

$f_{sbi}$  = fraction of the near-bed suspended sediment in the  $i$ th grain size range; and

$$\bar{c}_{bT} = \frac{\gamma_o \left( \frac{\tau_{bs}}{\tau_{bsc}} - 1 \right)}{1 + \gamma_o \left( \frac{\tau_{bs}}{\tau_{bsc}} - 1 \right)} (1 - \lambda_p) \quad (3-144b)$$

$$\gamma_o = 0.004 \quad (3-144c)$$

$$f_{sbi} = \frac{\Phi_i f_{bi}}{\sum_{i=1}^n \Phi_i f_{bi}} \quad (3-144d)$$

$$\Phi_i = \begin{cases} 1 & \text{for } u_{*s} / v_{si} > 1 \\ \frac{u_{*s} - u_{*sc}}{v_i - u_{*sc}} & \text{for } u_{*s} / v_{si} < 1 \end{cases} \quad (3-144e)$$

$$u_{*s} = \sqrt{\frac{\tau_{bs}}{\rho}} \quad (3-144f)$$

$$u_{*sc} = \sqrt{\frac{\tau_{bsc}}{\rho}} \quad (3-144g)$$

The McLean relation uses a single critical shear stress  $\tau_{bsc}$  evaluated using size  $D_{50}$ ; this value is applied to all grain sizes. The relation for the point  $z_b$  at which the near-bed concentrations are evaluated is

$$z_b = \max \left( \frac{a_D D_{84}}{a_o \delta_B(D_{84})} \right) \quad (3-144h)$$

$$\delta_B(D) = D \frac{A_1 \left( \frac{\tau_{bs}}{\tau_{bsc}} - 1 \right)}{1 + A_2 \left( \frac{\tau_{bs}}{\tau_{bsc}} - 1 \right)} \quad (3-144i)$$

$$a_D = 0.12 \quad (3-144j)$$

$$a_o = 0.056 \quad (3-144k)$$

$$A_1 = 0.68 \quad (3-144l)$$

$$A_2 = 0.0204(\ln D)^2 + 0.022(\ln D) + 0.0709 \quad (3-144m)$$

In the relation for  $A_2$  the grain size must be in millimeters. The McLean formulation can also be used to specify the entrainment boundary condition of Eq. (3-131a), in which case the functional form for  $E_{si}^*$  is simply taken to be

$$E_{si}^* = f_{sbi} \bar{c}_{bT} \quad (3-144n)$$

### 3.14.4 Grain-Size-Specific Bulk Predictors for Bed-Material Load

The relation of Ackers and White (1980) as generalized for mixtures by Proffitt and Sutherland (1983) has been presented in Section 3.7.13. In this form it predicts the transport rate and grain-size distribution of the bed-material load, i.e., bed load and bed-material component of suspended load. As a predictor of total bed-material load in its original form, which is not grain-size-specific, the relation of Ackers and White has been shown to perform quite well for both laboratory and field streams (Brownlie 1981; see also Chapter 2). The grain-size-specific dependency was, however, introduced with the aid of a hiding function developed for coarse material. It remains to be seen how well the relation sorts sand.

The bed-material load predictor of Yang (1973) has been presented in Chapter 2. That formulation uses only a single grain size. As discussed in Section 3.7.14, Yang and Wan (1991) have extended this formulation for sediment mixtures. The accuracy of the predictions of total bed-material transport rate summed over all sizes has been tested against data with excellent agreement. The accuracy of the predicted grain-size distributions of the bed load has not similarly been subjected to a thorough test.

The bulk predictor for bed-material transport rate of Karim and Kennedy (1981) was presented in Chapter 2. Karim (1998) has generalized the formulation for sediment mixtures. The generalization appears to apply specifically to sand-bed streams. Karim's relation takes the form

$$\frac{q_{bmi}}{F'_{ai} \sqrt{RgD_i} D_i} = 0.00139 \left( \frac{U}{\sqrt{RgD_i}} \right)^{2.97} \left( \frac{u_*}{v_{si}} \right)^{1.47} \eta_i \quad (3-145a)$$

$$\eta_i = C_1 \left( \frac{D_i}{D_{50}} \right)^{C_2} \quad (3-145b)$$

$$C_1 = 1.15 \left( \frac{v_{s50}}{u_*} \right) \quad (3-145c)$$

$$C_2 = 0.60 \left( \frac{v_{s50}}{u_*} \right) \quad (3-145d)$$

In these relations  $F'_{ai}$  is computed from  $F_i$  as

$$F'_{ai} = \frac{(F_i / D_i)}{\sum_{i=1}^n (F_i / D_i)} \quad (3-145e)$$

Karim (1998) reports good agreement between the predicted load and grain-size distribution and the observed values in three sand-bed streams: the Niobrara River, the Middle Loup River, and the Missouri River. The above formulation may be used in conjunction with the resistance formulation of Karim and Kennedy (1981), which was developed in tandem with the original bulk predictor of total bed-material load of that document.

In addition to the grain-size-specific bulk predictor for bed-load transport presented in Section 3.7.11, Wu et al. (2000) also present the following grain-size-specific bulk predictor for the bed material part of the suspended load:

$$\begin{aligned} W_{sui}^* &= \frac{Rgq_{si}}{\bar{f}_i u_{*s}^3} \\ &= 0.0000262 \frac{1}{(\tau_{si}^*)^{3/2}} \left[ \left( \frac{\tau_{si}^*}{\tau_{sui}^*} - 1 \right) \frac{U}{v_{si}} \right]^{1.74} \end{aligned} \quad (3-146)$$

The relation has the advantage of simplicity. Wu et al. report excellent agreement with data when Eqs. (3-85) and (3-146)

are used to predict grain-size-specific bed-material load, i.e.,  $q_{bmi} = q_i + q_{si}$ .

Recently Wright and Parker (2004b) have used Eqs. (3-143a), (3-143e), (3-143f), and (3-143g), Eqs. (2-177) to (2-181) of Chapter 2, and a consideration of flow stratification to develop a grain-size-specific predictor of suspended load in sand-bed rivers. Although the method is intended to be of general applicability, the formulation is specifically intended to capture flow stratification effects that can be significant in large, low-slope sand-bed streams.

### 3.14.5 Downstream Fining in Sand-Bed Streams

Downstream fining of bed sediment in a long reach of a large, low-slope sand-bed river is illustrated in Fig. 3-53 for the Mississippi River between Cairo, Illinois and the Head of Passes, Louisiana, a reach nearly 1800 km long (Waterways Experiment Station 1935, as quoted by Simons 1971). Figure 3-53a shows the streamwise variation of the complete grain-size distribution and Fig. 3-53b shows the streamwise variation of the mean grain size of sand only. The former figure documents the pinch-out of the gravel, the coarse sand, and then the medium sand as the bed fines. The latter figure documents a reduction in mean sand grain size from about 0.65 mm to under 0.20 mm over the reach.

Hydraulic sorting is only one cause of downstream fining. In the case of the Mississippi River, downstream fining may also be influenced by the delivery of successively finer sediment from tributaries farther downstream. In the case of the pattern of downstream fining in the middle Fly River, Papua New Guinea, illustrated in Fig. 3-54 (Pickup et al. 1979; Dietrich et al. 1999), however, the cause is unambiguously hydraulic sorting. This is because no important tributaries enter the Fly over the reach extending from 50 to 450 km in Fig. 3-54, so that the input of both water and sediment from tributaries is small.

The pattern of downstream fining given in Fig. 3-54 characterizes conditions before the advent of sediment disposal from the Ok Tedi copper mine in 1985. Since then both the sediment balance of the river and the pattern of downstream fining in the middle Fly River have been greatly modified, with median size reduced by about half and the intensity of downstream fining suppressed (Dietrich et al. 1999; Cui and Parker 1999).

The first attempt to numerically model downstream fining in any stream was the simple treatment of Deigaard (1980) applied to the sand-bed Niger River. Since that time the case of sand-bed streams has been neglected. Cui and Parker (1999), however, report on a model of downstream fining in the middle Fly River. The model uses water and sediment inputs specified on a daily basis, calculations of the flow based on a gradually varied implementation of the St. Venant shallow-water equation, and a Rousean formulation neglecting stratification effects for  $q_{si}$ . Bed evolution is computed from an implementation of Eq. (3-136), with  $L_a$

**Fig. 3-53.** Downstream fining in the Mississippi River, USA. (a) Downstream variation in grain-size distribution. (b) Downstream variation in mean grain size.

**Fig. 3-54.** Downstream variation in  $D_{50}$  and  $D_{90}$  in the middle Fly River, Papua New Guinea in 1979, before the opening of the Ok Tedi copper mine in 1985. Dietrich et al. (1999). Copyright John Wiley & Sons Limited. Reproduced with permission.

scaling with dune height and with the addition of the subsidence term in Eq. (3-116). The model also includes a simple formulation for overbank deposition, as outlined in the next section. Hydraulic sorting also appears to be the dominant mechanism of downstream fining on the sand-bed reach of the Beni River, Bolivia, studied by Aalto (2002).

Wright and Parker (2004a; 2004b) have demonstrated that stratification effects are usually negligible in sand-bed

streams with medium to steep slopes. In large, low-slope sand bed streams, however, stratification can be sufficient to (1) substantially suppress the bed-material suspended load and (2) substantially reorganize the size distribution of this load toward the finer. Stratification may thus play an important role in the pattern of downstream fining in such streams.

### 3.14.6 Grain-Size-Specific Formulations for Floodplain Deposition of Suspended Sediment

The ability of a river to access its floodplain during floods is illustrated in Fig. 3-55. The study of overbank deposition of sediment due to floods has been until recently the province of geographers and geologists rather than engineers. A summary of recent literature on floodplain processes can be found in Anderson et al. (1996).

In recent years engineers have been drawn into the field of floodplain sedimentation in order to (1) design river restoration projects, (2) predict the deposition of anthropogenic sediment on floodplains, and (3) track the accumulation of toxic metals adsorbed onto the finest sediment grains as they deposit on the floodplain. Figure 3-56 illustrates a floodplain that has been heavily damaged by a flood that carried toxic sediments overbank in 1910.

The Exner equation of sediment continuity, Eq. (3-103), is here modified to the form

**Fig. 3-55.** View of the floodplain of the Minnesota River, Minn. during the flood of record in 1965.

$$(1 - \lambda_p) B_c \left( f_{fi} \frac{\partial \eta_b}{\partial t} + L_a \frac{\partial F_i}{\partial t} \right) = - \frac{\partial B_c q_i}{\partial s} - \frac{\partial B_c q_{si}}{\partial s} - q_{obi} \quad (3-147)$$

in order to include overbank deposition of sediment during floods. Here  $q_{obi}$  denotes the volume rate of overbank deposition of sediment in the  $i$ th grain size range per unit time per unit channel length, including both banks. ( $B_c$  in this equation is modified to  $B_{ca}$  only after zeroing of the model, as described in Section 3.10.2.)

Narinesingh (1995), Narinesingh et al. (1999), and Parker et al. (1996) have independently devised very similar models for the computation of the parameter  $q_{obi}$ , one in the context of river restoration in the Netherlands and the other in the context of floodplain deposition of mine-derived sediment. The basis of both models is convective rather than diffusive. Consider the meandering river of Fig. 3-57. The total floodplain or meander belt width over which floodplain deposition takes place is denoted as  $B_f$ ; the value includes both sides of

**Fig. 3-56.** (a) View of a reach of Silver Bow Creek, Mont. in which the floodplain is so rich in toxic sediments that vegetation cannot take hold. The toxic sediment is derived from the Anaconda copper mine near Butte, Mont.; the flood that deposited the sediment occurred in 1910. (b) View of an uncontaminated, healthy tributary of Silver Bow Creek.

the river. Overbank flow is followed along a characteristic floodplain stream tube of length  $L_f$  from channel to channel. In the case of a vegetated floodplain, any sediment that deposits is unlikely to be resuspended. Let  $C_{fi}$  denote the depth-averaged volume concentration of sediment in the  $i$ th grain size range in the water column over the floodplain, and let  $H_f$  denote floodplain depth and  $U_f$  denote depth-averaged floodplain velocity. Where  $s_f$  denotes distance along the stream tube,

$$\frac{D}{Dt} (C_{fi} H_f) = U_f H_f \frac{dC_{fi}}{ds_f} = -v_{si} C_{fi} \quad (3-148)$$

Integrating along the stream tube from channel to channel, the volume deposition rate of material in the  $i$ th grain size range per unit time per unit distance normal to the coordinate  $s_f$  is given as

Fig. 3-57. Diagram illustrating floodplain deposition.

$$\begin{aligned} v_{si} \int_0^{L_f} C_{fi} ds_f &= v_{si} C_{ucfi} \frac{U_f H_f}{v_{si}} \left[ 1 - \exp \left( -\frac{v_{si} L_f}{U_f H_f} \right) \right] \\ &= U_f H_f C_{ucfi} \left[ 1 - \exp \left( -\frac{v_{si} L_f}{U_f H_f} \right) \right] \end{aligned} \quad (3-149)$$

where

$C_{ucfi}$  = concentration of sediment in the  $i$ th grain size range in the channel, averaged over that part of the channel flow that is above bank-full, i.e., over a layer with thickness  $H_f$

Now every such stream tube is of a different length, but one may reliably assume that  $L_f$  scales with  $B_f$  for most meandering streams. Assuming that the area of floodplain  $A_b$  delineated by a single bend scales as

$$A_b \approx B_f L_f \approx B_f^2 \quad (3-150)$$

and recalling that floodplain discharge  $Q_f$  is given by

$$Q_f = U_f B_f H_f \quad (3-151)$$

the volume deposition rate per unit floodplain area per unit time  $D_{fpi}$  scales as

$$\begin{aligned} D_{fpi} &\approx \frac{C_{ucfi} Q_f}{B_f L_f} \left[ 1 - \exp \left( -\frac{v_{si} L_f}{U_f H_f} \right) \right] \approx \\ &\frac{C_{ucfi} Q_f}{B_f^2} \left[ 1 - \exp \left( -\alpha_f \frac{v_{si} B_f^2}{Q_f} \right) \right] \equiv \\ &FI \frac{C_{ucfi} Q_f}{B_f^2} \left[ 1 - \exp \left( -\alpha_f \frac{v_{si} B_f^2}{Q_f} \right) \right] \end{aligned} \quad (3-152)$$

where

FI = dimensionless “floodplain number” and

$\alpha_f$  = dimensionless “attenuation coefficient,”

both of which might be expected to be of order unity. The parameter  $q_{obi}$  in Eq. (3-147) is thus given as

$$q_{obi} = D_{fpi} B_f = FI C_{ucfi} \frac{Q_f}{B_f} \left[ 1 - \exp \left( -\alpha_f \frac{v_{si} B_f^2}{Q_f} \right) \right] \quad (3-153)$$

The parameter  $C_{ucfi}$  can be computed from Eq. (3-139a) as

$$\begin{aligned} C_{ucfi} &= \frac{1}{H_f} \int_{H_{bf}}^{H_{bf}+H_f} \bar{c}_i dz \\ &= \frac{E_{si}}{H_f} \int_{H_{bf}}^{H_{bf}+H_f} \exp \int_{z_b}^z \left[ -\frac{v_{si}}{\kappa u_* z \left( 1 - \frac{z}{H} \right) F_{\text{strat}}(Ri_g)} dz' \right] dz \end{aligned} \quad (3-154)$$

where

$H_b$  = bank-full depth.

Equation (3-146) can be coupled to a model of channel-floodplain flow such as that described in Section 3.10.2 to perform the calculation of floodplain deposition for each time step for which the channel is overbank. The parameters FI and  $\alpha_f$  must at this point be calibrated for every application. Cui and Parker (1999), however, were able to obtain reasonable results with the values  $0.2 < FI < 0.72$  and  $\exp[-\alpha_f (v_{si} B_f^2)/Q_f] \ll 1$ .

The above formulation of overbank deposition is both preliminary and incomplete. For example, it does not encompass splay deposits that provide a mechanism for bringing relatively coarse bed sediment onto the floodplain (e.g., Aalto 2002).

### 3.14.7 Deposition of Fine Sediments in and Flushing from Gravels

As noted, sand and silt often move through a gravel-bed river as throughput load during floods, with little interplay with the bed beyond partial filling of the interstices of newly deposited gravels. When the concentrations of these fines are too high, or when the flow velocities are too low to prevent excess accumulation of within the gravel framework, the gravels can become polluted with fines. This fines pollution degrades the gravel bed as both spawning grounds and habitat for anadromous fish. The discharge of relatively sediment-free flushing flows, often from an upstream reservoir, can at least partially remove the fines and renew the gravel.

Reiser (1998) provides a summary of the ecological and biological requirements of gravel-bed rivers, with emphasis on the quality of the bed sediments. Diplas and Parker (1992) have described experimentally the process of pollution of gravel beds by fines; Huang and Garcia (2000) provide a predictive model of fines pollution. Milhous (1998) describes a numerical model for designing flushing flows in gravel-bed

streams. Wilcock et al. (1996) describe how flushing can be implemented on the Trinity River, California, and Wilcock (1998b) provides general criteria for the design of flushing flows.

### 3.15 TRACERS AND VERTICAL SORTING

#### 3.15.1 Tracers

The use of tracer particles has a venerable history in the study of bed-load transport of mixed sizes in gravel-bed rivers (e.g., Leopold et al. 1966). In the early days of their use tracer particles were painted and placed on the bed of a stream during a dry period or at low flow. Recovery rates after a flood tended to be poor. More recently magnetically tagged particles have been used, much improving the recovery rates.

One way to characterize the relative mobility of grains of different sizes is to quantify the average distance  $L_{ti}$  moved by tracers in each size class during a single flood as a function of grain size. Hassan et al. (1992), for example, found that the  $L_{ti}$  tends to decrease only weakly with increasing grain size  $D_i$  for the finer sizes in a mix, but declines notably with increasing grain size for sufficiently coarse grains. This result has been confirmed by Wilcock (1997b) and Ferguson and Wathen (1998). Field data for  $L_{ti}/L_{t50}$  versus  $D_i/D_{50}$ , where  $L_{t50}$  denotes the average distance moved by tracers with the surface median size  $D_{50}$ , are plotted in Fig. 3-58. The data points are for the Allt Dubhaig (Ferguson and Wathen 1998), and the solid line defines a relation determined by Church and Hassan (1992).

**Fig. 3-58.** Relative travel distance of tracers in each size class as a function of relative grain size. From Ferguson and Wathen (1998). (Copyright 1998 American Geophysical Union. Reproduced by permission of American Geophysical Union.)

Tracers also provide an approximate method for characterizing the bed-load transport rate. The relation of Haschenburger and Church (1998) can be generalized to estimate the volume bed-load transport rate per unit width  $q_i$  for the  $i$ th grain size range as

$$q_i = (1 - \lambda_p) v_{bi} L_a F_i \quad (3-155)$$

where

$v_{bi}$  = mean virtual velocity of the  $i$ th grain size; and  
 $L_a$  = thickness of the active layer over which the grains are mixed during a transport event.

The mean virtual velocity  $v_{bi}$  is computed as the mean distance moved by tracers in the  $i$ th grain-size range divided by the duration of the flood event during which they moved. It must be kept in mind that the value of  $q_i$  determined from Eq. (3-148) represents an average over one flood, as the tracers cannot usually be recovered until the flood has subsided.

Implementation of Eq. (3-155) requires knowledge of the thickness of the active layer  $L_a$ . This thickness has been inferred from the probability distribution of depth of burial of tracers as well as direct measurements of bed level variation in terms of scour and fill over one flood (e.g., Schick et al. 1987; Hassan 1990; Hassan and Church 1994; Wilcock 1997b; Haschenburger 1999). Figure 3-59 illustrates the use of “Leopold chains” to monitor scour and fill during a flood. Hassan and Church (1994), for example, have found that for single-peak floods the probability distribution associated with the depth of burial tends to follow an exponential curve, the exponent of which varies somewhat with grain size. The study indicates that a single flood is often sufficient to bury at least some tracers to a depth of  $5 D_{50}$  or more below the surface.

**Fig. 3-59.** Diagram illustrating the use of “Leopold” scour chains to measure scour and fill associated with a flood. From Haschenburger (1999). (Copyright 1999 American Geophysical Union. Reproduced by permission of American Geophysical Union.)

### 3.15.2 Extension of the Active-Layer Model to Describe Vertical Sorting

The exponential curves for probability of depth of burial over a single flood are reminiscent of the curve for the probability of entrainment of a grain per unit time as a function of depth below the mean bed surface hypothesized in Fig. 3-31c. That is, the exchange or active-layer approximation of Fig. 3-31d provides only the simplest possible description of the vertical exchange of particles of differing sizes associated with scour and fill. Schick et al. (1987), Hassan and Church (1994), and Haschenburger (1999) have devised probabilistic models for vertical exchange of particles that use a probabilistic description with continuous variation in the vertical, rather than the simplification of a single, well-mixed layer underlain by a substrate that is never accessed in the absence of mean bed degradation.

The vertical exchange outlined in the papers above was likely accomplished in most cases by random scour and fill in the absence of well-developed dunes. Ribberink (1987) has investigated the case of vertical sorting of different sizes of sediment in a dune field and has found a vertical structure of sorting that is too complex to explain in terms of the simple active-layer model. This vertical sorting can be at least partially seen in Fig. 3-2; a clearer schematization is given in Fig. 3-60 (Blom et al. 2001). Blom and Kleinhans (1999) and Blom and Ribberink (1999) have found that as opposed to the typical case in gravel-bed streams, in the presence of dunes the coarser material tends to accumulate at the base of the dunes, creating a partial barrier between the somewhat finer substrate below and the considerably finer material in the migrating dunes above. Niño and Aracena (1999) have found a similar result for the case of ripples. Hooke (1968) describes an extreme case in which pebbles fed onto a sand bed covered with dunes migrated downward to form a one-grain-thick immobile layer over which the dunes migrated.

In confirmation of the prediction of Suzuki and Michiue (1979), Blom and Kleinhans (1999) and Blom and Ribberink (1999) found that a wide grain-size distribution tends to suppress dune amplitude. In addition, increasing stage of flow tends to mitigate the vertical sorting pattern.

**Fig. 3-60.** Schematization of the pattern of vertical sorting generated by the successive passage of dunes over a bed of heterogeneous sediment. (Blom et al., 2003, 39(2), 102S, doi: 10.1029/2001WR001088. Copyright 2003 American Geophysical Union. Reproduced with permission of American Geophysical Union.)

The above observations have spurred the search for a formulation of the Exner equation for sediment continuity of size mixtures that is of more general validity than the active-layer model of Section 3.5. Ribberink (1987), Ashida et al. (1989), Egashira and Ashida (1990), and Di Silvio (1991) introduced formulations with multiple layers in the vertical, each able to exchange with adjacent layers. Armanini (1995) went one step farther and developed a diffusion model for vertical mixing that is intrinsically continuous in nature.

Recently Parker et al. (2000) succeeded in developing a vertically continuous version of the Exner equation of sediment continuity for multiple grain sizes. The relation is based on (1) the probability distribution associated with bed elevation fluctuations and (2) structure functions for variation in the entrainment and deposition rates of sediment of various sizes with depth below the mean bed layer. The treatment draws heavily on the entrainment model of Tsujimoto (1991) for bed-load transport, as outlined in Section 3.5.5. The formulation can be briefly outlined as follows.

Let  $\eta$  denote the local mean bed elevation averaged over fluctuations (see Fig. 3-31a) and let  $y = z - \eta$  denote elevation relative to the mean bed elevation. The probability density function of elevation fluctuation is denoted as  $p_e(y)$ , and the parameter  $P_s$  denoting the probability that the instantaneous bed is higher than elevation  $y$  is defined as

$$P_s(y) = 1 - \int_{-\infty}^y p_e(y) dy \quad (3-156)$$

The bed-load entrainment and deposition rates  $E_{bi}$  and  $D_{bi}$  are those specified in Section 3.5.5. The local volume concentration of sediment in the bed  $c_{bed}(y)$  is related to porosity as

$$c_{bed} = 1 - \lambda_p \quad (3-157)$$

and the mean value of  $c_{bed}$  is given as

$$\bar{c}_{bed} = \int_{-\infty}^{\infty} c_{bed}(y) p_e(y) dy \quad (3-158)$$

Let  $f_i(y)$  denote the grain-size fractions of the bed at any relative elevation  $y$  and  $f_{bi}$  denote, as before, the grain-size fractions in the bed load. The conditions for grain-size-specific sediment continuity then reduce to

$$\bar{c}_{bed} \frac{\partial \eta}{\partial t} = \sum_{i=1}^n (D_{bi} - E_{bi}) \quad (3-159a)$$

$$c_{bed} P_s \frac{\partial f_i}{\partial t} = p_e \left[ D_{bi} \left( \beta_{iD} f_{bi} - \frac{c_{bed}}{\bar{c}_{bed}} f_i \right) - E_{bi} \left( \beta_{iE} - \frac{c_{bed}}{\bar{c}_{bed}} \right) f_i \right] \quad (3-159b)$$

where

$\beta_{iD}(y), \beta_{iE}(y)$  = bias functions determining the grain-size-specific variation of deposition and entrainment rate with relative elevation  $y$ .

Defining

$$\beta_D = \sum_{i=1}^n \beta_{Di} f_{bi}, \quad \beta_E = \sum_{i=1}^n \beta_{Ei} f_i, \quad (3-160)$$

it can be demonstrated that

$$\beta_D = \beta_E = \frac{c_{\text{bed}}}{\bar{c}_{\text{bed}}} \quad (3-161)$$

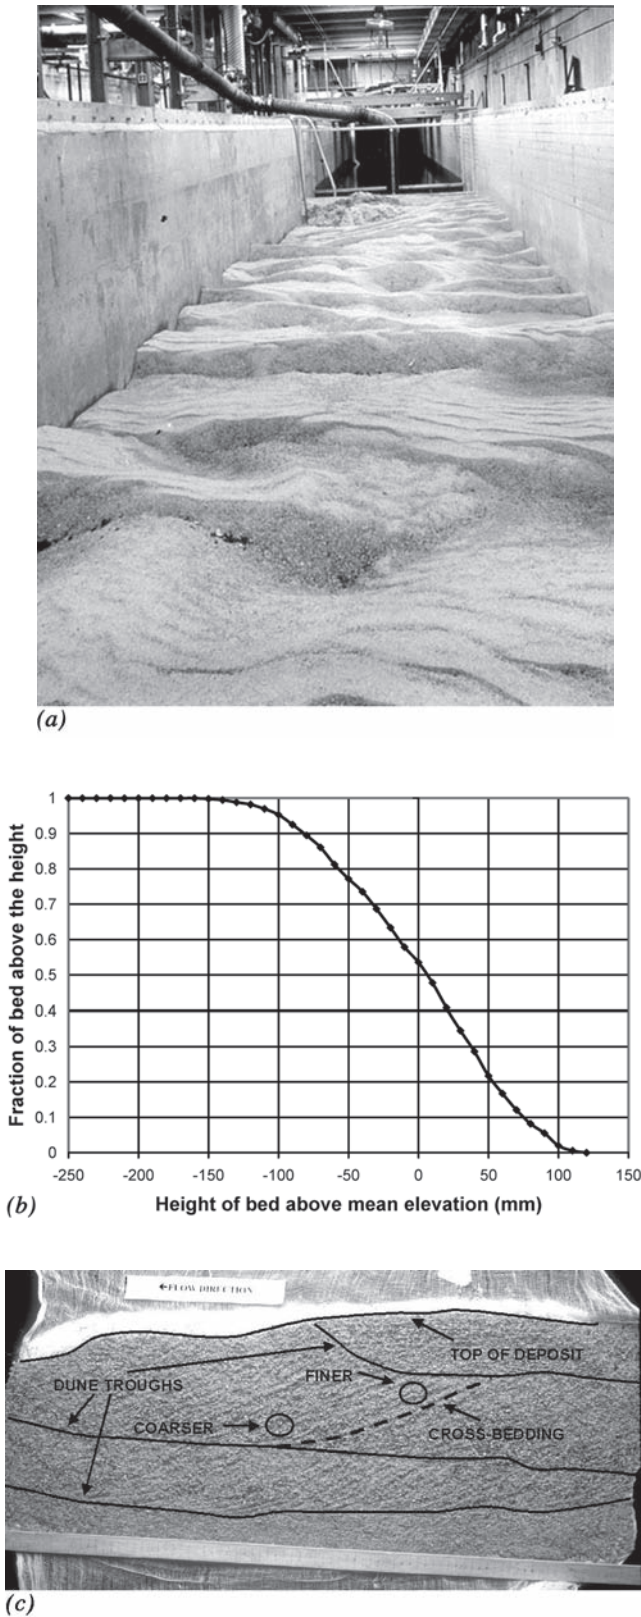

An appropriate integral in  $y$  of Eqs. (3-159a,b) under simplifying assumptions recovers the active-layer formulation of Eq. (3-40).

Parker et al. (2000) did not specify general forms for the bias functions necessary to implement the model with confidence. Blom et al. (2001) have, however, implemented it in the case of the vertical dispersion of tracers in uniform material. In addition Blom (2003) has adapted the formulation for mixtures and specified bias functions for rivers that transport significant amounts of both gravel and sand as bed load. Further development of such vertically continuous descriptions of grain-size-specific sediment continuity holds the key to at least statistically describing the vertical structure of grain sorting in rivers. A case in point is the stratigraphy created by passing dunes illustrated in Fig. 3-61.

## NOTATION

The following symbols are used in this chapter:

- $A_i$  = volume rate per unit bed area per unit time at which material is lost from gravel in the  $i$ th grain size range due to abrasion [ $\text{LT}^{-1}$ ];
- $A_{\text{sand}}$  = volume rate per unit bed area per unit time at which sand is produced by abrasion of gravel in the  $i$ th grain size range [ $\text{LT}^{-1}$ ];
- $A_{\text{silt}}$  = volume rate per unit bed area per unit time at which silt is produced by abrasion of gravel in the  $i$ th grain size range [ $\text{LT}^{-1}$ ];
- $A_T = \sum_{i=1}^n A_i$  [ $\text{LT}^{-1}$ ];
- $\hat{B} = B_{bf}/D_{50}$  = dimensionless bank-full width;
- $B_{bf}$  = bank-full channel width [L];
- $B_c$  = channel width [L];
- $B_{ca}$  = adjusted channel width for sediment transport calculations [L];
- $B_f$  = floodplain width [L];
- $B_v$  = width of valley flat [L];
- $C_f = \tau_b/(\rho U^2)$  = dimensionless bed friction coefficient;
- $C_{fi}$  = dimensionless depth-averaged volume concentration of sediment in the  $i$ th grain size range in the floodplain flow;
- $C_{fbf}$  = dimensionless bed friction coefficient at bank-full flow;
- $C_i$  = dimensionless depth-averaged volume concentration of sediment in the  $i$ th grain size range in the channel flow;
- $Cz = U/u_* = C_f^{-1/2}$  = dimensionless Chezy resistance coefficient;

**Fig. 3-61.** (a) Experimental dunes. (b)  $P_s(y)$  as a function of  $y$  for the bed of part (a). (c) Pattern of stratification and sorting created by the passage of dunes in the flume illustrated in part (a). From Parker et al. (2000). (With permission from ASCE.)

$Cz_{bf}$	= estimate of bank-full value of dimensionless Chezy resistance coefficient;	$\hat{E}_{si}$	= $E_{si}^* / F_i$ = dimensionless entrainment rate into suspension normalized with content in the active layer of the bed;
$C_{ucfi}$	= dimensionless depth-averaged volume concentration of sediment in the $i$ th grain size range in the layer of channel flow above the level of the floodplain;	$F_{aei}$	= $(F_i D_i^{-1/2}) / \left( \sum_{i=1}^n F_i D_i^{-1/2} \right)$ = mass fraction of surface material in the $i$ th grain size range adjusted for exposure in computing abrasion;
$\bar{c}_i$	= local dimensionless volume concentration of suspended sediment averaged over turbulence;	$F_{ai}$	= mass fraction of material in the $i$ th grain size range of surface armor;
$\bar{c}_T$	= $\sum_{i=1}^n \bar{c}_i$ = local dimensionless total volume concentration of suspended sediment;	$F'_{ai}$	= $(F_i D_i^{-1}) / \left( \sum_{i=1}^n F_i D_i^{-1} \right)$ = adjusted mass fraction of surface material in the $i$ th grain size range used in the formulation of Karim (1998);
$\bar{c}_{bi}$	= local near-bed dimensionless volume concentration of suspended sediment averaged over turbulence;	$F_g$	= mass fraction of the surface material that is gravel;
$c_{bed}$	= $1 - \lambda_p$ = dimensionless volume concentration of sediment in the bed deposit;	$F_i$	= mass fraction of surface material in the $i$ th grain size range;
$\bar{c}_{bed}$	= dimensionless layer-averaged value of $C_{bed}$ ;	$F_s$	= mass fraction of the surface material that is sand;
$D$	= grain size in mm [L];	$F_1$	= mass fraction of surface material in the first grain size range;
$D_{bi}$	= volume rate per unit bed area at which sediment in the $i$ th grain size range is deposited from bedload transport [ $LT^{-1}$ ];	$f_{bG}$	= mass fraction of bedload that consists of gravel (rather than sand);
$D_{bi}^*$	= $D_{bi} / \sqrt{RgD_i}$ = dimensionless bedload deposition rate;	$f_{bi}$	= mass fraction of material in the $i$ th grain size range of the bedload;
$D_{bulk60}$	= size such that 60 percent of a bulk bed sample is finer [L];	$\langle f_{bi} \rangle$	= mass fraction of material in the $i$ th grain size range of the bedload averaged over morphology;
$D_d$	= turbulent kinematic eddy viscosity [ $L^2T^{-1}$ ];	$f_i$	= local mass fraction of material in the $i$ th grain size range of the substrate;
$D_{do}$	= value of $D_d$ for unstratified flow [ $L^2T^{-1}$ ];	$\bar{f}_i$	= mass fraction of material in the $i$ th grain size range averaged over a thick layer of substrate just below the surface layer;
$D_g$	= surface geometric mean grain size [L];	$f_{ii}$	= mass fraction of material in the $i$ th grain size range that is interchanged across the surface-substrate interface as the bed aggrades or degrades;
$D_i$	= characteristic grain size of the $i$ th size range in mm [L];	FI	= dimensionless "floodplain" number in Eq. (3-153);
$D_m$	= surface arithmetic mean grain size [L];	$Fr_{bf}$	= $U_{bf} / \sqrt{gH_{bf}}$ = dimensionless Froude number of bank-full flow;
$D_{ug}$	= substrate geometric mean grain size [L];	$g$	= acceleration of gravity [ $LT^{-2}$ ];
$D_{um}$	= substrate arithmetic mean grain size [L];	$H$	= mean channel depth [L]
$D_{u50}$	= substrate median grain size [L];	$\hat{H}$	= $H_{bf} / D_{50}$ = dimensionless bank-full depth;
$D_x$	= grain size such that $x$ percent in a sample is finer [L];	$H_{bf}$	= channel bank-full depth [L];
$D\sigma$	= $D_g \sigma_g$ [L];	$H_f$	= depth of flow over floodplain [L];
$D_{16}$	= grain size such that 16% in a surface sample is finer [L];	$k_s$	= roughness height of bed [L];
$D_{50}$	= surface median surface grain size [L];	$L_a$	= thickness of active (surface) layer of the bed [L];
$D_{84}$	= grain size such that 84% in a surface sample is finer [L];	$L_{ti}$	= mean distance of travel of a tracer particle in the $i$ th size range [L];
$D_{90}$	= grain size such that 90% in a surface sample is finer [L];		
$E_{bi}$	= volume rate per unit bed area at which sediment in the $i$ th grain size range is entrained into bedload transport [ $LT^{-1}$ ];		
$E_{bi}^*$	= $E_{bi} / \sqrt{RgD_i}$ = dimensionless bedload entrainment rate;		
$E_{si}$	= volume rate per unit bed area at which sediment in the $i$ th grain size range is entrained into suspension [ $LT^{-1}$ ];		
$E_{si}^*$	= $E_{si} / v_{si}$ = dimensionless entrainment rate into suspension;		

$L_{i50}$	= mean distance of travel of a tracer particle with size $D_{50}$ [L];	$R$	= $(\rho_s - \rho)/\rho$ = dimensionless submerged specific gravity of sediment;
$L_{1/2}$	= distance of travel for abrasion to halve grain size [L];	$R_p$	= $(\sqrt{RgD} D)/\nu$ = a dimensionless particle Reynolds number;
$n$	= one of two parameters: (1) number of grain size ranges used to discretize the grain size distribution, and (2) cross-channel transverse coordinate [L];	$R_{pg}$	= $(\sqrt{RgD_g} D_g)/\nu$ = a dimensionless particle Reynolds number;
$n_L$	= exponent in a generic bedload transport relation;	$R_{pug}$	= $(\sqrt{RgD_{ug}} D_{ug})/\nu$ = a dimensionless particle Reynolds number;
$n_a$	= $L_a/D_{50}$ = dimensionless factor for active layer thickness;	$R_{p50}$	= $(\sqrt{RgD_{50}} D_{50})/\nu$ = a dimensionless particle Reynolds number;
$n_k$	= $k_s/D_{90}$ = dimensionless factor for roughness height;	$R_{pm}$	= $(\sqrt{RgD_m} D_m)/\nu$ = a dimensionless particle Reynolds number;
$P_s(y)$	= probability that the instantaneous bed is higher than relative elevation $y$ ;	$R_{pi}$	= $(\sqrt{RgD_i} D_i)/\nu$ = a dimensionless particle Reynolds number;
$p(\psi)$	= volume probability density of size $\psi$ in a sediment sample;	$Ri_g$	= dimensionless gradient Richardson number defined by Eq. (3-133b);
$p_e(y)$	= probability density of bed elevation fluctuations;	$S$	= dimensionless downchannel bed slope;
$p_f(\psi)$	= cumulative probability that the fraction of sediment in a sample is less than size $\psi$ ;	$S_e$	= dimensionless downchannel energy slope;
$Q$	= water discharge [ $L^3T^{-1}$ ];	$S_f$	= dimensionless downchannel friction slope;
$Q_{bf}$	= bank-full water discharge [ $L^3T^{-1}$ ];	$s$	= downchannel streamwise coordinate [L];
$\hat{Q}_{bf}$	= $Q_{bf}/(\sqrt{RgD_{50}} D_{50}^2)$ = dimensionless bank-full water discharge;	$s_v$	= downvalley streamwise coordinate [L];
$q$	= volume transport rate of bedload per unit width [ $L^2T^{-1}$ ];	$t$	= time [T];
$q^*$	= $q/(\sqrt{RgD} D)$ = a dimensionless Einstein number;	$U$	= depth-averaged or cross-sectionally averaged streamwise flow velocity [ $LT^{-1}$ ];
$q_{bmi}$	= $q_i + q_{si}$ = volume transport rate per unit width of bed-material load in the $i$ th grain size range [ $L^2T^{-1}$ ];	$U_{bf}$	= bank-full value of $U$ [ $LT^{-1}$ ];
$q_{bmi}^*$	= $q_{bmi}/(F'_{ai}\sqrt{RgD_i} D_i)$ = a dimensionless Einstein number for total bed-material load;	$\bar{u}$	= local streamwise flow velocity averaged over turbulence [ $LT^{-1}$ ];
$q_i$	= volume transport rate of bedload per unit width of $i$ th size range [ $L^2T^{-1}$ ];	$u_*$	= $\sqrt{\tau_b/\rho}$ = shear velocity [ $LT^{-1}$ ];
$q_i^*$	= $q_i/(F_i\sqrt{RgD} D)$ = a surface-based dimensionless Einstein number;	$u_{*bf}$	= $\sqrt{\tau_{bbf}/\rho}$ = estimate of shear velocity at bank-full flow [ $LT^{-1}$ ];
$q_{n,i}$	= volume transport rate of bedload per unit width in the $n$ (transverse) direction [ $L^2T^{-1}$ ];	$u_{*s}$	= $\sqrt{\tau_{bs}/\rho}$ = shear velocity due to skin friction [ $LT^{-1}$ ];
$q_{obi}$	= volume rate per unit streamwise distance at which sediment in the $i$ th size range is delivered from the channel to the floodplain [ $L^2T^{-1}$ ];	$V_p$	= particle volume [ $L^3$ ];
$q_{si}$	= volume transport rate of suspended sediment per unit width of $i$ th size range [ $L^2T^{-1}$ ];	$v_{bi}$	= mean virtual velocity of transport of the $i$ th grain size [ $LT^{-1}$ ];
$q_{s,i}$	= volume transport rate of bedload per unit width in the $s$ (streamwise) direction [ $L^2T^{-1}$ ];	$v_{si}$	= fall velocity of size $D_i$ [ $LT^{-1}$ ];
$q_T$	= $\sum_{i=1}^n q_i$ = total volume bedload transport rate per unit width [ $L^2T^{-1}$ ];	$W^*$	= $(Rgq)/u_{*s}^3$ = a dimensionless Suspended load transport rate;
$q_{ui}^*$	= $q_i/(\bar{f}_i\sqrt{RgD} D)$ = a substrate-based dimensionless Einstein number;	$W_i^*$	= $(Rgq_i)/(F_i u_{*s}^3)$ = a dimensionless bedload transport rate;
		$W_r^*$	= dimensionless reference value of $W^*$ ;
		$W_{sui}^*$	= $(Rgq_{si})/(\bar{f}_i u_{*s}^3)$ = a dimensionless suspended load transport rate;
		$W_{ui}^*$	= $(Rgq_i)/(\bar{f}_i u_{*s}^3)$ = a dimensionless bedload transport rate;
		$\bar{w}$	= local upward normal flow velocity averaged over turbulence [ $LT^{-1}$ ];
		$y$	= $z - \eta$ = local bed elevation relative to mean bed elevation [L];

$z$	= upward normal coordinate from the bed in the water column; vertical coordinate within the bed deposit [L];	$\tau_{bscm}$	= critical value of $\tau_{bs}$ for the onset of motion for the size $D_m$ [ $ML^{-1}T^2$ ];
$z_b$	= reference value of $z$ above the bed for calculations of near-bed suspended sediment concentrations [L];	$\tau_{bssrg}$	= surface-based reference value of $\tau_{bs}$ for the size $D_g$ [ $ML^{-1}T^2$ ];
$\alpha_d$	= grain size abrasion coefficient [ $L^{-1}$ ];	$\tau_{bssri}$	= surface-based reference value of $\tau_{bs}$ for the size $D_i$ [ $ML^{-1}T^2$ ];
$\alpha_{di}$	= grain size abrasion coefficient for $i$ th grain-size range [ $L^{-1}$ ];	$\tau_{bssr50}$	= surface-based reference value of $\tau_{bs}$ for the size $D_{50}$ [ $ML^{-1}T^2$ ];
$\alpha_v$	= grain volume abrasion coefficient [ $L^{-1}$ ];	$\tau_{bsucg}$	= substrate-based critical value of $\tau_{bs}$ for the size $D_{ug}$ [ $ML^{-1}T^2$ ];
$\beta$	= dimensionless coefficient in Eq. (3-118) for transverse bedload rate;	$\tau_{bsuci}$	= substrate-based critical value of $\tau_{bs}$ for the size $D_i$ [ $ML^{-1}T^2$ ];
$\beta_{iD}(y)$	= dimensionless grain-size-specific bias function for bedload deposition at level $y$ relative to the mean position of the bed;	$\tau_{bsuc50}$	= substrate-based critical value of $\tau_{bs}$ for the size $D_{u50}$ [ $ML^{-1}T^2$ ];
$\beta_{iE}(y)$	= dimensionless grain-size-specific bias function for bedload entrainment at level $y$ relative to the mean position of the bed;	$\tau_{bsurg}$	= substrate-based reference value of $\tau_{bs}$ for the size $D_{ug}$ [ $ML^{-1}T^2$ ];
$\gamma$	= exponent in power hiding relations	$\tau_{bsuri}$	= substrate-based reference value of $\tau_{bs}$ for the size $D_i$ [ $ML^{-1}T^2$ ];
$\eta$	= bed elevation [L];	$\tau_{bsur50}$	= substrate-based reference value of $\tau_{bs}$ for the size $D_{u50}$ [ $ML^{-1}T^2$ ];
$\eta_b$	= elevation to base of the active layer of the bed [L];	$\tau_s^*$	= $\tau_{bs}/(\rho RgD) =$ a dimensionless Shields number;
$\eta_f$	= elevation of top of floodplain [L];	$\tau_{scg}^*$	= $\tau_{bscg}/(\rho RgD_g) =$ a dimensionless critical Shields number;
$\kappa$	= 0.4; dimensionless von Karman constant;	$\tau_{sci}^*$	= $\tau_{bsci}/(\rho RgD_i) =$ a dimensionless critical Shields number;
$\lambda_p$	= dimensionless porosity of bed deposit;	$\tau_{scm}^*$	= $\tau_{bscm}/(\rho RgD_m) =$ a dimensionless critical Shields number;
$\nu$	= kinematic viscosity of water [ $L^2/T$ ];	$\tau_{sg}^*$	= $\tau_{bs}/(\rho RgD_g) =$ a dimensionless Shields number;
$\rho$	= density of water [ $ML^{-3}$ ];	$\tau_{si}^*$	= $\tau_{bs}/(\rho RgD_i) =$ a dimensionless Shields number;
$\rho_s$	= material density of sediment [ $ML^{-3}$ ];	$\tau_{sm}^*$	= $\tau_{bs}/(\rho RgD_m) =$ a dimensionless Shields number;
$\Sigma_{sin}$	= dimensionless channel sinuosity;	$\tau_{ssrg}^*$	= $\tau_{bssrg}/(\rho RgDg) =$ a dimensionless reference Shields number;
$\sigma$	= arithmetic standard deviation of surface grain-size distribution on $\psi$ scale;	$\tau_{ssri}^*$	= $\tau_{bssri}/(\rho RgD_i) =$ a dimensionless reference Shields number;
$\sigma_g$	= geometric standard deviation of surface grain-size distribution on $\psi$ scale;	$\tau_{ssr50}^*$	= $\tau_{bssr50}/(\rho RgD_{50}) =$ a dimensionless reference Shields number;
$\sigma_{sub}$	= subsidence rate due to tectonism or other effects [ $LT^{-1}$ ];	$\tau_{sucg}^*$	= $\tau_{bsucg}/(\rho RgD_{ug}) =$ a dimensionless critical Shields number;
$\sigma_u$	= arithmetic standard deviation of substrate grain-size distribution on $\psi$ scale;	$\tau_{suci}^*$	= $\tau_{bsuci}/(\rho RgD_i) =$ a dimensionless critical Shields number;
$\sigma_{ug}$	= geometric standard deviation of substrate grain-size distribution on $\psi$ scale;	$\tau_{sc50}^*$	= $\tau_{bsuc50}/(\rho RgD_{u50}) =$ a dimensionless critical Shields number;
$\tau_b$	= boundary shear stress at bed [ $ML^{-1}T^2$ ];	$\tau_{surg}^*$	= $\tau_{bsurg}/(\rho RgD_{ug}) =$ a dimensionless reference Shields number;
$\tau_{bbf}$	= estimate of boundary shear stress at bed at bank-full flow according to Eq. (3-14a);	$\tau_{suri}^*$	= $\tau_{bsuri}/(\rho RgD_i) =$ a dimensionless reference Shields number;
$\tau_{bf50}^*$	$\tau_{bbf}/(\rho RgD_{50}) =$ a dimensionless Shields number;	$\tau_{sur50}^*$	= $\tau_{bsur50}/(\rho RgD_{u50}) =$ a dimensionless reference Shields number;
$\tau_{bs}$	= boundary shear stress due to skin friction at bed [ $ML^{-1}T^2$ ];	$\tau_{su50}^*$	= $\tau_{bs}/(\rho RgD_{u50}) =$ a dimensionless Shields number;
$\bar{\tau}_{bs}$	= $(\tau_{bs,s}, \tau_{bs,n}) =$ vectorial boundary shear stress due to skin friction with components in the $s$ (streamwise) and $n$ (transverse) directions, respectively [ $ML^{-1}T^2$ ];		
$\tau_{bscg}$	= critical value of $\tau_{bs}$ for the onset of motion for the size $D_g$ [ $ML^{-1}T^2$ ];		
$\tau_{bsci}$	= critical value of $\tau_{bs}$ for the onset of motion for the $i$ th grain size [ $ML^{-1}T^2$ ];		

- $\tau_{s50}^*$  =  $\tau_{bs}/(\rho RgD_{50})$  = a dimensionless Shields number;  
 $\tau_{50}^*$  =  $\tau_b/(\rho RgD_{50})$  = a dimensionless Shields number;  
 $\phi$  =  $-\psi$ ; grain size on base-2 logarithmic scale;  
 $\psi$  = grain size on base-2 logarithmic  $\psi$  scale defined by Eq. (3-1);  
 $\psi_i$  =  $i$ th bounding grain size on  $\psi$  scale defining ranges in size distribution;  
 $\bar{\psi}_i$  =  $(\psi_i + \psi_{i+1})/2$  = characteristic size on  $\phi$  scale of  $i$ th grain size range;  
 $\psi_m$  = arithmetic mean size of surface material on  $\psi$  scale.

## CHAPTER 4

### *Fine-Grained Sediment Transport*

*Ashish J. Mehta and*

*William H. McAnally*

#### 4.1 INTRODUCTION

The origin of fine-grained sediment transport engineering as a component of hydraulics in the United States must be credited to the work of Hans Albert Einstein and his students at the University of California, Berkeley. Berkeley became a center of sediment transport research with Carl Gustav Gilbert of the U.S. Geological Survey, who, during the early part of the twentieth century, carried out sediment transport studies in a flume located within the Berkeley campus. These studies were conducted in response to a major sedimentation problem in the Sacramento-San Joaquin River delta and the San Francisco Bay due to the significant hydraulic mining activity in the Sierra Nevada mountains starting around the mid-nineteenth century. The bottom of the San Francisco Bay is dominated by fine sediment that is highly cohesive, and much of the early experimental work and its phenomenological interpretation for the development of transport formulas is derived from studies on that sediment.

Fine-grained sediment is generally characterized by size, composition, and plasticity. For fine-grained sediment transport, the first two are especially important and are briefly described here. For definitions related to plasticity, including the Atterberg limits see, for example, Lambe and Whitman (1969). With regard to size, Table 4-1 identifies coarse-grained versus fine-grained sediment and the degree of cohesion. Cohesion is due to electrochemical forces acting on the particle surface. Hence the degree of cohesion depends on the ratio of particle surface area to particle weight, that is, the specific surface area. Clay mineral particles, which occur in sizes less than 2  $\mu\text{m}$ , and many of which are platelike, have a high specific surface area and are cohesive. In contrast, small but less platy particles with comparatively low specific surface areas do not exhibit significant cohesion. Mantz (1977), for example, showed that, with respect to incipient motion, sediment consisting of crushed silica particles in the coarse silt range showed little cohesion and behaved like sand.

In Table 4-1, observe that cohesion increases as particle size decreases (and the associated specific surface area increases). As a result, the tendency for particles to cohere and form aggregates or flocs also increases with decreasing size. An indirect and very approximate measure of the relationship between particle size and cohesion was demonstrated by Migniot (1968), who tested several natural muds and clays in a settling column and plotted the ratio of floc settling velocity to (individual) particle settling velocity against particle size (in micro-meters). He showed that this ratio increased from a little over unity at 40  $\mu\text{m}$  to 300–400 at 1  $\mu\text{m}$ , because with decreasing particle size and increasing cohesion the floc size increased.

With regard to fine-grained sediment composition, two properties are important to transport, namely, the inorganic mineral content and the organic content, including biochemicals. The inorganic constituent can be a clay mineral or a nonclay mineral. Clays are crystalline chemicals composed of silica ( $\text{SiO}_2$ ), alumina ( $\text{Al}_2\text{O}_3$ ), and water, frequently along with appreciable quantities of iron, alkalis ( $\text{Na}^+$ ,  $\text{K}^+$ ), and alkaline earths ( $\text{Ca}^{++}$ ,  $\text{Mg}^{++}$ ). Clay minerals have the property of sorbing certain anions (e.g.,  $\text{NO}_3^-$ ) and cations (e.g.,  $\text{K}^+$ ), and retaining them in an exchangeable state; i.e., these anions and cations can be removed by other anions and cations by treatment with such ions in water solution (Grim 1968).

A characteristic gauge of clay mineral cohesion is the cation exchange capacity (CEC), expressed as milliequivalents of exchangeable ion (e.g.,  $\text{Na}^+$  in terms of  $\text{Na}_2\text{O}$ , whose equivalent weight is 31 g) per 100 g of clay (Grim 1968). The higher the CEC the greater the cohesion, which causes micro-meter-sized individual clay particles to coagulate, or flocculate, in water to form much larger aggregates, or flocs, when water salinity exceeds a critical value, which depends on the clay mineral. Even though flocs are particle-formed units, they contain mostly water. For example, a floc having a density of 1,090  $\text{kg/m}^3$  and composed of clay particles

**Table 4-1 Sediment Size and its Relation to Cohesion**

Size range (μm)	Classification	Degree of cohesion
>62	Coarse-grained	Cohesionless
40–62	Fine-grained: coarse silt	Practically cohesionless
20–40	Fine-grained: coarse silt	Cohesion increas- ingly important with decreasing size
2–20	Fine-grained: medium and fine silt	Cohesion important
<2	Fine-grained: coarse, medium, and fine clay	Cohesion very important

of density 2,650 kg/m<sup>3</sup> will contain nearly 95% water by volume, locked within the interstitial particulate fabric. For descriptions of floc properties, including size, density, and strength, see for example Krone (1963), Dyer (1989), Lick and Huang (1993), and Partheniades (1993).

The (individual) particle size in terms of nominal particle diameter, CEC, and critical salinity for the three most commonly found clays—kaolinite, illite, and smectite (or montmorillonite)—are given in Table 4-2. Also given is information on chlorite, which is rarer but is found in some large estuaries, e.g., San Francisco Bay (Krone 1962). Kaolinite has the lowest CEC and exhibits the lowest degree of cohesion, whereas smectite has the highest CEC and is the most cohesive of the four, with illite and chlorite in between. As salinity increases above the critical value, floc size, density, and strength vary. However, above a salinity of about 10 ppt, its effect on floc properties is comparatively minor (Krone 1962; 1986).

Two commonly found nonclay minerals in coastal and estuarine sediments are quartz and calcium carbonate, the latter being the dominant bottom material in many biogenically active temperate waters (Bentley and Nittrouer 1997). Numerous other nonclay materials can occur; for

example, sediment in San Francisco Bay contains iron flocs and organic matter (Krone 1962). Organic matter can measurably influence the electrochemical flocculation process and the composition of flocs (Dennett et al. 1998). This influence depends on the type of organic matter. Thus, for example, biopolymers can modulate floc properties through adhesive bridge formations (Wells and Goldberg 1993). Mucous filaments formed by bacteria can coat flocs and also reinforce the physicochemical bonds holding particles together (Kranck 1986; Luettich et al. 1993). McCave (1984) showed that active contributions to marine flocculation by zooplankton filtering can be significant compared to those by inorganic processes alone, and Kranck and Milligan (1980) reported that a mixture of 50% organic and 50% inorganic sediments settled an order of magnitude faster than an equivalent concentration of 100% inorganic sediment. In areas of high biodeposition, large suspended aggregates have been recorded *in situ* using a focused-beam laser (Law and Bale 1998).

Several measures of the influence of biochemicals on the erodibility of fine-grained sediment have been examined. Examples include the effects of chlorophyll-*a* (Montague et al. 1993) and colloidal carbohydrate (Amos et al. 1998; Sutherland et al. 1998) on the critical shear stress for erosion. Brief overviews of the interaction between physical and biological parameters in governing erodibility have been provided by, among others, Dade and Nowell (1991), Patterson (1997), and Black et al. (1998). Such interaction has also been examined in Couette flocculators (Drapeau and Dam 1994).

## 4.2 SEDIMENT CHARACTERIZATION

### 4.2.1 Characterization Tests

To make possible intercomparisons of transport-related data from different sites or studies, it is helpful to report values of basic sedimentary parameters that influence floc properties. Table 4-3 lists selected parameters, all of which can be determined through relatively simple and mostly

**Table 4-2 Clay Minerals, CEC, and Critical Salinity for Flocculation**

Clay mineral	Nominal diameter <sup>a</sup> (μm)	Cation exchange capacity (meq/100 g)	Critical salinity (ppt)
Kaolinite	0.36	3–15	0.6
Illite	0.062	10–40	1.1
Chlorite	0.062	24–35	— <sup>b</sup>
Smectite (or montmorillonite)	0.011	80–150	2.4

<sup>a</sup>Defined here as the diameter of a circle with the same surface area as platelike clay particles.

<sup>b</sup>Not reported.

Sources: Ariathurai et al. (1977); McAnally (1999).

documented laboratory test procedures. They include particle size, fall or settling velocity, sediment mineral composition, organic content, clay cation exchange capacity, and fluid salinity. These parameters are considered to be minimally essential; a much larger list has been compiled by Berlamont et al. (1993). There are, however, practical reasons for limiting the number of parameters used to identify a sediment sample. First, the actual number of parameters that determine the behavior of fine sediment in water is so large that it is currently unrealistic to come up with accurate predictive correlations between such parameters and transport-related quantities, e.g., the critical shear stress for erosion (Lee and Mehta 1994). Second, the cost of evaluating a large number of parameters is usually prohibitive for most technical studies. Finally, the six parameters chosen in Table 4-3 are considered to be adequate for a gross characterization of sediment for situations in which the transport is not overwhelmingly influenced by biochemical factors.

An early summary of work related to the erodibility of irrigation channels and agricultural lands is based on a different set of erosion-governing soil parameters including the dispersion ratio, plasticity index, and moisture content (TCECM 1968).

#### 4.2.2 Mud Definition and Rheology

Interpretation of the information contained in Table 4-1, according to which the degree of cohesion increases with decreasing particle size, becomes complex in the natural environment, in which mixtures of sizes commonly occur. Such mixtures, or muds, are typically (although not always) cohesive due to the presence of clay minerals. Several definitions of mud are found in the literature. Most are based on the *state* of mud. However, since the *transport* of mud is of present interest, mud is best characterized by its response to an applied stress, based on its rheology. Accordingly, the following definition of mud can be useful (Mehta 2002):

Mud is a sediment-water mixture of grains that are predominantly less than 63  $\mu\text{m}$  in size, exhibits a rheological behavior that is poroelastic or viscoelastic when the mixture is particle-supported, and is highly viscous and non-Newtonian when it is in a fluid-like state.

Other noteworthy parameters are fluid temperature and pH. Temperature affects floc behavior; however, over the normal range of temperature in temperate coastal and estuarine waters

**Table 4-3 Parameters for Characterization of Fine-Grained Sediment Transport**

Parameters	Comments
Particle size	Use standard procedure, e.g., the hydrometer test (ASTM 1993d) or the settling column bottom withdrawal test, preferably using sediment in native water. The exception to the standard procedure is that naturally wet samples should not be air-dried initially, i.e., before the test, because of the difficulty that may occur in completely dispersing the rewetted dry sample (Krone 1962). In this case, to obtain the total weight of the sample necessary for calculations, sediment accumulated at the bottom in the cylinder or column should be collected after the test by filtration and then air-dried. If the sample contains material larger than 75 mm, use the wet-sieving method to separate the coarse fraction (ASTM 1993d). If the organic content is greater than about 10%, this test should not be performed, because, as the organic matter will not deflocculate on addition of floc dispersing agent, the resulting size distribution will not correlate with transport behavior. Instead measure the settling velocity of the untreated, i.e., nondispersed sample.
Fall or settling velocity	Obtain the characteristic relationship between settling velocity and sediment concentration or dry density of the untreated, i.e., nondispersed, sample from measurements in a multiport settling column. See McLaughlin (1959) for test procedure.
Mineral composition	Obtain types and relative quantities of the principal clay and non-clay minerals using standard X-ray diffraction tests (Whittig and Allardice 1986; Rich and Barnhisel 1977).
Organic content	Loss of sample mass on ignition is often measured for this purpose through a standard test (ASTM 1993b). Sometimes this method yields an approximate value due to the loss of structural water from the sample. An alternative is to measure total organic carbon (Walkley and Black 1934).
Cation exchange capacity	Follow standard procedure for clay minerals (ASTM 1993c; SCS 1992). If the organic content is greater than about 10%, the CEC may be excessively high, not representative of the clay constituent.
Salinity	Report salinity if less than about 10 ppt. At higher salinities the influence of salinity on floc structure is comparatively minor (Krone 1962).

the effect is usually considered small and can instead be dominated by biogenic effects. Slightly acidic waters likewise appear to increase aggregation (Tsai and Hu 1997), but pH is not highly variable in estuarine waters and thus is usually ignored (CTH 1960; Partheniades 1971). On the other hand changing soil pH can alter bed stability to a significant extent (Ravisangar et al. 2001).

Inasmuch as the above definition of mud does not depend on whether the sediment is inorganic or organic, or on such factors as the degree of cohesion or biochemical binding, it encompasses most natural muds. Muds largely composed of silt-sized material have been found to be poroelastic; that is, the internal loss of energy is characterized by Coulomb damping arising from friction between grains. For such muds Darcy's equation for water seepage through the pores is used to determine the pore pressure (Yamamoto and Takahashi 1985; Foda 1987). Most muds also include significant clay-sized fractions, and these are usually considered to be viscoelastic; in such muds internal loss is due to grain-fluid contact (Dade and Nowell 1991).

Figure 4-1 compares four rheological models of materials (continua) in terms of the rate of strain,  $\dot{\gamma}$ , as a function of applied shear,  $\tau$ . Curve A is the Newtonian model, in which the dynamic viscosity,  $\mu = \tau / \dot{\gamma}$ , is independent of  $\dot{\gamma}$ . Curve B represents a pseudoplastic, which shows a shear-thinning behavior; i.e.,  $\mu$  decreases with increasing  $\dot{\gamma}$ . Curve C is the Bingham model, which represents a viscoplastic material that shows a purely Newtonian response, once  $\tau$  exceeds the Bingham yield strength,  $\tau_B$ . Otherwise it remains a solid. A pseudoplastic can be approximated as a Bingham plastic by extrapolation as shown, which defines what can be called the apparent Bingham yield strength,  $\tau_y$ . Last, curve D represents a dilatant or shear-thickening response, in which  $\mu$  increases with  $\dot{\gamma}$ . Most natural, soft muds are shear-thinning, although some seemingly show shear-thickening behavior over certain ranges of shear rate specific to the material (Faas 1995). True Bingham plastic sediments are rare in the coastal and estuarine environment, inasmuch as most soft muds creep even at very low rates of strain. However, many muds have been approximated as Bingham plastics for simplicity of treatment of their flow behavior (Krone 1963; Williams 1986; Mei and Liu 1987; Toorman 1995; Huang and Garcia 1996; 1998; 1999). On a slope over which gravity-induced bottom stress exceeds yield stress, fluid mud can creep and accumulate in downstream depressions in navigation channels and reservoirs (Ali and Georgiadis 1991; Einstein 1941).

A simple model representing the shear-thinning or shear-thickening behavior of mud is the Sisko (1958) power-law relation for the dynamic viscosity,

$$\mu = c_r \dot{\gamma}^{n_r - 1} + \mu_\infty \quad (4-1)$$

in which

$c_r$  = consistency of the non-Newtonian fluid, and  
 $n_r$  = coefficient characterizing flow behavior.

Fig. 4-1. Schematic drawing of models for the relationship between applied stress and rate of strain.

In (4-1),  $n_r < 1$  corresponds to shear-thinning flow behavior, and  $n_r > 1$  represents shear-thickening flow. When  $n_r = 1$  the flow is Newtonian with a constant viscosity  $\mu_\infty$ , since in that case the consistency,  $c_r$ , is nil. At high, theoretically infinite shear rate a shear-thinning material also becomes Newtonian with a viscosity  $\mu_\infty$ .

Ross (1988) summarized a few studies in which  $\mu_\infty$  was, empirically related to the suspension concentration,  $C$  (dry sediment mass divided by volume of sediment plus water), according to

$$\mu_\infty = \mu_w (1 + \alpha_r C^{\beta_r}) \quad (4-2)$$

where

$\mu_w$  = viscosity of water.

For example, for a kaolinite in fresh water, the rheometric data of Engelund and Zhaohui (1984) are commensurate with values of the coefficients  $\alpha_r = 1.68$  and  $\beta_r = 0.346$ , when  $C$  is measured in  $\text{kg/m}^3$ . In general, the range of  $C$  over which (4-2) applies varies with the sediment, from a low 5–10  $\text{kg/m}^3$  to a high 400–500  $\text{kg/m}^3$ .

Following Odd et al. (1993) and based on sediment from the Amazon and (4-1), Vinzon (1998) explicitly included the effect of concentration,  $C$  ( $\text{kg/m}^3$ ), and the shear rate,  $\dot{\gamma}$  (Hz), in the following Sisko-type relations for the kinematic viscosity,  $\nu = \mu/\rho$  ( $\text{m}^2/\text{s}$ ), where  $\rho$  is the fluid (nominally water) density:

$$\nu = C \exp(-0.78\dot{\gamma} - 10.24) \text{ for } \dot{\gamma} < 3.9 \text{ Hz} \quad (4-3a)$$

$$\nu = C \exp(-0.017\dot{\gamma} - 12.95) \text{ for } \dot{\gamma} \geq 3.9 \text{ Hz} \quad (4-3b)$$

Jinchai (1998) conducted rheometric tests on clayey mixtures of a kaolinite ( $K$ ), an attapulgite ( $A$ ), and a bentonite (which is a montmorillonite) ( $B$ ) in fresh water and found the following relations applicable to (4-1):  $\mu_\infty = 0.05CEC_s + 0.001$ ,  $n_r = -0.033CEC_s + 0.28$ ,

and  $\log c_r = 0.13CEC_s + 0.22$ . The mixture cation exchange capacity,  $CEC_s$ , was defined as

$$CEC_s = f_K CEC_K + f_A CEC_A + f_B CEC_B \quad (4-4)$$

where

$f$  = weight fraction of subscripted sediment, and

$CEC$  = cation exchange capacity corresponding to subscript

Note that given the water content (weight of water divided by weight of sediment)  $f_w$ , we have  $f_K + f_A + f_B + f_w = 1$ . The selected cation exchange capacities (in milliequivalents per 100 g of sediment) were 6 for  $K$ , 28 for  $A$ , and 105 for  $B$ . The water content (in percent) in the tests ranged from 86 to 423, and the range of  $CEC_s$  was 1.9 to 10.4 meq/100 g.

Mud viscosity typically decreases with increasing temperature. A simple rheological model can be used to explain this trend based on the theory of momentum exchange between molecules (Krone 1983). According to this theory and data on fluids, the logarithm of  $\mu$  varies linearly with the inverse of the absolute temperature.

At this point it is useful to introduce the relationship between (dry mass) concentration,  $C$ , and (wet) bulk density of mud,  $\rho$ . From mass balance,

$$C = \frac{\rho - \rho_w}{\rho_s - \rho_w} \rho_s \quad (4-5)$$

where

$\rho_w$  = water density,

$\rho_s$  = grain or particle density, and

$\phi = C/\rho_s$  = solids volume fraction (volume of solids divided by sum of the volumes of solids and water).

The three measures of sediment concentration in water, namely  $C$ ,  $\rho$ , and  $\phi$ , are frequently used in this chapter.

Starting with pure water, with increasing mud density,  $\rho$ , the state of a sediment-water mixture changes from fluid to soft solid to solid with rigidity increasing with increasing density. The transition from a fluid (mud) to a solid (bed)

with an interconnected particulate matrix depends on mud composition and stress history. As a rule of thumb, the transition density ranges from about 1,150 to 1,250 kg/m<sup>3</sup>. Since bed rigidity increases rapidly beyond about 1,250 kg/m<sup>3</sup>, it must be included explicitly in the rheological description of mud, especially because flow curves such as those shown in Fig. 4-1 are not easily obtained for dense muds, e.g., with density exceeding, say, 1,300 to 1,400 kg/m<sup>3</sup> (James et al. 1988). Thus, while for a fluid mud (4-1) is a reasonable descriptor of rheology, for dense muds linear viscoelastic models are used as simplified indicators of a characteristically very complex mud rheology. Two noteworthy constitutive models are the standard solid model in Fig. 4-2a and the Kelvin or Voigt model in Fig. 4-2b (Keedwell 1984). The respective constitutive equations are as follows:

*Standard solid:*

$$\tau + \frac{\mu}{G_1 + G_2} \dot{\tau} = \frac{G_1 G_2}{G_1 + G_2} \gamma + \frac{\mu G_1}{G_1 + G_2} \dot{\gamma} \quad (4-6)$$

*Voigt:*

$$\tau = G\gamma + \mu\dot{\gamma} \quad (4-7)$$

where

$\mu$  = viscosity,

$G_1$ ,  $G_2$ , and  $G$  = shear moduli of elasticity,

$\tau$  = shear stress,

$\gamma$  = strain, and the dot over  $\gamma$  signifies the time derivative.

Thus we note that the standard solid model is a combination of a Hookean solid element (i.e., an elastic spring of rigidity, or storage modulus,  $G_2$ ) and a Newtonian fluid element in parallel, with an additional Hookean element of rigidity  $G_1$  in series. Setting  $G_1 \rightarrow \infty$  and  $G_2 = G$  results in the Voigt model, a special case of the standard solid. If now  $G$  is set equal to zero, a Newtonian fluid element ensues. For fluid

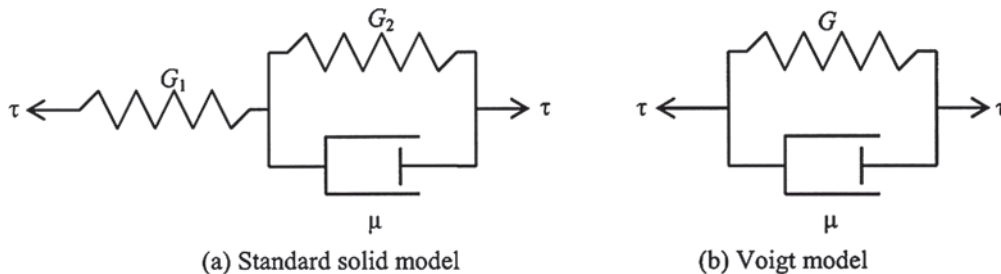

Fig. 4-2. Two linear viscoelastic models: (a) standard solid model; (b) Voigt model.

muds, viscoelasticity has been represented by the Maxwell (fluid) element, which includes a Hookean element and a Newtonian element in series (Li 1996).

Cyclic loading by the action of water waves on mud beds is a means by which loss of structure and rigidity occur, which in turn can lead to the generation of fluid mud. By embedding a miniature rheometer capable of measuring the speed of a high-frequency shear wave through the material, the change in rigidity with time following the inception of water wave motion can be determined. Thus, for example, for a Voigt solid it can be shown that  $G$  is approximately equal to  $\rho V^2$  where  $\rho$  is the material density and  $V$  is the shear-wave velocity (Mehta et al. 1995). Hence, by tracking the change in  $V$  in a constant density mud, the corresponding change in  $G$  can be estimated. In Fig. 4-3, the ratio  $V(t)/V(0)$  is plotted against time,  $t$ ;  $V(0)$  being the initial value of the shear-wave velocity  $V(t)$  at the onset of wave action. This laboratory result is for a clayey bed composed of an aqueous mixture of a kaolinite and an attapulgite of equal weight (AK in Table 4-4). The bed density was 1,170 kg / m, the mean water depth over the bed was 19 cm, and the monochromatic water wave amplitude was 2 cm at a frequency of 1 Hz. The initial rigidity  $G(0)$  was 4,680 Pa; however, in association with a drop in  $V$ , within the first half hour the rigidity decreased by 44%.

Determination of the coefficients in viscoelastic models, e.g., (4-6) and (4-7), requires a combination of creep and dynamic shear tests, ideally in a controlled-stress rheometer, in which mud response to stress can be measured directly (James et al. 1987, 1988; Jones 1997). Thus, for example, Jiang and Mehta (1995) found that all the muds they tested in this way and fit to (4-6) showed the coefficients  $\mu$ ,  $G_1$  and  $G_2$  to vary with the frequency of the forcing (small-amplitude) stress wave. This dependence suggests that (4-6) did not truly represent the rheology, since in that case the coef-

**Table 4-4 Properties of Mud used in Rheometry**

ficients would be independent of frequency. Equation (4-6) therefore must be treated as an operational (rather than theoretically correct) model. The coefficients were found to be related to frequency  $f$  (Hz) according to

$$G_1, G_2, \mu = \exp(\alpha_{rh}) f^{\beta_{rh}} \quad (4-8)$$

For muds characterized by particle size and constituents in Table 4-4, values of coefficients  $\alpha_{rh}$  and  $\beta_{rh}$  are given in Table 4-5. The range of frequency,  $f$ , was 0.02 to 40 Hz. Over such a wide frequency range mud response to dynamic loading may be further complicated by thermodynamic effects, inasmuch as while at low frequency the energy dissipation process is thought to occur isothermally, with increasing frequency the process becomes increasingly adiabatic (Krizek 1971).

In general, given the inherent limitations of the standard solid model and its application through (4-6) and (4-8), it has been found reasonable to simplify the rheological description of mud by treating it as a Voigt solid. In this case, characterization of the coefficients in rheometric tests is less cumbersome (Chou 1989; Maa and Mehta 1988).

In Tables 4-4 and 4-5, the effect of sediment composition on the viscoelastic parameters can be qualitatively gaged from the observed variability in the coefficients values. Also, for the Mobile Bay mud (MB), the effect of density can be evaluated. This is shown in Table 4-6, in which  $\mu$  and  $G_2$  are calculated for a representative frequency,  $f = 0.1$  Hz. For comparative purposes, the additional contribution from  $G_1$  to the constitutive behavior may be ignored. Observe the rapid increase in the values of  $\mu$  and  $G_2$  with an increase in  $\phi$  from 0.07 to 0.17.

The description of rheology provided thus far is limited to the effect of shearing the material by the application of a tangential stress. Under wave action, mud also undergoes cycles of compression and tension, for which models representing what is called extensional or elongational rheology are essential (Barnes et al. 1989). In simple dynamical systems, e.g., a viscoelastic element undergoing forcing by

normal stress with strain assumed to be important only in the direction of applied stress, it can be shown that the extensional viscosity and elastic modulus are related to their shear counterparts defined by (4-7). Given such relations, shear rheometry can be used to determine the extensional coefficients. Such a model has for example been used to calculate the thickness of the fluid mud layer generated by water waves (Li and Mehta 2001).

## 4.3 SEDIMENT TRANSPORT PROCESSES

### 4.3.1 Concentration Profile

The classification of fine-grained sediment transport processes is facilitated by a qualitative description of the vertical profile of the sediment-water mixture concentration or density, as shown in Fig. 4-4. In this description, the term “mobile” means moving horizontally. In contrast, “stationary” implies not moving horizontally. Starting from the water surface, in the top layer the sediment is well-mixed and mobile. In this layer the concentration is so low that fluid rheology is practically Newtonian; i.e., the viscosity is independent of the concentration and the rate of flow shear. The flocs settle independent of each other in the *free settling* mode, with a fall or settling velocity that is independent of concentration,

because the frequency of interparticle collisions is so low that collision outcomes leading to agglomeration or aggregation of particles and flocs are sparse (Krone 1962). The concentration profile is relatively smooth, and turbulent mass diffusion is practically neutral; i.e., upward diffusion of sediment is not significantly influenced by buoyancy stabilization due to the concentration gradient.

Below the mixed layer the suspension is initially nearly Newtonian and has been called concentrated benthic suspension (CBS) (Toorman 2001). With increasing depth the suspension becomes increasingly non-Newtonian as the concentration increases, and concurrently the frequency of interparticle collisions increases. The settling velocity usually increases with increasing concentration as the flocs become larger in the *floculation settling* mode. Upward mass diffusion due to turbulence is retarded by the concentration gradient due to the negative buoyancy of the suspension. Coupling between concentration-dependent settling velocity and concentration-gradient-dependent diffusion leads to the formation of a stratified structure of the concentration

**Fig. 4-4.** Classification of the vertical profile of sediment concentration (or density).

profile with vertical gradients called secondary lutoclines, which occur above what is called the primary lutocline. A lutocline is a sediment-induced pycnocline (Kirby and Parker 1977; Parker 1987). Its occurrence manifests as a steplike structure of the concentration profile. The primary lutocline occurs near the base of the stratified mobile suspension. This concentration gradient encompasses a shear layer that resembles the boundary layer above a rigid bed, with high shear production and energy dissipation. However, unlike a rigid bed, the “bottom” below the primary lutocline tends to have fluidlike consistency and is dragged by the flow above. Thus the flow velocity does not become zero at the lutocline, but at some depth below it. An important feature of the primary lutocline, in contrast to the usually less stable secondary lutoclines, is that it can persist even under significant flow-induced forcing. This persistence is due to the inability of the turbulent flow to dissipate the lutocline easily by mixing, as a result of the high degree of buoyancy stabilization from the sharp concentration gradient and the inability of the material below the lutocline to fall rapidly due to *hindered settling*. In this mode the settling flux decreases as the concentration increases with depth. Hindered settling is due to the low permeability coupled with increased buoyancy and viscosity of the sediment-water mixture, hence the inability of the interstitial water to easily escape upward.

The layer below the lutocline shear layer is commonly called fluid mud, which is mobile because it tends to move horizontally due to forcing by the flow above. Within fluid mud turbulence is heavily damped and may even collapse completely when a certain threshold concentration is exceeded (Winterwerp 1999), and the base of this layer is defined by the zero mean velocity plane. Below this plane, mud, having a low permeability, may still occur in a fluidlike state but remains stationary; i.e., within it there is practically no horizontal movement. The thickness of the fluid mud layer depends on the type, magnitude, and duration of forcing by tides and waves, on the availability of sediment, and to some extent on its composition. Whereas in low-suspended-sediment-concentration (e.g., a few tens of milligrams per liter at the most) and low-energy (e.g., microtidal sea and calm weather) environments fluid mud is often absent or forms thin layers, in highly energetic environments such as the Amazon estuary it can be several meters thick. In low-energy areas it is often generated episodically when storm waves and surges occur.

A fine-grained sediment bed, which has a very low permeability in comparison with that of a silty or sandy bed, can be differentiated from the suspension above by the effective normal stress, which is practically nil above the bed surface and increases below it with increasing concentration. This stress is the result of interparticle contact within the structured matrix of the bed. The upper part of the bed may undergo time-dependent deformations due to

oscillatory water motion by waves for example, whereas the bed below remains stationary.

#### 4.3.2 Unit Transport Processes

The description presented in Fig. 4-4 is an instantaneous one, because the concentration profile, along with the elevations and thicknesses of the various layers, changes continuously as the forcing changes. Thus, for example, due to continued deformation the bed particulate matrix can break up and generate fluid mud. Fluid mud can entrain sediment and raise the turbidity of the upper water column. Upon cessation of forcing by a current or waves, the water column will be clarified, and if the system remains disturbed, clear water and a hardened bed will eventually result. Such changes can be predicted provided we specify all relevant vertical and horizontal sediment transport fluxes. Since the horizontal transport load strongly depends on the vertical sediment transport mechanisms, we will identify the vertical *unit transport processes* (in qualitative analogy with the terminology once coined at MIT for chemical engineering processes) and fluxes that must be modeled to calculate the horizontal sediment load.

Consider the simplified concentration (or density) profile description shown in Fig. 4-5. Also shown is the horizontal velocity profile. At the boundary between (mobile) fluid mud and (mobile) suspension, sediment entrainment and settling fluxes must be specified. Entrainment of fluid mud depends on turbulent energy resulting from eddy generation in the boundary layer. In this process, the lutocline interface becomes destabilized, interfacial wave generation and breaking occur, and the lower fluid, with its higher sediment content, is ejected into the upper fluid, where sediment concentration increases. The entrained material is then carried above the lutocline by turbulent diffusion. At the bed surface marking the lower level of the fluid mud layer, the bed can undergo erosion, its rate depending on the magnitude of the flow-induced bed shear stress. Bed erosion occurs either by a gradual dislodgement and entrainment of the flocs at the bed surface, or by a more traumatic Mohr-Coulomb type failure of a sizeable thickness of the bed (Lambe and Whitman 1969) and subsequent, relatively rapid entrainment of the failed material. The former process is called surface erosion and the latter mass erosion. Once the material is entrained it can fall by gravitational settling, the settling flux depending on the settling velocity and sediment concentration. For a given settling velocity and concentration, the sediment deposition flux onto the lutocline or the bed is the highest when there is no flow, and decreases as the flow-induced bed shear stress increases. Deposition involves a sorting process by which heavier and stickier particles/flocs that arrive close to the bed by settling become attached to the bed, whereas the remaining material stays in suspension, or elastically rebounds upward from the bed surface (McAnally 1999). The fraction of depositable material decreases with increasing bed

**Fig. 4-5.** Unit transport processes governing sediment concentration (or density) profile dynamics.

shear stress, and above a certain shear stress practically no deposition occurs. When the rate of deposition is high, fluid mud can form because settling is hindered. At low rates of deposition, in case no fluid mud initially exists between the water column and the bed, the settling sediment may deposit to form a bed without generating fluid mud inasmuch as the rate of consolidation is greater than the rate of deposition.

Waves can loosen the bed and generate fluid mud. Technically, liquefaction is considered to occur due to breakup of the soil matrix by shear stresses, while the process of breakup due to excess pore pressure buildup is called fluidization (Toorman 2001). For simplicity, the term liquefaction will be used here, and will be considered to occur by stresses due to pore pressure gradients and associated flows within the bed, which weaken and eventually disrupt the soil matrix. This process manifests itself as a gradual disappearance of the effective normal stress, which becomes practically nil when fluid mud is generated. Once wave action ceases, fluid mud starts to dewater and reform as bed. Dewatering of fluid mud or a partially consolidated bed is described by hindered settling and consolidation. Consolidation is also accompanied by gelling due to rearrangement of water molecules within the pores.

In the above description, the identifiable unit transport processes include settling and deposition, consolidation and gelling, erosion and entrainment, and upward diffusion of eroded/entrained sediment. These processes are considered further in this chapter following a brief description of the particle and floc aggregation processes that govern particle/floc size, density, and strength.

## 4.4 AGGREGATION

### 4.4.1 Floc Transport

Figure 4-6 illustrates the concept of a fine sediment particle or a floc undergoing the process of aggregation, defined as the set of mechanisms by which floc size, density, and

strength change due to flow-particle (or flow-floc) and particle-particle (or floc-floc) interactions. A particle, either an individual grain or a floc of many grains, may originate in the water column or in the bed. Once in suspension, it is subjected to forces due to gravity, inertia, mean flow, turbulent fluctuations, and collisions with other particles in suspension. It may undergo aggregation in the water column, bonding with other particles and breaking apart from them. If the floc grows large enough, it settles toward the bed and can be considered to enter a notional “stirred layer” of high sediment concentration and high shear (Mehta 1991). There it may be deposited on the soft mud layer and eventually become part of the bed, or it may be broken into smaller particulate units and be picked up by the flow and begin the process anew (McDowell and O’Connor 1977).

Aggregation of individual grains into larger, multiple particle units occurs when a collision brings two particles close enough together for mutually attractive forces to overcome repulsive forces, and the two particles bond as a result of those attractive forces. Similarly, fluid forces and collisions exceeding floc strength will break flocs apart. The forces acting on waterborne fine particles include the following fluid and particle forces (Krishnappan 1990; McAnally 1999).

#### Fluid forces:

1. Brownian motion: Thermal motion of fluid molecules causes collisions between the molecules and individual particles, imparting “kicks” that move the particles in random directions.
2. Normal stresses: Small-scale turbulent eddies cause pressure forces that, like Brownian motion, impart random motion to particles of size similar to the eddies.
3. Shear stresses: Both laminar and turbulent shear flows impose tangential stresses on particles that are of the

**Fig. 4-6.** Schematic drawing showing transport and aggregation of cohesive sediment particles or flocs.  $L$  = lift force,  $W$  = particle submerged weight, and  $F$  = cohesion (adapted from McAnally 1999).

same size order as the distance over which the velocity changes significantly.

4. Mean flow drag: Any difference between the mean flow velocity and the particle mean velocity will result in a drag force due to pressure and frictional forces.

#### Particle forces:

5. Van der Waals attraction: Generated by mutual influence of electron motion within the particles, van der Waals forces act between all matter and are extremely strong, but decay very rapidly (from the 3rd to the 7th power) with distance, so particles must be very close together before the forces exert a significant influence.
6. Electric surface attractions and repulsions; The surface electrical charges of fine particles induce both attractive and repulsive forces between two similar particles.
7. Collisions; Colliding particles impart forces and torques on one another.

#### Other forces:

Once two or more sediment particles bond together, additional forces may act on them, including chemical and biochemical cementation and biopolymeric binding, and forces due to pore fluid motion at extremely small scales. Such forces require explicit consideration in theories meant to simulate natural aggregation (Hill 1992; Hill et al. 1992; Hill and Nowell 1995).

The electrical forces include predominantly negative surface charges of most fine sediment grains (exceptions are some metal hydroxides that have positive face charges and negative edge charges), which give most fine sediment grains a net negative charge. This charge induces a repulsive force between two similar grains. If the overall repulsive force is reduced and the positive edge of one grain approaches the negative face of another, the two grains may bond in a T-formation. The overall charge of a grain attracts a cloud of opposite-charge ions if they are available in the surrounding fluid. The cloud of ions, called the Gouy double layer, balances the grain's net charge and represents an equilibrium in the ion field between electrical attraction toward the grain and diffusion away from it. The double layer exerts a repulsive force on other like-charged grains and their double layer, just as the net charge does, and also extends outward some distance to keep grains farther apart. These electrical forces are weaker than the van der Waals force, but decay more slowly with distance, so they dominate the net force between grains unless other processes come into play as discussed below. In a fluid with abundant free ions the double-layer thickness is suppressed, reducing the distance over which

the repulsive forces act and permitting grains to approach more closely. The electrically neutral unit consisting of a mineral grain and its double layer is called a clay micelle (van Olphen 1977).

In nearly ion-free water the net grain charge keeps the clay micelles, and hence the cohesive grains, apart, and only those collisions bringing an edge (typically positive) directly to an oppositely charged face can bring the two close enough together to allow the van der Waals forces to bind them in an edge-to-face configuration. Adding only a few free ions (for example, by dissolving salt in the fluid) creates large ionic double layers and retards aggregation by repelling grains at larger spacings, but at some higher ionic concentration the double layer's diffusion is suppressed and it shrinks, permitting closer approach between grains and collisions that overcome the faces' electrical repulsion so that the short-range van der Waals forces can bind them face-to-face.

Under low ionic concentrations, floc structures can be likened to houses of playing cards with large pore spaces, low density, and low strength, because the edge-to-face connection puts only a few molecules within the range of the attractive forces. Such flocs commonly occur in freshwater lakes. At the higher dissolved-ion concentrations of upper estuaries and some rivers, the orientation of aggregated grains tends toward face-to-face contacts and most often resembles a deck of cards that has been messily stacked. With larger contact areas and shorter moment arms, such structures are significantly stronger than those formed by edge-to-face orientation (Burban et al. 1989; Parchure 1984).

#### 4.4.2 Order of Aggregation

Based on tests on estuarine sediments, Krone (1963) inferred a conceptual model of floc structure. In this model, initial aggregation creates small, compact flocs of primary grains with strong bonds, referred to as "zero order aggregates," designated  $p0a$  in Fig. 4-7. Subsequent collisions between zero order aggregates create slightly weaker bonds between two or more of these aggregates, leading to an assemblage of  $p0a$ 's, a particle aggregate-aggregate, or first order aggregate,  $p1a$ .

Fig. 4-7 Idealized floc structure depicting orders of aggregation.

Successive levels (orders) of aggregation lead to particle aggregate-aggregate-aggregates  $p2a$ , then  $p3a$ , and so on.

Based on rheometric experiments with sediments from five locations covering the U.S. Atlantic, Gulf of Mexico, and Pacific coasts, plus one inland river, Krone (1963) calculated up to 6 orders of aggregation with corresponding densities and strengths for each. As an example, results for San Francisco Bay sediment are given in Table 4-7. These properties refer to sediment in suspension. When the material deposits, overburden, gelling, and consolidation alter floc properties. As a result, there is only a remote connection between the density and strength of the suspended flocs and the erodibility of flocs at the bed surface, especially after the bed has aged following its formation by sediment deposition.

#### 4.4.3 Fractal Description

The floc model of Krone (1963), which assigns discrete structures to flocs, is notionally compatible with models of floc structure based on the fractal principle (e.g., Meakin 1988; Kranenburg 1994a; Winterwerp 1998; 1999). The basic model, which has long been used in wastewater treatment research, assumes that floc structure approximately conforms to the fractal property of geometric self-similarity. Self-similar structure leads to a power-law relationship between floc size and properties such as density and surface area. Thus, for example, the relationship between diameter and density for a three-dimensional floc can be expressed as

$$d_f = \sigma_f \rho_f^{1/(n_f-3)} \quad (4-9)$$

where

$d_f$  = floc diameter,  
 $\rho_f$  = floc density, and  
 $n_f$  = fractal dimension.

**Table 4-7 Characteristics of Aggregate Orders of San Francisco Bay Sediment**

Order of aggregation	Floc density <sup>a</sup> (kg/m <sup>3</sup> )	Floc strength (Pa)
0	1,269	2.2
1	1,179	0.39
2	1,137	0.14
3	1,113	0.14
4	1,098	0.082
5	1,087	0.036
6	1,079	0.020

<sup>a</sup>In sea water of density 1,025 kg/m<sup>3</sup>.

Source: Krone (1963).

The proportionality constant  $\sigma_f$  depends on the sediment and fluid properties. For example, Tambo and Watanabe (1979) report a range of 0.0002 to 0.0012, when  $d_f$  is measured in cm and  $\rho_f$  in g/cm<sup>3</sup>.

For bodies in three-dimensional (Cartesian) space,  $1 \leq n_f \leq 3$ . For a nonfractal solid sphere,  $n_f$  has a value of 3. Wiesner (1992) showed that for aggregation due to Brownian motion, an irreversible process,  $n_f$  should be about 1.78. For reversible processes such as flow shear-induced collisions, it should be about 1.9 to 2.1. He noted, however, that for distinct scales of structure, such as Krone's order-of-aggregation model, each scale may be characterized by a different fractal dimension and the overall apparent dimension will be larger, perhaps 2.1 to 2.6 for a second order aggregate ( $p2a$ ) structure. Kranenburg (1994a) noted that it would be inappropriate to assume that the complex, multi-component structure of real muds possesses completely self-similar geometry. He concluded that muds are probably only approximately self-similar, but that the concept seems useful in interpreting experimental results. These observations have been supported by experimental evidence (Winterwerp 1999); however, from field data Manning and Dyer (1999) reported that there was more variation in floc density for the same floc size than suggested by the fractal model.

#### 4.4.4 Floc Strength

Floc strength, i.e., resistance to breakup or disaggregation, is a function of cohesion, size, and orientation of particles within the floc and organic content (Partheniades 1971; Wolanski and Gibbs 1995), and to a lesser extent depends on salinity and pH (Raveendran and Amirtharajah 1995). Experimental results (e.g., Krone 1963; Hunt 1986; Mehta and Parchure 2000) show that as floc size and organic content increase, floc density and strength decrease. Partheniades (1993) reported that Krone's (1963) data for floc strength fit the expression

$$\tau_f = \alpha_c \Delta \rho_f^{\beta_c} \quad (4-10)$$

where

$\tau_f$  = floc strength (in Pa),  
 $\Delta \rho_f = \rho_f - \rho_w$  (in kg/m<sup>3</sup>),  
 $\rho_w$  = water density, and  
 $\alpha_c, \beta_c$  = empirical coefficients, e.g.,  $1.524 \times 10^{-7}$  and 3, respectively, for San Francisco Bay sediment.

The fractal model of Kranenburg (1994a) results in a floc strength that follows Eq. (4-10), with  $\beta_c = 2/(3-n_f)$ . Kranenburg noted that his expression brackets Krone's (1963) data for  $n_f = 2.1$  and 2.3.

Logically, for given sediment, floc density should be a function of the shearing intensity, sediment concentration and salinity. In practice, it is usually inferred from measured floc size and settling velocity, assuming free settling

and Stokes' law. Empirically, the relation  $\Delta\rho_f = \alpha_{cd} d_f^{-\beta_{cd}}$  is found to hold on a very approximate basis. For San Francisco Bay sediment, Kranck and Milligan (1992) and Kranck et al. (1993) reported  $\alpha_{cd} = 35,000$  and  $\beta_{cd} = 1.09$ , when  $d_f$  is measured in  $\mu\text{m}$ . These coefficients hold in the range of  $d_f$  approximately between 100 and 1,000  $\mu\text{m}$ . For Chesapeake Bay sediment Gibbs (1985) found  $\beta_{cd} = 0.97$ , which is close to the value of Kranck et al.

#### 4.4.5 Floc Size, Concentration, Turbulence, and Shear Stress

In Eq. (4-9),  $d_f$  may be considered to be the mean floc diameter. In addition, other statistical measures of size and their relationships with other parameters have been proposed. For example, Kranck (1986) and Kranck and Milligan (1992) noted that despite the dramatic shift in the particle size spectra due to coagulation of individual (i.e., dispersed) particles into flocs, a relationship was found between the modal floc size and the corresponding modal (individual) grain size. This was the case because the following equation could be fit to both individual particle spectra and floc spectra, with suitable adjustments of the coefficients:

$$C_v = C_{v0} d_f^\xi \exp(-\kappa_f \zeta d_f^2) \quad (4-11)$$

where

$C_v$  = volume concentration of sediment in any one size class, i.e., volume of sediment divided by volume of suspension,  
 $C_{v0}$ ,  $\xi$ ,  $\kappa_f$  = sediment-specific coefficients,  
 $\zeta = g(\rho_f - \rho_w)/8\nu\rho_w$ ,  
 $g$  = acceleration due to gravity, and  
 $\nu$  = kinematic viscosity of fluid.

**Fig. 4-8.** Examples of Eq. (4-11). Dashed curve shows dispersed grain size distribution and continuous curve is for flocs (based on (Kranck 1986; Kranck and Milligan 1992).

Note that  $\zeta d_f^2$  is the Stokes settling velocity. Examples of the fit of (4-11) are shown in Fig. 4-8 for (dispersed) grain size distribution and floc size distribution. Values of  $C_{v0}$ ,  $\xi$ ,  $\kappa_f$ ,  $\nu$ ,  $\rho_f$ , and  $\rho_w$  are based on the work of Kranck (1986) and Kranck and Milligan (1992). The respective set of values are 3.123 ppm, 0.608, 0.0055 s/ $\mu\text{m}$ ,  $10^{-6}$  m<sup>2</sup>/s, 2,650 kg/m<sup>3</sup>, and 1,000 kg/m<sup>3</sup> for dispersed grain distribution, and 0.001 ppm, 2.72, 0.00081 s/ $\mu\text{m}$ ,  $10^{-6}$  m<sup>2</sup>/s, 1,200 kg/m<sup>3</sup>, and 1,000 kg/m<sup>3</sup> for floc distribution. From settling tests using a flocculated marine glacial mud, Kranck (1986) reported wide-ranging values of  $C_{v0}$ ,  $\xi$ , and  $\kappa_f$ .

It is feasible to obtain a simple formula relating the median floc size to sediment concentration and turbulence (Galani et al. 1991; Lick et al. 1992): Winterwerp (1998) derived expressions for the equilibrium floc size resulting from a balance between floc formation and breakup, and also the maximum or limiting floc size in a given flow-sediment field. In the latter context, Krone (1963) proposed the following relation for the limiting size:

$$d_{flim} = \frac{2\tau_f \Delta R}{\mu_w \dot{\gamma}} \quad (4-12)$$

where

$\tau_f$  = floc strength,  
 $\mu_w$  = viscosity of water,  
 $\dot{\gamma}$  = local flow shear rate, and  
 $\Delta R$  = interpenetration distance for two colliding flocs.

Assume a moderate flow shearing rate (i.e., the vertical gradient of the horizontal flow velocity) of 10 Hz and a first order aggregate of San Francisco Bay sediment with a strength of 0.39 Pa (Table 4-7). Krone (1962) suggested 2  $\mu\text{m}$  to be a

**Fig. 4-9.** Diagram showing the relationship between floc diameter, suspended sediment concentration and shear stress (after Dyer 1989).

reasonable value of  $\Delta R$ . Substituting these values into Eq. (4-12) along with  $\mu = 0.001 \text{ Pa s}$  gives  $d_{\text{flim}} = 156 \text{ }\mu\text{m}$ .

On a graphical basis, from an analysis of data on modal floc sizes from a variety of experiments Dyer (1989) developed the plot of Fig. 4-9 relating the modal (equilibrium) floc size to suspended sediment concentration and shear stress. From a statistical mechanical representation of two- and three-body collision mechanisms between particles and flocs sorted out by size classes for sediment from the San Francisco Bay, McAnally (1999) developed a plot relating the equilibrium diameter (actually diameter at time equal to the 99.9% of the time required to reach full equilibrium), the suspended sediment concentration, and the local rate of energy dissipation in the fluid. The plot showed a qualitative resemblance to Fig. 4-9.

#### 4.4.6 Modes of Transport

Referring to Fig. 4-6 we note that the pickup and deposition of particles or flocs must inherently follow a transport regime somewhat different from that for cohesionless grains. Let us represent cohesion simply by a representative force  $F$ , which binds the cohesive particle to the bed. Also, let us assume that the entraining force is represented solely by the hydrodynamic lift  $L$ , i.e., excluding any contribution from drag. Accordingly, the condition for incipient entrainment will be  $L / (W + F) \geq 1$ , where  $W$  is the buoyant weight of the particle. On the other hand, the condition for deposition of a suspended particle will be  $L / W < 1$ .

Following the classical derivation of the bed load function by Einstein (1950), in which bed load is obtained under the condition of equality of number flux (i.e., number of particles per unit bed area per unit time) of entraining and depositing cohesionless particles, Partheniades (1977) examined the transport of cohesive particles. He showed that, under the assumption of  $L$  fluctuating (due to turbulence) between an upper and a lower bound (as opposed to Einstein's boundless Gaussian distribution), cohesion ( $F$ ) precludes, in general, the development of a bed load function, and hence bed load transport. This is so because under this scenario, for instance, deposition can occur exclusively, i.e., without corresponding erosion of bed. In other words, he showed that cohesive sediment is characteristically transported in suspension, rather than as bed load. This transport can occur either as bed material load or as wash load. As for the latter mode, lightweight organic detritus is often transported as wash load through rivers and tidal waters where currents are strong. In quiescent basins where currents become weak this material may be deposited and if so, would be reclassified as bed material load. It is essential to point out, however, that cohesive materials often form balls or pebbles (e.g., Jacinto and Le Hir 2001), and these comparatively hard particles have distinct and durable forms that can be transported as bed load; i.e., their transport can be represented in a large measure by a bed load function derived for coarse

sediment transport, when such "particles" occur in sufficiently large numbers per unit bed area.

To support his argument regarding the mode of transport of cohesive sediment, Partheniades (1977) used evidence from steady flow experiments on the deposition of initially suspended kaolinite in a flume. He showed that the variation of suspension concentration with time during deposition could be explained only if it was assumed that no erosion of the deposited material occurred during the depositional process. The main observation that supported this inference was that up to a fairly high suspension concentration, on the order of  $25 \text{ kg/m}^3$ , the sediment-carrying capacity of the flow was found to be independent of flow velocity; being dependent, instead, on how much sediment was externally introduced into the suspension. Later, Parchure (1984) showed that his steady-flow experimental results on the erosion of a variety of cohesive beds could be explained provided it was assumed that no deposition of the eroded sediment occurred. This inference was mainly based on the observation that at steady state, if the suspension was replaced by clear water without stopping the flow, no significant erosion subsequently occurred. Lick (1982), however, based his erosion rate expression on the assumption of continuous exchange, citing his own experimental evidence for simultaneous deposition and erosion.

Notwithstanding the analysis of Partheniades (1977), which relies on the single grain size analysis of Einstein (1950), the issue of whether erosion and deposition are "mutually exclusive" does not appear to have been fully resolved. The difficulty seems to be due largely to the nature of the experiments that have been conducted thus far; almost all based on relatively simple laboratory setups in which it has not been possible to "observe" particle transport close to the bed. In every case the behavior of particles with regard to near-bed entrainment and deposition has had to be inferred from essentially indirect evidence. For example, by tagging part of the initially suspended sediment with radioactive gold and comparing the rate of deposition of tagged sediment with that of untagged sediment sampled at mid-depth (rather than close to the bed surface, which is typically ill-defined and unidentifiable during deposition), Krone (1962) indirectly inferred that some of the deposited material had seemingly reentrained during the predominantly depositional process.

The question of bed sediment exchange becomes especially important in modeling sediment transport under oscillatory flows, due both to tides and to waves. Whereas in his modeling of tide-induced transport Hayter (1983) assumed mutually exclusive erosion and deposition, Jiang (1999) considered continuous exchange. Similarly, in wave-induced transport modeling, Maa (1986) assumed continuous exchange. Sanford and Halka (1993) showed that in situ measurement of resuspension of fine sediment in the Chesapeake Bay could be better modeled by assuming continuous exchange than by assuming nonsimultaneous erosion/deposition. On the other hand, Teeter (2001b) argued for nonsimultaneous exchange, citing the need to model sediment sorting

**Fig. 4-10.** Schematic description of vertical sediment fluxes (arrows) in the stirred layer actuated by bed erosion (adapted from Cervantes et al. 1995). Reproduced with permission of PIANC-COPEDEC.

during erosion/deposition, rather than continuous exchange, for an explanation of bed response to unsteady forcing in the prototype environment.

In order to conceptually bridge the knowledge gap between laboratory observed mutually exclusive erosion/deposition and the commonly encountered need to render these processes simultaneous in modeling resuspension in field applications, the schematic drawing of near-bed sediment exchange shown in Fig. 4-10 can be helpful (Cervantes et al. 1995; Mehta 1991). The layer extending from the bed (at  $z = 0$ ) to some suitable notional height  $\alpha_h$  may be idealized as a stirred layer mentioned earlier, within which entrainment of sediment from the bed starting at  $t = 0$  sets up a convective cell of upward diffusive flux of sediment and, as a result, gravity-induced settling flux. Under constant fluid stress-induced forcing at the bed these fluxes will eventually approach equality, erosion of the stratified bed will practically cease at some final depth where the applied shear stress equals the erosion shear strength, and a steady-state concentration of sediment in the water column will occur. Thus, by applying, at  $z = \alpha_h$ , laboratory expressions for erosion and deposition evaluated at  $z = 0$ , formulas compatible with mutually exclusive erosion/deposition can be used in simulating resuspension on a simultaneous basis. Even though this is merely a “convenient” interpretation of two unresolved concepts, it appears that the “insertion” of the stirred layer may be useful in explaining some flume experimental results meant to study deposition, but in which two-way exchange between bed and suspended sediment may actually have occurred (McAnally 1999).

## 4.5 SETTLING VELOCITY

### 4.5.1 Aggregation and Settling

The rate at which suspended flocs settle depends on their weight, diameter, and shape, which in turn are related to their order of aggregation, the latter being governed by the frequency of interparticle collisions. Three mechanisms that have been explicitly shown to influence aggregation in estuarine and coastal waters are Brownian motion, flow-induced shear, and differential settling (Krone 1962). By way of the last mechanism, particles/flocs of different settling velocities collide as they fall. For these three mechanisms, the

frequency functions of collision between two particles of sizes  $i$  and  $j$   $\beta_c$  are given as (McAnally 1999; Burban et al. 1989; Delichatsios and Probststein 1975; Saffman and Turner 1956)

$$\beta_c \begin{cases} \frac{2}{3} \frac{\kappa T F_c}{\mu} \frac{(d_i + d_j)^2}{d_i d_j} & \text{Brownian motion} \\ \left[ \frac{\pi F_c^2}{4} \sqrt{\frac{2}{15\pi}} \right] G_s (d_i + d_j)^3 & \text{fluid shear} \\ \left[ \frac{\pi F_c^2}{4} \right] (d_i + d_j)^2 |w_{si} - w_{sj}| & \text{differential settling} \end{cases} \quad (14-13)$$

where

$\kappa$  = Boltzmann constant;

$T$  = absolute temperature;

$\mu$  = dynamic viscosity of fluid;

$F_c$  = collision diameter correction factor (which varies between 0 and 1);

$d_i, d_j$  = sizes of colliding particles from  $i$  and  $j$  size classes, respectively;

$w_{si}, w_{sj}$  = corresponding settling velocities;

$G_s$  = measure of flow shear given by  $G_s = (\epsilon/\nu)^{1/2} = \nu/\lambda^2$ ;

$\epsilon$  = flow energy dissipation per unit mass of fluid per unit time;

$\nu = \mu/\rho_w$  = kinematic viscosity of fluid (nominally water) and

$\lambda$  = Kolmogorov turbulence microscale.

The settling velocities can be simply related to the corresponding diameters through Stokes' law:  $w_{si} = \Delta\rho_i d_i^2/18\mu$  and  $w_{sj} = \Delta\rho_j d_j^2/18\mu$

where

$$\Delta\rho_i = \rho_{si} - \rho_w;$$

$$\Delta\rho_j = \rho_{sj} - \rho_w;$$

$\rho_i, \rho_j$  = densities of  $i$  and  $j$  particles and

$\rho_w$  = water density.

Among others, Hunt (1982), Lick et al. (1992), and McAnally (1999) have described the manner in which the relative importance of the above three collision mechanisms changes as aggregation of particles proceeds. In Fig. 4-11 a comparison is made of these mechanisms based on Eq. (4-13) and typical water column conditions. Observe that as aggregation proceeds and the second particle size increases, fluid shear takes over as the dominant mechanism, while the influence of Brownian motion becomes negligible. Note also that when the two particles are of the same size, in this case  $1 \mu\text{m}$ , there is no contribution from differential settling because the two particles settle at the same rate, and therefore do not collide by that mechanism.

**Fig. 4-11.** Simulated relative contributions to the collision frequency for typical water column conditions in the estuary. First particle diameter is 1  $\mu\text{m}$  (after McAnally 1999).

In general, fluid shear is the most important of the three collision mechanisms, because it produces relatively tightly packed, durable flocs in comparison with the other two mechanisms (Krone 1963; 1986). Differential settling is important during and close to times of slack water. At very low flow shear Brownian motion becomes responsible for aggregation; however, the flocs thus produced tend to be weakly bonded.

#### 4.5.2 Settling Velocity and Concentration

Floc settling velocities typically range from  $1 \times 10^{-5}$  to  $1 \times 10^{-1}$  m/s for particles of size 10 to 1,000  $\mu\text{m}$  (Dyer 1989; van Leussen 1994; Moudgil and Vasudevan 1989). The settling velocity depends on the floc properties, especially size, density, and shape, which in turn are governed by the interparticle collision frequency and the outcome of collisions. Inasmuch as collisions depend on particle concentration in the suspension, suspended sediment concentration can be used as an approximate lumped parameter for estimating the settling velocity of flocs (Krone 1962). As a result, and given the convenience with which concentration can be measured, formulas relating the settling velocity to concentration have been proposed.

Following Wolanski et al. (1989), a general expression for the mean settling velocity divides the settling range into four zones—free settling, flocculation settling, hindered settling, and negligible settling. The settling velocity,  $w_s$ , in each zone can be expressed as (Hwang 1989)

$$w_s = \begin{cases} w_{sf} & C < C_1 \\ a_w \frac{C^{n_w}}{(C^2 + b_w^2)^{m_w}} & C_1 < C < C_3 \\ \sim \text{negligible} & C_3 < C \end{cases} \quad (4-14)$$

where

- $w_{sf}$  = free settling velocity;
- $C$  = suspension concentration;
- $a_w$  = velocity scaling coefficient;
- $n_w$  = flocculation settling exponent;
- $b_w$  = hindered settling coefficient;
- $m_w$  = hindered settling exponent and
- $C_1, C_3$  = zone concentration limits defined in Fig. 4-12.

Free settling occurs at low suspension concentrations when  $w_s$  is independent of  $C$ , and can be calculated from Stokes' law, especially when settling occurs under quiescent conditions. Between  $C_1$  and  $C_2$ ,  $w_s$  increases with concentration due to the formation of stronger, denser and larger flocs. In the hindered settling zone between  $C_2$  and  $C_3$ , the occurrence of an aggregated particulate network inhibits, or hinders, the upward transport of interstitial water in the deposit. As a result,  $w_s$  decreases with increasing  $C$  in this zone. At concentrations above  $C_3$ , settling becomes comparatively small as consolidation takes over.

Values of coefficients  $a_w$ ,  $b_w$ ,  $m_w$ , and  $n_w$  along with  $C_1$  are given in Table 4-8 based on the application of Eq. (4-14) to measured variations of the settling velocity (m/s) with concentration ( $\text{kg}/\text{m}^3$ ). In general,  $C_1$  ranges between 0.1 and 0.3  $\text{kg}/\text{m}^3$ , in agreement with the original observations of Krone (1962). In reality, the transition between free and flocculation settling is gradual and may occur over a wider concentration range, e.g., on the order on 0.01 to 0.3  $\text{kg}/\text{m}^3$  (Krone 1962; Ozturgut and Lavelle 1986). For computational purposes, it is convenient to select  $w_{sf}$  as the value of the settling velocity corresponding to the intersection of the curve for flocculation settling obtained from (4-14) with the vertical line corresponding to  $C_1 = 0.1 \text{ kg}/\text{m}^3$ .

The concentration  $C_2$ , corresponding to the peak settling velocity  $w_{sm}$ , can vary between 1 and 15  $\text{kg}/\text{m}^3$ . Odd and Cooper (1989) reported  $C_3$  to be on the order of 75  $\text{kg}/\text{m}^3$  in their measurements of settling rates of mud from the Severn

River estuary in United Kingdom. This value is in approximate agreement with the concentration at which a suspension changes to a bed due to the development of effective normal stress (Sills and Elder 1986).

From Eq. (4-14) we find that when  $C \ll b_w$ , i.e., the “low” concentration condition,

$$w_s = a_w b_w^{-2m_w} C^{n_w} \quad (4-15)$$

Equation (4-15), which describes flocculation settling, was derived by Krone (1962), who also provided a phenomenological explanation for the form of the equation. Using the data of Overbeek (1952) on the aggregation of initially dispersed particles, Krone determined the value  $n_w = 4/3$  and showed that it agreed with his data on settling of San Francisco Bay sediment in a flume as well as in a settling column.

When  $C \gg b_w$ , i.e., the “high” concentration condition, Eq.(4-14) reduces to

$$w_s = a_w C_w^{n_w - 2m_w} \quad (4-16)$$

where  $n_w - 2m_w$  must be less than zero, because hindered settling causes the settling velocity to decrease with increasing concentration. The form of Eq. (4-16) agrees with the experimental data of Richardson and Zaki (1954), who also derived it theoretically based on idealized geometric arrays of particles falling in the hindered settling mode.

From Eq. (4-14) the following useful quantities related to settling velocity and associated settling flux  $F_s = w_s C$  (Fig. 4-12) are obtained:

*Peak velocity,  $w_{sm}$ :*

$$w_{sm} = a_w b_w^{n_w - 2m_w} \frac{\left(\frac{2m_w}{n_w} - 1\right)^{m_w - n_w/2}}{\left(\frac{2m_w}{n_w}\right)^{m_w}} \quad (4-17)$$

*Concentration,  $C_2$ :*

$$C_2 = \frac{b_w}{\left(\frac{2m_w}{n_w} - 1\right)^{1/2}} \quad (4-18)$$

*Settling flux,  $F_s (=w_s C)$ :*

$$F_s = a_w \frac{C^{n_w+1}}{(C^2 + b_w^2)^{m_w}} \quad (4-19)$$

*Maximum settling flux,  $F_{sm}$ :*

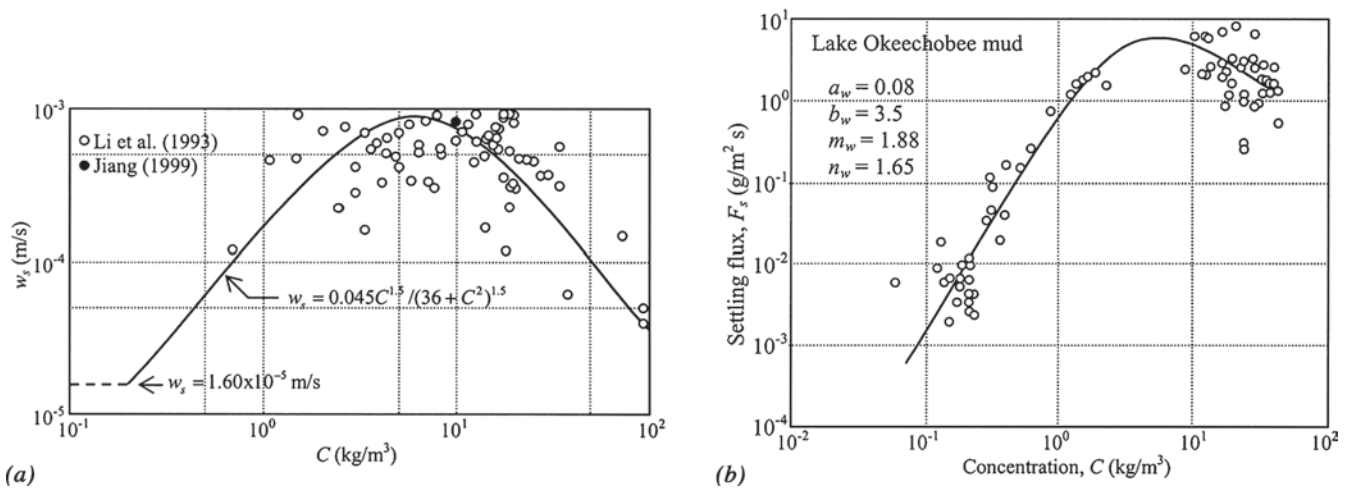

$$F_{sm} = a_w b_w^{n_w - 2m_w + 1} \frac{\left(\frac{2m_w}{n_w} - 1\right)^{m_w - \frac{n_w+1}{2}}}{\left(\frac{2m_w}{n_w} + 1\right)^{m_w}} \quad (4-20)$$

*Concentration at maximum flux,  $C'_2$ :*

$$C'_2 = \frac{b_w}{\left(\frac{2m_w}{n_w} - 1\right)^{1/2}} \quad (4-21)$$

Inasmuch as  $C'_2$  is obtained from Eq. (4-18) by replacing  $n_w$  by  $n_w + 1$ , it is characteristically greater than  $C_2$ . Physically this is so because of the dependence of settling velocity on concentration, which means that the settling flux is a nonlinear function of concentration. Thus, for example, from the data of Nichols (1984/1985) in Table 4-8 we find that  $C_2 = 4.4 \text{ kg/m}^3$  and  $C'_2 = 17.4 \text{ kg/m}^3$ . In a depositional environment, i.e., in the absence of significant reentrainment of sediment,  $C'_2$  marks the level of the lutocline. Consequently, in Fig. 4-4 this concentration corresponds to the upper level of the fluid mud layer. Likewise,  $C_3$  very approximately marks the transition between the fluid mud layer and the bed. The concentration  $C_1$  defines the transition between the mixed suspension layer and the stratified suspension layer. When entrainment is significant these concentration limits and the elevations at which they occur in the concentration profile tend to change, depending on the importance of entrainment in relation to settling.

An example of settling velocity data from the Jiaojiang estuary in China and data fit using Eq. (4-14) is shown in Fig. 4-13a. An illustration of settling flux variation with

**Fig. 4-13.** Settling velocity as a function of (a) suspension concentration during a neap tide in the Jiaojiang estuary, China (after Jiang 1999) and (b) suspended sediment concentration for Lake Okeechobee, Fla. mud (data from Hwang 1989; the curve is based on Eq. (4-19)).

concentration is shown in Fig. 4-13b, based on the data of Hwang (1989) from Lake Okeechobee in Florida. The curve is obtained from Eq. (4-19).

#### 4.5.3 Other Effects on Settling

Jiang (1999) found that deposition data from the flume experiments of Lau (1994) using a kaolinite under controlled conditions of fluid temperature showed a well-defined temperature dependence of the form

$$w_{s50}(C, T_c) = \Phi w_{s50}(C, 15) \quad (4-22a)$$

where

$w_{s50}(C, 15)$  = concentration-dependent median settling velocity as defined by Eq. (4-14) at temperature  $T_c = 15^\circ\text{C}$ , and

$$\Phi = 1.776(1 - 0.875T') \quad (4-22b)$$

where

$$T' = T_c / 15.$$

This finding suggests that the mean floc size decreases with increasing temperature, which is a reasonable conclusion because thermal activity of the clay micelle ions tend to increase the repulsive effect between grains, reducing the number of collisions available to pump sediment mass up the size distribution in an environment in which continued aggregation occurs.

In order to account for the effect of flow shear on the settling velocity, van Leussen (1994) and Teeter (2001a) proposed equations relating  $w_s$  to the flow shear rate, whereas Burban et al. (1990) relate  $w_s$  to shear stress. Winterwerp (1998) used Kranenburg's (1994) fractal model as a framework to formulate settling velocity relationships based directly on grain and floc sizes. Following van Leussen (1994), Malcherek and Zielke (1996) and Teisson (1997), Teeter (2001a), used the expression:

$$\frac{w_s}{w_{s|\dot{\gamma}=0}} = \frac{(1 + \lambda_1 \dot{\gamma})}{1 + \lambda_2 \dot{\gamma}^2} \quad (4-23)$$

in which  $w_{s|\dot{\gamma}=0}$  is obtained from a concentration dependent settling velocity function such as (4-14),  $G$  is the shear rate ( $\text{Hz}$  or  $\text{s}^{-1}$ ), and  $\lambda_1$  and  $\lambda_2$  are sediment-specific coefficients. From laboratory work on mud from San Francisco Bay, the values of these two coefficients are found to be 266 and 9, respectively.

Sheng (1986) showed that submerged vegetative canopies offer considerable resistance to settling and deposition. Ganju (2001) found that for Florida sediments the coefficient  $a_w$  in (4-14) depends on the organic content  $OC(\%/100)$  according to  $a_w = a_{w0} + a_1 OC + a_2 OC^2 +$

$a_3 OC^3 + a_4 OC^4$ , with  $a_{w0} = 0.2$ ,  $a_1 = 6.67 \times 10^{-4}$ ,  $a_2 = -1.7 \times 10^{-4}$ ,  $a_3 = 7.1 \times 10^{-6}$ , and  $a_4 = -1.3 \times 10^{-7}$ . Note that  $a_{w0}$  is the value of  $a_w$  when  $OC = 0$ . This relationship amounts to the trend of decreasing aggregate diameter and settling velocity with increasing organic content, because the aggregates become both smaller and lighter as the density and cohesion of the composite material decrease with increasing organic fraction.

## 4.6 DEPOSITION UNDER FLOW

### 4.6.1 Rate of Deposition

Referring to Fig. 4-6, if a settling floc approaches a bed where concentration, collision frequency, and shearing rate are high, it will either break apart and be reentrained or bond with particles at the bed surface and be deposited. Deposition can be characterized as the outcome of interaction between two stochastic processes occurring just above the bed—interfloc collisions causing both floc breakup and growth that creates a distribution of floc sizes and strengths, and the probability that a floc of a given strength and size will be deposited (Stolzenbach et al. 1992). Thus, the deposition rate is a function of floc settling velocity, concentration, and the near-bed shearing rate. The shearing rate is conveniently characterized by the bed shear stress.

A widely used expression for the sediment mass deposition rate  $\Psi$ , when only one size class is considered, is

$$\Psi = \frac{d\bar{C}}{dt} = -\frac{w_s \bar{C}}{h} \left( 1 - \frac{\tau_b}{\tau_d} \right); \quad \tau_b < \tau_d \quad (4-24)$$

where

$\bar{C}$  = depth-averaged suspended sediment concentration;  
 $h$  = water depth;  
 $\tau_b$  = bed shear stress; and  
 $\tau_d$  = critical stress for deposition.

When  $\tau_b \leq \tau_d$  all initially suspended sediment deposits and, conversely, no sediment deposits when  $\tau_b > \tau_d$ . Thus, in the free settling range ( $w_s = \text{constant}$ ), an exponential law of concentration decay is obtained from (4-24) by integration;

$$\frac{C}{C_0} = \exp \left[ - \left( 1 - \frac{\tau_b}{\tau_d} \right) \frac{w_s}{h} t \right]; \quad \tau_b < \tau_d \quad (4-25)$$

where

$C_0$  = initial suspension concentration;  
 $t$  = time;

and the bar over  $C$  is omitted for convenience of further treatment.

In the flocculation settling range, in which the settling velocity increases with increasing concentration, e.g., according to Eq. (4-15), the concentration-time relationship becomes logarithmic; i.e.,  $\log C$  decreases linearly with  $\log t$  (Krone 1993; Shrestha and Orlob 1996). However, Eq. (4-25) has been found to hold reasonably well up to concentrations on the order of  $1 \text{ kg/m}^3$  (Mehta and Lott 1987).

#### 4.6.2 Multiclass Deposition

Among others, Ockenden (1993) and Teeter (2001a; 200b) extended Eq. (4-24) to multiple grain sizes using

$$\Psi_i = \frac{dC_i}{dt} = -\frac{w_{si}C_i}{h} \left(1 - \frac{\tau_b}{\tau_{di}}\right); \tau_b < \tau_{di} \quad (4-26)$$

where for each size class  $i$ ,

- $\Psi_i$  = mass deposition rate;
- $C_i$  = depth-mean concentration;
- $w_{si}$  = settling velocity; and
- $\tau_{di}$  = critical shear stress for deposition.

Assumed  $\tau_d$  to vary between a minimum value  $\tau_{d1}$  for the finest sediment size class and a maximum  $\tau_{dM}$  for the coarsest class  $M$ , the concentration-time variation during deposition can be shown to depend on the magnitude of  $\tau_b$  in relation to  $\tau_{d1}$  and  $\tau_{dM}$ . The three types of curves that can result are shown schematically in Fig. 4-14. In this plot,  $C_f$  is the final, steady-state suspension concentration attained at the end of the transient period, during which the concentration decreases from its initial value. For further illustration, flume data on the deposition of a kaolinite and curves based on the multiclass relation of Mehta and Lott (1987) are shown in Fig. 4-15. The simulations are based on the equation

Fig. 4-14. Schematic drawing of concentration-time relationships during multiclass sediment deposition.

$$\frac{C}{C_0} = \frac{1}{C_0} \sum_{i=1}^M C_i = \sum_{i=1}^M \phi(w_{si}) \times \exp \left\{ - \left[ 1 - \frac{\tau_b}{\tau_{di}} \left( \frac{w_{sl}}{w_{si}} \right)^{\frac{\ln(\tau_{dM}/\tau_{d1})}{\ln(w_{sM}/w_{s1})}} \right] \frac{w_{sl}}{h} t \right\} \quad (4-27)$$

which is subject to the condition  $C_i = C_{0i}$ , the initial concentration for each class  $i$ , for all  $\tau_b \geq \tau_{di}$ , also for each class  $i$ . For a single-size sediment  $M=1$ , and Eq. (4-27) reduces to Eq. (4-25). It must be pointed out that Eq. (4-27) is based on multiclass distribution of floc settling velocity, rather than size. Given the histogram of  $w_{si}$  values obtained from settling velocity tests,  $\phi(w_{si})$  is the frequency of the  $i$ th class and  $w_{s1}$  is the smallest value of the settling velocity in the histogram. For simulation of the curves in Fig. 4-15, the range  $\tau_{d1}$  to  $\tau_{dM}$  was 0.04 to 1 Pa, which is typical in laboratory flumes. The histogram of settling velocity was derived from settling tests conducted with flocculated kaolinite in a settling column (Yeh 1979) and assumed to be applicable to flume conditions. A limitation of this approach is that the settling velocity is assumed to be unaffected by ongoing aggregation. Therefore, in those water bodies in which the flocs are composed of highly cohesive sediment and floc

Fig. 4-15. Concentration-time relationships for kaolinite deposition in a flume (after Mehta and Lott 1987).

growth/breakup is strongly influenced by flow shear, Eq. (4-27) as used may lead to errors in the prediction of the time-concentration history. Thus for example, whereas kaolinite, which is weakly cohesive, may be appropriate for (4-27), answers obtained using cohesive mud from the San Francisco Bay must be interpreted carefully (McAnally and Mehta 2000; 2002).

In a depositional environment such as a dead-end or finger canal, or wherever deposition is the dominant process, multiclass simulation enables the prediction of sorting by size (Lau and Krishnappan 1992), which typically manifests as a decrease in grain size with distance from the initial point of deposition (Lin 1986; Lin and Mehta 1997; McAnally 1999). However, in cases where resuspension cannot be ignored, the use of either Eq. (4-24) or (4-26) effectively amounts to a simulation of nonsimultaneous bed sediment exchange when the bed shear stress exceeds the critical stress for deposition. Size sorting also occurs during resuspension, particularly when the sediment is only weakly cohesive, such as a kaolinite, and this leads to a bed armoring effect because larger, especially unaggregated, grains erode less easily than the finer fractions (Teeter et al. 1997). However, since this selective resuspension process is less well understood than multiclass deposition, tracking particles, especially in the presence of ongoing aggregation of suspended matter, becomes cumbersome. To obviate this complexity in process modeling, it is convenient to assume a single size class only and to further consider  $\tau_d$  to be equal to the maximum value of  $\tau_b$  expected to be encountered in the simulation process (Jiang 1999). Then Eq. (4-24) reduces to  $\Psi = -w_s \bar{C}/h$ , which allows deposition to occur at all prevailing shear stresses.

It should be emphasized that (4-24) and (4-26) are based on laboratory data. Their applicability to the field requires a careful interpretation of the relationship between vertical gradients of concentration and their role in influencing the deposition rate. Also, when the total water depth is large, deposition is found to correlate with sediment concentration in the near-bed suspension layer, in contrast to depth-mean concentration, used in Eq. (4-24) and (4-26). Scale effects associated with the structure of turbulence also play a role (Sanford and Chang 1997).

## 4.7 CONSOLIDATION AND GELLING

### 4.7.1 Settling and Consolidation

If a clay mixture in water is allowed to settle, three stages of the settlement process can be identified, as shown schematically in Fig. 4-16 (Schiffman et al. 1985). In the first, flocculation stage, aggregation is important but no significant settling occurs. For some slurries, e.g., those of kaolinite, this stage may be only tens of seconds long, but for a bentonite slurry it may last effectively up to tens of minutes. In the second stage, flocs gradually settle and form a bed

layer, which undergoes what is called primary consolidation and associated dewatering. The initial settling process is complicated by a significant change in the structure of the newly deposited flocs. Krone (1963) conceptualized this change in terms of the aggregate order—when aggregates of order  $n$  deposit they form an initial “fluffier” and weaker layer of aggregates of order  $n + 1$ . When this layer exceeds a thickness on the order of 2.5 cm, overburden crushes the  $n + 1$  order aggregates to  $n$  order aggregates, which are then crushed further by overburden to result in aggregates of order  $n - 1$ ,  $n - 2$ , and so on.

The upper boundary of the settling zone in the second stage, which can generally be defined as a lutocline, drops with time until it meets the rising bed boundary at the onset of the third stage. In this stage, settling is terminated and bed consolidation continues. Accordingly, the bed surface gradually drops until no further consolidation takes place. Whereas the second stage may last from minutes to hours, the third stage can range between hours to days or months. In some case it may take years for full consolidation. During this stage, even after dewatering ends, internal rearrangements of particles may occur under secondary consolidation. It should be noted however, that in a large number of cases involving fresh estuarine deposits, consolidation is practically over in one to two weeks. Because this time scale coincides with the synodic spring-neap tidal cycle, consolidation plays an important role in governing estuarine sediment transport and budget.

The rate of settling, which is typically in the hindered mode, and consolidation are both governed by the rate at which interstitial or pore water escapes the particle matrix. Within the settling zone there is no significant effective normal stress; i.e., the pore water pressure is practically equal to the total hydrostatic pressure. Within the consolidation zone, because a part of the total weight

**Fig. 4-16.** Flocculation, settling, and consolidation zones (adapted from Schiffman et al. 1985).

of the slurry is supported by the particle matrix, the pore pressure is less than the total pressure, with the difference, equal to the effective stress, representing the particle-supported load. Figure 4-17a shows an instantaneous density profile within a settling silty clay in an experimental column, 4.75 h after test initiation starting with a uniformly mixed suspension having a density of  $1,090 \text{ kg/m}^3$  (Sills and Elder 1986). The corresponding measured profiles of total pressure (i.e., normal stress) and pore pressure are shown in Fig. 4-17b. The elevation separating the settling suspension (without effective stress) from the consolidating bed (with effective stress) is practically at 60 cm, close to the level of the lutocline at that point in time.

The settling behavior can be analyzed through the sediment continuity equation in the vertical direction, which yields the time-variation of the lutocline as it settles, and also the associated density profile within the suspension. Consolidation of soils in general has been simulated with non-linear, finite strain models (Gibson et al. 1967; 1981). For the estuarine environment, models for self-weight consolidation, i.e., settling due to the weight of the deposit itself, have been developed through linearized analytic solutions (e.g., Been and Sills 1981; Govindaraju et al. 1999) and nonlinear numerical solutions (e.g., Papanicolaou and Diplas 1999). Interest with respect to fine sediment transport is in tracking the change in the density of deposit, because both the bed shear strength and the mass of material eroded per unit time depend on density. Change in bottom elevation due to consolidation is usually of lesser interest, inasmuch as generally it is only a small fraction of the total water depth.

With regard to density determination during consolidation, the commonly used correlations between density and bed shear strength are empirical and inherently approximate. As a result the calculation of rate of erosion, which depends on the shear strength, is also approximate. Thus it often suffices to calculate the density to first-order accuracy. For this requirement, it is useful to consider simple approaches to track density though (hindered) settling and consolidation combined. Such approaches rely on the physical similarities between these two processes (e.g., Schiffman et al. 1985).

Following the continuity approach of Kynch (1952), and accounting for the accumulation or depletion of bed deposit by deposition or erosion, respectively, the sediment continuity equation can be written as

$$\frac{\partial h' C}{\partial t} = \frac{\partial w_{sc} C}{\partial z'} + q \quad (4-28)$$

where

- $h'$  = thickness of the consolidating layer;
- $w_{sc}$  = velocity or rate of consolidation;
- $z' = z / h'$ ;
- $z$  = vertical coordinate originating at the bottom and positive upward; and
- $q$  = net settling flux (i.e., deposition less erosion) of sediment mass at the top of the consolidating layer (Jiang 1999).

In general, two modes of consolidation can be recognized from the plot of consolidation rate against concentration,

**Fig. 4-17.** (a) Instantaneous density profile during settling of a silty clay in tap water; (b) corresponding total and pore pressure profiles (adapted from Sills and Elder 1986).

namely loose soil consolidation and compact soil consolidation. For these two modes, Toorman and Berlamont (1993) developed a combined relationship of the form

$$w_{sc} = w_{sc1} \exp\left(-\frac{C}{C_{s1}}\right) F_t + w_{sc2} \left(1 - \frac{C}{C_{s2}}\right)^{m_t} (1 - F_t); \quad (4-29)$$

$$F_t = \exp\left[-\left(\frac{C}{C_t}\right)^{n_t}\right]$$

where

- $F_t$  = characteristic mode transition (from loose soil to compact soil) function with  $n_t > 10$ ;
- $m_t$  = sediment-dependent constant;
- $C_t$  = mode transition concentration;

**Fig. 4-18.** Settling consolidation of sediment from the Ortega River, Florida.

$w_{sc1}, w_{sc2}$  = rates of consolidation for the first and the second modes, respectively;

$C_{s1}$  = concentration corresponding to the maximum settling flux; and

$C_{s2}$  = saturation concentration, i.e., maximum attainable compaction concentration.

Table 4-9 gives representative values of these coefficients. Data points for sediment from the Ortega River in Florida (Marván 2001) are shown in Fig. 4-18 along with a comparison with Eq. (4-28) assuming  $q=0$ , Eq. (4-29), and the corresponding coefficients from Table 4-9. Note that in addition to Eq. (4-28) the equation of conservation of total mass is needed to solve for  $h'$  and  $C$  (Jiang 1999). In Fig. 4-18 both the data and computations start with a uniformly mixed suspension of constant concentration (38.7 kg/m<sup>3</sup>). Observe the two identifiable (initially rapid, then slow) trends in the rate of fall of the bed deposit elevation. It can be shown that whereas the initial consolidation time is inversely proportional to the thickness of the deposit, subsequently this time becomes inversely proportional to the square of the bed thickness (Toorman 1996; Winterwerp 1999).

#### 4.7.2 Gelling

Clayey muds exhibit various degrees of thixotropy depending on composition. Thixotropy is an isothermal, reversible, time-dependent process occurring under conditions of constant composition and volume, whereby a material stiffens, or gels, while at rest and softens or liquefies upon remolding (Mitchell 1993). Once mud gels it is harder to erode than when it is remolded.

Day and Ripple (1966) showed that a bed of kaolinite in water practically lost its strength upon shearing, but the strength was recovered in about a day. This process is schematized in Fig. 4-19, in which  $S_p$  is the peak undisturbed strength and  $S_r$  is the remolded strength. These values can be determined from the unconfined compression test, or

**Fig. 4-19.** Schematic drawing of changes in soil strength due to repeated cycles of gelling and remolding (based on Mitchell, 1976).

vane shear test, for low strength soils (Lambe and Whitman 1969). A measure of the gelling effect is the sensitivity,  $S_t = S_p/S_R$ . Accordingly,  $S_t = 1$  implies no sensitivity, and 4 to 5 is considered very sensitive (Mitchell 1976). Gelling occurs because water molecules within the pore fluid and close to the clay surface form a “solid” layered structure through hydrogen bonding. When the sample is disturbed this structure collapses and water molecules are randomized. Gelling therefore can be detected through changes in the pore water pressure. Starting with a disturbed sample, as the material gels the pore water pressure drops with increasing ordering of water molecules. A tensiometer is commonly employed to record these changes (Kirkham and Powers 1972).

## 4.8 EROSION

### 4.8.1 Modes of Erosion

The four modes of erosion mentioned in Section 4.3.2 are surface erosion, mass erosion, fluid mud generation, and fluid mud entrainment. Note that generation of fluid mud is considered to be erosion because in this process there is a phase change from a bed to a suspension. This fourfold classification of erosion is meant mainly to understand and treat a very complex set of mechanisms through simplified analytic and empirical treatments. These treatments are considered in what follows.

### 4.8.2 Surface Erosion

Modeling surface erosion continues to pose problems, largely due to a lack of basic understanding of the way in which

the bed-water interface responds to flow-induced stress. For steady or quasi-steady (e.g., tidal) flows, numerous formulas relating the rate of bed surface erosion to the bed shear stress have been proposed. In this mode of erosion, particles or flocs at the bed surface are detached and entrained, thus causing bed scour. Some of the early formulas have been summarized by Mehta et al. (1982). Subsequent developments may be found in, among others, Jepsen et al. (1997); Piedra-Cueva and Mory (2001); and Taki (2001). These formulas are generally applicable to cases of low to moderate suspended sediment concentrations, up to about  $C_2$  in Fig. 4-12. At high concentrations settling of eroded sediment is hindered, and a layer of fluid mud is formed over the bed. The mechanism by which this layer erodes is not modeled well by simple, stress-based formulations used for surface erosion. Furthermore, damping of turbulence within fluid mud alters the bed shear stress from its value under clear or nearly clear water conditions. In that regard, Bedford et al. (1987) showed that, at least in the context of their experiments in Long Island Sound, the turbulent kinetic energy proved to be better correlated with resuspension than the Reynolds stress.

Following the stochastic theory of Einstein (1950) for coarse grain transport, and considering erosion to occur in the absence of deposition, Partheniades (1962; 1965) developed a phenomenological formula relating the rate of erosion to the bed shear stress. This formula and the flume data on mud erosion with which the formula was compared showed a nonlinear relationship between erosion rate and bed shear stress. Subsequently, Ariathurai (1974) assumed a straight line approximating the nonlinear relation, and attributed the resulting linearized formula to Partheniades (1962). This linear “Ariathurai-Partheniades” formula, which was essentially empirical, led to the expression, investigated extensively by Kandiah (1974),

$$\epsilon = \epsilon_M \left( \frac{\tau_b - \tau_s}{\tau_s} \right) \quad (4-30)$$

in which

$\epsilon$  = erosion rate or mass flux (mass eroded per unit bed area per unit time);

$\tau_b$  = bed shear stress;

$\tau_s$  = bed shear strength with respect to erosion; and

$\epsilon_M$  = the erosion rate constant, the value of  $\epsilon$  when  $\tau_b = 2\tau_s$ .

Equation (4-30) is characteristically applicable to homogeneous beds of uniform (i.e., nonstratified) density and indicates that  $\epsilon$  varies with the excess shear stress  $\tau_b - \tau_s$ . Thus, a plot of  $\epsilon$  versus  $\tau_b - \tau_s$  ideally appears as a straight line as illustrated in Fig. 4-20, in which the erosion rate and the shear strength (determined by the intercept of a given line with the horizontal axis) are seen to depend on the percentage (by weight) of montmorillonite in a mixture of this clay with Yolo loam from California. Also observe that the effect of the highly cohesive montmorillonite was to decrease the

**Fig. 4-20.** Erosion rate versus bed shear stress for mixtures of Yolo loam and montmorillonite. Percent indicates montmorillonite by weight (adapted from Kandiah 1974).

line slope due to an increase in the shear strength of the mixture.

For beds that are stratified with respect to density and shear strength, formulas that account for the variation in  $\tau_s$  with depth have been developed, e.g., by Parchure (1984) and Piedra-Cueva and Mory (2001). Although such formulas differ from (4-30), in most of them the erosion rate varies with the excess shear stress. This similarity, as well as experience from modeling applications, suggests that (4-30) can also be used for stratified beds with a reasonable degree of accuracy by allowing  $\tau_s$  to vary with depth, i.e., by replacing  $\tau_s$  by  $\tau_s(z)$ , where  $z$  denotes the vertical coordinate (Ariathurai et al. 1977; Hayter 1983).

**Fig. 4-21.** Erosion rate versus excess shear stress based on the analysis of Vinzon (1998) using data from Kineke (1993).

Vinzon (1998) used measured time series of near-bed velocities and suspended sediment concentrations at sites on the Amazon shelf off Brazil reported by Kineke (1993) to develop the linear plot shown in Fig. 4-21. The observed relationship is akin to the lines in Fig. 4-20 and therefore conforms to Eq. (4-30), but with a considerably greater degree of data scatter. Similar plots have been developed by, among others, Sanford et al. (1991) and Sanford and Halka (1993) using data from the Chesapeake Bay.

#### 4.8.3 Shear Strength

Although bed shear strength and bed density are neither uniquely interrelated nor are dimensionally homogeneous, efforts have been made to correlate these two parameters empirically, recognizing that, in general, the denser the soil the harder it is to erode. Thus, given  $\tau_{sh}$  as a measure of soil shear strength, relationships have been developed of the general form (Table 4-10)

$$\tau_{sh} = \zeta_s (\phi - \phi_\ell)^{\xi_s} \quad (4-31)$$

where

- $\phi$  = solids volume fraction;
- $\phi_\ell$  = limiting or minimum value of  $\phi$  below which  $\tau_{sh} = 0$ ; and
- $\zeta_s, \xi_s$  = sediment-specific coefficients.

Thus, according to Eq. (4-31),  $\tau_{sh}$  depends on the excess solids volume fraction,  $\phi - \phi_\ell$ . Measures of shear strength in general include the apparent Bingham yield strength ( $\tau_y$ ), the vane shear strength ( $\tau_v$ ) and the surface erosion shear strength ( $\tau_s$ ). Among these,  $\tau_y$  and  $\tau_v$  are representative of the bulk physical properties of the soil. As noted in Section 4.2.2,  $\tau_y$  is associated with soil rheology, and has been used, for example, to determine the bottom slope required to generate mud underflows (Mei and Liu 1987). Wotherspoon and Ashley (1992) correlated  $\tau_y$  to the liquid content of sewer sediment deposit. The quantity  $\tau_y$  is a measure of the bulk strength of the soil and has been used in geotechnical evaluations of cohesive soil consistency. Thus, for example, Annandale (1995) has suggested the classification given in Table 4-11.

Most studies on the erosion of submerged soils in the estuarine and marine environments are limited to “very soft” to “soft” cohesive materials identified in Table 4-11. This is because wave- and current-induced bed shear stresses in these environments are usually not large enough to erode stiffer soils. On the other hand, in rivers with high flow velocities, even firm soils can erode significantly over months and years (Jiang 1999). Thus, the vane shear strength is a convenient parameter commonly used to assess the erosion potential of cohesive soils in a given flow environment, even though it is not a highly accurate measure (Lee 1985).

**Table 4-10 Expressions Relating Shear Strength to Solid Volume Fraction**

Investigator(s)	Sediment	Shear strength, $\tau_{sh}$ (Pa)	$\phi_\ell^a$	$\zeta_s$	$\xi_s$	$\phi$ range <sup>a</sup>

**Table 4-11 Soil Consistency Classification Based on Vane Shear Strength**

Soil consistency	Identification	Vane shear strength (kPa)
Very soft	Easily molded by fingers	0–80
Soft	Molded by fingers with some pressure	80–140
Firm	Very difficult to mold; can be penetrated by a hand-spade	140–210
Stiff	Requires a hand pick for excavation	210–350
Very stiff	Requires a power tool for excavation	350–750

Source: Annandale (1995).

In contrast to  $\tau_y$  and  $\tau_v$ , the parameter  $\tau_s$ , which occurs in Eq. (4-30), is related to the strength of surface flocs. Referring to the results in Table 4-10, the characteristic difference between  $\tau_y$  and  $\tau_s$  is reflected in the value of the proportionality coefficient  $\zeta_s$ , which is considerably higher for  $\tau_y$  (mean  $\zeta_s = 1,200$ , excluding the data of Migniot 1968) than for  $\tau_s$  (mean  $\zeta_s = 10.6$ ). Likewise, the exponent  $\xi_s$  is higher for  $\tau_y$  (mean value 2.88) than for  $\tau_s$  (mean value 1.62). With respect to the sole correlation for  $\tau_v$ , observe that  $\xi_s = 1$ . It should be noted that this relationship of Hwang (1989) was developed for a lacustrine mud that contained a high amount (40% by weight) of organic material.

Conceptually the minimum value of  $\phi$ , namely  $\phi_\ell$ , is analogous to the space-filling volume fraction at which the particle matrix begins to exhibit a measurable shear modulus of elasticity, which increases with increasing  $\phi$  ( $> \phi_\ell$ ) (James et al. 1988). The same threshold condition, sometimes referred to as the “gelling point,” may apply to the development of

**Fig. 4-22.** Bed shear stress versus solids volume fraction and water content for Chikugo estuary (Japan) mud (after Kusuda et al. 1985).

normal effective stress in the soil (Ross 1988). Hwang (1989) determined that  $\phi_e = 0.06$  from a plot of measured  $\tau_v$  versus  $\phi$  by extrapolating the linear relationship ( $\xi_s = 1$ ) to  $\tau_v = 0$  when  $\phi = \phi_e$ . He further showed that this value of  $\phi_e$  ( $= 0.06$ ) was commensurate with the density below which the mud was in a fluid-like state, and was therefore devoid of measurable strength. As seen from Table 4-10, other investigators did not report  $\phi_e$ , and therefore only limited use can be made of this parameter at present. An example of data conforming to (4-31) but without a knowledge of  $\phi_e$  is shown in Fig. 4-22, based on the work of Kusuda et al. (1985) on mud from the Chikugo River estuary in Japan.

Two factors on which  $\zeta_s$ ,  $\xi_s$ , and  $\phi_e$  can be expected to depend are bed sediment composition and fluid chemistry. This dependence is reflected in the variability in the values of  $\zeta_s$  and  $\xi_s$  associated with  $\tau_s$  in Table 4-10. The relative importance of composition and chemistry cannot be separated easily in these cases, because the shear strength of a given soil can be significantly influenced by even minor changes in the chemical composition of pore water (Ravisangar et al. 2001). Furthermore, even though salinity is reported in many investigations on estuarine and marine muds, other chemical factors can also affect the soil fabric, thereby influencing soil erodibility. For example, Fig. 4-23 shows the results of Kandiah (1974) for a montmorillonite based on measurements of the sodium adsorption ratio (SAR). This ratio of sodium ions ( $\text{Na}^+$ ) to the sum of calcium ( $\text{Ca}^{++}$ ) and magnesium ions ( $\text{Mg}^{++}$ ) in the bed pore fluid is defined as

$$\text{SAR} = \frac{\text{Na}^+}{[0.5(\text{Ca}^{++} + \text{Mg}^{++})]^{1/2}} \quad (4-32)$$

**Fig. 4-23.** Flocculation-dispersion boundary curves for a montmorillonite at three pH ranges (adapted from Kandiah 1974).

where the ionic concentrations are measured in milliequivalents per liter. Figure 4-23 shows that this montmorillonite could be altered between dispersed (i.e., nonfloculated) and flocculated states merely by changing the pH of the pore fluid, either holding SAR constant or holding constant the total cation concentration in the pore fluid. Since a dispersed clay bed can erode with considerably greater ease than a flocculated bed of the same clay, Fig. 4-23 demonstrates that sediment composition alone cannot be a unique, or even dominant, determinant of bed erosion potential. This consideration underscores the need to use native water in laboratory erosion tests, or to reconstitute the eroding fluid based on an analysis of the native water with regard to its ionic composition. It is also a reason for in situ testing of bed erodibility in the prototype environment (Maa et al. 1993).

Inasmuch as  $\tau_s$  is a measure of the strength of flocs at the bed surface, it reflects the order of aggregation of these surface flocs. In a bed prepared by allowing suspended sediment to deposit, the bed density characteristically increases with depth due to sorting and consolidation. The rate of increase is usually the highest just below the surface and gradually decreases with depth until the overburden is no longer sufficient to cause further consolidation. In the estuarine environment, beds formed by deposition in this way tend to increase in density until they reach  $\sim 1,300$  to  $\sim 1,400 \text{ kg/m}^3$  at depths on the order of 20–60 cm. Increasing density with depth decreases the order of aggregation and increases the shear strength.

The trend of increasing shear strength with depth is seen in Fig. 4-24, in which shear strength profiles are given for the same bed of flocculated kaolinite in salt water, but after different periods of consolidation (Parchure 1984). The shear strength at a given consolidation period  $T_{dc}$  was determined by eroding the bed layer by layer. This procedure,

**Fig. 4-24.** Bed shear strength profiles for a bed of kaolinite in salt water (adapted from Parchure 1984).

credited to Thorn and Parsons (1980), was accomplished by increasing the flow-induced bed shear stress in steps, allowing the test to run at each step for a sufficiently long duration to cause bed scour to proceed to a depth at which no further erosion took place, because the shear stress at that depth was equal to the shear strength. In this way, the profile of strength variation with depth was constructed by knowing the applied stress at each depth. In Fig. 4-24 observe that because the aggregate order did not change at the surface due to the absence of overburden, the shear strength remained independent of the period of consolidation. Such a finding was also reported previously by Partheniades (1965), who correctly pointed out that this independence means that erosion occurs by breakup of inter particle bonds, and hence that this breakup process cannot be parameterized by such bulk soil indices as the

Atterberg indices. Beneath the surface however, increasing shear strength reflects increasing floc strength with decreasing aggregate order. Recognizing that the time-variation of erosion rate depends on the shear strength profile, which in turn depends on the density profile, Jepsen et al. (1997) correlated the erosion rate directly with bed density.

When inorganic fine sediment is mixed with other materials, the effect on shear strength can be significant (Ashley and Verbanck 1996). Two common cases of interest are mixtures of mineral particles with organic material and with sand. In Table 4-12, shear strength parameters of Eq. (4-31) from three studies are summarized (Mehta and Parchure 2000; Marván et al. 2002). In all cases the experiments were conducted in the laboratory using muds from water bodies in Florida. These bodies receive organic sediments from a variety of terrigenous and aqueous sources. Observe that the exponent  $\xi_s$  is 0.83 for sediment from the Ortega River with 28% (by weight) organic matter. This value may be compared with the mean value of 1.62 from Table 4-10 for largely inorganic sediment beds. The organic-rich samples from the Rodman Reservoir (45% organic content) and the Lower Kissimmee River basin (50% organic content) showed practically no dependence ( $\xi_s = 0$ ) of shear strength on density. Furthermore, these samples had very low shear strengths, on the order of 0.1 Pa.

The usually (but not always; see, e.g., Dennett et al. 1998) high erosion potential of organic-rich sediments is due to the comparatively light and weakly bound nature of the flocs or floccules. The lack of significant dependence of erosion on bed density may be explained as follows. Unlike clayey beds whose interface with water can be reasonably well defined, especially for dense beds, the organic-rich bed-water interface tends to develop a layer of “fluff” consisting of flocs released by way of elastic rebound from the bed with a thickness of a few floc diameters. Due to its low excess density, this fluff layer does not consolidate easily. Thus when fluid stress is applied, it is this layer of weakly interconnected particles,

**Table 4-12 Shear Strength Parameters for Organic-Rich Sediments**

with a low negative buoyancy, that is entrained. Further, as the layer erodes it is replenished by continual “release” of flocs from within the bed that is disturbed by flow-induced deformations. As a result, since the density of the fluff layer is determined by the released flocs rather than the bed, the shear strength is largely unaffected by bed density.

#### 4.8.4 Shear Strength of Fine/Coarse Sediment Mixtures

Fine sediment and sand can occur as interbedded layers alternating between fine- and coarse-grain layers (Jaeger and Nittrouer 1995), or as more homogenous mixtures. In general, bed stratigraphy reflects the depositional history of the accumulated sediment, and any subsequent changes brought about by physicochemical transformations and biogenic effects. Among the latter, bioturbation usually enhances homogeneity and causes the bed to become less resistant to erosion (Jaeger and Nittrouer 1999). In turn, coring data that show intact laminated structures may imply the absence of bioturbation (Kirby et al. 1994).

In a nonstratified bed composed of a mixture of sand and fine sediment, the shear strength may vary in a nonlinear way with the proportion of fine fraction. In order to demonstrate this effect, Torfs et al. (2001) derived the following expression for the critical shear stress of the homogeneous mixture:

$$\tau_{cm} = \left[ \frac{\alpha_{3cg} \tan \Phi_{cg}}{(\alpha_{1cg} + \alpha_{2cg} \tan \Phi_{cg})} + \frac{K' \zeta_s (\Phi_v - \Phi_{vc})^{\xi_s}}{g (\rho_{sm} - \rho) d_m} \right] \times g (\rho_{sm} - \rho) d_m \quad (4-33)$$

where  $\alpha_{1cg}$ ,  $\alpha_{2cg}$ ,  $\alpha_{3cg}$ ,  $\Phi_{cg}$ , and  $K'$  are sediment-specific constants,  $\zeta_s$  and  $\xi_s$  are defined per (4-31), and

- $\rho_{sm}$  = representative granular density of the mixture;
- $\rho$  = fluid density;
- $\Phi_v$  = solids volume fraction of the fine sediment-water mixture before it is mixed with sand;
- $\Phi_{vc}$  = value of  $\Phi$  below which the bed has practically no shear strength;
- $g$  = acceleration due to gravity; and
- $d_m$  = representative mixture diameter.

Torfs et al. have provided the necessary equations for the selection and calculation of these parameters.

In Fig. 4-25,  $\tau_{cm}$  is plotted against the fine sediment weight fraction of the mixture,  $\psi$ . The dependence of  $\tau_{cm}$  on  $\psi$  is embodied in the empirical relations  $K' = 60|\psi - 0.018|^{1.9} - 0.029$  for  $\psi \leq 0.018$  and  $K' = 0.88 - (1 - \psi)^{3.5}$  for  $\psi > 0.018$ . The comparison between (4-33) and the data of Torfs (1995) is wholly diagnostic, because these relations, as well as parameters in (4-33), were derived from the experimental data included in the figure. These data, obtained in a laboratory flume, were on the erodibility of mixtures of a

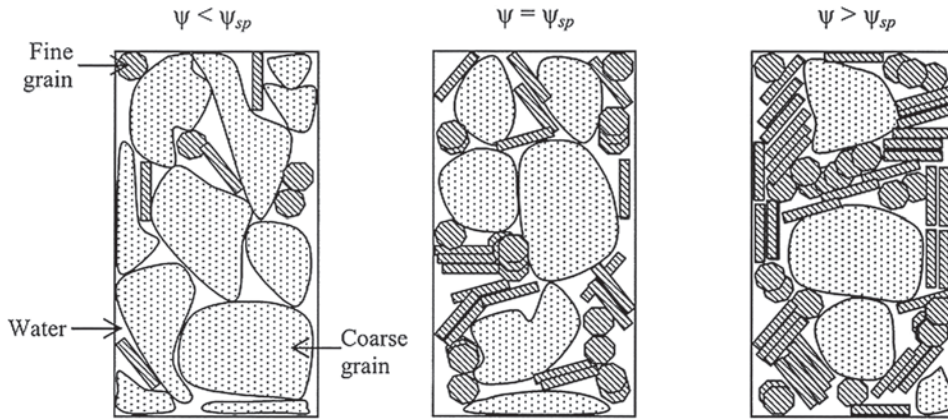

Fig. 4-25. Critical shear stress for erosion of kaolinite/sand and natural mud/sand mixtures versus fine-grain weight fraction: data points of Torfs (1995) and curve based on (4-33) (after Torfs et al. 2001).

kaolinite with 0.23 mm diameter sand and, also, mixtures of a natural mud with the same sand. Starting with  $\psi = 0$  corresponding to pure sand (at a nominal bulk density of 1,850 kg/m<sup>3</sup>), the fine fraction was increased without changing the mixture bulk density, up to a maximum value of  $\psi = 0.38$ . The variation of  $\tau_{cm}$  with  $\psi$  is observed to be nonmonotonic and seemingly passes through a minimum, yielding values of  $\tau_{cm}$  that may at first be lower than those for sand (0.35 Pa), then increase to values larger than for sand, and increase further with increasing  $\psi$ . Notwithstanding the fact that this description is constrained by the paucity of data, and by possible albeit unquantified uncertainties in the estimates of the bed shear stress (Torfs 1995), it can be elaborated upon as follows.

Referring to Fig. 4-26, when a small quantity of fines is added to sand, a reduction in the intergranular friction between sand particles due to partial filling of pore spaces by the fines causes sand grains to erode with greater ease than in the absence of fines, thus lowering the critical stress for erosion below that for pure sand. This effect increases with increasing fine fraction until an interconnected, “space-filling” network of fines is established, when the threshold of motion becomes minimum. Given this condition, any further increase in the fine fraction causes the bed surface to be increasingly influenced by the fines. This is so because as clayey particles increasingly surround sand grains, sand-sand contacts decrease and also, the number of sand grains per unit surface area of bed decreases. Finally, as the fine fraction approaches unity, one can expect  $\tau_{cm}$  to approach  $\tau_s$ , the bed shear strength of the fine sediment (Panagiotopoulos et al. 1997).

**Fig. 4-26.** Schematic drawings of a saturated bed composed of large and small grain populations. Left: small grain fraction is less than space-filling; center: small grain fraction is space-filling; right: small grain fraction exceeds space-filling value (after Torfs et al. 2001).

#### 4.8.5 Erosion Rate Constant

The erosion rate constant  $\epsilon_M$  in (4-30) generally depends on the same factors that influence  $\tau_s$ . A noteworthy effect studied in the laboratory is the variation of  $\epsilon_M$  with fluid temperature. In that regard, surface erosion of cohesive beds has been treated as a mechanism that is phenomenologically akin to the rate process theory for chemical reactions (Paaswell 1973). Conceptually, erosion occurs when a threshold “energy of activation” is exceeded, and interparticle electrochemical bonds are broken. Following this concept it can be shown that  $\epsilon_M$ , and hence the rate of erosion  $\epsilon$ , increases with increasing temperature in such a way that  $\log(\epsilon/T)$  varies linearly with  $1/T$ , where  $T$  is the absolute temperature. This behavior can be represented by

$$\frac{\epsilon}{T} = \exp\left(\Delta - \frac{\Lambda}{T}\right) \quad (4-34)$$

Equation (4-34) was shown by Kelly and Gularte (1981) to hold for the erosion of a bed of grunite, with  $\Delta = 34.7$  and  $\Lambda = 10,145$ . These coefficients are specific to the sediment-fluid mixture used and were obtained at a constant eroding flow velocity of 0.18 m/s. Their magnitudes conform to the units of  $\epsilon$  in  $\text{g/m}^2 \text{ s}$  and  $T$  in K. In general, these coefficients can be expected to depend on the physicochemical properties of the sediment and fluid, on the solids weight fraction  $\phi$  and, especially with respect to  $\Delta$ , on the applied bed shear stress. As Lau (1994) indicated, an increase in temperature only marginally affects the van der Waals attractive force at the particle surface, but the interparticle repulsive force increases significantly. As a result, particle-particle bonds rupture more easily at higher temperatures, thereby leading to enhanced erosion.

Based on the observation that the rate of erosion decreases as the shear strength increases, Arulanandan et al. (1980) defined another erosion rate constant  $\epsilon_N = \epsilon_M/\tau_s$ , and plotted it against  $\tau_s$  derived from erosion tests on a large number of

soil samples. Introducing this modified rate constant conveniently redefines (4-30) in terms of  $\epsilon_N$  and  $\tau_s$  as

$$\epsilon = \epsilon_N (\tau_b - \tau_s) \quad (4-35)$$

It was found that, notwithstanding data scatter, in the mean  $\epsilon_N$  decreased monotonically and exponentially with increasing  $\tau_s$ . Compilation of laboratory data from numerous studies in addition to those of Arulanandan et al. (1980), when examined collectively, suggests that the empirical relationship between  $\epsilon_N$  and  $\tau_s$  may be extended to include data grouped by sediment and fluid composition. Despite the evidently approximate nature of the resulting curves relating  $\epsilon_N$  to  $\tau_s$ , this approach affords a crude means to calculate the erosion rate from (4-30) knowing the bed density, inasmuch as the shear strength in related to density via (4-31). Accordingly, the plot shown in Fig. 4-27 was prepared based on the relationship

**Fig. 4-27.** Erosion rate constant  $\epsilon_N$  versus bed shear strength  $\tau_s$  for different bed groups identified in Table 4-13. (after Mehta and Parchure 2000).

**Table 4-13 Coefficients for (4-36) and Properties of Groups 1-7**

Group no.	Coefficients in (4-36) <sup>a</sup>		Clay content (%)	Cation exchange capacity (meq/100 g)
	$\chi_s$	$\lambda_s$		
1	1.345	0.368	24	13
2	2.892	0.372	27	18
3	3.905	0.356	28	15
4	4.938	0.355	23	15
5	6.594	0.382	27	15
6	9.011	0.386	33	16
7	10.582	0.252	19	23

<sup>a</sup>These values of  $\chi_s$  and  $\lambda_s$  apply when  $\tau_s$  is in Pa and  $\epsilon_N$  is in g/N s.

Source: Mehta and Parchure (2000).

$$\epsilon_N = \epsilon_{N0} \exp(-\chi_s \tau_s^{\lambda_s}) \quad (4-36)$$

for which the value of  $\epsilon_{N0}$  was conveniently chosen as 200 g/N s. Mehta and Parchure (2000) provide actual fits of (4-36) with data within each of seven groups. These groups and the coefficients  $\chi_s$  and  $\lambda_s$  for each group are given in Table 4-13. As observed therein,  $\chi_s$  and  $\lambda_s$  show a weak correlation with the cation exchange capacity of the sediment, although evidently the exchange capacity is by no means the sole determinant of soil erodibility. Observe also that while  $\lambda_s$  varies within a narrow range (0.252 to 0.386),  $\chi_s$  varies over an order of magnitude (1.345 to 10.582), which implies that this parameter is sensitive to soil composition. The curves in Fig. 4-27 highlight the wide range of  $\epsilon_N$  values that can occur for a given  $\tau_s$ . The form of (4-36) is consistent with the observation of, among others, Galani et al. (1991), who showed that  $\epsilon_N$  decreases with increasing duration of consolidation of the bed, which essentially increases the bed shear strength.

Using Eq. (4-35) along with (4-31), (4-34), and (4-36), the following erosion rate expression is obtained:

$$\epsilon = \epsilon_{N0} T \exp\left(\Delta - \frac{\Lambda}{T}\right) \exp\left(-\chi_s \left[\zeta_s (\phi - \phi_l)^{\xi_s}\right]^{\lambda_s}\right) \times \left[\tau_b - \zeta_s (\phi - \phi_l)^{\xi_s}\right] \quad (4-37)$$

The application of (4-37) can be illustrated by the following example of erosion in a channel. Consider values of the coefficients  $\epsilon_{N0}=200$  g/N s,  $\chi_s=2.892$ ;  $\lambda_s=0.372$ ,  $\zeta_s=1.65$ ,  $\xi_s=1.00$ ,  $\phi_e=0$ ,  $\Delta=27.0$ , and  $\Lambda=10,145$ . Now consider a bed of density  $\rho=1,545$  kg/m<sup>3</sup> subject to a flow-induced bed shear stress  $\tau_b=1$  Pa at a water temperature  $T=27^\circ$  C (300° K). With  $\rho_w=1,000$  kg/m<sup>3</sup> and  $\rho_s=2,650$  kg/m<sup>3</sup>, we

**Fig. 4-28.** Nondimensional entrainment rate against Richardson number. Comparison between data on fluid mud entrainment (dark circles), corresponding curve based on (4-39), salt entrainment data (upper and lower bounds) reported by Christodoulou (1986) and salt entrainment relation obtained from (4-39) (after Mehta and Srinivas, 1993).

obtain  $\phi=0.33$  from Eq. (4-5). Equation (4-37) then yields  $\epsilon=2.98$  g/m<sup>2</sup> s.

#### 4.8.6 Mass Erosion

Mass erosion, in which the bed fails and releases chunks or clasts of material, has been modeled on Eq. (4-30), even though this relation was derived for surface erosion (Mehta and Lee 1994). This approach, although very approximate, is convenient because one merely has to calibrate for  $\epsilon_M$  and  $\tau_s$ . Mass erosion is often considered to occur when stiff beds are subjected to high stresses (Ariathurai et al. 1977). However, even weak beds can mass erode at comparatively low stresses. In flume tests, Hwang (1989) reported mass erosion of beds of organic-rich sediment from Lake Okeechobee in Florida (Table 4-4). Starting with no flow and increasing the bed shear stress in steps, resuspension initially occurred by surface erosion, and at high stresses (but low compared to those for stiff clays, for example) the 3- to 4-cm-thick bed failed almost entirely. A feature of the erosion process was that in some cases  $\epsilon_M$  and  $\tau_s$  were considerably higher for mass erosion than for surface erosion of the same bed. Thus, for example, for a bed of density 1,200 kg/m<sup>3</sup>,  $\epsilon_M$  and  $\tau_s$  for surface erosion were  $5.6 \times 10^{-6}$  kg/m<sup>2</sup> s and 0.65 Pa, respectively, whereas the corresponding values for mass erosion were  $5.6 \times 10^{-4}$  kg/m<sup>2</sup> s and 1.8 Pa.

Recognizing the rapidity with which mass erosion occurs, Ariathurai et al. (1977) introduced a simple model, which

essentially amounts to instantaneous erosion of a bed layer of thickness  $\Delta z_b$  in time  $\Delta t$ ,

$$\epsilon = \rho_b \frac{\Delta z_b}{\Delta t} \quad (4-38)$$

where  $\epsilon$  is the mass rate of erosion (or erosion flux) and  $\rho_b$  is the bed density. Equation (4-38) applies when the bed shear stress exceeds the shear strength for mass erosion. The thickness  $\Delta z_b$  was determined by calibration against data on the time-variation of the suspended sediment concentration in the Savannah River estuary, Georgia.

When a water jet impinges on a fine-grained soil a hole develops when the jet momentum exceeds the requisite critical value. In this mass erosion process, the rate of erosion is usually measured as the time-rate of change of the cube-root of the hole volume. Traditionally, this rate is expressed as a function of the erosion-governing parameters through dimensional analysis (Hanson 1990; Hollick 1976; Moore and Masch 1962).

#### 4.8.7 Fluid Mud Entrainment

Sediment entrainment can occur due to hydrodynamic instabilities at the interface between very soft mud and water, resulting in the generation and breakup of the interfacial billows by shear flow. This process has been described in terms of a balance between production of turbulent kinetic energy, buoyancy work in entraining the sediment, and viscous energy dissipation (Uittenbogaard 1995; Kranenburg 1994b; Scarlatos and Mehta 1993; Winterwerp et al. 1993; Winterwerp and Kranenburg 1997a). Bottom response in this case is distinct from surface erosion of sediment flocs, which occurs over typically harder cohesive beds (Taki 1990). In the prototype environment, interfacial undulations can occur at the frequency of surface wave forcing, i.e., in the forced mode, and also in the free mode. In the forced mode, additional, low-frequency oscillations can occur as a result of interactions among the forcing wave frequencies (Jiang 1993). In the free mode the interface tends to oscillate at the buoyancy (Brunt-Väisälä) frequency (Jiang 1999; Wright et al. 1988).

Based on laboratory tests in a flume, Mehta and Srinivas (1993) proposed the relation for the rate of sediment entrainment

$$E = \frac{dz_b/dt}{U} = A Ri^{-1} - D Ri \quad (4-39)$$

where

$E$  = dimensionless entrainment rate, i.e., the rate of change of bottom height,  $dz_b/dt$ , divided by  $U$ , the characteristic flow velocity above the water-mud interface;

$A$  and  $D$  = sediment dependent coefficients; and

$Ri$  = the global Richardson number, defined as

$$Ri = \frac{hg(\rho - \rho_w)/\rho_w}{U^2} \quad (4-40)$$

In Eq. (4-40),  $h$  is a characteristic water depth above the interface,  $\rho$  is the suspension density, and  $\rho_w$  is water density. In Fig. 4-28,  $E$  is plotted against  $Ri$  and compared with data on the entrainment of a clayey fluid mud in a laboratory flume. Values of the coefficients are  $A = 5.2 \times 10^{-3}$  and  $D = 1.6 \times 10^{-5}$ . Since the second term on the right hand side of (4-39) arises from the effect of settling,  $D$  depends on the settling velocity. Setting  $D = 0$  leads to the inverse dependence of  $E$  on  $Ri$ , as in salt entrainment. In Fig. 4-28, the resulting expression is compared with data on the entrainment of salt water into fresh water compiled by Christodoulou (1986). Observe that due to the settling effect, at relatively high values of  $Ri$  sediment entrains much less efficiently than salt. Several factors are responsible for the drop in the entrainment rate at high  $Ri$ , including the viscous effect and wall friction. In addition, increased resistance to entrainment due to density stratification plays a role. When these and related effects can be explicitly included in the entrainment rate formulation, the final equation is found to be similar in form to Eq. (4-30) (Kranenburg and Winterwerp 1997; Winterwerp and Kranenburg 1997b). Referring to Eq. (4-40), one may define a critical value  $Ri_c$  of the Richardson number above which sediment entrainment can be assumed to be zero, as suggested by Odd and Cooper (1989). In Fig. 4-28  $Ri_c$  is seen to be close to 20.

When fluid mud is mobile, i.e., has been set in motion by flow above the interface,  $U$  must be replaced by  $\Delta U$ , the characteristic difference between the velocity above and below the interface. It is common to find layers of fluid mud set in motion by tidal flows, as shown in Fig. 4-29 from measurements in the Avon River, U.K. (Kendrick and Derbyshire 1985). Ross (1988) examined fluid mud layer motion as a simple Rayleigh flow problem (Phan-Thien 1983) in which the layer is set in motion by the downward diffusion of momentum. Trowbridge and Kineke (1994) provided a fuller treatment, both datawise and from the perspective of non-Newtonian flow modeling of fluid mud driven by flow over the Amazon Shelf.

## 4.9 WAVE-INDUCED EROSION

### 4.9.1 Nearshore Zone

In shallow nearshore waters the mode of erosion of bottom mud depends on waves and on the bottom condition. As schematized in Fig. 4-30, the sediment-active zone is bounded by the shoreline and the terminal depth, defined as that depth seaward of which wave action is unable to reach the bottom to cause significant changes in the bed profile. The nearshore profile is subdivided by the wave breakerline

**Fig. 4-29.** Flow velocity and concentration profiles below lutecline in the Avon River, UK (adapted from Kendrick and Derbyshire, 1985).

into the surf zone and the offshore zone between this line and the terminal depth.

Although the terminal depth has been shown to be a reasonably well-defined parameter (depth of closure) characterizing the active sand profile, for fine sediment profiles laden with fluid mud it is a notional depth that requires quantitative assessment. Fluid mud generation has been examined in laboratory flumes and in the lacustrine environment where wave forcing dominates (e.g., Lindenberg et al. 1989; Li 1996), and it appears that rough estimates of the thickness of the fluid mud layer formed under sustained wave action can be obtained by calculating the depth, i.e., the lower level of the fluid mud layer, at which the wave-induced (maximum) lift on a unit sediment mass balances

**Fig. 4-30.** Definitions related to the sediment-active nearshore zone (after Rodriguez 2000).

the resistance to liquefaction due to gravity and cohesion (Li and Mehta 2001). Hence the terminal depth,  $h_c$ , corresponds to the critical condition when the layer thickness reduces to nil. Accordingly, it can be shown that this depth can be estimated from  $h_s = \alpha_d \log(\beta_d H_s)$ , where  $H_s$  is a characteristic maximum wave height, and  $\alpha_d, \beta_d$  are coefficients that depend on the bed properties and also on the wave period (Rodriguez 2000). This equation is applicable to areas where the terminal depth is on the order of 1 m or higher. Very little prototype information on  $\alpha_d, \beta_d$  is available, inasmuch as the distance from the shoreline up to which the muddy bottom is regularly or episodically turned over by waves has not been explored in any systematic way. From data on waves, water depths, and fluid mud thickness in Lake Okeechobee in Florida,  $\alpha_d = 20.4$  and  $\beta_d = 0.73$  have been obtained, with the wave height and water depth measured in meters (Rodriguez 2000; Li 1996).

The position of the breakerline, and hence the breaker (water) depth below mean water level, depends on the shape of the profile and the degree of wave damping. Profile shape, in turn, depends on the composition of bottom material and also on whether it is molded by waves or tide (Friedrichs 1993; Roberts et al. 2000). Wave breaking in the surf zone tends to erode and rapidly disperse the eroded material over the water column. In the comparatively less energetic zone seaward of the breakerline mud liquefaction by waves can occur, and transport of the resulting soft mud is often the main reason for profile changes. It appears that apart from gravity slide, which is typically seaward, fluid mud transport can occur landward due to streaming, a second-order hydrodynamic effect associated with wave propagation at the water surface and at the interface between water and fluid mud, and the associated fluid velocities. Depending on the direction of wave incidence, streaming can be in the cross-shore direction or both cross-shore and alongshore directions (Shibayama et al. 1986; Sakakiyama and Bijker 1989; Jiang and Mehta 1996; Rodriguez and Mehta 1998).

Depending on tide and wave conditions, bottom sediment properties and sediment sources and sinks, muddy coast profile shapes can be “convex-upward” or “concave-upward,” the latter being qualitatively akin to sandy beach profiles (Kirby 1992; Friedrichs 1993; Lee 1995). By assuming wave height to decrease with distance by damping due to viscous dissipation within bottom mud, and wave breaking in the surf zone, Lee (1995) obtained the following expression for the profile depth,  $h(y)$ , below mean water level

$$h = h_0 e^{4k_i(y_0 - y)} \left( \frac{y}{y_0} \right)^2 + F_0 y e^{-\beta_0 y} \quad (4-41)$$

where

$y$  = distance from shoreline;

$h_0, y_0$  = coordinates of the offshore end of the profile;  
 $k_i$  = wave damping coefficient;  
 $F_0$  = bottom slope at  $y = 0$ ;

and the coefficient  $\beta_0$  accounts for the offshore extent of the combined influence of bottom slope at the shoreline and scour due to wave breaking at the shoreline.

Relatively few measurements of the wave-damping coefficient applicable to muddy coast profile dynamics seem to have been made. From two nearshore wave gages that were 3.4 km apart in the Gulf of Mexico off Louisiana, Tubman and Suhayda (1976) recorded a 48% reduction in wave energy corresponding to  $k_i = 0.00020$  1/m. Near Triangular

Marsh in Corte Madera Bay, California, Liang and Williams (1993) also reported  $k_i = 0.00020$  1/m based on wave data. An example of fitting Eq. (4-41) to a convex-upward profile measured along the coast of Louisiana (Kemp 1986) is shown in Fig. 4-31 (Lee 1995). A similar comparison for a concave-upward profile is shown in Fig. 4-32. When the profile is molded by tide, the shape is different from (4-41) and is strongly influenced by the tidal range (Kirby 1992; Friedrichs 1993; Roberts and Whitehouse 2001).

The coefficient  $k_i$  is particularly sensitive to mud density. Lee and Mehta (1997) for instance showed that in the muddy bottom environment of the Gulf of Mexico off Mobile Bay in Alabama,  $k_i$  increased from 0.0005 1/m to 0.023 1/m as the

Fig. 4-31. Comparison of (4-41) with profile data from Louisiana coast obtained by Kemp (1986).

Fig. 4-32. Comparison of Eq. (4-41) with profile from the west coast of Malaysia (after Lee and Mehta, 1997).

**Table 4-14 Coefficients in (4-41) for Concave and Convex Profile Configurations**

Location (source)	Profile state	$F_0$		$\beta_0$ (1/m)		$k_i$ (1/m)	
		Mean	Std. dev.	Mean	Std. dev.	Mean	Std. dev.
Malaysia, China, U.S. (Lee and Mehta 1997)	Concave (81 profiles)	0.059	0.083	0.046	0.054	0.42	0.13
	Convex (15 profiles)	0.026	0.019	0.015	0.0084	0.016	0.027

mud density decreased from 1,302 to 1,139 kg/m<sup>3</sup>. In general, the wave attenuation coefficient,  $k_i$ , is related to wave amplitude according to  $k_i = -(1/\ell)\ln(a_i/a_0)$ , where  $a_0$  is the wave amplitude at  $y=y_0$  and  $a_i$  is the amplitude at a shoreward distance  $\ell$ . Based on 96 profiles,  $F_0$ ,  $\beta_0$ , and  $k_i$  were correlated with the state of the profile (Lee 1995), considering concave-upward profiles to be “erosional” and convex-upward profiles to be “accretionary.” The resulting values (means and standard deviations) of these three parameters are given in Table 4-14.

#### 4.9.2 Profile Stability Factor

Profile stability, i.e., whether a given profile will accrete, will remain as it is, or will erode, can be characterized by the ratio of an overall shore stabilizing factor,  $F_s$ , to an overall shore destabilizing factor,  $F_D$ . A profile stability number,  $S$ , can then be defined (Mehta and Kirby 1996) as

$$S = 1 - \frac{F_S}{F_D} \quad (4-42)$$

With respect to Eq. (4-42) the three cases that can arise are (1)  $F_D = F_S$  or  $S = 0$ , signifying marginal stability; (2)  $F_D > F_S$  or  $S > 0$ , for destabilizing or eroding conditions; and (3)  $F_D < F_S$  or  $S < 0$ , for stable or accretionary conditions. Summing the corresponding individual stabilizing and destabilizing factors,  $f_{Di}$  and  $f_{Si}$ , respectively,  $F_D$  and  $F_S$  are obtained from  $F_D = \sum \alpha_{Di} f_{Di}$  and  $F_S = \sum \alpha_{Si} f_{Si}$ , where  $\alpha_{Di}$  and  $\alpha_{Si}$  are weighting coefficients, subscript  $i$  represents a particular factor, and  $\sum$  denotes summation. By definition, the weighting coefficients must satisfy the conditions:  $\sum \alpha_{Di} = 1$ ;  $\sum \alpha_{Si} = 1$ . Equation (4-42) can now be stated as

$$S = 1 - \frac{\sum \alpha_{Si} f_{Si}}{\sum \alpha_{Di} f_{Di}} \quad (4-43)$$

To calculate  $S$  from Eq. (4-43) for a given shoreline, all relevant factors and the corresponding weighting coefficients must be evaluated. For a broad categorization stability, the effectiveness of individual factors contributing to  $S$  can be considered to assume the following values and associated effects on stability: 0 = no or low effect,

$\pm 1$  = moderate effect,  $\pm 2$  = significant effect, and  $\pm 3$  = very significant effect. Further, one may conveniently consider that “moderate” effect for any particular factor corresponds to marginal stability ( $S = 0$ ), i.e., a noneroding, nonaccreting profile. Thus, in Eq. (4-43), setting  $S = 0$  and each  $f_{Di}$  and  $f_{Si}$  to unity yields  $0 = 1 - (\sum \alpha_{Si} / \sum \alpha_{Di})$ , which is consistent with the definition of the weighting coefficients. It follows from this qualitative assignment of parametric values that the weighting coefficients represent the relative magnitudes of the various factors when they individually have moderate effects.

Although numerous shore destabilizing factors actually contribute to profile stability, noteworthy factors include waves and storm surge, structures, tides, and biophysicochemical processes. The corresponding stabilizing factors are sediment supply, bottom hardness, structures, morphologic control, sediment composition, vegetative cover, and biophysicochemical processes.

Waves, storm surge, and intrusive structures often contribute significantly to erosion, as do tides (and associated currents) when they are strong. Because storm surge data are not commonly available, one may consider waves as surrogates for the storm surge effect, even though wave and storm surge statistics are often not entirely interdependent. Also, an influence not easily quantified is the sediment transporting role of a storm surge and the ensuing change in the profile.

Among biological processes, bioturbation is probably the most important destabilizing factor, although biochemical production of gas, e.g., methane, can also destabilize the bottom. Such factors as air and water temperature, salinity and water quality parameters, and the various positive and negative feedbacks linking physical and biophysicochemical processes further complicate biologically driven systems, which tend to play an important role, at times even a dominant one, in areas where waves and tides are comparatively weak.

Sediment supply is a characteristically significant factor governing shore stability because, irrespective of the magnitude of the erosive forces, a profile can hold fast or accrete as long as the rate of sediment supply equals or exceeds the rate of depletion. Conversely, if sediment supply becomes

insufficient, the likelihood of a shoreline remaining static is low, especially in the long run, except perhaps through hardening by structural means. Bottom hardness, as defined by standard measures of soil strength, can be quite important in distinguishing between overconsolidated and weakly consolidated beds.

Some structures can promote stability by sheltering a coast from erosive forces, and their role can be as noteworthy as that of bottom hardness. Other structures can have the opposite effect, namely, one of shoreline destabilization by reduction or elimination of sediment supply. In a similar vein, morphologic control can be exerted by offshore bathymetry on wave action and associated alongshore water and sediment transport. Shoreline configuration can be equally significant, for instance by promontories in sequestering sediment and thereby enhancing stability. Sediment composition partly determines hardness, although hardness also depends on consolidation and gelling. On the other hand, given two sediment beds of the same density, the less cohesive material is likely to erode more easily than the other.

Vegetative canopies tend to impart stability, as do certain benthic biological processes, e.g., surficial mats produced by secretions including mucopolysaccharides. Finally, tide and tidal currents can also influence stability through intertidal wetting and drying, because desiccation can measurably enhance profile hardness by soil encrustation.

From an inspection of the effects of the various factors at several muddy coasts, the following expression for  $S$  can be defined:

$$S = 1 - \frac{0.25f_{Ssed} + 0.20f_{Sbh} + 0.15f_{Sst} + 0.15f_{Smor} + 0.10f_{Scom} + 0.10f_{Sveg} + 0.05f_{Sbio}}{0.40f_{Dwv} + 0.30f_{Dst} + 0.25f_{Dtc} + 0.05f_{Dbio}} \quad (4-44)$$

where subscripts are *wv* for waves, *st* for structures, *tc* for tide and tidal currents, *sed* for sediment supply, *bh* for bottom hardness, *mor* for morphology, *com* for sediment composition, *veg* for vegetation, and *bio* for biophysicochemical effects.

To fully assess the applicability of Eq. (4-44) in predicting shore stability, extensive data sets for evaluating the coefficients and factors are required. Here we will illustrate how this might be accomplished by considering some diagnostic examples, giving consideration only to the most important factors contributing to stability.

The Gulf of Mexico shoreline of Louisiana near Cheniere au Tigre undergoes seasonal fluctuations due to a variable wave climate, and its mean position is stabilized by mud supply derived ultimately from the Mississippi River (Kemp 1986). In this moderate coastal environment, the mean astronomical tidal range is on the order of 0.5 m, which is modulated by frequency contributions from frontal-wind-induced oscillations, especially in winter. The shore, backed by marsh

vegetation, has a biogenically active mud flat morphology with sediment diameter in the range 1 to 5  $\mu\text{m}$  and is dominated by fluid mud. On the basis of a scale for effects ranging from 0 to  $\pm 3$  the following values will be assigned:  $f_{Dwv}$ ,  $f_{Ssed}$ ,  $f_{Sbh}$ ,  $f_{Sveg}$ , and  $f_{Sbio}$  all equal to unity, and the remainder equal to zero. Equation (4-44) then yields  $S = -0.50$ , which is less than zero, and correlates with the observed seasonal mean stability of the shoreline, notwithstanding longer term changes due to the relative rise in sea level experienced in this region.

The value of  $S$  for Louisiana and other sites including India (Mathew and Baba 1995), Indonesia (Tarigan et al. 1996), and Suriname (Eisma et al. 1991; Wells 1983), are given in Table 4-15. Along the coast of Kerala in India, mudbanks are believed to be enhanced in part by the inclement monsoonal waves but are less active in fair weather, because the high monsoonal waves are able to transport quantities of mud from an offshore pool to the shore by streaming. At the end of the monsoon, in the absence of significant streaming, the nearshore-transported mud is thought to slide offshore and to not return until the onset of the following monsoon (Mathew and Baba 1995).

The shorelines of Indonesia at Teluk Waru, Madura, and Surabaya are partly sheltered against waves by neighboring islands, and in conjunction with the absence of significant sediment supply they exhibit marginal stability. In general, notwithstanding the example from India, which is unique in

**Table 4-15 Calculated Stability Numbers versus Observed Shore Stability**

Location	Stability number, $S$	Observed profile stability
Louisiana	-0.50	Generally stable, with seasonal variability
Kerala (monsoon), India	~0	Shore-attached mudbanks occur at specific locations
Kerala (fair weather), India	0.75	Mudbanks are absent
Teluk Waru, Indonesia	~0	Marginally stable environment
Surinam	~0	Mudbanks are stable over short term; translate alongshore over a decadal time scale
Selangor, Malaysia	0.67	Eroding coast
Madura, Indonesia	~0	Marginally stable environment
Surabaya, Indonesia	~0	Marginally stable environment

terms of the historically transient nature of the mudbanks, if a long-established muddy coast is currently eroding, it is natural to look for possible anthropogenic causes of the altered state of the shoreline. Thus, for example, at the Selangor coast of Malaysia where  $S = 0.67$ , this once-stable mangrove-fringed coast has been eroding in recent decades due to reduced detrital supply from rivers as a result of diversion of river waters for agricultural usage (Midun and Lee 1989).

#### 4.9.3 Erosion by Breaking Waves

Referring to the surf zone in Fig. 4-30, among others, Azam (1998) and Yamanishi et al. (1998) have shown that the erosion of mud bed is caused by the impact force as the wave breaks. An expression for the mass flux or the rate of bed erosion,  $\epsilon_b$ , can be introduced as (Rodriguez 2000)

$$\epsilon_b = \epsilon_{bw} \left( \frac{H_b - H_{bc}}{H_{bc}} \right)^{\delta_b} \quad (4-45)$$

where  $H_b$  is the breaker height,  $H_{bc}$  is the critical value of  $H_b$  below which there is no measurable erosion,  $\epsilon_{bw}$  is the value of  $\epsilon_b$  when  $H_b = 2H_{bc}$  and  $\delta_b = 1$ , and  $\delta_b$  is a sediment-specific coefficient. In (4-45)  $\epsilon_b$  is conveniently considered to depend on the breaker height, i.e., the wave height at the seaward end of the surf zone, rather than the local wave height within the surf zone, and thus represents a mean value applicable over the entire surf zone. This is often a reasonable approximation because, as a result of wave damping by bottom mud, the surf zone over a muddy bottom tends to be considerably narrower than that over a rigid or sandy bottom. However, in general, with increasing surf zone width the applicability of Eq. (4-45) becomes increasingly qualitative, unless  $H_b$  is replaced by the corresponding local wave height and the equation is locally calibrated for  $\epsilon_{bw}$ ,  $H_{bc}$ , and  $\delta_b$ .

Coefficients in Eq. (4-45) from some studies are given in Table 4-16. In each case the rate of erosion was determined by comparing nearshore bottom profiles at different

**Fig. 4-33.** Erosion rate within the surf zone as a function of breaking wave height for the northern shore of Lake Erie using data of Gelinas and Quigley (1973). Curves are based on Eq. (4-45) (after Rodriguez 2000).

times, calculating the associated volumetric changes, and from these the corresponding mass changes, given the bottom density. Illustrative plots of Eq. (4-45) are shown in Fig. 4-33. The data are for a consolidated glacial till from the northern shore of Lake Ontario in Canada (Gelinas and Quigley 1973). With regard to Eq. (4-45) it is observed that, although both a linear regression fit ( $\delta_b = 1$ ) and a power-law fit ( $\delta_b = 0.5$ ) appear to be reasonable, the power-law fit is better (regression coefficient  $r^2 = 0.80$ ) than the linear fit ( $r^2 = 0.71$ ). In all other cases given in Table 4-16,  $\delta_b = 1$  was found to be reasonable, contingent upon the typically sparse data sets used to fit Eq. (4-45) (Rodriguez 2000).

#### 4.9.4 Erosion by Nonbreaking Waves

Here we will consider the offshore zone (Fig. 4-30), i.e., the zone seaward of the surf zone up to the depth of closure, under nonbreaking waves and when the bed is not liquefied, i.e., no significant layer of fluid mud is present. In this case,

**Table 4-16** Coefficient Values for Eq. (4-45) for Breaking Wave-Induced Erosion

Source: Rodriguez (2000).

erosion rate formulas determined for wind-generated as well as mechanically produced waves in flumes tend to support the validity of the functional form of Eq. (4-30), i.e., the erosion rate expression developed for steady flows. Relevant information is summarized in Table 4-17, in which characteristic parameters are given for the expression

$$\epsilon = \epsilon_w \left( \frac{\tau_b - \tau_s}{\tau_s} \right)^{\delta_w} \quad (4-46)$$

For  $\delta_w = 1$ , Eq. (4-46) reduces to Eq. (4-30). In fact, as seen from Table 4-17, experimental data at times have yielded values of  $\delta_w$  close to unity. In Eq. (4-46),  $\tau_b$  is the peak value of the bed shear stress during the wave cycle, and the shear strength  $\tau_s$  can differ from that associated with current-induced erosion due to the effect of cyclic loading on the soil matrix (Maa 1986; Mimura 1993). An example of (4-46) is shown in Fig. 4-34 based on the work of Maa (1986) in a flume in which a kaolinite, as well as mud from Cedar Key in Florida, was eroded by waves. The associated wave characteristics are given in Table 4-17.

#### 4.9.5 Fluid Mud Entrainment by Waves

Laboratory flume tests show that when wave action above a threshold value necessary for bed liquefaction continues for a sufficient length of time, an equilibrium thickness of the fluid mud layer occurs. This threshold depends on bottom mud density and rheology, and fluid layer thickness increases with increasing wave height (Li 1996). Results from some laboratory tests are given in Table 4-18. On the prototype scale, in Lake Okeechobee, Florida, fluid mud thickness ranges between 0.05 and 0.20 m, depending on the water depth (Li and Mehta 2001). Thicker layers of fluid mud are found off the coast of Louisiana (Kemp 1986); the coast of Suriname/Guayana (Augustinus 1987; Eisma et al.

Fig. 4-34. Erosion rate relationship for nonbreaking waves obtained by Maa (1986).

1991); the Amazon shelf (Kineke and Sternberg 1995); and the southwestern coast of India (Mathew and Baba 1995).

In the offshore zone (Fig. 4-30), when the surficial layer at the bottom occurs as very soft or fluid mud, its entrainment can be described by an expression paralleling that used to quantify fluid entrainment from a stratified flow interface, e.g., Eq. (4-39). Li (1996) developed the following relation for the net rate entrainment by waves over fluid mud,  $\epsilon_f$  (mass per unit bottom area per unit time), in which the first

Source: Li (1996).

term represents upward entrainment and the second embodies entrained sediment settling onto the fluid mud:

$$\epsilon_f = \begin{cases} \alpha_w \rho u_b \left( \frac{R_c^2}{R_g} - R_g \right) - w_s C_a & R_g < R_c \\ 0 & R_g \geq R_c \end{cases} \quad (4-47)$$

In Eq. (4-47),

- $\rho$  = density of the fluid mud;
- $u_b$  = near-bottom velocity amplitude;
- $\alpha_w$  = sediment-dependent coefficient;
- $C_a$  = near-bottom sediment concentration; and
- $R_g$  = Richardson number, given by:

$$R_g = \frac{(\rho_m - \rho_w) g \delta_{bl}^2}{\rho_w \Delta u_i^2} \quad (4-48)$$

In Eq. (4-48),  $\delta_{bl}$  = wave boundary layer thickness (see footnote of Table 4-17) and  $\Delta u_i$  = absolute value of the maximum (horizontal) wave velocity difference across the interface. In Eq. (4-47)  $R_c$  is the critical value of  $R_g$  below which no entrainment is assumed to occur. This equation is plotted in Fig. 4-35 using the laboratory data of Maa (1986) and Li (1996) on the entrainment of natural and clayey sediments by waves in a flume. The coefficients  $\alpha_w = 2 \times 10^{-6}$  and  $R_c = 0.043$  were selected for both sets of data. In general, when direct measurements are not available, the calculation of the velocities  $u_b$  and  $\Delta u_i$  can be carried out as follows.

When bottom mud is soft, wave-induced orbital motion tends to penetrate the water-mud interface and, in turn, due to the high viscosity of mud (Table 4-6), wave damping often becomes significant. Several models have been used to determine the velocity field in two-layered (water and mud) flows in which energy dissipation is significant in the lower (mud) layer. An early model is due to Gade (1958), who assumed the lower layer to be a viscous fluid and the water layer above to be inviscid. He further limited his solution

for the velocity field to waves in shallow water. Dalrymple and Liu (1978) considered both layers to be viscous and did not restrict the water depth. MacPherson (1980) assumed the lower layer to be viscoelastic and water to be inviscid. Piedra-Cueva (1993) extended the work of MacPherson by introducing a boundary layer at the water-mud interface. Jiang (1993) expanded on the solution of Dalrymple and Liu by including second order effects. The velocities  $u_b$  and  $\Delta u_i$  for the plot of Eq. (4-44) in Fig. 4-34 were derived by Li (1996) using the solutions of Jiang. A brief review of these and other models is provided in Rodriguez (2000).

A case of a simple flow field is one in which damped oscillation of the fluid mud layer is ignored in comparison with the orbital velocity above the interface. Then one has  $\Delta u_i \approx u_b$ , which can be easily calculated assuming the applicability of, for instance, the Airy wave theory (e.g., Dean and Dalrymple 1991) by ignoring the boundary layer effect in the water layer. In the simplest case of a shallow water wave the bottom velocity can be obtained from

**Fig. 4-35.** Dimensionless wave-induced entrainment flux as a function of Richardson number (after Li and Parchure 1998).

$$u_b = \frac{H}{2} \left( \frac{g}{h} \right)^{1/2} \quad (4-49)$$

where  $H$  is the local wave height and  $h$  is the water depth.

## 4.10 DIFFUSION

### 4.10.1 Diffusion and Stratification

The (negative) buoyancy effect due to sediment-induced stratification tends to restore fluid lumps moved upward by turbulent diffusion back to their original positions, and thereby restricts the vertical transfer of momentum and sediment mass. This effect can be simply characterized by the way in which the momentum and mass mixing lengths vary with sediment concentration. In general, as the concentration increases the mixing length decreases, and below the lutocline almost complete turbulent collapse may occur, essentially leading to viscous flow (Jiang 1999; Winterwerp 1999; Jiang and Mehta 2000).

The Fickian flux due to vertical diffusion is

$$F_d = K_v \frac{\partial C}{\partial z} \quad (4-50)$$

where

$K_v$  = diffusion coefficient.

From the analogy between sediment-induced density stratification and that induced by salinity and thermal gradients, along with the so-called Reynolds analogy between momentum and mass transport (Bird et al. 1960), expressions relating  $K_v$  to turbulence-mean flow and sedimentary parameters have been derived. Thus, for example, based on the phenomenological development of Rossby and Montgomery (1935), Munk and Anderson (1948) proposed the semiempirical formula

$$K_v = K_{v0} \left( 1 + \beta_v Ri_g \right)^{\gamma_v} \quad (4-51)$$

where

$K_{v0}$  = “neutral” diffusivity in homogenous flow and  $\beta_v$  and  $\gamma_v$  are sediment-dependent coefficients.

In Eq. (4-51), in which the second term within parentheses represents buoyancy correction to neutral diffusion, the gradient Richardson number  $Ri_g$  is defined as

$$Ri_g = \frac{g}{-\rho} \frac{\partial \rho / \partial z}{(\partial u / \partial z)^2} \quad (4-52)$$

where

$u$  = local horizontal velocity.

With reference to the well-known mixing length concept of Prandtl and von Karman,  $K_{v0}$  can be stated as

$$K_{v0} = \kappa u_* z \left( \frac{h-z}{h} \right) \quad (4-53)$$

where

$\kappa$  = Karman constant and

$u_* [=(\tau_b/\rho_w)^{1/2}]$  = friction velocity (Guo and Wood, 1995).

The use of (4-53) (with a nominal value of  $\kappa=0.4$ ) is contingent on the assumption of a logarithmic boundary layer velocity profile in the nonstratified water column. In reality, a Monin-Obukhov correction to the boundary layer velocity profile must be applied when stratification is significant (Friedrichs et al. 2000).

Jobson and Sayre (1970) noted that vertical mixing of suspended sediment in open-channel flow occurs as a result of two diffusion processes that can be shown to be additive. These processes include diffusion due to tangential components of turbulent velocity fluctuations and the centrifugal force arising from the curvature of fluid particle path lines. Based on these observations, they derived the following expressions for  $K_{v0}$ :

$$K_{v0} = \alpha_j \kappa u_* z \left( 1 - \frac{z}{h} \right) + \beta_j u_* h \left( \frac{1-z/h}{0.9} \right)^3 \quad \text{for } \frac{z}{h} \geq 0.1 \quad (4-54)$$

$$K_{v0} = \alpha_j \kappa u_* z \left( 1 - \frac{z}{h} \right) + \beta_j u_* h \left( \frac{z/h}{0.1} \right)^3 \quad \text{for } \frac{z}{h} \leq 0.1$$

Coefficients values from flume tests were reported to be  $\alpha_j = 0.038$  and  $\beta_j = 0.98$ .

Values of the coefficients in Eq. (4-51) for forcing by current and applicable to fine sediment transport are given from some sources in Table 4-19. In general, fewer sets of values of these coefficients are available than for momentum transfer (Ross 1988; Jiang 1999). Momentum diffusivity can be converted to mass diffusivity if the turbulent Schmidt number  $S_c$ , i.e., the ratio of momentum to mass diffusivity, is known from measurement. From estuarine measurements, Oduyemi

Costa (1989)/current	1.0-8.0	-2.0
Hwang (1989)/waves	0.5	-0.5
Jiang (1999)/current	10	-0.5

(1986) found that the behavior of these two diffusivities over a tidal cycle was not self-similar, meaning that the  $S_c$  varied over the tide. Costa (1989) also reported that  $S_c$  varied with tide in Hangzhou Bay in China, in the range of 0.94 to 2.45.

Starting with a homogeneous suspension, the behavior of the diffusive flux  $F_d$  according to Eq. (4-50) along with Eq. (4-51) and (4-52) can be examined as a function of the concentration gradient,  $\partial C/\partial z$ . The resulting trend is illustrated in Fig. 4-36. It is assumed that  $\rho$  in the denominator of Eq. (4-51) is equal to water density  $\rho_w$ . Furthermore, the velocity gradient  $\partial U/\partial z = u_*'/\kappa z$  is based on the logarithmic velocity profile, and  $\partial \rho/\partial z = [1 - (\rho_w/\rho_s)] \partial C/\partial z$ . Relevant values are  $h = 3$  m,  $u_*' = 0.1$  m/s,  $z = 0.1$  m,  $\kappa = 0.4$ ,  $\rho_w = 1,000$  kg/m<sup>3</sup>,  $\rho_s = 2,650$  kg/m<sup>3</sup>,  $\beta_v = 4$ , and  $\gamma_v = -2$ . Observe the effect of increasing negative buoyancy in limiting upward diffusion.

Glenn and Grant (1987) developed a correction factor for sediment-induced stratification due to the effects of waves superimposed on current. In general, the use of higher order turbulence closure schemes for modeling diffusion partially obviates the empirical limitations of Fickian closure described here (Nunes Vaz and Simpson 1994). Among others, Sheng and Villaret (1989) modeled resuspension using a second-order closure model for turbulence, which also yielded a better measure of the bottom stress than from the usual assumption of a constant bottom drag coefficient and wave-induced velocity unaffected by suspended sediment. In fact, turbulence damping due to suspended sediment was shown to measurably reduce bottom drag, hence resuspension. The same trend was found by Adams and Weatherly (1981) using a similar modeling approach.

#### 4.10.2 Wave Effect

To model diffusion according to Eq. (4-50) for wave-induced processes, appropriate formulations for  $K_{v0}$  must be used.

Fig. 4-36. Dependence of vertical mass diffusive flux on suspended sediment concentration gradient.

Several formulas have been proposed (e.g., Homma et al. 1965; Bhattacharya 1971; Kennedy and Locher 1972). A brief review of the subject is found in Dyer (1986). Focusing on the ambient water column rather than the near-bottom wave boundary layer, Hwang and Wang (1982) proposed the expression

$$K_{v0} = \alpha_{wd} \frac{H^2}{2} \frac{\sinh^2 k(h+z)}{\sinh^2 kh} \quad (4-55)$$

in which

$H$  = wave height,

$h$  = water depth,

$k$  = wave number,

and the diffusion scaling coefficient  $\alpha_{wd}$  for a given sediment depends on the flow field.

In Eq. (4-55), the vertical coordinate  $z$  is measured positive upward from the mean water level, so at the bottom  $z = -h$ . Based on wave energy dissipation in the water column and experimental data, Thimakorn (1984) arrived at an expression for  $K_{v0}$  that is akin to Eq. (4-55), with  $\alpha_{wd} = 1.77/\sinh kh$ . In Lake Erie, Lick (1982) reported a mass diffusivity, value  $K_{v0}$ , of 25 cm<sup>2</sup>/s. For calculation of  $K_v$  from  $K_{v0}$  using Eq. (4-51), Table 4-19 provides values of the coefficients  $\beta_v$  and  $\gamma_v$  from wave-induced resuspension studies by Ross (1988) and Hwang (1989).

Under wave action, vertical diffusion of sediment tends to be considerably less efficient than in a current in the sense that whereas, under waves, the sediment tends to remain sequestered within a comparatively thin bottom boundary layer, under a current-induced thicker boundary layer the material is swept upward much more easily, thus resulting in a greater suspension height (Li and Parchure 1998). Furthermore, release of bed pore water and associated chemical constituents appears to be influenced by a diffusive sublayer close to the bed, which seemingly restricts upward entrainment. On the other hand, heaving motion of mud, especially when it is soft, enhances upward transport (Li et al. 1997). When heaving and relative motion between water and mud at the interface become significant, the calculation of bed shear stress must also account for the "slippage" between the two layers (Maa 1986). In addition, there seems to be an effect on bottom drag associated with the flocs at the bed. Typically, the drag coefficient for a cohesive bed, especially one composed of soft mud, tends to be low. For example, from flume experiments Dixit (1982) reported values of the Manning's bed resistance coefficient,  $n$ , to be on the order of 0.011. As postulated by Gust (1976), such a low value may in part be due to an elastic deformation of flocs induced by flow at the bed surface. Bed resistance is also mitigated by the effect of sediment-induced buoyancy. Li and Gust (2000) further ascribe the reduction effect to severe damping of turbulence in the wall boundary layer.

## 4.11 APPLICATIONS

The description of fine sediment behavior given in the preceding sections is used in engineering studies to predict sediment movement and deposition and to design sediment management measures (Zeigler and Nisbet 1994; 1995). A few examples will illustrate how they are used.

### 4.11.1 Measurement

Measurement of fine sediment transport rate and bed changes is accomplished by several methods, none of which provides a complete picture of the important processes. The greatest difficulty lies in measuring near the active bed-water interface and at lutoclines, where intrusive instruments may disrupt the processes to be measured.

The depth-mean suspended sediment mass transport rate is obtained from

$$q(x, y, t) = \int_0^{h(x, y, t)} C(x, y, z, t) u_s(x, y, z, t) dz \quad (4-56)$$

in which

$x$  and  $y$  = the longitudinal and transverse coordinates, respectively;

$z$  = the vertical coordinate;

$h(x, y, t)$  = the instantaneous water depth; and

$u_s$  = the sediment velocity vector.

Because it is currently unrealistic to deal with the sediment velocity, which is difficult to quantify, especially for flocculated sediments,  $u_s$  is characteristically replaced by the corresponding fluid velocity,  $u$ . Thus, assuming isokinetic motion of water and sediment, we restate Eq. (4-56) as

$$q(x, y, t) = \int_0^{h(x, y, t)} C(x, y, z, t) u(x, y, z, t) dz \quad (4-57)$$

Suspended sediment load in the water column away from the bed is obtained by direct or indirect methods. Direct sampling involves collecting water samples at several depths while simultaneously measuring the flow velocity profile, and repeating these measurements at several locations along a cross section. The water samples may be taken by submerged bottle-type samplers or by pumping to a bottle on a vessel or platform. Samples are then analyzed for sediment concentration, usually by filtration and drying. Integration of the product of sediment concentration, flow velocity, and cross-sectional area over the profile yields an estimate of sediment discharge. Flow velocities can be measured by devices using vanes or propellers held at the sampling point, but the preferred method is now an acoustic Doppler current profiler (ADCP), either sitting on the bed or held just below the water surface, which emits multiple sound pulses and measures the time and frequency of reflected sound waves to compute three-dimensional velocities. Analysis of the

reflected wave intensity can also be used to estimate suspended sediment concentration, but requires careful, site-specific calibration of the signal against standard methods (Teeter et al. 1996; Land et al. 1997).

Other methods of measuring the sediment load include optical backscatter sensors (OBS), which emit a beam of light, measure the intensity of reflected light, and convert that reading to a sediment concentration. Such devices must be calibrated to the sediment in transport at each site, because the particle's reflectance is a function of shape, color, size, and surface coating (Downing and Beach 1989). Optical transmissometers are used in both low-concentration (Bocuniewicz et al. 1991) and high-concentration (Costa 1989) environments.

Measuring the location of the bed is commercially important for navigable waterways because it defines the depth available for navigation (Parker 1994), and scientifically important for defining rates of erosion and deposition. Despite its importance, the process is fraught with uncertainty in definition of what the bed surface is and where it is. Acoustic depth-sounding equipment is standard in most waterways and works well when the bed is composed of sand-size or larger sediment. For muddy beds the technique may or may not yield accurate results, because the acoustic signal is reflected by sharp density gradients, not by specific densities; thus the acoustic record may suggest that the bed occurs at the first fluid density inflection, such as is shown in Fig. 4-4, producing a bed elevation estimate that is one to several meters above the actual firm bed. In the presence of fluid mud, multiple density inflection points may produce multiple false bed locations (Parker and Kirby 1982). More accurate and reliable methods for locating the bed include nuclear density meters (Parker and Kirby 1982) and towed devices that respond to both suspension density and viscosity (Alexander et al. 1997).

### 4.11.2 Modeling

For many years physical models based on scaling principles were the primary engineering tool of choice for fine sediment studies (Herrmann and Letter 1990; Letter and McAnally 1977), but have now been largely replaced by numerical models which solve the equations of transport and bed change using computational methods.

In some situations involving steady or periodic flows, Eq. (4-57) can be solved through simple modeling techniques (e.g., McAnally 1999; Krone 1985). In steady and also quasi-steady flows such as those due to tides, and when the suspended concentration does not exceed a few tens of milligrams per liter, the classical Rouse (1937) profile of suspended sediment (Dyer 1986; Hill et al. 1988) is often found to be adequate to describe the variation of concentration  $C$  with depth. In this development the settling velocity is assumed to be independent of  $C$  and vertical diffusion is assumed to be neutral. Depth variation of  $C$  is obtained under the assumption of the equality of upward

diffusion and settling fluxes. The resulting profile of  $C$  along with the well-known logarithmic variation of flow velocity  $\bar{u}$  with depth (Dyer 1986) can be used to calculate the sediment load via (4-57).

Introduction of time-dependence of  $C$  in the Rouse formulation leads to a one-dimensional (vertical) model that has been used extensively in modeling the time-variation of the vertical profile of  $C$  due to tide as well as waves (e.g., Adams and Weatherly 1981; Maa and Mehta 1988; Sheng and Villaret 1989; Le Hir et al. 2001; Teeter 2001a, 2001b).

In most cases, it becomes essential to use complex two- or three-dimensional time-dependent numerical models to calculate  $u$  and  $C$ , incorporating the described unit transport processes, i.e., settling and deposition of suspended material, consolidation of the fresh deposit, and erosion and entrainment of the fresh as well as of the consolidated deposit (Zeigler and Nisbet 1994; Cardenas et al. 1995; Costa 1995; Zeigler and Nisbet 1995; Jiang 1999).

The solved governing equations for transport of suspended sediment load, either cohesive or noncohesive, are usually the general advection-diffusion equations,

$$\begin{aligned} \frac{D}{Dt} = \frac{\partial}{\partial x} \left( K_x \frac{\partial}{\partial y} \right) + \frac{\partial}{\partial y} \left( K_y \frac{\partial C}{\partial y} \right) \\ + \frac{\partial}{\partial y} \left( K_z \frac{\partial C}{\partial z} \right) + \sum_{\text{sources}} - \sum_{\text{sink}} \end{aligned} \quad (4-58)$$

where the left hand side is the total derivative and  
 $C$  = suspended sediment concentration;  
 $t$  = time,  
 $x, y$ , and  $z$  = spatial coordinates, and  
 $K_x, K_y$ , and  $K_z$  = directional diffusion coefficients.

The source term as represented in (4-58) denotes external sediment that enters the system being modeled, such as that due to shoreline or bluff erosion and river or slough runoff. Organic sediments can both be internally produced, e.g., by photosynthesis, and arrive from external sources. Sediments that leave the system are represented in the sink term. Erosion and deposition of sediment within the system is handled through the bottom boundary condition when the model includes the variation of flow and sediment properties in the vertical ( $z$ ) direction. In depth-averaged models, erosion and deposition become (external) source and sink, respectively.

A bed model, which describes the density, resistance to erosion, and other characteristics of the sediment bed, keeps track of the net deposition/erosion and thus the elevation of the bed and the variation of properties with depth into the bed (see, for example, McAnally and Thomas 1989). One of the first models in which the bed was discretized into horizontal layers, with density and erodibility indices changing from layer to layer, is due to Ariathurai et al. (1977), who applied the model to simulate tidally driven fine sediment

deposition in the dredged channel leading to the port of Savannah, Georgia. Maa (1986) extended this concept to wave modeling, in which the bottom density, erodibility, and rheological parameters were varied with depth. It is now recognized that an eventual goal of modeling should be to simulate the solid and fluid phases on a continuous rather than discretized basis (Teisson 1997; Toorman, 2001). Simulation of phase changes between the bed and suspension due to erosion/deposition must be integral to such a development, as opposed to the present piecemeal approach based on unit transport processes. It is certain that considerable additional experimental work will be required to fully evolve such a modeling approach.

Two aspects of modeling that are essential for simulating cohesive bottom related processes include fluid mud transport and bed stratification. In estuaries with large tidal ranges such as the Severn in the UK (Kirby 1986; Smith and Kirby 1989), the Loire in France (Le Hir et al. 2001), and the Amazon in Brazil (Kineke 1993; Geyer 1995; Vinzon and Mehta 2001), fluid mud tends to persist through the entire tidal cycle and plays a major role in determining the sediment budget. In the microtidal to mesotidal environment, such as along much of the U.S. coastal zone, thick layers of fluid mud are less common in fair weather, but can become significant in terms of their contribution to the total sediment load when, for example, storm waves occur (Kemp and Wells 1987).

The technology of sediment modeling has evolved rapidly in recent decades, and any description of the state of the art will quickly become obsolete. The one-dimensional numerical model HEC-6 and its variations are widely used for rivers and occasionally estuaries (e.g., Thomas et al. 1988). The TABS-MD and other systems of models have been extensively used for estuarine sediment transport (Donnell et al. 1991; McAnally 1989; Willis and Crookshank 1997), and the 2DV model LAEM-SED has been used in a few estuaries (Smith et al. 1987; Johnson et al. 1989). Three-dimensional models constitute the state of the art in fine sediment modeling, and are exemplified by applications reported by, among others, Teeter and Callegan (2000).

#### 4.11.3 Case Studies

Indian River Inlet, Delaware, connects Indian River Bay and Rehoboth Bay to the Atlantic Ocean on the U.S. East Coast. In 1938–1940 the previously ephemeral inlet was stabilized by parallel jetties 150 m apart with a maximum inlet depth of about 6 m below mean low water. Almost immediately the sandy inlet bed began to scour, and by 1991 nearly all of the inlet was deeper than 12 m and some holes exceeded 30 m in depth. Scour had uncovered lagoonal cohesive clay deposits at depths of about 11 m and the deepest holes had eroded through the clay layer, exposing consolidated Pleistocene sand and gravel (CTH 1994). Concern over the

possibility of further erosion undermining the jetties and a state highway bridge over the inlet prompted an analysis of the inlet's stability, a question usually associated with cohesionless sediments, but in this case one in which the erodibility of cohesive sediments was a controlling factor. The Corps of Engineers CTH (1994) analyzed the inlet's stability, employing a mix of field, laboratory, and desktop calculations as summarized below.

The average depth of the bays is 1.5 m below mean low water. Mean tide range is approximately 1 m in the offshore area, 0.6 m in Indian River Bay and 0.3 m in Rehoboth Bay. Small freshwater inflows (usually less than 100 m<sup>3</sup>/s) create a longitudinal salinity gradient in the bays, with minor to no vertical stratification occurring under normal conditions. In 1992 the inlet had an average cross-sectional area of about 2,100 m<sup>2</sup>. Tidal flow speeds through the inlet exceeded 2 m/s under spring tides.

A vessel-mounted 1,200-KHz ADCP was used to measure current speed and direction profiles along 12 ranges. Each range was profiled during peak ebb and peak flood flows for two tidal cycles. The ADCP measured three-dimensional velocity vectors, averaging within zones, or bins, approximately 50 cm deep. Sediment samples were taken to characterize the erodibility of the cohesive sediments and to obtain grain size distributions of the exposed bed sands. Clam-shell samples, drag bucket samples, and cores were taken at 10 locations throughout the inlet. Laboratory erosion tests were conducted to define the two characteristic parameters of Eq. (4-30) for the cohesive sediment samples. Tests were conducted in a particle entrainment simulator (PES) (Tsai and Lick 1986), a vertical loop sediment tunnel (VOST) (Teeter and Pankow 1989), and a rotating cylinder erosion device (see, e.g., Chapuis and Gatién 1986). Lee and Mehta (1994) have reviewed these and several other types of erosion-measuring devices reported in the literature. The PES induced bed stresses up to 0.7 Pa by means of a vertically oscillating grid, whereas the VOST generated horizontal flow stresses up to 3 Pa and the rotating cylinder generated stresses up to 16 Pa. The value of the erosion shear strength  $\tau_s$  developed from those experiments was 4 Pa for an intact sample and 5.8 Pa for a remolded sample. The erosion rate constant for the tested sediments ranged from  $5.8 \times 10^{-4}$  to  $1 \times 10^{-3}$  kg/m<sup>2</sup> s.

Typical mean flow velocities for the inlet were obtained by smoothing measured values and then adjusting them to an appropriate tide range and inlet cross-sectional area by means of the Keulegan (1967) tidal inlet method. Half-hourly shear stresses on the bed were estimated via Manning's flow velocity equation. These stresses were used to compute erosion rates for neap, mean, and spring tides using Eq. (4-30) and then composited to create annual erosion rates. Comparison with observed historical rates led to adjustment of the laboratory-derived erosion rate coefficients to make the bed somewhat more erodible, which was probably caused by

sand abrasion of the clay bed leading to more rapid erosion than by water flow alone.

The calculations showed that the clay bed would stop eroding at an inlet size of about 2,800 m<sup>2</sup>, or about 30% larger than the then existing inlet size. Based on these and other, sand-based calculations, it was decided to do nothing other than continue monitoring the inlet to ensure that the predicted size stability would occur.

Hayter and Gu (2001) applied a two-dimensional numerical model (HSCTM-2D) to the problem of contaminated sediment transport in the Maurice River-Union Lake, New Jersey, system in order to predict the effects of dredging on sediment and arsenic distribution in the system. Union Lake is a 4-km-long impoundment on the Maurice River about 40 km upstream of Delaware Bay. Its average width is 1.6 km. Bed sediments were contaminated with arsenic concentrations above 0.05 mg/l, and the model was used to compare natural flushing of arsenic from the system to a proposed remedial plan that would remove some contaminated sediments by dredging. Data collected for the modeling effort included daily stages and discharges; suspended sediment concentrations and arsenic concentrations in the river, tributaries, and lake during storms and normal conditions; cross-sectional hydrographic surveys; sediment cores that were analyzed for grain size distribution, mineral composition, density, organic content, and arsenic concentration; and bed pore water samples that were analyzed for arsenic, pH, and conductivity. Sedimentation traps were deployed in the system to accurately measure deposition rates; however, the traps were lost during high flow events and provided no data.

The model solved the depth-averaged form of Eq. (4-58) for three sediment size classes, plus selected dissolved and suspended contaminants, using the finite element method. Depth-averaged water velocities and water surface elevations were computed by a companion module that solved the Reynolds form of the Navier-Stokes equations. The cohesive sediment source-sink terms in Eq. (4-58) employed Eq. (4-26) for deposition rate to the bed and a form of Eq. (4-37) for bed erosion rate. The bed sediment density structure and thickness were computed by a one-dimensional finite strain model developed by Cargill (1982).

The model was validated by adjustment to, and comparison with, 3-year-long data as described above. As is the case in most engineering studies, the data were less complete and comprehensive than in the ideal case, and the results were interpreted in light of those limitations. Numerical experiments were then performed, using a synthetic typical year's flows that included four storm events. Model results showed that arsenic flushing times (time required for arsenic concentrations to decline to less than 120 mg/kg throughout the system) ranged from 15 years for the no-action alternative to 4 years for dredging contaminated sediments out of the river and lake. The estimated error in flushing times was  $\pm 1.2$  years, based on the model validation and a sensitivity analysis of arsenic desorption rates.

Rodriguez (2000) examined the problem of assessing the fate of mud placed off the beach, from where it may be carried away mainly by wave-induced currents. Referring to the elemental control volume in Fig. 4-37, and considering the cross-shore distance coordinate  $y$  to be the dependent variable and water depth  $h$  to be the independent one, the sediment continuity equation can be conveniently stated as

$$\frac{\partial y}{\partial t} = -\frac{1}{m\rho_D} \frac{\partial q_x}{\partial x} - \frac{1}{\rho_D} \frac{\partial q_y}{\partial h} \quad (4-59)$$

where

$q_x$  and  $q_y$  = the components of mass sediment fluxes per unit length in the  $x$  and  $y$  directions, respectively;

$\rho_D$  = the dry density of the deposit; and

$m = \partial h / \partial y$  = the local bottom slope.

Equation (4-59) makes possible tracking changes in the bottom contour position with time, as opposed to tracking water depth. The output at every time step is therefore a bottom contour “map” dependent on the fluxes  $q_x$  and  $q_y$  (Perlin and Dean 1983).

In Eq. (4-59),  $q_x$  must be determined in accordance with Eq. (4-57) from the product of the cross-shore distributions of suspension concentration and water velocity (Rodriguez and Mehta 2000). The corresponding cross-shore flux  $q_y$  can be related to the difference in the instantaneous rate of wave energy dissipation and the corresponding dissipation rate over an “equilibrium” or “target” profile (Lee and Mehta 1997).

The simplest application of Eq. (4-59) is to waves normally incident on a coast with shore-parallel contours (Coakley et al. 1988). In this case the alongshore transport mode is switched off in the model, so that profile change, either accretion or erosion, is due to sediment moving landward or seaward. The erosion of a beach consisting of over-consolidated till along Lake Ontario in Canada was reported by Davidson-Arnott (1986), who also noted that as the

**Fig. 4-37.** Elemental control volume and suspended sediment fluxes in open coast waters.

profile translated landward the eroded material was carried away beyond the sediment-active profile, leaving practically no sediment deposit within this zone. Profile evolution over the period 1980–1984 is simulated in Fig. 4-38 (Rodriguez 2000).

When obliquely incident waves and alongshore current occur, simulation of profile evolution becomes considerably more complicated, due to the effects of alongshore as well as cross-shore forcing on shore processes. At the Mahin coast in Nigeria, waves are dominated by swell originating at storm centers in the southern Atlantic region. The tide is semidiurnal with a mean range of 1.5 m, and the beach and nearshore material consist mainly of poorly sorted silt with mean size ranging from 20 to 50  $\mu\text{m}$ . Due to submarine canyons that act as sinks of littoral drift, this region is starved of sediment supply. In the 1970s a navigation cut was dredged perpendicular to the coast near the village of Awoye about 20 km west of the Benin River (Fig. 4-39) to connect inland creeks and canals with the ocean. This cut apparently enabled larger waves to penetrate inland, exacerbating the erosion of the shoreline in the vicinity. In addition, salt water intrusion occurred, which in turn affected vegetation sensitive to brackish water. The ensuing die-back exposed bottom sediment otherwise protected by rooting and considerably increased land loss (Eedy et al. 1994).

Shoreline erosion adjacent to the cut was in response to a combination of wave-induced and tidal forcing, consistent with sediment transport associated with the typical flood and ebb flow distributions that develop near a tidal inlet or cut. Accordingly, sediment eroded by wave action along the shoreline was drawn toward the cut by flood flow. During ebb flow, the material that had accumulated near the entrance was jetted offshore. Since the lost near-shore sediment was not replenished by alongshore drift, shoreline recession occurred. As observed from Fig. 4-39,

**Fig. 4-38.** Glacial till profiles at Grimsby, Lake Ontario, Canada measured by Davidson-Arnott (1986) and comparison with simulated profiles (after Rodriguez 2000).

**Fig. 4-39.** Shoreline recession in the vicinity of Awoye (after Rodriguez 2000).

erosion was rapid in the first few years, and a recession on the order of 1.5 to 2.0 km occurred near Awoye between 1972 and 1991.

It is instructive to examine the bathymetric change near Awoye by considering it to be due to an equivalent effect of shore-normal waves over a bottom with shore-parallel contours disturbed by a cut acting as a sediment sink. The resulting change in the bottom, in this case due to increasing deviation from the initial "target" profile, is shown in Fig. 4-40 (Rodriguez and Mehta 2001). In order to mimic the observed (Fig. 4-39) pattern of bottom change, sediment was withdrawn through the cut at a rate of 800 kg/s. This exceptionally high rate merely reflects the rapid rate of erosion that actually occurred. At the end of the initial period of 7 years covered in the simulation the shoreline was recessed by about 1 km.

**Fig. 4-40.** Simulated contour recession due to the effect of a dredged channel (after Rodriguez and Mehta 2001).

## CHAPTER 5

### *Sediment Transport Measurements*

*P. Diplas, R. Kuhnle, J. Gray, D. Glysson, and T. Edwards*

#### 5.1 GENERAL

*P. Diplas, R. Kuhnle, J. Gray, and D. Glysson*

Sediment erosion, transport, and deposition in fluvial systems are complex processes that are treated in detail in other sections of this book. Development of methods suitable for the collection of data that contribute to understanding these processes is a still-evolving science. Sediment and ancillary data are fundamental requirements for the proper management of river systems, including the design of structures, the determination of aspects of stream behavior, ascertaining the probable effect of removing an existing structure, estimation of bulk erosion, transport, and sediment delivery to the oceans, ascertaining the long-term usefulness of reservoirs and other public works, tracking movement of solid-phase contaminants, restoration of degraded or otherwise modified streams, and assistance in the calibration and validation of numerical models.

This chapter presents techniques for measuring bed-material properties and suspended and bed-load discharges. Well-established and relatively recent, yet adequately tested, sampling equipment and methodologies, with designs that are guided by sound physical and statistical principles, are described. Where appropriate, the theory behind the development of the equipment and guidelines for its use are presented.

The theory and statistical methods described in the bed-material section represent the developments that have taken place mainly since the 1970s. Research on bed-material sampling techniques commenced later than research in the other two areas discussed in this chapter, and the relevant work is available almost exclusively in journals and conference proceedings. Therefore, emphasis has been placed on several key aspects of the concepts and development of bed-material sampling techniques. Improving and validating existing sediment-sampling techniques remains an active area of research today. It is worth mentioning that the meth-

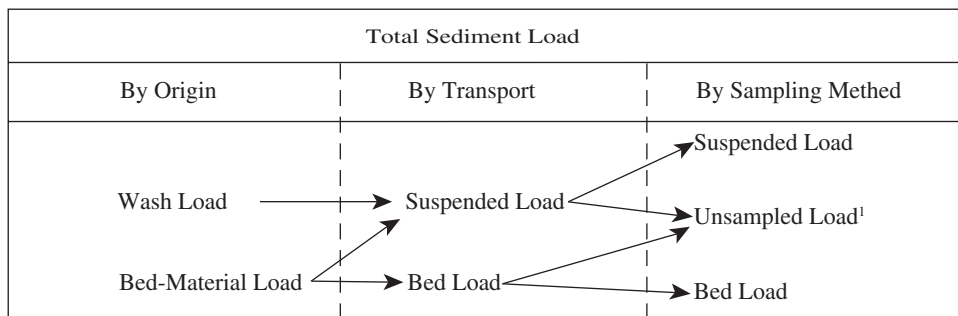

ods discussed in this section can be used to estimate the necessary size of suspended or bed-load samples in order to determine their sediment size characteristics at a desirable level of accuracy.

Many of the concepts described in the section on suspended-sediment sampling were developed in the mid-twentieth century, although several new sampler types and modifications to traditional sampling methods have been developed. The collection of accurate bed-load samples has always been a challenge, because of the spatial and temporal variability associated with its transport. Several studies have successfully sampled bed load on small streams with semipermanent installations. For many projects, however, sampling programs using manually operated portable samplers continue to be the method of choice. The most common types of manually operated samplers, along with several new analyses that define improved techniques for measuring and calculating the accuracy of manually collected bed-load samples, have been reviewed. These new analyses provide needed information on the expected errors associated with bed-load data collected using a given sampling design.

Bed-material sampling is usually conducted during low flows. Bed-load and suspended-sediment sampling can be conducted over the entire hydrograph, although emphasis is usually directed toward higher flows and particularly floodflows.

##### 5.1.1 Terminology

Bed material, suspended sediment, and bed load can be defined by their origin, or operationally by their method of collection (Fig. 5-1). Bed material is the sediment mixture of which the streambed is composed (ASTM International 1998). However, bed-material data will necessarily reflect the attributes of the sampler and its means of deployment. Hence, bed material collected by a US BM-54 would represent the topmost 5 cm of a bed composed of material finer than medium-sized pebbles.

<sup>1</sup>That part of the sediment load that is not collected by the depth-integrating suspended-sediment and pressure-difference bedload samplers used, depending on the type and size of the sampler(s). Unsamped-load sediment can occur in one or more of the following categories: a) sediment that passes under the nozzle of the suspended-sediment sampler when the sampler is touching the streambed and no bedload sampler is used; b) sediment small enough to pass through the bedload sampler's mesh bag; c) sediment in transport above the bedload sampler that is too large to be sampled reliably by the suspended-sediment sampler; and d) material too large to enter the bedload-sampler nozzle.

**Fig. 5-1.** Components of total sediment load considered by origin, by transport, and by sampling method.

The total amount of sediment in transport can be described by its origin as being composed of bed-material load plus wash load. Bed-material load is that part of the total load that is composed of particle sizes present in appreciable quantities in the shifting portions of the streambed (ASTM International 1998). Wash load is that part of the total load composed of particles, usually finer than 0.062 mm in diameter, that are found, if at all, only in relatively small quantities in the bed (ASTM International 1998). Again, the operational definition of sediment in transport is in part a function of the types of samplers used to obtain the data. Suspended-sediment and bed load discharge are the quantities of suspended sediment and bed load passing through a stream cross section per unit time, respectively. Suspended-sediment discharge can include some of the bed-material load component and includes all of the wash load component. Bed load discharge includes some of the bed-material load component. Data from physical samples of suspended sediment and bedload, necessarily obtained by use of samplers, may not equal the sum of bed-material load plus washload (Fig. 5-1). This is a result of one or more factors associated with the range in size of sediments in transport, and the characteristics and deployment methods of the suspended-sediment and bedload samplers.

### 5.1.2 History of Development of Sediment-Sampling Equipment

The initial attempts to develop sediment-sampling equipment were made by independent investigators. The equipment lacked calibration and was deployed using widely different operating techniques. Most instruments were designed with limited attention to, or knowledge of, sediment transport concepts or the influence of the equipment on the local flow pattern (Glysson 1989a). As a result, data obtained by different investigators before the 1940s were

not comparable, nor could their accuracy be evaluated. It became apparent that reliable sediment data could not be obtained unless equipment, data collection, and analytical methods were standardized.

In 1939, various agencies of the U.S. government organized an interagency program to study methods and equipment used in measuring the sediment discharge of streams and to improve and standardize equipment and methods where practicable (FISP 1941). The Federal Interagency Sedimentation Project (FISP) (Skinner 1989; Glysson and Gray 1997) was created under the sponsorship of the Committee on Sedimentation of the Federal Water Resources Council. The comprehensive study of sampling equipment included suspended-sediment, bed-load, and bed-material samplers. As a result of research conducted by the FISP and others, an integrated system of sediment samplers, sampling, and analytical techniques has been developed and is widely used around the world.

Progress is being made in improving available or devising new technologies to measure selected characteristics of fluvial sediment. Instruments that operate on acoustic, differential density, pump, focused beam reflectance, laser diffraction, nuclear, optical backscatter, optical transmission, and spectral reflectance principles have been developed (Wren et al. 2000). Ideally, a surrogate parameter that varied as a function of the sedimentary property of interest (such as concentration, particle-size distribution, or particle or bed form movement) would be available, which could be automatically monitored and recorded.

The literature is full of descriptions of emerging technologies for measuring selected characteristics of fluvial sediment; for example, see Lee (1990); Mertes et al. (1993); Lodhi et al. (1997); Gray and Schmidt (1998); Agrawal and Pottsmith (2001); Byrne and Patiño (2001); Christiansen et al. (2001); Gartner and Cheng (2001); Land and Jones (2001); Larsen et al. (2001); Rubin et al. (2001); Schoellhamer (2001); Gray

et al. (2005). Although some techniques show considerable promise, none is yet commonly accepted nor extensively used. Isokinetic samplers—primarily those developed by the FISP and described by Edwards and Glysson (1999)—generally are considered the standard against which other types of samplers are calibrated (Morris and Fan 1997; Wren et al. 2000). Adoption of any sediment surrogate technology for large-scale sediment-monitoring programs should be predicated on favorable comparisons between an adequate number of comparative data from the surrogate technology and data from isokinetic samplers collected for a sufficient time period over a broad range of flow and sedimentary conditions. Hence, the following sections focus primarily on methods for obtaining bed-material, suspended-sediment and bed-load data available at the advent of the twenty first century.

## 5.2 BED-MATERIAL MEASUREMENT TECHNIQUES

*P. Diplas*

### 5.2.1 Introduction

Many hydraulic, geomorphic, and ecological aspects of river behavior are closely linked to the characteristics of the material composing a river's streambed. Flood levels, sediment transport rates, and streambed stability, for example, depend on the grain-size distribution of the bed material. Similarly, the quality and quantity of stream habitats are greatly influenced by the amount of fine particles present in the streambed. Recent surveys undertaken by the U.S. Environmental Protection Agency (USEPA 1994) and the U.S. Fish and Wildlife Service (USDA 1994) concluded that stream siltation was the most important factor causing water quality impairment and adversely affecting fishery habitats in streams. Various best management practices, such as reforestation and slope stabilization, are typically employed to reduce sediment input into streams and thus minimize the adverse effects of fine sediment on stream ecology. To effectively gauge the success of these practices, the bed-material size distribution within streams must be monitored. It is therefore evident that there is a need to use accurate and efficient techniques for collecting, analyzing, and interpreting results obtained from bed-material samples.

### 5.2.2 Sediment-sampling Issues

For certain phenomena, and the feasibility study phases of some engineering projects, knowledge of the median grain size,  $D_{50}$ , or some other single sediment parameter might be adequate. However, for other cases, knowledge of the entire size distribution, and especially of its tails, might be essential. For example, channel grain roughness is typically associated with the coarser sizes of the bed material, e.g.,  $D_{90}$ , whereas

for spawning habitat studies the size of the finer portions, e.g.,  $D_{10}$ , is more critical (Waters 1995). An appropriate method should sample the correct bed-material population and collect the entire range of particle sizes available within it in a way that consistently and accurately represents the parent material distribution. The analysis of the sampled material should render an unbiased grain-size distribution, such as that typically provided from a volumetric sample analyzed in terms of weight through the use of a series of sieves. Furthermore, it is desirable to estimate the effort, or sample size, required to determine various sediment sizes with a certain accuracy or degree of precision.

The requirements stated here are rather difficult to meet in the field, especially for the case of gravel-bed streams. The difficulties stem from three ubiquitous characteristics of sediment deposits in gravel streams: the presence of a wide range of sediment sizes, from clay to gravel or coarser particles, which at times may span up to five orders of magnitude; the vertical stratification in terms of particle size (Church et al. 1987; Diplas and Sutherland 1988); and the considerable spatial variability, or patchiness, of bed surface sediments (Mosley and Tindale 1985).

Three distinct horizontal layers are typically present in gravel-bed streams. The top layer, or pavement, is in direct contact with the flow and thus dictates the grain roughness of the channel boundary and the stability of the channel bed. The makeup of the second layer, or subpavement, affects the quality of spawning grounds (Diplas and Parker 1992). The third, or bottom, layer represents the bulk of the subsurface material. Although all three layers seem to contain the same range of particle sizes, the top layer is usually the coarsest and the subpavement has the highest proportion of finer particles. Each of the top two layers is usually as thick as the coarsest particle size present and all three represent different sample populations. In some cases, for example when there is no excess infeed of fine sediment into a river reach due to human activities within the surrounding basin, the second layer is absent. It is this condition that is most frequently mentioned in the literature.

Not only does a gravel bed's composition change vertically, but also it varies laterally and longitudinally. On the stream reach scale, this inhomogeneity can easily be seen on a depositional bar, which contains several distinct areas each having a different particle composition (Bluck 1982; Diplas 1994), and in the contrast between the grain sizes found in pools and in riffles (Sear 1996). On larger scales, the fining of the bed material in the downstream direction has been well documented (Church and Kellerhals 1978; Parker 1991).

The results of extensive sediment sampling undertaken by numerous researchers indicate that there is not a single grain-size distribution type capable of describing the material in different fluvial deposits. Although the lognormal has been proposed in many textbooks as the distribution representing most fluvial sediments, in reality things are more complicated. For example, it has been suggested that in about 50% of the cases, samples obtained from gravel streams possess bimodal

distributions (Kondolf and Wolman 1993), whereas there is no convincing evidence to support the use of a single distribution even for materials located within the same stream.

The need to use proper procedures for collecting and analyzing bed-material samples, which take into consideration some of the features observed in natural streams, has only recently been recognized. Such procedures are necessary for field and laboratory studies as well as for calibrating and validating numerical models dealing with stream behavior. Considerable effort has been devoted to this subject during the past two decades.

### 5.2.3 Sample Collection and Analysis Methods

Some of the methods commonly used for sediment sampling include volumetric, grid, areal, transect, and photographic methods. The analysis of a sample may vary depending on the method used for collecting it.

Volumetric or bulk sampling is the method most commonly used in obtaining the size distribution of the grains in a sediment deposit. The extracted sample consists of a predetermined volume that is large enough so that its dimensions are independent of the dimensions of individual grains (Kellerhals and Bray 1971). The sample is then sieved, and the results are plotted in terms of grain (sieve) size versus percentage by weight passing that sieve size. One tonne of material is considered a practical limit for hand sieving (Church et al. 1987). Dry sieving is usually limited to particles having diameter equal to or coarser than 0.0625 mm. For particles smaller than this size, hydraulic settling methods are typically employed. These two methods may not provide equivalent measures of particle size. Bulk sampling procedures are appropriate for deposits that are isotropic with respect to grain size and other sediment properties (e.g., particle shape and density), such as sandy streams and the bottom layers of gravel streams. Bulk sampling is desirable because it provides unbiased estimates of the size distribution of the sediments available in the deposit. Strictly speaking, for the volumetric sample to be unbiased it should be analyzed in terms of the volumes occupied by the various grain sizes. However, when the specific weight of all the particles in the sample is the same, a condition that is typically met in most samples, this is equivalent to analyzing the sample in terms of weight through the use of the sieves. A question that arises is with respect to the minimum excavation depth necessary to render a sample volumetric. Experiments have indicated that the minimum depth required for a sample to be volumetric is about twice the size of the largest particle present in the sampled deposit (Diplas and Fripp 1992).

The pavement and subpavement layers, though, each having thickness roughly equal to the size of the coarsest particle present, have volumes that are dependent upon the size of the sediments and thus cannot be sampled volumetrically

(Kellerhals and Bray 1971). A volumetric sample of a gravel bed would combine the different sample populations found in the pavement, subpavement, and bottom layers. The resulting grain-size distribution would not accurately describe any of these layers. Therefore, in the presence of vertical size (or any other sediment property) stratification, it is necessary to devise surface-oriented methods that would be able to collect sediment from each stratum separately. Such methods should be able to infer three-dimensional information about the makeup of the sediment deposit from things represented on a two-dimensional surface.

Wolman (1954) was the first to introduce the use of the grid method for sampling fluvial sediments. This method is suitable for collecting sediment from a single layer of bed material such as the pavement. The sample consists of only the particles that lie directly below an established grid covering the area of interest. The grid may be established in several ways. A wire mesh may overlie the sampled area or for larger areas a pacing procedure may be used (Kellerhals and Bray 1971). A method used widely in the field is a variant known as Wolman's walk method. In this method an operator paces off at regular intervals and picks up the particle below his toe. Systematic sampling on a predefined, regular grid gives the highest accuracy for a given number of collected stones (Underwood 1970). Random sampling is not as efficient.

The particle's size is usually measured with a gravelometer (Hey and Thorne 1983). Gravelometers, shown in Fig. 5-2, are templates that contain square holes consistent with sieve openings. The smallest aperture that a particle can fit through is recorded as the grain size. Gravelometers are convenient for measuring particles that can be handled with one hand, up to about 216 mm (Church et al. 1987). However, some particles, even smaller than 216 mm, might be buried within the channel bed and thus it might be difficult to remove and measure them (Marcus et al. 1995). A gravelometer, together with waterproof paper or a tape recorder, makes it possible

Fig. 5-2. A gravelometer.

for a single operator to sample an area and record the number, size, and possibly location of stones with the help of a GPS apparatus or a well-defined grid, without retaining any of the material (Fripp and Diplas 1993). Larger or embedded stones, however, may have to be measured with a tape. In this case, the intermediate axis is the closest to a sieve diameter. The distribution is obtained by plotting the grain size versus the percentage of stones in the sample that are finer than this size. This method is a type of grid-by-number sampling. In the presence of very large, exposed boulders, areal photos might be necessary to account for their contribution to the overall grain-size distribution.

To reduce the effort spent in the field, an adaptation of the grid-by-number approach has been proposed, using photographs of a sediment deposit, together with a grid of known spacing (Ritter and Helley 1969; Adams 1979). Determining the actual dimensions of the particles from the photographs is the main difficulty encountered in this case. The results seem to be biased, typically smaller than the real particle sizes measured in the field (Kellerhals and Bray 1971; Church et al. 1987). This bias is attributed to imbrication angle, grain packing, shadow effects, and scale distortion, factors that tend to be variable from site to site. To overcome the limitations of the photographic method, Ibbeken and Schleyer (1986), among others, have proposed digitizing the particle outline from an enlarged print and then measuring its dimensions. The use of the photographic method is deemed to be adequate for estimating the median size of a sediment deposit, containing gravel and larger particles, with moderate accuracy (Church et al. 1987). Recent developments in image analysis hold promise for further improvements in the use of the photographic method (Russ and Dehoff 2000).

In the absence of any structural features within a riverbed, the grid spacing does not affect the outcome of a sampling exercise. The only requirement in this case is that if two or more grid points fall on the same particle, the particle must be counted as many times. However, in natural streams, particle clusters and other features tend to dominate the bed morphology (Church et al. 1987; Hassan and Church 2000). To avoid serially correlated results it is therefore recommended that the spacing between grid points be at least  $2D_{\max}$ , where  $D_{\max}$  is the largest particle size present in the sampled deposit (Rice and Church 1998). About 1,500 particles per day can be measured and recorded in an exposed area by a team of two operators using a gravelometer (Rice and Church 1996). The corresponding time for the case of a submerged deposit will be longer and will depend on the depth and temperature of the water.

An areal sample consists of all the grains that are exposed on the surface of a specified area. One can use wax, clay, or other adhesives, paint, and photographs to sample an area (Kellerhals and Bray 1971; Adams 1979; Diplas and Sutherland 1988; McEwan et al. 2000). If an area is spray-painted, the painted particles can later be picked by hand. Wax poured onto the surface of a sample will harden and remove all of the surface particles and possibly some below

that. The wax sample is melted and poured away, leaving the grains to be sieved. Moist pottery clay may also be used to obtain a surface sample; however, unlike wax, it can be used underwater as well as on dry surfaces, making it more suitable for field sampling (Diplas and Fripp 1992). A pistonlike apparatus, shown in Fig. 5-3, contains a round flat plate that is covered with a layer of clay. Surrounding the piston is a plastic shield, which protects the sample from the river's current. The piston is pushed against the surface material and retrieves the gravel sample. Finally, the sample is placed into a sieve with openings smaller than the smallest particle of interest and wet sieved to remove the clay (Fripp and Diplas 1993). The size distribution is obtained by plotting size versus percent weight in total sample. A sample recorded in this manner is known as an area-by-weight sample.

## 5.2.4 Bias of Sampling Methods

**5.2.4.1 Equivalence of Samples** Grid and areal sampling techniques allow collecting a sample from a specific population, such as the pavement and subpavement, but cannot be compared to one another because surface-oriented

**Fig. 5-3.** The device used to collect areal samples. A thin layer of clay has been applied on the flat plate inside the piston.

samples, like all nonvolumetric samples, are biased (Kellerhals and Bray 1971).

In general, for a sampling procedure to be unbiased, the exponent of the removed sample, expressed as  $D^y$ , minus the exponent of the method used for analysis, expressed as  $D^z$ , should be zero. This renders the sampling procedure dimensionless (Underwood 1970). For example, a bulk sample is unbiased because  $y = z = 3$ . Similarly, a grid sample analyzed by number is unbiased and equivalent to a volumetric sample because  $y = z = 0$ . The zero-dimensionality of these sampling and analysis methods allows the presentation of the results as a fraction or percent. Delesse (1848) was the first to show that the volume fraction of solids is equal to their area fraction captured in a planar section ( $y = z = 2$ ). The equivalency of the point count fraction and the volume fraction of solids was demonstrated for the first time by Thomson (1930). An areal sample, though analyzed in terms of weight, is biased. To convert such an areal sample into its volumetric equivalent, Kellerhals and Bray (1971) suggested the formula

$$p(V-W)_i = Cp_i(A) D_i^x \quad (5-1)$$

where

$p(V-W)_i$  = percentage of material retained on sieve size  $i$  based on a volumetric sample;

$p(A)_i$  = percentage of material retained on sieve size  $i$  by an areal sampling method;

$D_i = \sqrt{D_i D_{i+1}}$  = geometric mean of two consecutive sieve sizes  $i$  and  $i + 1$ ; and

$C$  = a constant that is used to adjust the sum of the converted volumetric equivalent percentiles to 100.

The exponent  $x$  is equal to  $y - z$ , and as such it depends on the type of adhesive used in collecting the sample. For example, when an adhesive that removes only the rocks found at the very top of the sampled surface was used ( $y = 2$  and  $z = 3$ ), as with clay or adhesive tape, laboratory tests indicated that  $x = -1$ , in agreement with the theory (Diplas and Sutherland 1988). However, when wax was used as the adhesive,  $x$  attained an average value of  $-0.47$  (Diplas and Fripp 1992). Furthermore, the exponent for all the clay samples remained relatively constant, whereas the exponent for the wax samples varied significantly depending on the wax temperature and the makeup of the bed material. Wax penetrates the pores of the surface material and picks up subsurface grains, rendering the sample partly volumetric rather than strictly areal ( $2 \leq y \leq 3$ ) (Church et al. 1987; Diplas and Fripp 1992). As a result, the value of the exponent  $x$  for wax samples can vary between  $-1$  and  $0$  (Diplas and Sutherland 1988). Therefore, wax does not consistently remove the same material and should be avoided as an adhesive for sampling. Fig. 5-4 shows a clay sample analyzed by weight and a volumetric sample, both obtained from the same deposit. Whereas the areal sample

significantly overestimates the grain-size characteristics of the sediment deposit, the converted size distribution (using Eq. 5-1 with  $x = -1$ ) is close to the distribution obtained from the volumetric approach. As explained earlier, a grid-by-number sample is unbiased and thus the exponent  $x$  becomes zero. This is demonstrated in Fig. 5-5 for a sample of known volumetric size distribution. A complete list of the values of the exponent  $x$  necessary to convert a sample collected and analyzed with one method to that of another is shown in Table 5-1.

An approach to sampling a sediment deposit that has been suggested in the literature is to remove all the material up to the depth of the largest particle present and analyze it by weight. Such a sample provides a volumetric representation of the smallest grains, an areal representation of the coarsest grains, and in between for the intermediate sizes. In this case  $2 \leq y \leq 3$  and  $z = 3$ . A more accurate statement, though, would be that  $y = 3$  for the smallest grains,  $y = 2$  for the coarsest ones, and  $2 < y < 3$  for the

**Fig. 5-4.** A clay sample analyzed by weight (triangles) and converted using Eq. 5-1 with  $x = -1$  (squares). Diamonds represent the results of a volumetric sample of the same deposit analyzed by weight.

**Fig. 5-5.** Results of a 400-stone grid sample performed on a natural sediment deposit with the actual grain-size distribution curve.

**Table 5-1 Conversions Based on the Recommendations of Kellerhals and Bray (1971)**

Conversion From	Conversion to								
	Volume-by-weight	Volume-by-area	Volume-by-number	Grid-by-weight	Grid-by-area	Grid-by-number	Area-by-weight	Area-by-area	Area-by-number

intermediate sizes. Therefore, this procedure is biased, resulting in a sample that overestimates the degree of coarseness of the material. To render this sample unbiased, it is necessary to use different values for the exponent  $x$  in Eq. (5-1) for the different parts of the sampled material, with  $x = 0$  for the smallest particles and  $x = -1$  for the coarsest (see Fig. 5-4 in Diplas and Fripp 1992). An average value of  $x$  is typically employed in Eq. (5-1) to obtain the approximately equivalent volumetric distribution. Although this value depends on the makeup of the particular deposit, a limited number of tests have indicated that  $x \approx -0.4$  for samples having a depth of about  $D_{90}$  (Diplas and Fripp 1992).

In most cases, the exponent in Eq. (5-1) assumes values different from unity. This suggests that nonvolumetric samples are nonlinearly biased. Therefore, samples that are not volumetric equivalents cannot be compared directly with each other, even if the samples are collected and analyzed by the same method (Diplas 1992; Diplas and Fripp 1992). In other words, each non-volumetric sample has its own bias, which depends on the sampling method used and the actual size distribution of the sampled deposit, and must be converted to a volumetric (unbiased) equivalent before comparing it to a sample taken by the same or another method. This is demonstrated in Fig. 5-6, which shows the size distributions of two samples obtained by the use of clay from two different deposits and analyzed by weight through the use of sieves. These deposits have volumetric grain-size distributions with identical median values (8 mm) but different standard deviations. The corresponding median values of the areal samples analyzed by weight, however, are 14.5 and 22.8 mm. Thus, an appropriate method must first sample the correct population, and second convert it to a volumetric equivalent.

**5.2.4.2 Truncation of Sample Populations** Sediment size distributions also become biased when the technique employed cannot sample the entire range of grain sizes in a representative way, thus resulting in a truncated sample.

**Fig. 5-6.** Clay samples (open symbols) of two sediment deposits and the corresponding volumetric samples (solid symbols).

Truncation can occur at either the lower or upper end of a size range. When material smaller or larger than a specific size is truncated from the sample, it changes the frequency distribution of the particles and all its statistical measures (Fripp and Diplas 1993). It is difficult to determine the degree of change because the percentage of the bed material that belongs to the truncated portion of the sample is unknown. Truncation, besides its effect on determining  $D_{50}$  and other statistical parameters, may severely affect the estimates for  $D_{90}$  and  $D_{10}$ .

Truncation of the smaller size particles occurs in the Wolman's walk method and similar grid-sampling techniques. The reason for this is the inability of an operator whose eyes are averted from the sampled location to distinguish among

particles smaller than about 15 mm, approximately the width of the index finger, in an unbiased way (Fripp and Diplas 1993). Other researchers suggest that, for a properly trained person, truncation for grid samples starts between 2 and 8 mm (Wolman 1954; Kellerhals and Bray 1971). The more conservative values would be appropriate for sampling under water, where the problem becomes even more difficult because of low water temperature and the use of gloves by operators. One way to partially remedy the problem when the operator is unable to choose between two or more small particles is to designate that the outcome of the trial resulted in a particle smaller than a predetermined size, say 10 mm. Although the shape of the grain-size distribution below this size is not known, the proportion of these particles is estimated, thus avoiding a truncated sample (Petrie and Diplas 2000).

Truncation of the larger particle sizes may occur when clay, or some other adhesive, is used to obtain an areal sample in the presence of very coarse particles. For example, clay is only capable of consistently removing particles less than about 40 mm (Diplas and Fripp 1992).

**5.2.4.3 Operator Error** The accuracy of a grid sample is influenced by random and systematic errors. The former are due to the natural variability of the grain sizes present within the sediment deposit and their significance is reduced as the sample size increases, according to some statistical criteria. The latter are associated with biases exhibited by the operator and are not affected by the sample size (Hey and Thorne 1983). As a result, as the sample size increases, differences between samples obtained by different operators become more pronounced. Unless special precautions are taken, Hey and Thorne (1983) concluded that systematic, operator-related errors become the dominant type for grid samples exceeding 100 particles. There are two major sources of operator bias: (1) inappropriate selection of particles, and (2) erroneous measurement of their size (Hey and Thorne 1983; Marcus et al. 1995). The first can be rectified by using well-defined grid points that unambiguously identify the particle to be chosen. This is more difficult to accomplish under submerged conditions. Selection and measurement of particles below a size that operators cannot distinguish (e.g., 10 mm) should also be avoided. Much larger errors are exhibited within this smaller size range when samples obtained by different operators are compared (Marcus et al. 1995). The second operator bias can be corrected by using a consistent and repeatable means of measuring the particle size, such as the gravelometer. The best strategy for curtailing systematic sampling errors is to provide the operators with thorough training in the field. It has been suggested that, when possible, a single, carefully trained operator be employed to monitor changes in a sediment deposit over space or time (Hey and Thorne 1983; Marcus et al. 1995; Wohl et al. 1996). Although such an approach does not necessarily preclude the occurrence of bias, it has the potential for providing more consistent results.

## 5.2.5 Sample Size and Accuracy

**5.2.5.1 Determining Sample Size** If truncation is not a problem, and a sample is converted to a volumetric equivalent, an unbiased sample has been obtained. However, one important issue remains, and that is its accuracy. How accurate a sample needs to be can vary depending on what the results are being used for. The accuracy with which a sample describes the true statistical parameters of the bed material depends a great deal on its size, the shape of its size distribution, and its standard deviation. Typically, the larger the sample size, the higher the accuracy. Unfortunately, sampling large amounts of material is often physically or economically impractical. Considerable effort has been spent on calculating the minimum sample size needed to obtain a desired level of accuracy. Normally, the sample size is determined either by weight or by the number of stones.

**5.2.5.2 Sample Size Determined by Number** The size of grid sample necessary to provide consistent estimates of the mean grain size of a sediment deposit has been discussed frequently in the literature. Originally, Wolman (1954) suggested that 100 stones constituted an adequate sample size. Bray (1972) and Church and Kellerhals (1978) found that samples of 50 stones were sufficient. Hey and Thorne (1983) stated that samples as small as 40 stones provide repeatable estimates of the mean grain size, whereas Mosley and Tindale (1985) suggested 70 particles, and Edwards and Glysson (1999) indicated that at least 100 pebbles should be collected. Based on these results and the experience of others (e.g., Yuzyk 1986; Kondolf 1997), it is proposed that 100-stone grid samples be used to provide routine estimates of the sediment mean grain size.

Even more important to consider, though, is the development of methods that specify the sample size necessary to determine a certain sample characteristic, e.g., the median particle diameter, with a desired level of accuracy after the collected material has been analyzed. The level of accuracy may be considered in absolute terms, e.g., mm or  $\phi$  (phi) units, or in relative terms, e.g., percent error. The results of a grid-by-number procedure are presented in terms of frequency by number, a process that is well suited to statistical treatment. Statistical methods can be used in a variety of ways. If the distribution type describing the particle sizes available in a deposit, together with an estimate of its mean and standard deviation values, is known beforehand, well-established methods that are easily accessible from books can be employed (e.g., Gilbert 1987). If such information is not available, as is typically the case, either a two-stage sampling approach or methods that do not require prior knowledge of the distribution should be used.

The first step in a two-stage sampling scheme is to undertake a preliminary or pilot sampling program that will provide an advance estimate of the variation that a particle size of interest, e.g.,  $D_{84}$ , exhibits (Durand 1971). These

results can be used to guide the extent of the sampling effort required to determine this size with a desired degree of accuracy and confidence level. Student's  $t$ -distribution can be used for that purpose (Gilbert 1987; Durand 1971). This approach is recommended by the International Organization of Standards (ISO 1992).

The bootstrap (Rice and Church 1996) and the binomial (Fripp and Diplas 1993) are two methods that can be used to estimate the sample size necessary to determine the confidence intervals around a *specific* grain-size percentile without knowing or making any assumptions about the grain-size distribution type of the sampled deposit (Petrie and Diplas 2000). The bootstrap is a numerically intensive method that requires a grid sample that is sufficiently large, possibly in excess of 1,000 or even 2,000 stones (Sprent 1998), to accurately represent the population grain-size distribution of the parent material. The sizes of all these stones are recorded and subsequently stored in a computer. The standard error for a given percentile is determined by considering its variation obtained from a great number of subsamples, all drawn from the large grid sample in a random fashion through the use of a computer program. Each subsample has the same number of particles and represents a replicate sample that could have been made in the field. To obtain stable error estimates, it is recommended that more than 100, and preferably closer to 200, sub/replicate samples be considered (Efron and Tibshirani 1991; Rice and Church 1996). The largest subsample size considered with the bootstrap

method should not exceed one-third the size of the actual grid sample collected in the field.

The use of binomial distribution for grid sampling was initially suggested by Fripp and Diplas (1993) and modified by Petrie and Diplas (2000) for estimating grid sample errors at specified percentiles. The binomial distribution considers only two possibilities for each particle sampled: (1) it is within a specified size class (e.g., smaller than a certain size) or (2) it is outside the specified size class (Ott 1988). Fig. 5-7 shows the way that the results of this approach can be used when the percentiles of interest are  $D_{50}$ ,  $D_{16}$ , and  $D_{84}$ . Based on the accuracy level required, 95% in this case, the necessary sample size that will allow an acceptable error band is determined. For example, a grid sample of 100 stones is necessary to keep the confidence intervals around the median size  $D_{50}$  within  $\pm 10\%$  ( $D_{40}$  and  $D_{60}$  of the grain-size distribution). The error around  $D_{50}$  in absolute terms, e.g., mm or  $\phi$  (phi) units, is determined after the sample has been collected, analyzed, and plotted in terms of a frequency-by-number distribution so that  $D_{40}$  and  $D_{60}$  can be determined. It is through this last step that the standard deviation of the grain-size distribution is factored in the error estimate. Fig. 5-8 provides a graph for determining the error bands for  $D_{10}$ ,  $D_{30}$ ,  $D_{70}$ , and  $D_{90}$  at 95% accuracy levels, or confidence coefficient,  $\alpha$ , of 0.05. The validity of this approach has been verified through extensive laboratory tests and computer simulations (Diplas and Crowder 1997; Petrie and Diplas 2000).

Except for the case of median size, the confidence intervals obtained through the use of the exact binomial

Fig. 5-7. Binomial sample size determination graph for  $D_{16}$ ,  $D_{50}$ , and  $D_{84}$  for  $\alpha = 0.05$ .

Fig. 5-8. Binomial size determination graph for  $D_{10}$ ,  $D_{30}$ ,  $D_{70}$ , and  $D_{90}$  for  $\alpha = 0.05$ .

distribution are not symmetric around a specified percentile (Figs. 5-7 and 5-8). As can be seen from Figs. 5-7 and 5-8, the largest percentile error for a given sample size is always that for the median grain size. This does not necessarily mean that  $D_{50}$  suffers the largest error in absolute terms. As a matter of fact, because the part of the cumulative distribution around  $D_{50}$  tends to have the steepest slope, the median size will typically have the smallest absolute error. Similarly, the fact that two percentiles equidistant from the median size, e.g.,  $D_{10}$  and  $D_{90}$ , have the same relative percent error (Fig. 5-8) does not mean that these sizes will have the same absolute error in mm or  $\phi$  units as well, except for the case of a symmetric distribution. The absolute error depends on the shape of the distribution surrounding the percentile of interest. Thus, the binomial approach supports the well-accepted notion that for a distribution that is skewed toward the coarser grains, a given sample size will result in better estimates of the coarser particles, e.g.,  $D_{90}$ , than the finer particles, e.g.,  $D_{10}$ . Furthermore, for two distributions having the same numerical value for a certain percentile, e.g.,  $D_{50}$ , but different overall ranges of particle sizes, or different standard deviations, the relative percent error will be the same but the absolute error will be larger for the distribution having the larger standard deviation (Fripp and Diplas 1993).

The curves describing the confidence intervals in Figs. 5-7 and 5-8 approximately follow the expression  $1/\sqrt{n}$ , where  $n$  is the number of stones in the sample. This suggests that if a sample is quadrupled in size, a 50% reduction of the per-

centage error results. For example, Fig. 5-7 indicates that a 400-stone sample provides confidence intervals at a distance of  $\pm 5\%$  around the median diameter, compared to  $\pm 10\%$  for a sample of 100 stones. It is therefore suggested that for  $\alpha = 0.05$ , sample sizes larger than 400 stones are not warranted for most studies, because significantly greater effort is required to achieve relatively modest gains in accuracy (Fripp and Diplas 1993; Rice and Church 1996).

The use of the exact binomial distribution in calculating the required sample size,  $n$ , given the particle size value of interest ( $p_i$  in percent, e.g.,  $D_{84}$ ), the desirable accuracy level,  $\alpha$ , and the maximum allowable error,  $E$ , requires a rather tedious iterative procedure. Nowadays, though, computer programs are available for these types of calculations. Another, much simpler approach would be to employ the normal approximation of the binomial distribution. This approximation is valid when both  $np_i$  and  $n(1-p_i)$  are larger than 20, whereas for values between 5 and 20 it can still be employed, especially if the continuity correction is implemented (Ott 1988). Experience has shown that, except for the case of small sample size and the case of the particle size of interest being very fine or very coarse, the estimates obtained by the normal distribution approximate those obtained through the exact binomial fairly well. The required sample size,  $n$ , based on the binomial approximation is estimated by the expression

$$n = \frac{z_{(\alpha/2)}^2 p_i (1-p_i)}{E^2} \quad (5-2)$$

where

$z_{(\alpha/2)}$  = a value obtained from tables prepared for the normal distribution curve for a given confidence interval of  $100(1-\alpha)$ .

As can be seen from Eq. (5-2), in contrast to the results provided by the exact binomial, the normal approximation of the binomial distribution results in symmetric confidence intervals, with the upper confidence limit for  $p_i$  given by  $\tilde{p}_{iu} = p_i + E$  and the lower limit by  $\tilde{p}_{il} = p_i - E$ .

Whenever it is desirable to generate confidence intervals about the entire grain-size distribution, the multinomial distribution needs to be employed to account for all possible outcomes of sieve analysis dictated by the number of particle size classes considered (Burdick and Graybill 1992; Petrie and Diplas 2000). Whereas the binomial and bootstrap methods deal with a single size or percentile, one confidence interval at a time, the multinomial approach deals with all size classes at the same time, simultaneous confidence intervals. Therefore, a simultaneous confidence interval with a confidence level of  $\alpha$  around a grain-size curve states that there is a probability of  $(1-\alpha)$  that the population grain-size curve is within the confidence interval at each size class. As a result, simultaneous confidence intervals are wider than one-at-a-time intervals. The additional parameter that needs to be considered in the multinomial case is the number of sieves or size classes. Even though this number is not known before the sample is collected, it can be estimated by surveying the site and making a visual approximation of the largest and smallest particles present in the deposit. The

range of sizes between these two particles, together with the estimated number of particles that need to be removed, will dictate the number of sieves necessary for the analysis of the sample (Emerson and Hoaglin 1983; Russ and Dehoff 2000). Fig. 5-9 shows the error bands around the median size diameter, with  $\alpha = 0.05$ , calculated using the multinomial distribution for different numbers of sieves  $k$  (Petrie and Diplas 2000). The binomial distribution is a special case when  $k = 2$ . The Goodman (1965) method, one of several techniques that have been proposed for calculating simultaneous confidence intervals for multinomial proportions, has been used to draw these curves. This method is relatively easy to use and consistently meets the required confidence coefficient (May and Johnson 1997). The formula proposed by Goodman is as follows,

$$n(p_i - \hat{p}_i)^2 = \chi_{\alpha/k, 1}^2 \hat{p}_i (1 - \hat{p}_i) \quad i = 1, 2, \dots, k \quad (5-3)$$

where

$n$  = sample size;  
 $p_i$  = sample estimate for proportion of size class  $i$ ;  
 $\tilde{p}_i$  = confidence interval proportions for size class  $i$ ; and  
 $\chi_{\alpha/k, 1}^2$  = upper  $100(1-\alpha/k)$  percentage point of the  $\chi^2$  distribution with one degree of freedom.

Equation (5-3) provides two  $p_i$  values for each size class considered, one corresponding to the proportion for the upper confidence interval ( $\tilde{p}_{iu} = p_i + E_{iu}$ ) and another for the lower confidence interval ( $\tilde{p}_{il} = p_i - E_{il}$ ). For the median size

Fig. 5-9. Error bands around  $D_{50}$  for different grid sample sizes and numbers of sieves  $k$  obtained using the multinomial distribution ( $\alpha = 0.05$ ).

( $p_i = D_{50}$ ),  $E_{50u} = E_{50l}$ , whereas for every other percentile the upper and lower errors are different.

Fig. 5-9 indicates that a 180-stone grid sample is necessary for estimation of the median size within  $\pm 10\%$  when eight sieves are used to analyze it. This is 80% larger than the binomial results for the same error bands (Fig. 5-7). Another way of presenting the multinomial results is shown in Figs. 5-10 to 5-12. In all these cases, the number of stones that need to be collected is determined when the maximum acceptable error,  $E$ , the confidence level,  $\alpha$  ( $= 0.05$  in all these plots), and the number of sieves that will be used for the analysis are known. Because for the case of the median size the error bands are symmetric, one figure is sufficient (Fig. 5-10). For any other percentile, two figures are necessary, one for the upper and another for the lower confidence limits. Figs. 5-11 and 5-12 represent the respective figures for  $D_{84}$ . The expression in Eq. (5-3) dictates that for two grain sizes  $D_i$  and  $D_j$  with  $i + j = 100$ ,  $E_{iu} = E_{ju}$  and  $E_{il} = E_{jl}$ . Therefore, Figs. 5-12 and 5-11 can be used to determine the upper and lower confidence limits, respectively, for  $D_{16}$ . An example showing the entire grain-size distribution obtained from a 50-stone grid sample together with the confidence intervals determined from the multinomial distribution for  $\alpha = 0.05$  and  $k = 10$  is drawn in Fig. 5-13. For comparison purposes, the exact binomial confidence intervals for the same sample are also included in this figure.

The binomial/multinomial approaches estimate the sample size based on a desirable/acceptable error presented in terms of percentage points. This might be preferable to error estimates in terms of absolute units because in the former

case the error scales with the properties of the unknown distribution and its particle sizes. For an appropriate choice of error in terms of absolute units it is necessary to have prior knowledge of the grain size to be considered.

Grid-by-number is the most efficient technique for sampling sediment. It requires the smallest sample size for achieving a given degree of accuracy (Petrie and Diplas 2000; Russ and Dehoff 2000). For nonuniform deposits exhibiting spatial variation in the bed-material size, use a grid of constant size. This approach will sample the various patches proportionally (make grid size sufficiently small to capture the contribution of the patches). Reporting the data in an array form can reveal the spatial characteristics exhibited by the bed material. The method developed by Crowder and Diplas (1997) can be used to identify boundaries of sediment patches and other variations in terms of grain size.

**5.2.5.3 Sample Size Determined by Weight** The volumetric method is the approach most commonly used for sampling and analyzing mineral aggregates. It is not surprising, therefore, that a large number of recommendations regarding appropriate sample size have been put forth by various researchers and organizations (De Vries 1970; Mosley and Tindale 1985; Church et al. 1987; Fripp and Diplas 1993; Ferguson and Paola 1997; Bunte and Abt 2001). It is worth mentioning that the methods described here can also be used to calculate the weight of material that needs to be collected with bed or suspended-load sampling devices to determine their size distribution or just a representative grain size.

The most widely quoted criteria for sample volumes of fluvial sediments are those proposed by De Vries (1970)

**Fig. 5-10.** Multinomial sample size determination graph for  $D_{50}$  with  $\alpha = 0.05$ . Petrie and Diplas (2000). Copyright 2000 American Geophysical Union. Reproduced by permission of American Geophysical Union.

**Fig. 5-13.** Fifty-stone grid sample results and actual grain-size distribution with 95% multinomial ( $k = 10$ ) and binomial confidence intervals.

and Church et al. (1987). De Vries suggested bulk samples expressed in terms of mass,  $m$ , to satisfy three accuracy levels, high, normal, and low. The required total sample mass is obtained as a function of the mass of the  $D_{84}$  grain size and can be expressed as follows (Bunte and Abt 2001):

$$m = 0.8 \times 10^{\beta} \rho_s D_{84}^3 \quad (5-4)$$

where meters and kilograms are the units of all the terms. The coefficient of 0.8 is based on empirical results obtained from laboratory experiments with sand and fine gravel ( $D < 14$  mm); its value might be different for sizes and shapes other than those used by De Vries. The exponent  $\beta$  takes the value of 5 for high, 4 for normal, and 3 for low level of accuracy. Prior knowledge, or estimation, of  $D_{84}$  is necessary to determine the sample mass. Because 1 t of material is typically considered the practical limit for hand sieving, excessive amounts of material are required to meet the high-accuracy criterion for sediments coarser than fine gravel. This is a typical requirement of the various methods that have been suggested for volumetric sampling. Although this appears to be a major limitation, the fact is that grain-size stratification in gravel streams precludes the use of the volumetric method in streams that do not possess predominantly sandy or fine gravel sediment deposits.

To provide guidance for obtaining accurate, yet manageable volumetric samples, Church et al. (1987) suggested a sliding method that provides the necessary sample mass based on the  $D_{\max}$  particle size present in the deposit. For bed material with  $D_{\max} < 32$  mm,  $32 \text{ mm} < D_{\max} < 128$  mm, and  $D_{\max} > 128$  mm they suggested that the sample mass,  $m$ , be 1,000, 100, and 20 times the mass of  $D_{\max}$ , respectively. One problem with this approach is that the resulting expression is not a monotonic function of the mass of  $D_{\max}$ . More specifically, deposits having  $D_{\max}$  values near the beginning of one of the larger two size ranges require smaller sample masses than deposits having  $D_{\max}$  values near the end of the previous size

range. To remedy this problem and unite the three sample-mass criteria, Yuzyk (1986) proposed a staircase approach, whereas Bunte and Abt (2001) fitted the following regression equation through the corner points of the staircase function,

$$m = 2,882 D_{\max} - 47.6 \quad (5-5)$$

with  $m$  in kilograms and  $D_{\max}$  in meters. Equation (5-5) should be used for  $D_{\max} > 32$  mm, whereas the Church et al. criterion should be employed for  $D_{\max} < 32$  mm. It is evident that the Church et al. method and its variations do not maintain consistent accuracy levels for the various size ranges. Furthermore, these methods do not account for the effect of standard deviation (e.g., Gale and Hoare 1994).

To obtain consistent results and volumes that are determined on the basis of a desirable degree of accuracy, two-stage sampling methods need to be employed (Hogan et al. 1993; Ferguson and Paola 1997; Petrie and Diplas 2000). During the first stage, a sample is obtained to approximate the size distribution of the parent material or some of its main characteristics, such as  $D_{50}$  and standard deviation. Hogan et al. proposed computer-generated replicate samples, whereas Petrie and Diplas suggested nonlinear transformations of grid-by-number plots and their confidence intervals for determining the necessary volumetric sample size. Though both of these methods are nontrivial to carry out, they are valid for any grain-size distribution. Ferguson and Paola have provided simpler expressions for calculating the sample volume; however, their results are limited to deposits having lognormally distributed particle sizes.

## 5.3 SUSPENDED-SEDIMENT SAMPLERS AND SAMPLING METHODS

*J. Gray, D. Glysson, and T. Edwards*

### 5.3.1 Introduction

This section focuses on collection of suspended-sediment data. It includes criteria for a sediment data set; descriptions of manual suspended-sediment samplers and methods for their deployment; description, installation, and operation of automatic samplers; and a summary of equipment used for obtaining water-sediment subsamples.

The origins of suspended-sediment sampling and transport measurements go back at least to 1808, when Gorsse and Subuors collected samples of the Rhone River at Arles, France. Baumgarten's samples collected in the River Garonne at Marmande, France, from 1839 to 1846 resulted in what were probably the first sediment discharge computations. Sediment discharge measurements in the United States began in 1838 when Captain Talcott sampled the Mississippi River. The fluvial sediment measurements made in the Rio

Grande at Embudo, New Mexico, beginning January 15, 1889 represent the beginning of the U.S. Geological Survey's sediment program (Glysson 1989a). Fluvial sediment measurements have been made regularly in the Rio Grande since 1897; the lower Colorado River since 1909; and the upper Colorado River basin since 1925. A detailed investigation of sediment loads starting in 1942 as part of the Missouri River Project included determination of the feasibility of storage reservoirs on streams transporting heavy sediment loads. Beginning in about 1930, extensive sediment surveys have been made in many other streams of the United States (FISP 1940; Nelson and Benedict 1950; Glysson 1989a; Turcios et al. 2000; USGS 2000b; Turcios and Gray 2001). After the end of World War II, the number of sites at which the USGS collected daily suspended-sediment data increased rapidly, peaking at 360 in 1982 (Glysson 1989a; Osterkamp and Parker 1991). By 2003, only 120 daily-record sediment sites were being operated in the 50 states, although suspended-sediment and bed-load data were being collected periodically at 615 and 49 sites, respectively (USGS 2004).

The earliest suspended-sediment samples were collected using instantaneous samplers, such as the open container or pail used by Riddell in the lower Mississippi River at New Orleans from 1843 to 1848 (Nelson and Benedict 1950). Subsequently developed samplers included those that could be filled at a selected depth below the water surface and horizontal trap-type samplers that aligned in the direction of flow (FISP 1940). After 1900, and particularly during the period from 1925 to 1940, many new sediment samplers were developed. By 1939, at least nine different types of sediment samplers were being used by U.S. Federal agencies (Glysson 1989a). Most of the samplers had been developed by independent investigators, lacked calibration, and were deployed using various operating techniques. A survey of sediment-sampling equipment used in the United States indicated that the 30 instantaneous samplers studied had very limited applicability, either because of poor intake-velocity characteristics or because of the short filament of water-sediment mixture sampled (FISP 1940; 1941; Nelson and Benedict 1950). As a consequence, data reliability and comparability suffered. For example, a consistent decrease in suspended-sediment discharges measured at gauges in the Colorado River Basin—originally attributed to changes in climatic, land use, or other factors—was probably the result of bulk oversampling of sediment by the Colorado sampler, a weighted bottle-type sampler (FISP 1940) used in the southwest United States from the 1920s to the 1940s. Tests of the Colorado sampler by Topping et al. (1996) found that the Colorado sampler preferentially oversampled coarser material, resulting in overestimation of the mass of suspended-phase material by a factor of about 3. This conclusion is consistent with mid-1940s changes in slope in the relations between water discharge and suspended-sediment discharge for three Colorado River Basin stream gauging sites (Thompson 1982; 1984; 1985), although comparative tests at the San Juan River

near Bluff, Utah, indicate that the Colorado River Sampler collected an average of 82% of the sediment mass obtained by the US D-43 suspended-sediment sampler (Nelson and Benedict 1950). The US D-43 sampler, which replaced the Colorado River Sampler in the mid-1940s, and subsequently developed isokinetic samplers sample the water-sediment mixture isokinetically, that is, collecting a filament of water at the ambient stream velocity, thereby providing an unbiased sample for subsequent sedimentary analysis.

Paul C. Benedict, the principal U.S. Geological Survey (USGS) engineer involved in the midcentury development of sediment-sampling equipment, once remarked in relation to sampler development during the 1920s and 1930s that “all this development work was being done with no knowledge of the physical laws governing the transport of sediment or of the intake characteristics of the samplers themselves” (Glysson 1989a). The data obtained by the different investigators during this period were not comparable, nor could their accuracy be evaluated. It became apparent that consistent and comparable sediment data could not be obtained unless equipment and data-collection and analytical methods were standardized.

In 1939, various agencies of the U.S. government organized an interagency program to study methods and equipment used in measuring the sediment discharge of streams, and to improve and standardize equipment and methods where practicable (FISP 1941). The Federal Interagency Sedimentation Project (FISP) (Skinner 1989; Glysson and Gray 1997) was created under the sponsorship of the Committee on Sedimentation of the Federal Water Resources Council. The comprehensive study of sampling equipment included suspended-sediment, bed-load, and bed-material samplers. As a result of research conducted by the FISP and others, an integrated system of sediment samplers, sampling, and analytical techniques has been developed and is widely used around the world.

### 5.3.2 Criteria for a Sediment Data Set

Collection of data to enable reliable sediment-transport estimates is often difficult, time-consuming, and expensive. It is frustrating to obtain data for a location and set of conditions of interest, only to subsequently discover that not all of the requisite parameters were quantified (Glysson 1989b), or that the collected data were inappropriate for the analysis at hand.

The types of data required depend on the goals of the assessment and the intended storage medium for the data. For example, sediment-concentration and water-discharge data are needed to compute continuous records of suspended-sediment discharge (Porterfield 1972; Koltun et al. 1994; McKallip et al. 2001). Other relevant data include particle-size distributions of suspended sediment and bottom material. The integrity of large-scale, long-term monitoring programs, such as the Vigil Network (Osterkamp and Emmett 1992),

or that proposed for North America (Osterkamp et al. 1998; 2004), the United States (Osterkamp and Parker 1991), and Canada (Day 1991), is particularly dependent on the reliability and comparability of the data collected.

The most reliable databases accept only selected data types representing sediment and ancillary variables obtained using a consistent set of protocols. For example, sediment data stored by the USGS as part of the National Water Information System—World Wide Web (NWISWeb) and other databases (Turcios et al. 2000; USGS 2000a; 2000b; Turcios and Gray 2001) are collected by techniques described by Edwards and Glysson (1999) and analyzed in a USGS-approved laboratory by techniques described by Guy (1969); Matthes et al. (1991); Knott et al. (1992; 1993); and the USGS (1998a; 1999).

One commonly used analogue for suspended-sediment concentration—total suspended solids (TSS)—is not comparable to suspended-sediment concentration data under some circumstances, and fundamentally is unreliable when applied to open-channel flows (Gray et al. 2000; USGS 2001). TSS data tend to underestimate suspended solid-phase concentrations, by a proportionate amount of 25% to 34% (Gray et al. 2000). This tendency has important ramifications for computing sediment discharges. Instantaneous sediment discharges computed from TSS data may differ substantially from those computed from suspended-sediment concentrations and the same water-discharge time series, with the TSS-generated loads usually biased low (Glysson et al. 2001). This result is of particular concern for sites where the percentage of sand-size material in water samples can exceed about a quarter of the sediment mass percent and where concentrations of sand-size material in transport increase with flow. No broadly applicable and reliable means of adjusting TSS data to estimate suspended-sediment concentration data in open-channel flow has been identified (Glysson et al. 2000).

Glysson (1989b) divided data-set requirements for computing sediment transport using the more common sediment-transport equations for noncohesive sediments into three categories: sediment, hydraulic, and others. Required sediment parameters include suspended-sediment concentration, bed-material particle-size distributions, particle specific gravity, and bed load discharge and particle-size distributions when bed load is the target parameter. Additional sediment parameters are specific diameters, sample method of collection, sampler and nozzle type, the analyzing laboratory, and the method that is used to analyze the samples.

Water discharge, watercourse stage, cross-sectional geometry, width, depth, area, hydraulic radius, and a slope parameter are required hydraulic parameters. Water temperatures should always be measured. Other parameters to be measured include a roughness coefficient, particle shape, bed-form information, and dissolved-solids concentrations. A site description that may include a channel classification based on one or more channel classification schemes should be included.

### 5.3.3 Units of Measurement

The concentration of suspended sediment is reported in milligrams of sediment per liter of water-sediment mixture (mg/L). However, as a matter of convenience, it is determined in the laboratory in parts per million (ppm), which is the dry weight of suspended material per million equal weights of water-sediment mixture (Porterfield 1972). The units of mg/L and ppm are equivalent at concentrations less than 8,000 mg/L. The equivalent value for mg/L at concentrations  $\geq 8,000$  ppm can be calculated using the equation

$$C_{\text{mg/L}} = C_{\text{ppm}} / (1 - C_{\text{ppm}} (6.22 \times 10^{-7}))$$

where

$C_{\text{mg/L}}$  = sediment concentration, in mg/L; and  
 $C_{\text{ppm}}$  = sediment concentration, in ppm.

### 5.3.4 Samplers and Sampling Methods

The purpose of a suspended-sediment sampler is to obtain a representative sample of the water-sediment mixture moving in the stream in the vicinity of the sampler intake. There are two categories of suspended-sediment samplers: manually operated samplers and automatic samplers. Manually operated samplers include instantaneous and isokinetic samplers. Isokinetic samplers include those with rigid sample bottles (bottle samplers) and with flexible bags (bag samplers). Additional information on samplers for sediment and other water-borne constituents can be obtained from the Federal Interagency Sedimentation Project (FISP 2000; Davis 2005).

#### 5.3.4.1 Manually Operated Samplers

**5.3.4.1.1 Instantaneous Samplers** Instantaneous samplers are applicable for sampling flows that do not meet the following criteria for deployment of an isokinetic sampler: sampling depths of greater than about 0.3 m and mean velocities greater than approximately 0.5 m/s. At small depths, the part of the stream from the streambed to the isokinetic sampler nozzle, referred to as the unsampled zone, becomes unacceptably large with respect to the total depth. At small velocities, only silt- and clay-size material typically is in suspension, and these finer size fractions tend to be fairly uniformly distributed with depth (Colby 1963; Guy 1970). Under these circumstances, an instantaneous sample from the water column may provide a reasonably accurate estimate of the concentration at the sampled point, or in the sampled vertical. Instantaneous samplers may also be deployed at flow velocities too high to submerge an isokinetic sampler, or when the presence of debris makes normal sample collection dangerous or impossible.

Although nonisokinetic samplers may provide acceptable results under certain sediment-transport conditions, such as when fine material constitutes all or nearly all of the

sediment load, conditions for which nonisokinetic sampling is appropriate are often not apparent at the time of collection. The most reliable suspended-sediment samples are obtained using isokinetic samplers.

The simplest instantaneous sampler is an open bottle used to obtain a surface, or dip, sample. The WBH-96 weighted bottle sampler (FISP 2000) is deployed with a hand line in still or slow-moving water. The Van Dorn sampler and Kemmerer sampler are thief-type samplers that are typically used for still-water sampling, such as in lakes and reservoirs,

but that may be useful in slow-moving streamflows (Webb and Radtke 1998).

**5.3.4.1.2 Isokinetic Samplers** Isokinetic samplers are designed to collect a representative velocity-weighted sample of the water-sediment mixture. Water approaching the nozzle of an isokinetic sampler undergoes essentially no change in speed or direction as it enters the nozzle orifice (Fig. 5-14). When deployed using prescribed methods at strategic locations in a cross section, an isokinetic sampler integrates a sample proportionally by velocity and area, resulting in a

**Fig. 5-14.** Relation between intake velocity and sample concentration for (A) isokinetic and (B, C) non-isokinetic sample collection of particles larger than 0.062 mm.  $\bar{V}$  = mean stream velocity,  $V_n$  = velocity in the sampler nozzle,  $\bar{C}$  = mean sediment concentration in the stream, and  $C_s$  = sample sediment concentration.

discharge-weighted sample. A discharge-weighted sample contains a concentration and size distribution representative of the material in transport at the time the sample was collected.

A list of isokinetic samplers available from the FISP is shown in Table 5-2. FISP isokinetic samplers are designed to sample at a relative sampling rate—a dimensionless value defined as the velocity through the nozzle divided by the approaching stream velocity—of 1.0 at a 1.2 m/s (3.9 ft/s) flow velocity. In practice, FISP isokinetic samplers are designed to ensure that the water velocity entering the nozzle is within 10% of the ambient stream velocity throughout the samplers' operating velocity range (Broderick Davis, Federal Interagency Sedimentation Project, 2001, written communication).

Concentration errors in samples collected with isokinetic-type samplers may stem from a combination of the size of suspended material and the relative sampling rate. The relation between percent error in concentration and relative sampling rate for sediments with a density of 2.65 and median diameters of 0.45, 0.15, 0.06, and 0.01 mm in flows of 1.5 m/s is shown in Fig. 5-15 (adapted from FISP 1941). Under these test conditions, relative sampling rates for 0.45-mm-size sediments can range from 0.75 to 1.3 without introducing more than about a 10% error in sample concentration values. Conversely, at relative sampling rates less than 0.25, resultant concentration errors can exceed 100%. The range of errors tends to decrease with decreasing sediment size. For example, 0.01-mm-size sediments have less than a 5% error for relative sampling rates ranging from about 0.2 to almost 5 (Fig. 5-15). In each case, relative sampling rates less than about 1.0 result in positive concentration bias, and those larger than about 1.0 result in zero or negative concentration bias.

The FISP's suite of depth-integrating samplers and point-integrating samplers (Davis 2005) are isokinetic samplers. A depth-integrating sampler is designed to isokinetically and continuously accumulate a representative sample from a stream vertical while transiting the vertical at a uniform rate (FISP 1952). A depth-integrating sampler collects and accumulates a velocity or discharge-weighted sample as it descends and ascends at a constant rate through the sampling vertical provided that the appropriate transit rate is not exceeded and the sample container does not overflow.

The point-integrating sampler uses an electrically activated valve, enabling the operator to isokinetically sample points in, parts of, or the entire vertical. For stream cross sections less than 9 m deep (30 ft), the full depth can be traversed in one direction at a time by opening the valve and depth integrating either from surface to bottom or vice versa. Stream cross sections deeper than 9 m (30 ft) can be integrated in segments of 9 m (30 ft) or less by collecting integrated-sample pairs consisting of a downward integration and a corresponding upward integration in separate containers.

The FISP (1963) provides the following summary of point-integrating sampler characteristics that make them

useful in conditions beyond the limits of the simpler depth-integrating samplers:

Point-integrating samplers are more versatile than the simpler depth-integrating types. They can be used to collect a suspended-sediment sample representing the mean sediment concentration at any point from the surface of a stream to within several centimeters of the bed, as well as to integrate over a range in depth. These samplers were designed for depth integration of streams too deep (or too swift) to be sampled in a continuous round-trip integration. When depth integrating, sampling can begin at any depth and proceed either upward or downward from that initial point through a maximum vertical distance of 9 m (30 ft).

**5.3.4.1.3 Rigid-Bottle Samplers** When a rigid-bottle suspended-sediment sampler is submerged with the nozzle pointing directly into flow of sufficient velocity, a part of the streamflow enters the sampler container via the nozzle and air in the container exhausts under the combined effect of three forces:

1. A positive dynamic head at the nozzle entrance due to the flow;
2. A negative head at the end of the air-exhaust tube due to flow separation;
3. A positive pressure due to difference in elevation between the nozzle entrance and the air-exhaust tube.

Under these conditions, a calibrated isokinetic sampler will collect a sample with a sediment concentration and size distribution essentially unchanged from those at the sampling point in the stream, and a representative sample will result. However, when the sample in the container reaches the level of the air exhaust, the intake flow-rate drops, and circulation of the streamflow into the nozzle and out of the air-exhaust tube occurs. Because the velocity of the water flowing through the bottle is less than the stream velocity, coarser particles in transport tend to settle in the sample bottle, causing the sample to become enriched in sediment. Additionally, the resulting subefficient sampling rate may increase the positive concentration bias. Substantial errors in sediment concentration and particle-size distribution can result from samples collected using an incorrect or uncontrolled sample rate. The magnitude of errors tends to increase concomitant with increases in the percentage and size of suspended sand-size material (FISP 1941; Fig. 5-15). Edwards and Glysson (1999) and the USGS (1998b) provide more information on ranges in transit rates required to sample isokinetically.

**5.3.4.1.4 Handheld and Handline Samplers: US DH-81, US DH-48, US DH-59, US DH-76, and US DH-95** Where streams are wadable or access can be obtained from a culvert, low bridge span, or cableway, any of six lightweight samplers can be used to obtain suspended-sediment samples via a wading rod or handline. The US

<sup>1</sup>Samplers designated in *italics* may also be used for water-quality sampling as described in the *U.S. Geological Survey National Field Manual for the Collection of Water Quality-Data* (variously dated).

<sup>2</sup>For rigid-bottle samplers, the maximum recommended velocity for sampler deployment is based either on measured isokinetic limitations or, for prototypes of samplers tested at Anthony Falls Hydraulic Laboratory flume, on the maximum velocities used in tests. Bag samplers were determined to retain isokinetic characteristics at the highest velocities tested. Their maximum recommended velocity was selected to correspond with the velocity at which the angle of the suspension cable was drawn back just shy of “excessive” by testing personnel—25 to 30 degrees—and upon safety considerations.

<sup>3</sup>The 0.48-mm (3/16-in) internal diameter nozzle is designated for use in high-velocity flows.

<sup>4</sup>A minimum isokinetic velocity of 1.1 m/s (3.5 ft/s) applies to the D-99 sampler using a 6-L (6.3-quart) flexible bag and a 0.48-mm (3/16-in) internal diameter nozzle.

<sup>5</sup>A minimum isokinetic velocity of 0.61 m/s (2 ft/s) applies to the D-99 sampler using a 3-L (3.2-quart) flexible bag and a 0.64-mm (¼-in) or 0.79-mm (5/16-in) internal diameter nozzle.

**Fig. 5-15.** Effect of sampling rate on measured sediment concentration for four sediment size distributions, adapted from Federal Interagency Sedimentation Project (1941).

DH-81 sampler (Fig. 5-16A; Table 5-2), which is deployed by a wading rod, consists of a US DH-81A adapter and US D-77 cap and nozzle (Webb and Radtke 1998; Edwards and Glysson 1999). All parts are autoclavable, enabling the collection of a depth-integrated sample for bacterial analysis. Any bottle having standard mason jar threads can be used with the US DH-81 sampler. The unsampled zone—the distance from the centerline of the nozzle to the streambed when the sampler contacts a flat bed—varies depending on the size of bottle used. The US DH-81 is particularly useful for sampling in cold weather because the plastic sampler head and nozzle attach directly to the bottle, eliminating a metal body. Under subfreezing conditions, a metal sampler body conducts heat away from the nozzle, air exhaust, and bottle more rapidly, resulting in increased potential for ice blockage of the nozzle and/or the exhaust port.

The rod-suspended US DH-48 sampler (Fig. 5-16B; Table 5-2) features a streamlined aluminum casting that partially encloses the sample container (FISP 1952; Edwards and Glysson 1999). The container, usually a 0.45-L glass milk bottle, is sealed against a gasket recessed in the head cavity of the sampler by a hand-operated, spring-tensioned pull-rod assembly at the tail of the sampler.

The US DH-59 and US DH-76 samplers (Figs. 5-16C and D, respectively; Table 5-2) are designed for use in unwadable streams with maximum depths less than 4.6 m and flow velocities up to about 1.5 m/s. The fundamental difference between the samplers is that the US DH-59 accommodates a 0.45-L sample bottle, whereas the US DH-76 uses a 0.9-L container. The tailfin assembly for each sampler ensures sampler alignment parallel to the flow direction with the intake nozzle entrance oriented upstream.

The US DH-95 sampler (Fig. 5-16E) is designed to make possible collection of unbiased samples for trace-element analyses in addition to samples collected for suspended-sediment analyses (McGregor 2000a) in depths less than 4.6 m at flow velocities up to about 2.4 m/s. The sampler is designed to use a 1-L Teflon or plastic bottle, a US D-95 Teflon cap, and a US D-77 sampler cap and nozzle. The bottle cavity is machined from a low-lead bronze casting and is plastic-coated. The tail section is constructed from plastic.

**5.3.4.1.5 Cable-and-Reel Samplers: US D-74, US D-95, US P-61A1 US P-63, US P-72** The US D-74 (Figs. 5-17A and B), US D-74AL, and US D-95 (Fig. 5-17C) depth-integrating samplers can be used to obtain suspended-

**Fig. 5-16.** Handheld and hand-line samplers. (A) The US DH-81 suspended sampler with an attached wading rod. (B) The US DH-48 suspended-sediment sampler with an unattached wading rod. (C) The US DH-59 suspended-sediment sampler with hanger bar. (D) The US DH-76 suspended-sediment sampler with hanger bar. (E) The US DH-95 suspended-sediment sampler with hanger bar.

sediment samples in unwadable streams less than 4.6 m deep (Table 5-2). A third cable-and-reel sampler, the US D-77, is being phased out by the USGS and is also no longer being manufactured by the FISP (USGS 2002), although the US D-77 cap and nozzles will continue to be manufactured for use with other FISP samplers.

The bronze US D-74 and aluminum US D-74AL are designed to be suspended from a bridge, cableway, or boat. These samplers replaced the US D-49, which in turn replaced the US D-43 for general use. The US D-74 sampler completely encloses a 0.9-L sample container or a standard 0.45-L milk bottle when an adapter is used. The sampler head is hinged at the bottom and swings downward to provide

access to the sample-container chamber. The body includes tail vanes that serve to align the sampler and the intake nozzle with the flow.

The US D-95 sampler, like the US DH-95 (Fig. 5-16E), is designed to make possible collection of unbiased samples for trace-element analyses in streams not exceeding 4.6 m in depth (McGregor 2000b) at stream velocities ranging from 0.5 to 2.3 m/s. The bronze body casting is coated with plastic and the tail section is constructed from plastic to help avoid metal contamination during water-quality sampling.

Point-integrating suspended-sediment samplers in wide use are the US P-61A1 (Fig. 5-17D), US P-63, and US P-72

**Fig. 5-17.** (A) The US D-74 suspended-sediment sampler. (B) The US D-74 suspended-sediment sampler open. (C) The US D-95 suspended-sediment sampler. (D) The US P-61A1 point-integrating suspended-sediment sampler. (E) The US D-96 suspended-sediment sampler. (F) The US D-96 suspended-sediment sampler with tray extended.

(Table 5-2). These samplers also can be used in depth-integration mode.

An operator-controlled sampler solenoid valve powered by a nonsubmersible battery pack makes possible collection of a sample at a discrete depth, or can start and stop depth-integrated sample collection. Automatic pressure equalization at depth precludes a sudden inrush of

sample due to a static-head differential when the valve is opened.

The US P-61A1 (Fig. 5-17D; Table 5-2) is calibrated for use in velocities up to 2 m/s, but there is evidence to suggest that it can collect samples isokinetically at velocities of at least 3 m/s (Wayne O'Neal, FISP, 2000, written communication). The US P-63 and US P-72 are lighter and heavier

versions and have higher and lower flow-velocity limits, respectively, but otherwise are functionally similar to the US P-61A1.

Because of the comparatively complex nature of point-integrating samplers, the user may find it useful to seek additional information given in FISP reports (1952; 1963; Davis 2005) or to obtain information directly from the FISP (FISP 2000).

**5.3.4.1.6 Bag Samplers** Samplers using collapsible bags as the sample container have been used since the 1970s (Stevens et al. 1980). Nordin et al. (1983) tested a large-volume bag sampler in the Rio Orinoco and Rio Amazonas, South America. Moody and Meade (1994) deployed a bag sampler of the type devised by Stevens et al. (1980) in the Mississippi River and selected tributaries.

As with rigid-bottle isokinetic samplers, water enters the bag sampler through a nozzle. However, bag samplers have no exhaust port, and the sample container is a collapsible bag. Air is manually expelled from the bag before submersion of the sampler. The transit rate for a bag sampler is constrained by the intake-nozzle and the bag volume, in addition to the maximum rate of 0.4 times the mean flow velocity in the vertical that applies to all depth-integrating samplers. When a Teflon bag is used, they are capable of collecting unbiased samples for trace-element analyses in addition to those collected for suspended-sediment analyses.

The US D-96 collapsible bag sampler (Fig. 5-17E and F; Table 5-2) was the first such sampler developed in part to address the limitations and disadvantages associated with bottle samplers and experimental bag samplers (Davis 2000; Webb and Radtke 1998). This cable-suspended sampler can provide up to 3 L of sample for subsequent unbiased trace-element analyses in addition to physical-sediment analyses. It is fabricated from bronze and aluminum castings with a high-density polyethylene tail. All metal parts are plastic-coated with commercially available "PlastiDip." A sliding tray (Fig. 5-17F) in the sampler holds the nozzle holder with nozzle in place and supports a perfluoroalkoxy bag.

The US D-96 sampler will collect velocity-weighted samples in streams with velocities from 0.6 to 3.8 m/s. At a maximum transit rate of 0.4 times the mean flow velocity in the vertical, the US D-96 sampler is capable of sampling to a depth of 12 m (39 ft) with a 7.9-mm (5/16-in.) nozzle, 18 m (60 ft) with a 6.4-mm (¼-in.) nozzle, and 34 m (110 ft) with a 4.8-mm (3/16-in.) nozzle (Davis 2000). Bag samplers with smaller and larger capacities than the US D-96 sampler are also available. The 13-kg (29-lb) US DH-2 is a hand-line sampler capable of collecting a 1-L sample. The 125-kg (275-lb) US D-99 is a cable-suspended sampler capable of collecting a 6-L sample.

**5.3.4.2 Manual Sampling Methods** The most common purpose of sediment sampling is to determine the instantaneous mean discharge-weighted suspended-sediment concentration at a cross section. Derived concentration val-

ues are combined with water discharge to compute the measured suspended-sediment discharge. A discharge-weighted suspended-sediment concentration representative of the mean value in the cross section is desired for this purpose and for the development of coefficients to adjust data collected by observers and automatic samplers.

Ideally, the best method for sampling any stream to determine sediment discharge would be to collect the entire flow of the stream over a given time period, remove the water, and weigh the sediment. This method is rarely feasible. Instead, the sediment concentration in the flow is determined by collecting depth-integrated suspended-sediment samples that define the mean discharge-weighted concentration in the sample vertical, and collecting sufficient verticals to define the mean discharge-weighted concentration in the cross section (Edwards and Glysson 1999).

**5.3.4.2.1 Single-Vertical Sampling** The objective of collecting a single-vertical sample is to obtain a concentration value representative of the mean discharge-weighted suspended-sediment concentration in the vertical being sampled at the time the sample was collected. An isokinetic sampler deployed at a constant rate in a downward and upward transit will collect a sample weighted for the variations in velocity and concentration in the vertical from the surface to the top of the unsampled zone. The following equation demonstrates this concept:

$$C_i = \frac{\int_{B_i+UZ}^{D_i} c_i(s) v_i(s) ds}{\int_{B_i+UZ}^{D_i} v_i(s) ds} \quad (5-6)$$

where

- $C_i$  = mean suspended-sediment concentration in vertical  $i$ ;
- $B_i$  = elevation of the streambed in vertical  $i$ ;
- $UZ$  = distance from the bed to the nozzle of a sampler resting on the bed (unsampled zone);
- $D_i$  = elevation of the water surface in vertical  $i$ ;
- $c_i(s)$  = concentration at depth  $s$  in vertical  $i$ ;
- $s$  = depth in the vertical; and
- $v_i$  = velocity at depth  $s$  in vertical  $i$ .

The method used to obtain the mean concentration of suspended sediment in a vertical thus depends on the flow conditions and particle-size distribution of the sediment in transport. These conditions can be generalized to four types of situations:

1. Low velocity ( $v < 0.6$  m/s) when little or no sand is being transported in suspension;

2. High velocity ( $0.6 \leq v \leq 3.7$  m/s) when depths are less than 5.6 m;
3. High velocity ( $0.6 \leq v \leq 3.7$  m/s) when depths are greater than 5.6 m; and
4. Very high velocity ( $v > 3.7$  m/s).

*First case.* In the first case, where  $v < 0.6$  m/s, barring extremely shallow depths, the velocity is low enough so that little if any sand is in suspension. The distribution of any silt- and clay-size material ( $<0.062$  mm in diameter; Folk 1974) in transport is relatively uniform from stream surface to bed (Guy 1970). The sampling error for this case is 10% or less with relative sampling rates in a range from about 0.2 to at least 5.0 (Fig. 5-15). Consequently, it is less important to collect the sample isokinetically with fines in suspension than it is when sand-size particles ( $\geq 0.062$  mm in diameter; Folk 1974) are in suspension. In shallow streams, a sample may be collected by manually submerging an open-mouthed bottle into the stream. The mouth should be pointed upstream and the bottle held tilted upward at approximately a  $45^\circ$  angle from the streambed. The bottle should be filled by moving it from the surface to the streambed and back. An unsampled zone of about 8 cm should be maintained in order to obtain samples that are compatible with depth-integrated samples collected at higher velocities and to avoid collecting streambed material. If the stream is not wadable, a weighted-bottle type sampler, such as the US WBH-96, may be used (Webb and Radtke 1998). Samples collected in this manner are not discharge-weighted.

*Second case.* In the second case, when  $0.6 \leq v \leq 3.7$  m/s and the depth is less than 4.6 m, a depth-integrating sampler described in Table 5-2 that is suitable for the ambient streamflow condition should be used. The method of sample collection basically is the same for all these samplers, whether used while wading or deployed from a bridge, cableway, or boat. Insert a clean sample container into the sampler and ensure that the air-exhaust tube and/or nozzle is unobstructed. Then lower the sampler to the water surface so that the nozzle is above the water, and the lower tail vane or back of the sampler is in the water to orient it parallel to the flow. The sampler then is lowered at a constant rate until it touches the bottom. It is immediately retrieved at a constant rate until it clears the water surface. Although the ascending transit rate need not be equal to the descending rate, in practice it is simpler to maintain a constant rate in both directions. However, both rates must be constant to obtain a velocity- or discharge-weighted sample. The rates should be such that the bottle fills to near its optimum level (Johnson 1997; Edwards and Glysson 1999).

For streams that transport heavy loads of sand, and perhaps for some other streams, at least two complete depth integrations of the sample vertical should be made as close together in time as possible, one bottle for each integration. Each bottle then constitutes a sample and can be analyzed separately or, for the purposes of computing the sediment

record (a time series of sediment discharges often reported as daily values), concentration values representing two or more bottles can be averaged as a set and tagged with a single time of collection. This set is used as a single sediment-concentration value for computing the sediment record. Analytical results from two or more individual bottles for a given observation are useful for checking sediment variations among bottles, which is advantageous in the event that sediment concentrations in samples collected consecutively from the same vertical differ markedly. Immediately after collection, the sample should be inspected by briefly swirling or agitating the container and then observing the quantity of sand particles that collect in the bottom of the container. If there is an unusually large estimated mass of sand among bottles with similar sample volumes, or the mass of sand inexplicably differs among the bottles, at least one more sample from the same vertical should be taken immediately. The sample container suspected of having too much sand should be marked as having "excess sand," or, if it is likely to be contaminated, the sample should be discarded. If a container is overfilled or if water is ejected from the nozzle when the sampler is raised past the water surface, the sample should be discarded. A clean container must be used to resample the vertical.

*Third case.* In the third case, where  $0.6 \leq v \leq 3.7$  m/s and the depth is greater than 4.6 m, rigid-bottle depth-integrating samplers cannot be used because the depth exceeds the maximum allowable depth for these samplers. In this case, one of the point-integrating or bag-type samplers must be used. The method for collection of a sample using the bag-type sampler is similar to that used with the depth-integrating samplers.

The point samplers may be used to collect depth-integrated samples in verticals where the depth is greater than 4.6 m. For streams with depths of 4.6 to 9.1 m, a procedure for sampling modified from that described by Edwards and Glysson (1999) is as follows:

1. Insert a clean bottle in the sampler and close the sampler head.
2. Lower the sampler to the streambed, keeping the solenoid valve closed; note the depth to the bed.
3. Start raising the sampler to the surface, using a constant transit rate. Open the valve at the same time the sampler begins the upward transit.
4. Keep the valve open until after the sampler has cleared the water surface. Close the valve.
5. Remove the bottle containing the sample, check the volume of the sample, and mark the appropriate information on the bottle. (If the sample volume exceeds allowable limits, discard the sample and repeat depth integration using a higher transit rate.)
6. Insert another clean bottle into the sampler and close the sampler head.
7. Lower the sampler until the lower tail vane is touching the water, allowing the sampler to align parallel to the flow.

8. Open the valve and lower the sampler at a constant transit rate until the sampler touches the bed.
9. Close the valve the instant the sampler touches the bed (by noting the depth to the streambed in step 2 above, the operator will know when the sampler is approaching the bed).

If the stream depth is greater than 9.1 m, the process is similar, except that the descending and ascending integrations are broken into segments no larger than 9.1 m. Samples collected by this technique may be composited for each vertical if the same transit rate is used. Otherwise, samples should be analyzed separately. A single mean concentration is computed for the vertical.

*Fourth case.* In the fourth case, where  $v > 3.7$  m/s, the velocities are too large to deploy depth- or point-integrating samplers safely. In this case, and when the presence of debris, ice in flow, or other factors makes normal sample collection dangerous or impossible, surface or dip samples may be collected.

A surface sample is one taken on or near the surface of the water, with or without an isokinetic sampler. At some locations, stream velocities can be so large that even the heaviest, most streamlined samplers will not reach the streambed in one or more sampled verticals. Under such conditions, it can be expected that all but perhaps the largest sediment particles in suspension will be well mixed within the flow; and, therefore, a sample from near the surface, non-depth-integrated, may contain a concentration and size distribution representative of the entire vertical. However, results from these samples should be correlated with those from depth-integrated samples collected under more normal flow conditions as soon as possible after the large velocities diminish. Along with the depth-integrated sample, a sample should be collected in a manner duplicating the sampling procedure used to collect the surface or dip sample. Analytical results from these samples will be used to adjust those from the surface or dip sample collected during the higher flow, if necessary, to facilitate the use of these data in sediment-discharge computations and data analyses.

**5.3.4.2.2 Multivertical Sampling** A depth-integrated sample collected using the procedures outlined in the previous section will accurately represent the discharge-weighted suspended-sediment concentration in a vertical at the time of the sample collection. Samples collected at appropriately spaced verticals can be used to calculate the instantaneous sediment concentration at a cross section. The International Standards Organization (ISO 1993) lists three methods for suspended-sediment data collection in a cross section: the equal-discharge-increment, equal-width-increment, and equal-area-increment methods. The equal-area-increment method is rarely used in the United States. The first two methods are described in the following sections (Edwards and Glysson 1999).

**5.3.4.2.3 The Equal-Discharge-Increment Method** With the equal-discharge-increment (EDI) method, sam-

ples are obtained from the locations representing equal increments of discharge. The EDI method requires that three criteria be met:

1. Samples are collected isokinetically;
2. The vertical represents the mean concentration and particle-size distribution for the subsection sampled;
3. The discharges on both sides of the sampling vertical are predetermined proportions of the total discharge, which requires information on the lateral distribution of discharge in the cross section.

The mean discharge-weighted suspended-sediment concentration in a cross section using the EDI method is calculated from the mean concentrations from individual verticals (see "Single Vertical Sampling") as follows:

$$C_{xs} = \frac{1}{n} \sum_{i=1}^n C_i \quad (5-7)$$

where

$C_{xs}$  = mean discharge-weighted suspended-sediment concentration in the cross section;

$n$  = number of verticals used in the EDI measurement; and

$C_i$  = mean concentration in the vertical  $i$  (see Eq. (5-6)).

The distribution of discharge can be derived from a discharge measurement made immediately prior to selecting sampling verticals (Rantz 1982), or, if the channel is relatively stable, on an analysis of the lateral distribution of discharges measured over a range of historical flows. If such knowledge can be obtained, the EDI method can save time and labor (compared to the equal-width-increment method, discussed in the next section), especially on larger streams, because fewer verticals are required (Hubbell et al. 1956).

The inverse of the number of verticals,  $n$ , to be sampled by the EDI method is multiplied by 100% to derive  $q_{\text{percent}}$ , the percentage of discharge to be represented in samples collected in each vertical. The location of a vertical nearest the left bank is selected at a point at which the cumulative discharge to the left of the vertical is one-half of the total discharge times  $q_{\text{percent}}$ . The location of a vertical nearest the right bank is selected at a point at which the cumulative discharge to the right of the vertical is one-half of the total discharge times  $q_{\text{percent}}$ . All other verticals are selected at points where the cumulative discharge between adjacent verticals is equal to the total discharge times  $q_{\text{percent}}$ .

For example, from the discussion in the previous paragraph, samples are to be collected from five increments of equal discharge from a 100-m-wide cross section of a river flowing at 500 m<sup>3</sup>/s. The percentage of the total discharge to be represented in samples collected from each vertical is 1/5 times 100%, or 20%. The location of the vertical nearest the left bank is selected at the point at which the cumulative discharge to the left of that vertical is 0.5 times 500 m<sup>3</sup>/s

times 20%, or at the point in the cross section where 50 m<sup>3</sup>/s of discharge occurs between the vertical and the left bank. Likewise, the vertical nearest the right bank is selected at the point at which 50 m<sup>3</sup>/s occurs between that vertical and the right bank. The other three verticals are located at points separating adjacent verticals by discharges of 100 m<sup>3</sup>/s, the product of the total river discharge of 500 m<sup>3</sup>/s, times  $q_{\text{percent}}$ , 20%. The location of each vertical represents the centroid of the discharge in its respective subarea, with each subarea containing equal increments of discharge.

Samples are collected from each EDI method vertical as described previously in the "single-vertical" section. The descending and ascending transit rates in any one vertical need not be equal, nor do the rates need to be equal from vertical to vertical. Although different diameter nozzles for the isokinetic sampler can be used from vertical to vertical, it complicates the data-collection procedure and hence the practice is discouraged.

The EDI method requires a minimum of four verticals; rarely are more than nine verticals necessary. The greater the potential heterogeneity in the distribution of suspended-sediment concentrations and particle-size distributions in the cross section, the more verticals should be selected.

If an equal amount of sample is collected at each vertical, the samples can be composited and analyzed as a single sample. In most cases, the samples are analyzed separately and the results of the analyses are added and then divided by the number of subsections to derive a mean discharge-weighted sediment concentration. One advantage of this method is that data describing the cross-sectional variation in concentrations are produced. Additionally, a bottle containing an abnormally large sediment concentration compared to others in the set (because of recirculation or to punching the nozzle into the bed) can be identified and excluded from the calculated mean cross-sectional suspended-sediment concentration to preclude a biased result.

The bed of a sand channel can shift substantially, at single points and across segments of the width, over a period ranging from weeks to fractions of an hour. This not only makes it difficult at best to establish a relation between stage and the cross-sectional discharge distribution from one visit to the next, but also makes it impossible to be certain the discharge distribution does not change between the time of the water-discharge measurement and sample collection (see Guy 1970). Under conditions where the lateral distribution of flow changes rapidly, the EDI method may yield unreliable results.

**5.3.4.2.4 The Equal-Width-Increment Method** A cross-sectional suspended-sediment sample obtained by the equal-width-increment (EWI) method requires a sample volume proportional to the amount of flow at each of 10 or more equally spaced verticals in the cross-section (Edwards and Glysson 1999). Equal spacing between EWI verticals across the stream and sampling at an equal transit rate at all verticals yields a cumulative sample volume proportional to the total discharge. This method first was used by Colby in

1946 (FISP 1963) and is used most often in relatively shallow, wadable streams and/or sand-bed streams where the distribution of water discharge in the cross section is unstable. It also is useful where suspended-sediment concentrations in the cross section are substantially heterogeneous, such as in streams where tributary flow has not completely mixed with the flow.

The mean discharge-weighted suspended-sediment concentration in a cross section using the EWI method is calculated from the mean concentrations from individual verticals (see "Single Vertical Sampling") as follows:

$$C_{xs} = \frac{\sum_{j=1}^J \text{Vol}_j C_j}{\sum_{j=1}^J \text{Vol}_j} \quad (5-8)$$

where

$C_{xs}$  = mean discharge-weighted suspended-sediment concentration in the cross section;

$J$  = number of sample bottles used in the EWI measurement;

$C_j$  = concentration in the sample bottles  $j$ ; and

$\text{Vol}_j$  = the total volume of water collected in sample bottle  $j$ .

The number of verticals required for an EWI sediment-discharge measurement depends on the distribution of concentrations and flow in the cross section at the time of sampling, as well as on the a relative assessment of the desired accuracy of the result. For many streams, statistical approaches and experience are needed to determine the desirable number of verticals. Until such experience is gained, the number of verticals used should be larger than that deemed to be minimally necessary. In all cases, a minimum of 10 verticals should be used for streams exceeding 1.5 m wide. For streams less than 1.5 m wide, as many verticals as possible should be used, as long as they are spaced a minimum of 7.6 cm apart, to allow discrete sampling of each vertical and to avoid overlaps. Through general experience with similar streams, field personnel can estimate the required minimum number of verticals to yield a desired level of accuracy. For all but the widest and shallowest streams, 20 verticals usually are ample.

The width of the increments to be sampled, or the distance between verticals, is determined by dividing the stream width by the number of verticals,  $n$ , necessary to collect a discharge-weighted suspended-sediment sample representative of the sediment concentration of the flow in the cross section. The locations of the two verticals nearest to the banks are at a distance of one-half of the total width divided by  $n$ . The locations of the other verticals are separated from adjacent verticals by a distance of the total width divided by  $n$ . The locations of these verticals represent the centroid of subareas with boundaries one-half the distance to adjacent verticals. Hence, only the widths of the subareas necessarily are equal.

The EWI sampling method requires use of the same size nozzle for a given measurement, and all verticals must be traversed using a transit rate that will not result in overfilling the sample bottle at the deepest and fastest vertical in the cross section. The descending and ascending transit rates must be equal for all verticals and during the sampling traverse of each vertical. By using this equal-transit-rate technique with a standard depth- or point-integrating sampler at each vertical, a volume of water proportional to the flow in the vertical will be collected.

For example, from the previous paragraphs, samples from 12 verticals are to be collected from a stream with a surface width of 120 m with zero width referenced to the left bank. The location of the leftmost vertical is at a distance of one-half of 120 m divided by 12, or 5 m from the left bank. The 12 verticals are located 10 m apart with the rightmost vertical 5 m from the right bank. The second vertical from the left bank is located at 15 m, and the 12th vertical from the left bank is located at 115 m.

Because the maximum transit rate must not exceed  $0.1 v_m$ ,  $0.2 v_m$ , or  $0.4 v_m$  (a  $0.4 v_m$  transit rate applies to all bag samplers) depending on the nozzle size and bottle volume ( $v_m$  equals the mean ambient velocity in the sampled vertical), and because the minimum rate must be sufficiently fast to keep from overfilling any of the sample bottles, the transit rate to be used for all verticals is limited by conditions at the vertical containing the largest discharge per unit width, or, in operational terms, the largest product of depth times mean velocity. A discharge measurement can be made to determine the location of this vertical. In practice, this location often is estimated by sounding for depth and acquiring a feel for the relative velocity with a sampler or wading rod. The transit rate required at the maximum discharge vertical then must be used at all other verticals in the cross section and usually is set to provide the maximum sample volume in a round-trip transit. It is permissible to sample at multiple verticals using the same bottle as long as the bottle is not overfilled. If a bottle is overfilled, the contents must be discarded, and all verticals previously sampled using that bottle must be resampled, using a sufficient number of bottles to avoid overfilling.

**5.3.4.2.5 Advantages of the Equal-Discharge-Increment and Equal-Width-Increment Methods** Some advantages and disadvantages of both the EDI and EWI methods have been noted in the previous discussion. It must be remembered, however, that both methods, if properly used, will yield similar cross-sectionally averaged results.

The advantages of the EDI method are as follows:

1. Fewer requisite verticals typically result in a reduced collection time, which is particularly advantageous during periods of rapidly changing discharge;
2. Bottles composing a sample set may be composited for single laboratory analysis when equal volumes of sample are collected from each vertical;

3. The cross-sectional variation in concentration can be determined if samples are analyzed individually;
4. Duplicate cross-sectional samples can be collected during the measurement;
5. A variable transit rate can be used among verticals.

The advantages of the EWI method are as follows:

1. No antecedent knowledge of flow distribution in the cross section is required;
2. Variations in the distribution of concentration in the cross section may be better integrated in the composite cross section sample due to the larger number of verticals sampled;
3. Analytical time and costs are minimized as sample bottles are composited for single laboratory analysis;
4. This method is easily learned and used due to the straightforward spacing of sample verticals based on stream width, rather than on the cross-sectional distribution of discharge;
5. Generally, less total time is required on site if no discharge measurement is deemed necessary and the cross section is relatively stable during the measurement.

The advantages of one method are, in many cases, the disadvantages of the other. The USGS (1998b) considers the EDI method the most universally applicable and useful discharge-weighted sampling method.

**5.3.4.2.6 Transit Rates for Suspended-Sediment Sampling** A sample obtained with an isokinetic sampler using depth integration is quantitatively weighted according to the velocities through which it passes. Therefore, if the sampling vertical represents a specific width of flow, the sample is considered to be discharge weighted because, with a uniform transit rate, the suspended sediment conveyed at varying velocities throughout the sampled vertical is given equal time to enter the sampler.

The transit rate used with any depth-integrating sampler must be regulated to make possible the collection of representative samples (i.e., isokinetically collected). An insufficient transit rate can result in an unacceptable sample due to overfilling of the sample container. An excessive transit rate can result in intake velocities less than the stream velocity due to a large entrance angle between the nozzle and streamflow lines caused by the vertical movement of the sampler in the flow (FISP 1952). Transit rates should never exceed the product of 0.4 and the mean velocity ( $0.4 v_m$ ) in a vertical with any isokinetic sampler.

Additional limitations may be imposed on maximum transit rates for rigid-bottle depth-integrating samplers due to changes in hydrostatic pressure during deployment. The maximum allowable transit rate is attained when the rate of change in the internal pressure due to filling equals the rate of change of hydrostatic pressure. If the sampler is lowered too fast in the vertical, inflow through the nozzle is insufficient to

increase the pressure in the container at the same rate; consequently, hydrostatic pressure increases at a greater rate than pressure in the container. The resulting pressure imbalance causes the sample to enter the nozzle at a velocity greater than the ambient stream velocity. Stream water can also enter the exhaust port under these circumstances. Both potential outcomes result in violation of isokinetic sampling principles (Stevens et al. 1980). Likewise, if the sampler is raised too rapidly, the hydrostatic pressure will decrease at a greater rate than the pressure inside the container. This pressure imbalance will result in reduced flow of sample into the container with respect to the ambient stream velocity. Either outcome—larger or smaller intake velocities with respect to the ambient stream velocity—can result in collection of a sample that contains neither a representative concentration nor particle-size distribution of suspended sediment.

The maximum allowable transit rate for rigid-bottle samplers can be determined with knowledge about (1) the depth of the sample vertical, (2) the mean velocity of the vertical, (3) the nozzle size being used, and (4) the sample bottle size used in the sampler. Different combinations of nozzle diameters and bottle volumes result in maximum transit rates ranging from about  $0.1v_m$  to  $0.4v_m$ . Tables providing isokinetic transit rates as a function of nozzle diameters and bottle volumes are provided by the USGS (1998b). Graphs delineating permissible and optimal transit rates for a combination of sample container and nozzle sizes as a function of stream depth and mean velocity are provided by Edwards and Glysson (1999). A vertical transit pacer is available to assist in quantifying the transit rate for a reel-deployed sampler (FISP 2001).

**5.3.4.2.7 Point-Integrated Sampling** A point-integrated sample is a sample of the water-sediment mixture collected isokinetically from a single point in the cross section. Point-integrated samples are collected using one of the point-integrating samplers previously presented. Multiple point samples may be used to define the distribution of sediment in a vertical, the vertical and horizontal distributions of sediment in a cross section, and the mean cross-sectional sediment concentration.

The purpose for which point samples are to be collected determines the collection method to be used. If samples are collected for the purpose of defining the horizontal and vertical distribution of concentration and/or particle-size distributions, samples collected at numerous points in the cross section with any of the “P” type samplers will be sufficient. Normally, 5 to 10 verticals are sufficient for horizontal definition of suspended-sediment concentrations. Vertical distributions can be adequately defined by obtaining samples from a number of points in each sample vertical. Specifically, samples should be taken with the sampler lightly touching the bed, 0.3 m off the bed, at from 6 to 10 additional points in the vertical above that point, and from near the surface. Each point sample should be analyzed separately.

If point samples are collected to define the mean concentration in a vertical, 5 to 10 samples should be collected from

the vertical. The sampling time for each sample (the elapsed time that the nozzle is open) must be equal. This result will ensure that sample volumes collected are proportional to the flow at the point of collection. These samples may be composited for a single laboratory analysis. If the EDI method is used to define the stationing of the verticals, the sampling time may be varied among verticals. If the EWI method is used, a constant time for collecting samples from all verticals must be used.

The mean discharge-weighted suspended-sediment concentration in a cross section using the point-integration and EDI sampling methods is calculated from the mean concentrations from individual sampling points as follows:

$$C_{xs} = \frac{1}{n} \sum_{i=1}^n \left[ \frac{\sum_{d=1}^{D_i} \text{Vol}_{id} C_{id}}{\sum_{d=1}^{D_i} \text{Vol}_{id}} \right] \quad (5-9)$$

where

$C_{xs}$  = mean discharge-weighted suspended-sediment concentration in the cross section;

$D_i$  = total number of points sampled in vertical  $i$ ;

$n$  = number of verticals in which point samples are collected;

$C_{id}$  = suspended-sediment concentration in a sample from point  $d$  of vertical  $i$ ; and

$\text{Vol}_{id}$  = volume of sample collected from point  $d$  of vertical  $i$ .

If multiple points are sampled with a single bottle, computation of the mean sample concentration is accomplished by treating the contents of the bottle as if collected at a single point.

### 5.3.5 Automatic Samplers

Some sediment-monitoring programs and studies include sites where collection of sediment samples is required at a frequency, at a time, and/or under a set of conditions that cannot be accommodated through manual sampling. Safety considerations, remoteness or inaccessibility of site location, flow conditions, operational costs, and other factors may render manual collection of sediment and flow data at a site impractical or impossible. In lieu of manual sampling, automatic samplers may be deployed to accommodate sediment data-collection needs at some sites.

Automatic samplers are useful for collecting suspended-sediment samples during periods of rapid discharge changes from storm-runoff and in reducing the need for manual measurements associated with intensive sediment-collection programs (FISP 1981). However, under some circumstances, use of automatic samplers to collect data can actually result in costs greater than those for an observer at the same site. Automatic samplers, and particularly pumping samplers,

often require more frequent site visits by the field personnel than would be required at the conventional observer station, owing to their mechanical complexity, power requirements, and limited sample capacity. Use of automatic samplers does not preclude the need for collecting medium- and high-flow cross-sectional samples. Additionally, use of automatic samplers typically results in reduced data quality. This result is particularly true for automatic sample collection from streams conveying high percentages of suspended sand-size material.

As noted previously, emerging technologies for monitoring suspended sediment show great promise, although none is commonly accepted nor extensively used. The most commonly used automatic samplers are automatic pumping samplers, which require power to obtain water samples. Single-stage samplers, which rely on changes in stream stage and/or velocity to collect water-sediment samples on the rising phase of a hydrograph, are also available.

**5.3.5.1 Automatic Pumping Samplers** Automatic pumping samplers generally consist of a pump, bottle-container unit, and sample distribution, activation, and intake systems. Ideally, this combination of components should be designed to meet the following criteria (Bent et al. 2001; Edwards and Glysson 1999):

1. Stream velocity and sampler intake velocity should be equal to allow for isokinetic sample collection if the intake is aligned into the approaching flow;
2. A suspended-sediment sample should be delivered from stream to sample container without a change in sediment concentration or particle-size distribution;
3. Cross contamination of samples caused by residual sediment in the sampler plumbing between sample-collection periods should be prevented;
4. The sampler should be capable of sampling over the full range of suspended-sediment concentrations and particle sizes;
5. Sample container volumes should meet minimum sample analysis volume requirements;
6. The inside diameter of the intake should be at least three times the diameter of the largest particles sampled, although small enough to maintain a mean sample velocity that will substantially exceed the fall velocity of those particles;
7. The sampler should be capable of vertical pumping lift elevations of about 10 m from intake to sample container for clear water;
8. The sampler should be capable of collecting a reasonable number of samples—usually at least 24—dependent upon the purpose of sample collection and the flow conditions;
9. Some provision should be made for protection against freezing, evaporation, and dust contamination of collected samples;
10. The sample container unit should be constructed to facilitate removal and transport as a unit;
11. The sampling cycle should be initiated in response to a timing device, flow change, or external signal based on a set of criteria that maximizes the potential for collecting samples at desired points over one or more hydrographs;
12. The capability of recording the sample-collection date and time should be present;
13. The provision for operation using ac power or dc battery power should be present.

Nearly all of the automatic pumping samplers in use today are available commercially. The PS-69, CS-77, and PS-82 pumping samplers are no longer manufactured.

The ISCO 6700 and American Sigma 900 automatic pumping samplers, for example, share various features for collecting water samples. Both are computer-controlled portable samplers capable of collecting up to 24 1-L samples based on time, flow, and/or other user-selected criteria. They use built-in peristaltic pumps and operate on ac power or dc battery power. Both samplers feature a back-flush cycle to reduce cross contamination between consecutively collected samples.

Neither sampler is capable of sampling clear freshwater if the peristaltic pump is at an elevation of about 9.7 m or more above that of the water surface. Cavitation can occur at smaller heads with larger specific gravities associated with increasing suspended-sediment concentrations and/or lower barometric pressures. Where lift requirements potentially exceed the capacity of a sampler, an auxiliary pump may be used to pump water to the sampler under a positive pressure. Gray and Fisk (1992) describe an automatic pumping sampling system used to collect samples of highly concentrated streamflow in Arizona and New Mexico. An auxiliary pump in a diving bell affixed at an elevation of a meter or two above that of the water surface at low flow pumps stream water to a gauging station. In the gauging station, a commercial sampler modified to collect 9-L samples periodically draws an aliquot of the pumpage from the auxiliary pump via a Y connector in the intake line. A data-collection platform controls collection of up to 24 samples based on time, stage, and rate-of-stage-change criteria. The data-collection platform records hydrologic information and data related to the number and times of samples collected and periodically updates a USGS database via satellite.

**5.3.5.1.1 Installation and Use Criteria** The decision to use a pumping sampler for collection of sediment samples usually is based on physical and fiscal criteria. Installation of an automatic pumping sampler requires careful planning before installation, including selection of the sampler site location and an evaluation of available or newly collected data to maximize the potential to collect useful pumping sampler data.

Before installation of an automatic pumping sampler, many of the problems associated with installing stream-gauging equipment must be addressed. In addition, specific data concerning the sediment-transport characteristics at the proposed sampling site must be obtained and evaluated prior to emplacement of the sampler and location of the intake within the streamflow. Logistically, the sample site must be evaluated as to accessibility, availability of electrical power, location of a bridge, cableway, or other means to safely obtain manual measurements at the site, and normal range of ambient air temperatures inherent in local weather conditions. The availability of a local observer to collect periodic reference samples also should be considered. The sediment-transport characteristics should include detailed information on the distribution of concentrations and particle sizes throughout the sampled cross section over a range of discharges. Glysson (1989b) describes other information requirements associated with collection of sediment data.

#### 5.3.5.1.2 Placement and Orientation of Sampler

**Intake** The primary concept to consider when placing a sampler intake in the streamflow at a sample cross section is that only one point in the flow is being sampled. Therefore, to yield the most reliable and representative data, the intake should be placed at the point where the concentration and particle-size distribution are most representative of the mean sediment concentration for the cross section over the full range of flows. This idealistic concept has great merit, but the mean cross section concentration almost never exists at the same point under varying streamflow conditions. It is even less likely that specific guidelines for locating an intake under given stream conditions at one stage would produce the same intake location relative to the flow conditions at a different stage. These guidelines would have even less transfer value from cross section to cross section and stream to stream. For these reasons, some generalized guidelines are outlined here and should be considered on a case-by-case basis in placing a sampler intake in the streamflow at any given cross section (Edwards and Glysson 1999):

1. Select a stable cross section in a reach with reasonably uniform depths and widths to maximize the stability of the relation between sediment concentration at a point and the mean sediment concentration in the cross section. This guideline is of primary importance in the decision to use a pumping sampler in a given situation; if a reasonably stable relation between the sample-point concentration and mean cross section concentration cannot be attained by the following outlined steps, an alternate location for the installation should be considered.
2. Consider only the part of the vertical that could be sampled using a standard US depth- or point-integrating suspended-sediment sampler, excluding the unsampled zone, because data collected with a

depth- or point-integrating sampler will be used to calibrate the pumping sampler.

3. Determine, if possible, the depth of the point of mean sediment concentration in each vertical for each size class of particles finer than 0.25 mm from a series of carefully collected point-integrated samples.
4. Determine, if possible, the mean depth of occurrence of the mean sediment concentration in each vertical for all particles finer than 0.25 mm.
5. Use the mean depth of occurrence of the mean sediment concentration in the cross section as a reference depth for placement of the intake.
6. Identify or install a means to fix the intake at the desired location in flow. The attachment feature and intake should have a high probability of remaining in place at high flows and should be not be prone to collecting debris.
7. Adjust the depth location of the intake to avoid interference by dune migration or contamination by bed material.
8. Adjust the depth location of the intake to ensure submergence at all times.
9. Locate the intake in the flow at a distance far enough from the bank to eliminate any possible bank effects. Avoid placing the intake in an eddy.
10. Place the intake in a zone of high velocity and turbulence to improve sediment distribution by mixing, reduce possible deposition on or near the intake, and provide for rapid removal of any particles disturbed during a purge cycle.

Because of the generalized nature of these guidelines and because selected guidelines may prove to be mutually exclusive, it will often be impossible to satisfy them all when situating a pumping sampler intake into streamflows. The investigator is encouraged, however, to try to satisfy these guidelines or, at the very least, to satisfy as many as possible and to minimize the effects of those not satisfied.

The orientation of the pumping sampler intake nozzle can drastically affect sampling efficiency. There are five ways in which an intake could be oriented to the flow (see Fig. 5-18): (1) normal and pointing directly upstream (Fig. 5-18A), (2) normal and horizontal to the flow (Fig. 5-18B), (3) normal and vertical with the orifice up (Fig. 5-18C), (4) normal and vertical with the orifice down (Fig. 5-18D), and (5) normal and pointing directly downstream (Fig. 5-18E). Of these five orientations, A, C, and D should be avoided because of high sampling errors and trash-collection problems. Orientation B, with the nozzle positioned normal and horizontal to the flow, is the most common alternative used. The major problem with this orientation is that sand-size particles may not be adequately sampled (see the following section on pumped-sample data analysis). Orientation E, pointing directly downstream, may be advantageous over orientation B (Winterstein and Stefan 1986). When the

**Fig. 5-18.** Examples of pumping-sampler intake orientations. (A) Normal and pointing directly upstream. (B) Normal and horizontal to flow. (C) Normal and vertical with the orifice up. (D) Normal and vertical with the orifice down. (E) Normal and pointing directly downstream.

intake is pointing downstream, a small eddy is formed at the intake, which envelops the sand particles and thus allows the sampler to collect a more representative sample of the coarse load. Regardless of the intake orientation selected, the ratios of concentrations representative of the mean cross-sectional concentration and those from pumped samples are needed to define the sampling efficiency over a broad range of flows.

**5.3.5.1.3 Activation** The advent of the microprocessor as an integral part of the sampler, or as an external controller, provides many options for controlling pumping samplers that can be tailored to data-collection requirements on-hand. Gray and Fisk (1992) describe a method for controlling an automatic water sampler based on time, stage, and rate-of-stage-change criteria. Their technique is designed to provide adequate definition of the flood hydrograph to make possible reliable computations of daily sediment and associated solid-phase radionuclide discharges. Lewis (1996) describes a means for controlling an automatic sediment sampler based on real-time turbidity measurements. A technique for controlling an automatic water sampler that provides unbiased estimates of suspended-sediment discharges, based on time-stratified sampling and

selection at list time, is described by Thomas (1985; 1991), and Thomas and Lewis (1993a).

**5.3.5.2 Single-Stage Samplers** Single-stage samplers were developed to meet the urgent needs for instruments useful in obtaining sediment data on streams where remoteness of site location and/or rapid changes in stage make it impractical to use a conventional depth-integrating sampler. They are generally less reliable, both in operation and in data accuracy, than depth-integrating samplers. However, even approximate information on the concentration of sediment between visits to the stream can be important if nothing better is available (FISP 1961; Edwards and Glysson 1999).

The US U-59 series single-stage samplers designed and tested by the FISP consist of a 0.45-L milk bottle or other sample container, a 4.7-mm inside diameter air exhaust, and a 4.7- or 6.4-mm inside diameter intake constructed of copper tubing. Each tube is bent to an appropriate shape and inserted through a stopper sized to fit and seal the mouth of the sample container. There are four models of US U-59 samplers. That designated US U-59A is designed for collection of silt- and clay-size sediments in low (less than about 0.7

m/s stream velocities. Those designated US U-59B, US U-59C, and US U-59D are for collection of sand-size and finer material in stream velocities less than 1, 1.6, and 2.1 m/s, respectively. A US U-59D single-stage suspended-sediment sampler is shown in Fig. 5-19A.

The US U-59 series of samplers obtains a sample on the rising phase of the hydrograph from a point near the water surface when the water level inside the intake tube reaches the weir elevation. As the sample siphons from the intake orifice into the sample bottle, air from the sample bottle vents out of the exhaust tube. The sampler is designed to cease filling when the sample elevation reaches the inner exhaust tube orifice. The sample velocity in the intake tube is a function of various factors, including stream velocity, intake orifice orientation, turbulence, and the presence of obstructions in the intake or exhaust tube.

The sampling operation just described is somewhat idealistic because, in reality, the operation is affected by various factors including flow velocity and turbulence. These factors alter the effective pressure at the nozzle entrance, which in turn alters the sampler's intake velocity.

The US U-59 sampler has many limitations with respect to good sampling objectives. It is a type of point sampler because it samples a single point in the stream at whatever stage the intake nozzle is positioned when immersed in flow. Its primary purpose is to collect a sample automatically, and it is used at stations on flashy streams or other locations that are difficult to visit in time to manually collect samples. Besides being automatic, the US U-59 is simple and inexpensive compared to automatic pumping samplers; a bank of them can be used to obtain a sample at various elevations during the rising hydrograph. However, despite these seemingly

important advantages, the US U-59 sampler has many limitations. Following are the most important of these limitations:

1. Samples are collected at or near the stream surface, so that, in the analysis of the data, theoretical adjustments for vertical distribution of sediment concentration or size are necessary.
2. Samples usually are obtained near the edge of the stream or near a pier or abutment; therefore, theoretical adjustments for lateral variations in sediment distribution are required.
3. Even though combinations of size, shape, and orientation of intake and air-exhaust tubes are available, the installed system may not result in intake ratios sufficiently close to unity to sample sands accurately at parts of the runoff hydrograph.
4. Covers or other protection from trash, drift, and vandalism often create unnatural flow lines at the point of sampling.
5. Water from condensation may accumulate in the sample container prior to sampling.
6. Sometimes the sediment content of the sample changes during subsequent submergence.
7. The device is not adapted to sampling on falling stages or on secondary rises.
8. No specific sampler design is best for all stream conditions.
9. The time and gauge height at which a sample was taken may be uncertain.
10. At high velocities, flow can circulate into the intake nozzle and out the air exhaust. This can result in an

**Fig. 5-19.** (A) US U-59D single-stage suspended-sediment sampler and (B) Modified single-stage sampler. Reprinted from Gray and Fisk (1992) with permission.

increase in the concentration of coarse material in the sample by at least an order of magnitude.

Gray and Fisk (1992) developed a modified single-stage sampler that provides a measure of protection against vandalism and flood damage while minimizing the potential for water circulation (Fig. 5-19B). Various single-stage samplers are arranged vertically inside a protective polyvinyl chloride (PVC) pipe capped at both ends. Screw-cap 0.9-L bottles are used to provide a larger sample volume and a more positive seal. External air-exhaust orifices extend through the top cap to the highest elevation feasible for the site, reducing the potential for its inundation. External intake orifices are set flush with the exterior PVC pipe so that debris cannot snag on them. A hinged lockable door provides access to the 0.9-L sample bottles.

The US U-73 single-stage sampler is more sophisticated than the previously described single-stage samplers. It can be used to obtain samples on the rising and falling phases of a hydrograph. Additionally, it features an exterior design that allows for a degree of protection from trash or drift without additional covers or deflection shields. Aside from these advantages, the US U-73 has the same limitations and should be used under the same conditions as the US U-59 sampler. Although the US U-73 sampler is no longer stocked by the FISP, plans are available for its construction (FISP 2000).

The investigator using single-stage samplers may find protective measures necessary to avoid blockage of intakes or air exhausts due to nesting insects. In freezing temperatures, precautions against sample-container breakage due to expansion of a freezing sample are advised.

The percent sand-size material should be analyzed for all samples collected by single-stage samplers. This analysis will help identify instances of bias in concentrations resulting from sample recirculation.

### 5.3.6 Subsampling Equipment

Samples of water-sediment mixtures are sometimes subsampled, or split into multiple parts to make possible different analytical determinations on the subsamples. The validity of data obtained from subsamples depends on their comparability of selected constituent concentrations to those in the original sample. Subsamples tend to have larger constituent variances than the original, and also may be biased. Subsampling should be avoided unless it is necessary to achieve the ends of the sampling program.

Before 1976, USGS guidelines on manual sample splitting required compositing the water sample into a large, clean jug or bottle, shaking it for uniform mixing, and then withdrawing the required number of samples (USGS 1976). In 1976, the 14-L churn splitter was introduced to facilitate the withdrawal of a representative subsample of a water sediment mixture (Capel and Larson 1996; Lane et al. 2003). A fluoropolymer version of the churn splitter for trace-element

subsampling is also available (FISP 2002). The cone splitter, a device developed to split water samples for suspended sediment and other water-quality constituents into up to 10 equal and representative aliquots, was introduced for wide-scale use in 1980 (Capel and Nacionales 1995; Capel and Larsen 1996).

Based on test results on the sediment-splitting efficiency of the churn and cone splitters (USGS 1997), the USGS has approved the use of the churn splitter for providing subsampling when the original sample's sediment concentration is less than 1,000 mg/L at mean particle sizes less than 0.25 mm. The cone splitter is approved for providing subsamples at sediment concentrations up to 10,000 mg/L at mean particle sizes less than 0.25 mm. The test data suggests that the cone splitter's acceptable concentration range exceeds 10,000 mg/L, and may be as large as 100,000 mg/L.

## 5.4 BED LOAD SAMPLERS

*R. Kuhnle*

The part of the total sediment load that is transported by traction or saltation on or immediately above the streambed is termed the bed load. Sediment transported as bed load can range in size from fine sands to coarse gravel depending on the flow strength. The separation of sediment in transport into bed load and suspended load is artificial, as there is often no clear-cut break between the two groups. The distinction is convenient, however, because most suspended sediment samplers currently in use have an unsampled zone that extends from the bed to several centimeters up into the flow. The sediment in transport in this zone near the bed is often referred to as the unmeasured load and consists of the bed load plus the lowermost fraction of the suspended load.

Knowledge of the rate of bed load transport is important for several reasons. The bed load is part of the total sediment load that represents net erosion from upstream areas of the watershed. Sediment conveyed downstream may fill reservoirs and channels, which impedes navigation, may increase the likelihood of flooding, and may degrade water quality and aquatic habitats. Local erosion and deposition of the bed material may also cause instability of the channel banks. Any long-term program of channel stabilization or rectification must take into account the transport of bed load and ensure that sediment is not accumulating or eroding.

The rate and size of sediment in transport as bed load varies dramatically with time at a point, and spatially at a given time over a cross section of a channel (Figs. 5-20A and B), even when the flow is steady (Ehrenberger 1932; Leopold and Emmett 1976; Carey 1985; Hubbell et al. 1985; Iseya and Ikeda 1987; Kuhnle and Southard 1988; Whiting et al. 1988; Kuhnle et al. 1989; Gray et al. 1991). This creates the challenge of designing a sampler that will sample with equal efficiency over widely varying transport rates, and collect

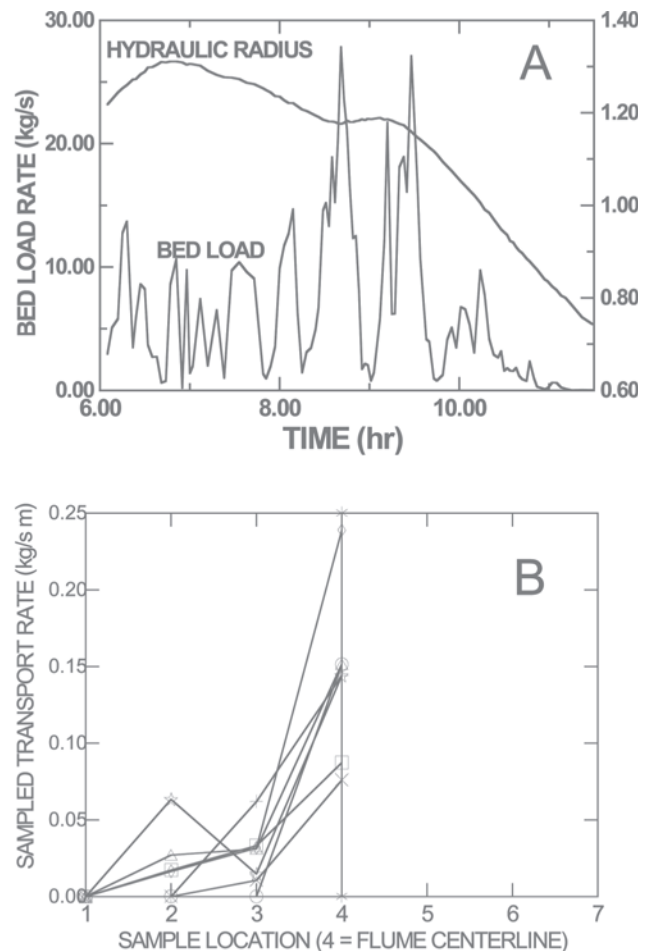

enough samples at a point and across the cross section to adequately define the mean rate for a given flow strength.

The determination of bed load has relied on three general methods (Hubbell 1964): direct measurement, using bed load transport relations, or measuring the erosion or deposition of bed-material sediment in a confined area. None of these techniques is suitable for a wide range of uses. Direct measurements suffer from the difficulty of deploying the samplers and collecting a sufficient number of samples, whereas no one bed load transport relation has been shown to have general applicability (e.g., Gomez and Church 1989; Vanoni 1975, pp. 221–222), and many areas do not have a convenient area to carry out erosion or deposition measurements. Therefore, no general empirical or theoretical technique is completely adequate for determining the discharge of bed load in natural streams and rivers.

The placement of any type of bed load sampler onto a bed must alter the local flow pattern and movement of sediment to some extent. The degree of disturbance a sampler will cause in local conditions is dependent on many things; among them are the shape and size of the sampler, the local flow velocity, the characteristics of the bed-material sediment, and the presence or absence of bed forms. The degree to which the sampler affects the local flow conditions will be reflected in the efficiency of the sampler in collecting samples of the bed load. To estimate the relation between the sampled rate and the true rate, the sampler will need to be calibrated. The calibration of a sampler is plagued by the problem of comparing the amount of sediment collected by the sampler to the undisturbed bed load movement that would have occurred if the sampler had not been in place (Einstein 1937). Due to the extreme variability of bed load transport processes this is an extremely difficult problem to solve and persists to this day.

#### 5.4.1 Types of Bed Load Samplers

Over the past 100 years, several types of bed load samplers have been developed by researchers at a variety of locations. These samplers may be generalized into three types: samplers installed into the bed of a channel (pit and trough samplers), manually operated portable samplers, and noninvasive samplers. Each of these sampler types has its use in the sampling of bed load. Perhaps the most accurate of these three types are the pit or trough samplers; however, the difficulty and high cost of their installation and servicing preclude their use in many studies. Portable samplers have the advantage of low setup costs, but personnel must be on site continuously during sample collection, sampler deployment may be difficult, and the number of samples needed to characterize temporal and spatial variability is usually large. Also, no generally accepted method has been developed for calibrating portable samplers. Samplers that use noninvasive techniques show much promise, but have not been developed to the point where they can be widely useful for the measurement of bed load transport.

**Fig. 5-20.** (A) Bed load transport rate and flow changes with time, Goodwin Creek, station 2. Samples were collected in the center of the structure during runoff event on 11/08/86 (Kuhnle et al. 1989). (B) Plots of lateral sets of samples collected at Goodwin Creek, station 2, during 02/27/87 transport event. The distance between sample locations is 1.5 m. Lateral samples were collected on one side of the structure centerline (Kuhnle 1992b).

**5.4.1.1 Manually Operated Portable Samplers** Bed load samplers of this type have been developed and used in many countries to determine rates of bed load movement for sediment varying in size from 1 to 300 mm (FIARBC 1940; Hubbell 1964). The development of bed load samplers has often been associated with individual project studies. These samplers have been classified as to their type of construction and principle of operation, mainly as basket samplers, pan or tray samplers, and pressure-difference samplers (Hubbell 1964). Basket and pan samplers cause an increased resistance to flow through the sampler and water velocity in the sampler is therefore lower than in the free stream. This reduction in flow velocity in the sampler reduces the shear stress and the rate of bed load transport in the vicinity of the sampler, with the result that some particles accumulate at the entrance to

the sampler and others are diverted away. The pressure-difference type samplers are designed to eliminate the reduction in water velocity in the sampler, and thus any reduction in the rate of bed load movement at the entrance to the sampler. The velocity in the sampler is made equal to that of the flow by creating a decrease in pressure at the exit of the sampler nozzle by having a gradual increase in area. Pressure-difference samplers generally have a hydraulic efficiency (ratio of flow velocity in sampler to flow velocity for same location without sampler) of about one or greater (Hubbell et al. 1985). One key parameter in the design of pressure-difference samplers is to make the hydraulic efficiency large enough to prevent sediment from depositing in front of the sampler, but not so large as to cause scouring of the bed and oversampling.

For a bed load sampler to operate correctly, it should be used within the range of conditions for which it was designed. The most restrictive of these design elements include bed load particle sizes as compared to the inlet opening of the sampler; bed load rates as compared to the size of the catchment volume; water depth according to whether the sampler was designed for wading or cable suspension; and flow velocities as related to resistance of the sampler in the flow and range of calibration velocities. Only a few of these types of samplers have been calibrated and there is no widespread agreement on the methodology to use to calibrate a bed load sampler (Engel and Lau 1980; Hubbell et al. 1985; Thomas and Lewis 1993b). Calibrations of these samplers indicate a mean efficiency of about 45% for basket or pan type and vary from 80% to 180% for pressure-difference types. These efficiencies may vary with transport rate, sediment size, and sediment gradation.

Descriptions of some pressure-difference bed load samplers that are in current use are presented in Table 5-3. These include the Federal Interagency Sedimentation Project BL-84

(Fig. 5-21) (Davis 2005); the 7.62-cm-square Helley-Smith (Helley and Smith 1971); the 15.24-cm-square Helley-Smith; the Toutle River-2 (Childers 1992); the Elwha River (Childers et al. 2000); the Delft-Nile sampler (Van Rijn and Gaweesh 1992); and the BTMA-2 (Duizendstra 1999). Typical problems with operation of pressure-difference samplers include the following (Van Rijn and Gaweesh 1992):

1. The initial effect: Sand particles of the bed may be stirred up and trapped when the instrument is placed on the bed (oversampling).
2. The gap effect: A gap between the bed and the sampler mouth may be present initially or generated at a later stage under the mouth of the sampler due to migrating ripples or erosion processes (undersampling).
3. The blocking effect: Blocking of the bag material by sand, silt, clay particles, and organic materials will reduce the hydraulic coefficient and thus the sampling efficiency (undersampling).
4. The scooping effect: The instrument may drift downstream during lowering to the bed, and may be pulled forward (scoop) over the bed when raised again so that it acts as a grab sampler (oversampling).

Five types of conditions occurring during collection of bed load samples with the Delft-Nile sampler were recognized by Gaweesh and Van Rijn (1994) using a video camera mounted near the sampler on the Nile and Rhine Rivers. Two of these types of conditions (the gap effect and scooping effect) were found to result in either significant under- or oversampling by the Delft-Nile sampler. Gaweesh and Van Rijn (1994) recommended removing the highest and lowest 10% of the collected samples based on the fact that these two types each occurred approximately 10% of the time. This technique was found to improve the results of their field bed load sampling.

**Table 5-3 Portable Bed Load Samplers**

Sampler name	Sediment sizes (mm)	Entrance width (m)	Entrance height (m)	Type of sampler	Hydraulic efficiency (%)	Sampling efficiency (%)	Capacity of sampler (kg)

**Fig. 5-21.** Photograph of Federal Interagency Sedimentation Project BL-84 samplers. (A) Hand version: BLH-84. (B) Cable-mounted version: BL-84. The ratio of the inlet area to the outlet area is 1.40 on this sampler.

The orientation of the Helley-Smith sampler with respect to the mean flow velocity vector has also been found by Gaudet et al. (1994) to affect the efficiency of sediment sampling. If the sampler was misaligned as little as  $10^\circ$  from the mean flow velocity vector, significant decreases in sediment sampler efficiency were found by Gaudet et al. (1994). Although misalignment may not be a problem in many situations, sampling in complex flow fields could be affected by this problem.

These potential problems with pressure-difference samplers have been recognized by researchers over the years and design and sampling procedure changes have been made to correct for these problems. Stay lines have been used successfully by several researchers to aid in controlling the sampler in high-velocity conditions (Childers 1992). Samplers with flexible bottoms, guide fins, larger collection bags (Bunte et al. 2001), bottom sensors, and underwater video cameras (Dixon and Ryan 2001) have been designed to solve these problems. The BTMA-2 sampler (Duizendstra 1999) is perhaps the most advanced system in use to date to avoid the problems outlined above that occur with pressure-difference samplers.

**5.4.1.1.1 Manually Operated Portable Sampler Calibrations** Most types of portable samplers cause some degree of disruption to the flow and some degree of disruption to the transport of bed material as well. Unless steps are taken in portable sampler design to increase the flow through the sampler, sediment will tend to be deposited in front of or inside the sampler orifice and low and erratic sampling efficiencies will result. To improve the sediment-sampling efficiency of portable samplers, pressure difference nozzles were designed (Helley and Smith 1971) to increase the flow of water through the sampler. Thus hydraulic efficiency in pressure difference samplers is designed to be equal to or greater than 100% (Druffel et al. 1976). Hydraulic efficiencies are readily measured in laboratory flumes, however, sediment-sampling efficiencies are much more difficult to measure.

Unless a sampler works perfectly and collects an unbiased sample of the sediment in transport, a calibration coefficient is needed to correct the sampled rate to the actual rate.

$$q_b = \alpha c_s \quad (5-10)$$

where

$q_b$  = actual bed load transport rate;  
 $c_s$  = sampled transport rate; and  
 $\alpha$  = calibration coefficient.

Equation (5-10) assumes that the actual bed load rate is a linear function of the sampled rate. In general,

$$q_b = f(c_s) \quad (5-11)$$

where  $q_b$  is an unknown function of  $c_s$ . If  $q_b$  is not a linear function of  $c_s$ , their mean values will not satisfy equation (5-10) and the use of means will lead to erroneous results (de Vries 1973). This complicates considerably the calibration of bed load samplers. One proposed solution to this problem is to compare the actual and sampled bed load transport rates that occur for the same probability (Einstein 1937; de Vries 1973; Hubbell et al. 1985). This procedure was termed "probability matching" by Hubbell et al. (1985) and was used to define composite calibration curves for several portable samplers. The results from the probability matching procedure were disputed by Thomas and Lewis (1993b). As an alternate method of analysis, Thomas and Lewis (1993b) transformed the sampler and bed load trap data from Hubbell et al. (1985) to obtain a linear relation between the two variables. Their results from this transformed data indicated that pressure-difference samplers with higher nozzle ratios (3.22) collected more sediment than the ones with lower ratios (1.4), and that samplers with smaller orifices performed more uniformly than ones with larger orifices (0.076 m square versus 0.152 m square).

Other researchers have worked on the problem of portable bed load sampler calibration (Emmett 1980; Engel and Lau 1980; Ryan and Porth 1999). Engel and Lau (1980) developed a dimensional analysis technique and used it with data collected from a scale model of a basket sampler to calculate a calibration curve for the full-sized basket sampler used by the Water Survey of Canada. The efficiency of the

basket sampler was found to vary from about 50% at low trap numbers (low transport rates) to about 25% at high trap numbers. Emmett (1980) calculated calibration curves for the original version of the Helley-Smith sampler (Helley and Smith 1971), using data collected on the East Fork River. Bed load transport data collected using the trough conveyor-belt sampler on the East Fork River, when compared to data collected with the Helley-Smith sampler, yielded efficiencies near 100% for grain sizes from 0.5 to 16 mm. Ryan and Porth (1999) compared data collected from three pressure difference samplers, the original Helley-Smith sampler, the BL-84, and an original design Helley-Smith sampler constructed of sheet metal. The data from the three samplers were compared to data on bed load obtained from surveying sediment accumulation in a weir pond. Calculations of annual bed load for all three samplers (Ryan and Porth 1999) were well within an order of magnitude of the accumulations measured in the weir pond. Studies comparing different portable samplers to each other have been made by Childers et al. (1989); Childers (1991; 1992); Gray et al. (1991); and Pitlick (1988). These studies demonstrate that relatively minor differences in sampler design can cause large differences in the size of the collected samples. The original version of the Helley-Smith sampler has been shown in one study to have an sediment efficiency of nearly 100% (Emmett 1980) for one set of conditions and to oversample for another set of conditions (Hubbell et al. 1985). Gray et al. (1991) found that the original Helley-Smith sampler tended to collect more material at high sediment transport rates and collect less material at lower rates than an early version of the BL-84 bed load sampler. The sometimes conflicting results, however, serve to underline the complexity of the transport of bed load by streams and rivers and to highlight the importance of the conditions of the streams in which the measurements are collected.

**5.4.1.2 Pit and Trough Samplers** One of the most accurate ways to sample bed load is through the use of carefully designed and installed pit or trough samplers (Hubbell 1964; Poreh et al. 1970). These samplers are installed in the bed of the channel by burying the sampler so that the top is flush with the surface of the bed. Pit and trough samplers range from simple containers to complicated weighing and recording instruments. Basic ones consist of small containers that catch and retain all bed load sediment that is transported to the sampler (e.g., Waslenchuk 1976; Murphy and Amin 1979; Church et al. 1991; Wilcock et al. 1996). Samplers of this type capture the total or minimum amount (if the sampler is filled in an unknown time) of sediment transported as bed load during the measurement period. For studies in which information on the beginning of bed load transport and the rates of transport during the measurement periods are needed, recording pit samplers (Fig. 5-22) have been designed and used successfully (Reid et al. 1980; Lewis 1991; Kuhnle 1992; Laronne et al. 1992).

**Fig. 5-22.** Schematic cross section of box sampler: (1) outer box, (2) inner box, (3) slotted cover, (4) pressure pillow, (5) bubble tube outlet, (6) water surface, (7) tubes from bubbler and pillow, (8) stream bank, (9) instrument house, (10) air trap, (11) valves, (12) pressure transducer, (13) power supply, (14) bubble gauge, and (15) wires to remote telemetry system (Kuhnle 1991).

For sand-bedded channels, experiments have shown that samplers having slot widths of 100 to 200 grain diameters collect nearly 100% of the bed load (Einstein 1944). Sand particles often move by making brief excursions into the flowing water and then falling back to the bed. The specification of slot widths for sand grains was determined from the probable lengths of these excursions. As particle sizes increase into the gravel size range, transport occurs with grains spending progressively more time in contact with the bed (gravel-size grains usually slide or roll along the bed) and the parameter for slot widths from Einstein is no longer applicable. Poreh et al. (1970) have shown in a laboratory flume that when the ratio of the stream parallel slot length to the sediment grain diameter is about 35 for grain sizes between 1.88 and 4.5 mm, the efficiency of a channel-wide pit sampler approaches 100%. Poreh et al. (1970) also recommend using an unerodable apron upstream of the sampler to reduce the effect of bed forms on sampler performance. Slot lengths parallel to flow should not be made too much larger than necessary as secondary flows in the trap increase with slot length (Ethembabaogla 1978) and may cause smaller grains moving as bed load to be excluded from the trap (Wilcock et al. 1996). Some pit samplers (Kuhnle 1992) have incorporated flow transverse vanes to break up secondary flows in the sampler. Another potential problem with pit traps with widths narrower than the channel width is the lateral entry of sediment into the slot. Emmett (1980) calculated that when only part of the slot was used to sample on the East Fork River, bed load transport was consistently overestimated by a factor of 1.3 compared to using the whole width of the slot. Lewis (1991) described the use of low-profile fences along the top of the sampler cover to minimize the possibility of lateral entry of sediment into the sampler.

Most pit samplers have been designed to be installed permanently at one location. Installation of pit samplers requires access to the streambed. After sediment transport events, pit samplers usually must be emptied manually or with a slurry pump. These requirements favor installations on streams that either are ephemeral or drop to very low base flows between sediment transport events (Reid et al. 1980; Lewis 1991; Kuhnle 1992; Laronne et al. 1992). More complicated pit-type bed load samplers with systems to continuously remove the accumulated bed load sediment have been constructed on larger streams; however, the cost of the installation and servicing rises considerably (Enoree River, FIARBC 1940; East Fork River, Leopold and Emmett 1976; Emmett 1980).

Einstein (1944) and Hubbell (1964) have described a semiportable pit sampler for use in sand-bedded streams that automatically dredges a place in the bed of the stream for the sediment trap. Following installation of the sediment trap, a valve is thrown and the dredging pump is used to continuously remove the sediment as it accumulates in the trap. The sediment and water slurry is then routed to a weighing tank and then returned to the stream. Some preliminary investigations have been conducted with a sampler of this type by Einstein (1944) and Hubbell (1964). The sampler would be restricted to streams with sand beds and low flow velocities. For most streams, several of these samplers would need to be used simultaneously to assure adequate coverage of the cross section.

**5.4.1.3 Vortex Tube Bed Load Samplers** Vortex tubes have been used to sample bed load successfully at several locations (Milhous 1973; Hayward and Sutherland 1974; O'Leary and Beschta 1981; Tacconi and Billi 1987). The design of these samplers was based on a vortex tube sand trap that was designed for excluding unwanted bed load sediment from irrigation and other canals (Robinson 1962). These samplers consist of a 45° diagonal slot in a concrete broad crested weir constructed across the channel at the measurement site (Fig. 5-23). A vortex is generated in the diagonal slot and from 5% to 15% of the flow carries the bed load sediment to a trap on the side of the channel. The sediment is then weighed and sampled and returned to the stream downstream of the weir. Robinson (1962) reports that when designed correctly, such samplers remove approximately 80% of the sediment with size greater than 0.5 mm from the stream. The efficiency of these samplers for smaller and larger grain sizes would be expected to be lesser and greater respectively. Milhous (1973) estimates that the overall efficiency of the vortex tube sampler on Oak Creek to range from 85% for low transport rates to 95% for higher sediment transport rates with all grains larger than 4.76 mm trapped.

Vortex tube samplers have been shown to be effective bed load samplers on small gravel-bed streams. These samplers have many of the same disadvantages, however, as pit samplers. They are not portable and the initial construction cost is high. One important advantage that vortex tube samplers have over pit samplers is that the sediment is delivered to the side of the stream and does not need to be removed from the

**Fig. 5-23.** Sketch of bed load measuring station using a vortex-tube trap on Virginio Creek (from Tacconi and Billi 1987, p. 586). Copyright 1987, John Wiley and Sons Ltd. Reproduced with permission.

sampler after the transport event. Therefore, the sampler will not fill before the transport event is completed.

**5.4.1.4 Other Methods** Several other methods have been used experimentally to measure the rate of bed load transport. These methods include particle imaging (Drake et al. 1988), bed form tracking (Simons et al. 1965; Willis 1968; Willis and Kennedy 1977; Engel and Lau 1980; Kuhnle and Derrow 1994; Garcia 1998; Tate and Rubin 1998; Dinehart 2001; Rubin et al. 2001), magnetic tracking (Reid et al. 1984; Carling et al. 1993), and acoustic techniques (Thorne et al. 1989). Although these methods show varying degrees of promise for improved samplers, none has been developed to the extent that it can be considered a standard technique for sampling bed load in streams and rivers. Such things as the necessity of clear water, bed forms, magnetic bed material, or the calibration of sediment generated noise all currently combine to limit the extent that the above techniques will be usable.

**5.4.1.5 Summary** A variety of sampler types are available to sample the bed loads of streams and rivers. It is clear that no one sampler type is generally superior to the others for the collection of bed load data. All of the types reviewed above have advantages and disadvantages in different situations. Pit

and trough samplers have been shown to operate reliably on relatively small gravel-bed streams; however, their use on larger streams and rivers would be very difficult. Portable samplers are generally inexpensive to acquire, but may be expensive to operate and suffer from uncertain calibrations. Bed load samplers that use acoustic, optical, magnetic, bed form tracking, or other emerging technologies have shown a great deal of promise, but have not been proven to be reliable to date except under controlled laboratory conditions.

#### 5.4.2 Bed Load Discharge Measurements

Measurement of bed load is difficult because it is highly variable in both space and time (Ehrenberger 1932; Hubbell 1964; Leopold and Emmett 1976; Carey 1985; Hubbell 1987; Whiting et al. 1988; Dinehart 1989; Kuhnle et al. 1989; Wathen et al. 1995; Powell et al. 1998). Bed load generally varies greatly both longitudinally along the channel and transversely across a cross section. These variations are caused by several factors and are difficult to predict. Causes of the variations include the presence of dunes or other bed forms; locally varying shear stress due to bed topography, secondary flow, or turbulence changes; varying supply of bed material from upstream sources; and changes in bed surface grain sizes. The design of bed load sampling needs to account for the spatial and temporal variability inherent in the processes of bed load transport. Pit, vortex-tube, or other samplers that sample for long periods of time and encompass a significant portion of the width of a stream cross section integrate the fluctuations in bed load transport rate in a cross section. In many instances time, monetary constraints, or logistics precludes the use of these types of samplers, however. The use of portable samplers that essentially only collect samples at a point for short periods of time is often the only practical way to collect samples of bed load. To effectively use portable samplers, the number and location of the samples collected must be carefully designed to assure sufficient information about the temporal and spatial variability is collected. To accomplish this task, information on the scales of spatial and temporal variability is needed.

Several studies have concentrated on the temporal variability of bed load transport. Carey (1985) and Carey and Hubbell (1986) have shown that a series of 120 bed load samples collected at a point in a sand-bed stream yielded a distribution very similar to that proposed by Hamamori (1962). Hubbell and Stevens (1986) showed that bed load data collected in a large flume at the Saint Anthony Falls Hydraulic Laboratory, as well as bed load data from other researchers, were reasonably well approximated by the Hamamori distribution. Kuhnle (1996) showed that sample durations of several minutes to tens of minutes were required to obtain an adequate estimate of the mean bed load transport rate in laboratory flume experiments. Gomez et al. (1990), using the flume data collected by Hubbell et al. (1987), determined that at-a-point bed load transport samples should cover the

movement of at least one primary bed form past the sampling location. Preferably, more than one primary bed form should be covered by the sampling period. Gaweesh and Van Rijn (1994) found that 25 samples should be taken distributed along the bed form length to adequately represent the variability of bed load transport in sand-bed rivers.

Only a limited number of studies have documented spatial variability by collecting bed load samples simultaneously at several locations across a channel (Leopold and Emmett 1976; Hubbell et al. 1987; Powell et al. 1998). Emmett (1980) tested the Helley-Smith sampler using the bed load rates calculated from the East Fork River trough sampler. This study yielded a calibration of the Helley-Smith sampler on the East Fork River and a test of the sampling technique used with the Helley-Smith sampler to arrive at a mean cross-sectional bed load rate. Emmett found that sometimes all or most of the bed load transport occurred in a narrow part of the channel. The location of this high-transport zone was stable on short time scales (hours), but not necessarily for longer periods of time. Emmett (1980) recommended that two sampling traverses should be conducted, each of which should consist of at least 20 equally spaced cross-channel locations, to describe the spatial variation across the channel. It was recommended that spacings between samples range from 0.5 to 15 m apart.

Hubbell and Stevens (1986; Hubbell 1987) generated simulated bed load data that varied in time according to the Hamamori (1962) distribution and assumed several different patterns of lateral variation in bed load transport. The generated bed load record was "sampled" using traverses of 4 and 20 equal positions across the cross section. In cross sections in which the lateral variability was moderately nonuniform, the numbers of samples needed to predict the mean transport rate to within 30% were comparable for sampling designs that collected samples at 4 and 20 positions in each transect. For nonuniform lateral distributions the number of samples required for the 4-position transect was approximately double that required for the 20-position.

Gaweesh and Van Rijn (1994) determined the number of positions required to obtain relative errors in bed load transport rates less than 20% over the width of the Nile River at several cross sections. This analysis was based on measured flow velocities on the cross sections and applying the transport formula of Engelund and Hansen (1967) at each potential sampled position. Gaweesh and Van Rijn (1994) concluded that irregular cross sections should be divided into seven subsections and 25 samples should be collected distributed equally along the bed form length at each subsection to obtain an overall relative error of 20%.

Gomez and Troutman (1997) conducted a study in which process errors due to different sampling techniques were evaluated for simulated bed load records that represented the temporal and lateral variations that would be expected for dune beds. Gomez and Troutman found that four or five sampling traverses, and collection of 20 to 40 samples at a rate of five

or six samples per hour, were necessary to adequately sample the bed load of a hypothetical stream. These samples would be collected over a period of 3 to 8 h, which would allow a number of bed forms to pass through the sampling section.

The accuracy associated with the collection of bed load transport on a large sand-gravel-bed river was calculated by Kleinhans and Ten Brinke (2001). They evaluated the uncertainty of the integrated transport for bed load by assuming the transport samples were normally distributed without measurement and prediction errors. This evaluation was applied to sediment transport data collected using modified Helley-Smith samplers on the Waal River in the Netherlands. Their calculations yielded an uncertainty of 10% to 20% in integrated bed load transport, using five subsections and 30 samples/subsection. A major problem identified in this study was the long periods of time required for the collection of these samples (3.5 days) and the changes in discharge that occurred over that time.

Studies that yield guidance on the numbers of traverses and samples that are required to reliably calculate the mean bed load rate are useful, but suffer from several shortcomings. Perhaps most critical of these shortcomings is the fact that the time and length scales of temporal and lateral variability in streams are poorly known and generally vary with time at a given location and from stream to stream. To design an adequate sampling strategy these time and length scales must be known at least approximately before the sampling procedure is defined. In the recommendations previously reviewed above (Emmett 1980; Hubbell and Stevens 1986; Gaweesh and Van Rijn 1994; Gomez and Troutman 1997; Kleinhans and Ten Brinke 2001), the amount of time required to collect the recommended number of samples is too long for many streams. Flow in many streams and rivers is not steady for periods of hours to days. For streams in which variable flow is the norm, portable samplers will not be practical unless many flow events can be sampled. Edwards and Glysson (1999) concluded that no one sampling protocol can be used at all stations. They recommend that to the extent possible, a sampling protocol should be derived for each site where bed load is to be sampled. Initial samples collected can provide information to serve as a basis for developing the sampling plan.

## CHAPTER 6

# *Fundamentals of Fluvial Geomorphology*

*D. S. Biedenharn, C. C. Watson, and C. R. Thorne*

Geomorphology is the study of landforms and the processes responsible for making and modifying them. Fluvial geomorphology is the study of landforms whose genesis and evolution are affected by flowing water. A river or stream constitutes a geomorphic system and in working on a natural watercourse the complete system must be considered because, even though a project may directly involve only a small portion of the system, it has the potential to trigger morphological responses in any part of the system. It is impossible to predict the types and locations of morphological responses without a good understanding of the fluvial system, and this demands thorough knowledge of the water and sediment regimes of the river, because the water discharge and associated sediment load drive morphological processes in the system. Water and sediment regimes in rivers derive from the natural climatic, geologic, topographic, and biologic characteristics of the watershed, together with land use and water resource management effects in developed watersheds. It is these watershed attributes and activities that control runoff and sediment sources, the magnitude and distribution of flows, the caliber and type of sediment, and the manner in which water and sediment are supplied to the channel network. In turn, interaction of the flow and sediment load with the materials forming the bed and banks of the channel dictate the three-dimensional morphology of the alluvial channel and its propensity for stability or change (Schumm 1977).

The purpose of this chapter is to present an overview of some basic concepts of fluvial geomorphology and river mechanics, with an emphasis on their application to engineering design of channel rehabilitation projects. In this chapter, “channel rehabilitation” is used in a broad sense that encompasses all aspects of channel modification to achieve a desired channel improvement, whether for river restoration, flood control, navigation, water supply, channel stability, sediment control, or other beneficial use. Regardless of the goals of the rehabilitation project, sound understanding

of geomorphic processes and forms in fluvial systems is essential to successful performance of channel rehabilitation projects.

### 6.1 BASIC CONCEPTS

The six fundamental concepts that should be considered in designing engineering works in rivers and watersheds are:

1. The channel in the project reach is only part of the broader fluvial system;
2. The fluvial system is dynamic;
3. The fluvial system behaves with complexity;
4. Adjustment and response in the system are nonlinear, and abrupt changes can be triggered by relatively small external perturbations or the crossing of geomorphic thresholds;
5. System evolution and response are time-scale-dependent and engineering geomorphic analyses must include a historical perspective; and
6. System evolution and response are space-scale-dependent and the physical size of the system or subsystem must be considered in engineering geomorphic analyses.

#### 6.1.1 The Fluvial System

Schumm (1977) provides an idealized sketch of a fluvial system (Fig. 6-1). Zone 1 is the upper portion of the system, that is, the watershed or drainage basin; this portion of the system functions as the zone of sediment supply. Zone 2 is the middle portion of the system, that is, the river; this portion of the system functions as the sediment exchange and transfer zone. Zone 3 is the lower portion of the system, which may be an estuary, delta, lake, floodplain, wetland, or reservoir; this portion of the system functions as the zone of sediment deposition. These three zones are idealized, because in real

Fig. 6-1. The fluvial system (Schumm 1977, with permission from S. Schumm).

systems sediments can be eroded, transported, and stored in any of the zones. However, within each zone one process is usually dominant, and Schumm's idealized schematization illustrates graphically how sediment processes throughout the system are connected.

In planning any type of engineering alteration to a stream, the potential impacts of disrupting or breaking sediment connectivity in the fluvial system must be considered. For instance, if a channel rehabilitation project is planned for a specific reach of stream in Zone 2, the design engineer must ensure, from a system viewpoint, that the scheme does not interfere unduly with the transfer of sediment from the source zone upstream (Zone 1) to the storage zone downstream (Zone 3).

The fundamental concept that a stream is part of a larger, complex system was eloquently encapsulated by Hans Albert Einstein (1972):

If we change a river we usually do some good somewhere and "good" in quotation marks. That means we achieve some kind of a result that we are aiming at but sometimes forget that the same change, which we are introducing, may have widespread influences somewhere else. I think if, out of today's emphasis of the environment, anything results for us it is that it emphasizes the fact that we must look at a river or a drainage basin or whatever we are talking about as a big unit with many facets. We should not

concentrate only on a little piece of that river unless we have some good reason to decide that we can do that.

### 6.1.2 The System Is Dynamic

Fluvial processes in each of Schumm's idealized zones are dominated by activity. Zone 1 is the sediment source zone, implying that erosion dominates, driving channel change through net incision or valley widening. Zone 2 is the exchange and transfer zone, implying that as runoff and sediment yield from the watershed increase, the transport capacity of the stream is able to keep pace, exchanging sediment between transport and storage while maintaining dynamic equilibrium in channel form and reworking the floodplain. Zone 3 is the zone of sediment accumulation, implying that deposition dominates, with channel change and long-term storage increasing as sediment accrues in this zone. The functioning of each zone indicates that the system is dynamic and that change in the fluvial system is not only natural, but also essential to its operation.

From an engineering viewpoint the impacts of these dynamics and channel changes may be very significant. For example, loss of 100 ft of stream bank due to channel migration may endanger a home or destroy valuable agricultural land. From a geomorphic viewpoint, channel migration is to be expected and channel shifting represents a natural

manifestation of the fluvial system. Indeed, it may not even signal a departure from conditions of natural, dynamic equilibrium. In planning channel rehabilitation measures, engineers must realize that when faced with having to work on a dynamic fluvial system we must try to understand the fluvial system and avoid disrupting it unduly while we are accomplishing our design task. Where disruption, for example, through perturbing the balance between sediment supply and transport capacity, is inevitable, we must predict the system response and take appropriate steps to prevent or at least mitigate adverse responses.

### 6.1.3 Complexity

Landscape changes are usually complex (Schumm and Parker 1973). The stream and its watershed are a landscape system; change to one portion of the system may result in complex changes, both locally and throughout the remainder of the system.

During complex response, the system responds through the activation of different processes at different locations and times in response to one triggering event or intervention. Consequently, when a fluvial system is subjected to an engineering intervention, changes should be expected to occur throughout the system and over a prolonged period. For example, channelization of a reach of the stream usually accelerates stream velocities, disrupting the sediment-transfer system by increasing sediment transport capacity and allowing the stream to carry away more sediment than is being supplied from upstream. This sediment imbalance results in bed erosion that can migrate upstream through the headcutting process and in increased sediment output that can migrate downstream as a wave of deposition. Through time, headcutting migrates upstream, increasing sediment supply to the channelized reach and eventually causing aggradation there. Thus, in response to a single external intervention, channelization, the affected reach can experience an initial degradational response followed by a secondary aggradational response. This type of complex response not only is theoretically possible, but also has been observed in nature. For example, several Yazoo Basin streams in north Mississippi that were channelized in the 1960s responded initially through degradation, but later exhibited aggradation (Harvey and Watson 1986; Watson et al. 1997). Over the 40 years since the initial perturbation, repeated waves of degradation, temporary stability, and aggradation have occurred, but dynamic equilibrium has still not yet been reestablished.

### 6.1.4 Thresholds

Rivers and watersheds are described theoretically as nonlinear, complex systems (Richards and Lane 1997) in that they display discontinuous responses to progressive and incremental change in control variables. In the context of fluvial geomorphology, threshold behavior is characterized by

progressive change in one variable that eventually results in abrupt change in the system. In engineering terms, the crossing of a geomorphic threshold may be evidenced either by an abrupt change in the rate, direction, or type of change in a naturally evolving fluvial system, or by a disproportionately strong response to a perturbation by an engineering intervention. Bank collapse due to channel incision has been cited as an example of threshold behavior (Thorne and Osman 1988) and may be used to illustrate the phenomenon and related consequences. As an alluvial river accumulates sediment on its bed, morphological evolution occurs through progressive channel aggradation. As aggradation continues, the channel slope gradually increases until, eventually, a limiting condition for bed slope with respect to sediment transport is reached. At this moment the trend of morphological evolution switches from aggradation to degradation as a geomorphic threshold (critical channel slope) is crossed.

Schumm (1973) argued that drainage basins exhibit both *extrinsic* thresholds and *intrinsic* thresholds. In the preceding example, channel change was driven by gradual accumulation of sediment on the bed, which could occur as part of sediment storage in Zone 3 in the natural system. This would be characteristic of an intrinsic threshold. Extrinsic thresholds are crossed when the system is perturbed by an external factor that triggers a disproportionate morphological response. The design engineer must be aware of the existing geomorphic thresholds, the possibility that a natural system may be close to an intrinsic threshold, and the widespread adverse effect that an ill-planned channel stabilization project may have if it causes the system to cross a threshold.

Alluvial channels have a measure of resilience that enables perturbations and imposed changes to be absorbed by morphological adjustments without widespread disequilibrium in the system. Greater resilience implies that the system is a greater distance from a geomorphic threshold than a less resilient system. Systems of greater resilience are less sensitive to change, and those of low resilience are highly sensitive to perturbation.

Threshold theory is often expressed in terms of apparently simple examples, such as the transition between meandering and braiding. This is often quoted as representing a geomorphic threshold, even though Leopold and Wolman recognized as long ago as 1957 that there is actually a continuum of planforms (Leopold and Wolman 1957). Bledsoe (1999) demonstrated that whereas a meandering stream may respond to an increase in bed-material mobility by braiding, it may also respond by incising. In fact, for a given sediment size ( $D_x$ ), increasing energy (expressed as a mobility index) can result in either a braided or an incised channel, depending on the relative erosion resistance of the bed and bank materials. Also, the threshold mobility index is not single-valued, but is better characterized by a stochastically determined range of values (Fig. 6-2). These findings illustrate that in practice, the geomorphic threshold behavior of alluvial streams may be complex.

**Fig. 6-2.** Probability (%) of incising or braiding (dashed lines) is shown as a function of  $SQ$  (vertical axis) and  $D_{50}$  (horizontal axis) for sand beds. Discharge is represented by annual flood as first priority and then by bank-full flow (reprinted from Bledsoe and Watson 2001, with permission from Elsevier).

### 6.1.5 Time

Geomorphologists usually refer to three time scales when analyzing rivers:

1. Geologic time,
2. Modern time, and
3. Present time.

Geologic time is expressed in thousands or millions of years, and in this time frame the river is affected by major geologic and climatic changes such as formation of mountain ranges, changes in sea level, and climate change. Equilibrium is not possible over geologic time because, inevitably, the system evolves as material is washed from the mountains to the plains and responds to external changes. The modern time scale describes a period of tens of years to several hundred years, and has also been called the graded time scale (Schumm and Lichty 1965). During this period, a river may adjust to a balanced condition; that is, it may be fully adjusted to prevailing watershed water and sediment regimes and largely retain the same form as it operates in dynamic equilibrium. Present time is considered to be an even shorter period, perhaps 1 year to 10 years. Within this very short time frame, equilibrium may be static—that is, change in the system may be insignificant. Although the duration of these time scales is suggested, no fixed rules govern these definitions. The design of a major project may require less than 10 years, and numerous minor projects are designed and built within the limited scope of observations made during present time. However, project life often extends into graded time,

when static equilibrium cannot be assumed to apply. From a geomorphological viewpoint, engineers build major projects in an instant of time, and base their design on an instantaneous snapshot of the river, but still expect these projects to operate successfully and last for a significant period in a dynamically changing system.

Recognition of the importance of time is especially important in considering the postconstruction performance of a project. Society demands a quick return on its investments and projects are expected to produce positive results almost instantaneously. Often, success or failure of a project is judged within one or two years, regardless of whether formative events have occurred to drive geomorphic recovery from construction impacts, or design events have occurred to test whether the project works as intended. With respect to the morphological impacts of a river engineering project, it must be remembered that short-term channel stability or adjustment is not necessarily indicative of long-term behavior. For this reason, the morphological performance of channel projects should be monitored and appraised over a period longer than a few years before a project is declared to have been successful.

### 6.1.6 Scale

The size or scale of the fluvial system has a bearing on the way in which it evolves toward a natural equilibrium, adjusts to catchment and climate change, and responds to engineering interventions. The time taken for the system to evolve,

adjust, or respond increases with the scale of the system. As a general rule, a small stream will react more rapidly to engineering works than a large stream. For instance, channel adjustments in the Mississippi River are still occurring in response to artificial meander cutoffs constructed in the 1930s, and it may require over 100 years before morphological changes triggered by the cutoffs are completed (Biedenharn 1995; Biedenharn and Watson 1997). Conversely, some small bluff line streams in north Mississippi that were channelized in the 1960s have adjusted through initial degradation, secondary aggradation, and dynamic stability within a period of less than 25 years (Watson et al. 2002).

The physical size of a stream also conditions and may limit the type of engineering works that are appropriate and feasible. Although the materials involved in alluvial stream mechanics (basically water, sediment, and vegetation) are scale-independent, the ways that they interact are not. For example, the morphological impact and significance of a large tree on the bank of a small stream is quite different from that of a similar tree on the bank of a large river. From an engineering perspective, it is particularly important to recognize that analyses, techniques, and solutions designed for one scale of stream may not be directly transferable to another. Deciding whether an analytical tool, stabilization technique, or channel enhancement solution developed for streams of a particular size is transferable to streams at other scales demands a thorough understanding of the underpinning science and engineering principles involved. It is not enough to have demonstrated repeatedly that a given approach *works* when applied to streams of a particular scale. Before tools, techniques, or solutions developed for one scale of system are promulgated for wider application, it must be established *how* and *why* they work. Principles, such as stabilizing a retreating bankline by increasing bank erosion resistance and mass stability or by retarding near bank

velocities, are transferable across different scales of river; however, the hydraulic models, bank stability analyses, and structural measures appropriate to control bank retreat successfully may not be.

## 6.2 CHANNEL MORPHOLOGY

Alluvial rivers and streams are dynamic and continuously change position, shape, and other morphological characteristics in response to variations in discharge, sediment load, and boundary conditions. It is therefore important to study not only the existing morphology of the river but also possible variations during the lifetime of the project. The river morphology is determined by the water discharge, quantity and character of the sediment load, characteristics of the bed and bank materials (including vegetation), geologic controls, and valley topography. Morphological changes and adjustments take place in response to variations in any of these parameters through time or human activities. To predict the behavior of a river in a natural state or as affected by human activities, we must understand how fluvial and geotechnical processes operate on the boundary materials to form and adjust the morphological features of the channel through time.

A schematic diagram defining the morphological features associated with straight and meandering channels is shown in Fig. 6-3. The *thalweg* is the trace of the deepest point of the channel. The thalweg and associated line of maximum velocity cross from side to side within the channel, and this pattern of flow affects the overall cross-sectional geometry of the stream. At a bend, there is a concentration of flow in the outer half of the channel due to secondary flow. This causes the scour depth to increase at the outside of the bend, to produce a *pool*. As the thalweg crosses the channel downstream of a bend, the velocity distribution and cross-sectional shape become more symmetrical, and scour depths decrease

Fig. 6-3. Features associated with (a) straight and (b) meandering rivers.

because of deposition of sediment eroded from the pool upstream. This area is known as the *riffle* or *crossing*.

Pool-riffle sequences are characteristic of cobble, gravel, and mixed load rivers of moderate gradient ( $S < 5\%$ ) (Sear 1996). Riffles are topographic high points in an undulating bed profile and pools are low points. Typically, sediment grain size is coarser on riffles than in pools. A sorting mechanism was proposed by Keller (1971) to explain this variation. According to Keller, fine sediment is removed from riffles during low flows and deposited in pools because velocities and bed shear stresses are higher at riffles (Keller 1971). As discharge rises, velocity and shear stress in the pool increase quickly, with little, if any, increase over the riffle. Consequently, the formative flow velocities and shear stresses in pools are higher than at riffles, resulting in scour

of large sediment from the pools and deposition on the next riffle downstream. However, field evidence for this conceptual explanation is equivocal. Ashworth (1987), Petit (1987), and Clifford (1990) have measured the shear stress reversal hypothesized by Keller, but other studies have suggested that pool and riffle velocities equalize at bank-full flow, but do not reverse (Lisle 1979; Carling 1991).

Yalin (1971) suggests that pools and riffles may be explained by macro-turbulent eddies generated at the boundaries of a straight, uniform channel, which produce alternate acceleration and deceleration of flow. Yalin showed theoretically that the longitudinal spacing of faster and slower zones would average  $\pi w$  ( $w$  = channel width) for macro-turbulent eddies with diameters similar to the channel width. This is about half the riffle spacing of five to seven times

Fig. 6-4. Typical plan, profile, and cross-sectional views of pools and crossings.

the channel width observed in nature (Keller and Melhorn 1973). Hey (1976) proposed a resolution to this difference between theory and observation by proposing that the largest eddies in a stream do not scale on the width, but the half-width, with the centerline of the channel acting as a line of symmetry. According to Hey's hypothesis, riffles would be spaced at  $2\pi w$ , which better accords with observations.

The cross-sectional shape of a stream varies systematically with distance along the channel in relation to the plan geometry, the type of channel, and the characteristics of the sediment that is formed and transported within the channel. The cross section at a bend is typically deeper at the *concave* (outer bank) side, with a nearly vertical bank, and has a sloping bank formed by the point bar at the *convex* side. The cross section is more trapezoidal or rectangular at a crossing (Fig. 6-4). Cross-sectional dimensions and shape are described by a number of variables. Some of these, such as the *area* ( $A$ ), *width* ( $w$ ), and *maximum depth* ( $dm$ ), are self-explanatory. Other commonly used parameters warrant explanation. *Wetted perimeter* ( $P$ ) refers to the length of the wetted cross section measured normal to the direction of flow. *Average depth* ( $d$ ) is calculated by dividing the cross-sectional area by the channel width. *Width-depth ratio* ( $w/d$ ) is the channel width divided by the average depth. *Hydraulic radius* ( $R$ ), which is important in hydraulic computations, is defined as the cross-sectional area divided by the wetted perimeter. In wide channels, with  $w/d$  greater than about 20, the hydraulic radius and the mean depth are approximately equal. The *conveyance*, or capacity, of a channel is related to the area and hydraulic radius and is defined as  $AR^{2/3}$ .

*Bars* are depositional features that occur within a channel. The types, sizes, frequency of occurrence, and locations of bars are related to the quantity and caliber of the sediment load, local sediment transport capacity, and the morphology of the reach. The most common types of bars are point bars, middle bars, and alternate bars.

*Point bars* form at the inside (convex) bank of bends in a meandering stream (Fig. 6-5). The size and profile of the point bar are influenced by the characteristics of the flow, the degree of sinuosity, and the quantity and caliber of the sediment deposited at the bend. The development of a point bar is driven by reduction in the sediment transport capacity at the inner bank and sediment sorting due to the action of transverse flows and secondary currents (Dietrich et al. 1984), often coupled with flow separation at the inside of the bend downstream of the apex (Leeder and Bridges 1975). *Middle bar* is the term given to areas of deposition lying within, but not connected to, the banks. Middle bars in meandering rivers may form at riffles, especially where the crossing reaches between consecutive bends are long, and in bends, due to the development of a chute channel that separates part of the point bar from the inner bankline. Figure 6-6 shows a typical middle bar on the Mississippi River formed by this process. *Alternate bars* are regularly spaced depositional features positioned on opposite sides of a straight or slightly sinuous

channel (Fig. 6-7a) and may be precursors to meander initiation or braiding. *Braid bars* are sediment features found between the subchannels of multithread, braided rivers (Fig. 7b). Braid bars are highly mobile, and deflection of flow due to bar movement is responsible for the shifting pattern of anabranches and the frequent bank attack that characterize braided river morphology.

*Sinuosity* ( $P$ ) is a commonly used parameter to describe the degree of meandering in a stream. Sinuosity is defined as the ratio of distance measured along the channel (channel length) to distance measured along the valley axis (valley length). A perfectly straight channel has a sinuosity of unity, whereas a channel with a sinuosity of 3 or more would have tortuous meanders. *Meander wavelength* ( $L$ ) is the straight-line repeating distance for the meander waveform, as depicted in Fig. 6-8, and is twice the inflection point spacing. The *meander path length* is the channel length between inflection points. *Meander amplitude* ( $A$ ) is the width of the meander bends measured perpendicular to the valley or straight-line axis (Fig. 6-8). The ratio of amplitude to meander wavelength is generally within the range from 0.5 to 1.5.

Fig. 6-6. Typical middle bar.

(a) Alternate

(b) Braided

**Fig. 6-7.** Typical bar patterns: (a) alternate, (b) braided.

Meander wavelength and amplitude are primarily dependent on water and sediment discharge, but are usually locally modified by spatial variation in the erodibility of the material in which the channel is formed. The effects of different bank materials are responsible for the irregularities found in the alignment of natural channels. In rare cases where the material forming the banks is practically homogeneous, meanders take a form that may be approximated by a sine-generated curve with a uniform meander wavelength. The *meander belt* is formed by and includes all the locations historically held by a stream due to meander development and

migration. It should be noted that the width of the meander belt is usually greater than the meander amplitude and, in many cases, may include all of the active floodplain.

The *radius of curvature* ( $r_c$ ) is the radius of the circle defining the centerline curvature of an individual bend, measured between the bend entrance and the bend exit (Fig. 6-8). The *arc angle* ( $\theta$ ) is the angle swept out by the radius of curvature. The ratio of radius of curvature to width ( $r_c/w$ ) is a very useful parameter in the description and comparison of meander behavior and, in particular, bank erosion rates. The radius of curvature is dependent on the same factors as the meander wavelength and width. Meander bends generally develop a radius-of-curvature-to-width ratio ( $r_c/w$ ) of 1.5 to 4.5, with the majority of bends falling in the range from 2 to 3. Nanson and Hickin (1986) examined the influence of  $r_c/w$  on bend migration rate and reported that maximum bank erosion rates occurred when the channel acquired an  $r_c/w$  between 2 and 3. This finding has been supported by many empirical studies, for example, Thorne (1991). Plots of erosion rate versus  $r_c/w$  do, however, display wide scatter and Biedenharn et al. (1989) showed that part of this scatter could be explained by variations in the erodibility of the outer bank material (Fig. 6-9).

*River slope* is one of the best indicators of the ability of a river to do morphological work. In general, rivers with steep slopes are much more active with respect to channel changes achieved through sediment movement, bed scour, bar building, and bank erosion. Slope can be defined in a number of

**Fig. 6-8.** Definition sketch for channel geometry (FISRWG 1998, with permission from the USDA).

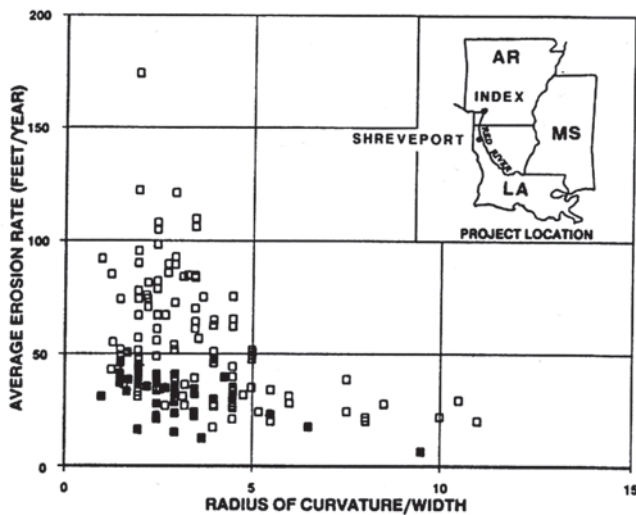

Fig. 6-9. Average annual erosion rate versus  $r/w$  for meander bends of the Red River. Open symbols represent free, alluvial bends and closed symbols, constrained bends (Biedenharn et al. 1989, with permission of ASCE Publications).

ways, however, leading to inconsistency in the way slope is used to represent the ability of a river to do morphological work. Ideally, energy slope should be used to calculate stream power, but the data required are seldom available. In gauged streams, water surface slope may be calculated using stage readings at consecutive gauging stations along the channel. However, many small streams are ungauged. In ungauged streams, thalweg slope is often used to calculate stream power. The thalweg profile not only provides a reasonable basis for calculation of stream power, but also may aid in locating bed controls due to geologic outcrops, other nonerodible materials, or inputs of relatively immobile sediments from steep tributaries. Repeat thalweg profiles are particularly useful in identifying bed-level adjustments through aggradation, degradation, local scour, and fill. When

different slopes are used to calculate stream power, it must be kept in mind that the thalweg, water surface, and energy slopes are not necessarily equal.

### 6.3 SEDIMENT TRANSPORT

One aspect of river engineering that causes considerable confusion and misunderstanding is the terminology associated with sediment transport. In discussing the sediment transport, it is important to be familiar with the terminology adopted and the nature of the load being discussed. Over an extended period, a common terminology has emerged, and although it is not universally agreed upon or applied, it provides the basis for at least reducing inconsistency.

*Total sediment load* is the mass of granular sediment transported by a stream. It can be broken down by source, transport mechanism, or measurement status (Table 6-1). *Bed load* is a component of total sediment load made up of particles moving in continuous or frequent contact with the bed. Transport occurs at or near the bed, with the submerged weight of particles supported by solid-solid contact with the bed. Bed load movement takes place by processes of rolling, sliding, and saltation. *Suspended load* is a component of the total sediment load made up of sediment particles moving in continuous or semicontinuous suspension within the water column. Transport occurs above the bed, with the submerged weight of particles supported by anisotropic turbulence within the body of the flowing water. *Bed-material load* is the portion of total sediment load composed of grain sizes that are found in appreciable quantities in the streambed. The bed-material load is the bed load plus the coarser portion of the suspended load, that is, particles of a size that are found in significant quantity in the bed. *Wash load* is the portion of the total sediment load composed of grain sizes finer than those found in appreciable quantities in the streambed. *Measured load* is the portion of total sediment load that is sampled by conventional suspended load samplers. The sediment sampled in

Table 6-1 Classification of the Sediment Load

Measurement method	Transport mechanism	Sediment source
<i>Unmeasured load</i>	<i>Bed load</i>	<i>Material load</i>
<i>Measured load</i>	<i>Suspended load</i>	
		<i>Wash load</i>

deriving the measured load includes a large proportion of the suspended load, but excludes that portion of the suspended load moving very near the bed (that is, below the sample nozzle) and all of the bed load. *Unmeasured load* is that portion of the total sediment load that passes beneath the nozzle of a conventional suspended load sampler, moving in near-bed suspension and as bed load.

## 6.4 CHANNEL-FORMING DISCHARGE

Morphological studies have revealed that channel form depends on a delicate balance between the flows of water and sediment that shape the channel, the processes by which channel form is changed, and the ability of the boundary materials to resist change. Variability of water and sediment discharges is a characteristic of the watershed and, over a sufficiently long period, the morphology of the channel will adjust to accommodate the range of flow events responsible for regulating the balance between the erosive and resistive forces that mold the channel. Consequently, the shape and dimensions of an alluvial river channel are adjusted to and reflect the wide range of flows that entrain, transport, and deposit boundary sediments (Lane 1955). The concept that there is a single discharge that, if it prevailed all the time, would produce the same width, depth, slope, hydraulic roughness, and planform as those produced by the actual range of discharges is attractive, but viewed in this context it is clearly a gross simplification. The single discharge best able to represent the actual spectrum of sediment-transport events to yield the same bank-full morphology as that shaped by the natural sequence of flows is referred to as the channel-forming flow or the dominant discharge. Dunne and Leopold (1978) define channel maintenance flow as the most effective discharge for moving sediment, forming or removing bars, forming or changing bends and meanders, and generally doing work that results in the average morphological characteristics of channels. Their definition of channel maintenance flow is very similar to the concept of channel-forming discharge.

In a regulated canal system, the dimensions of the channel can appropriately be based on a single design discharge. Empirical analysis of the relationship between that discharge and the dimensions for a stable, unlined canal formed in alluvial materials produced the regime theory. Early work on regime theory stems from design of straight canals in the Indian subcontinent (Inglis 1941; 1947; 1949), and North America (Blench 1952; 1957). Later, flume experiments extended the regime approach to channels with meandering planforms (Ackers and Charlton 1970a; 1970b). However, for widely varying flows emanating from a natural watershed, the problem of identifying the single channel-forming discharge is both challenging and critical.

Soar (2000) recently reviewed the huge literature pertaining to the concept of channel-forming flow. This concept is closely related to the theory of dynamic equilibrium, which

is characterized by fluctuations of channel form around an average condition that persists through time. In perennial rivers, recovery of equilibrium following a major event occurs relatively quickly, partly because rapid vegetation growth encourages sedimentation (Hack and Goodlett 1960; Gupta and Fox 1974). Hence, the long-term time-averaged condition is a valid representation of the channel form. Recovery in the ephemeral channels of semiarid regions tends to take longer, reflecting the influence of relatively wet and dry periods on vegetation growth (Schumm and Lichty 1965; Burkham 1972). In arid areas, infrequent floods impart long-lasting imprints on channels because more frequent flows do not have the power to restore a regime condition (Schick 1974). It has been concluded that the channel-forming flow concept may be inapplicable to ephemeral rivers that exhibit highly variable flow regimes, because there may not be a single discharge that can explain channel form (Stevens et al. 1975; Baker 1977). This is because channel morphology is likely to be perpetually in disequilibrium with the prevailing flows rather than fluctuating around an average state.

Channel-forming flow or dominant discharge is actually a geomorphological concept and not strictly a measurable parameter. However, a number of discharges that may be taken to represent the channel-forming flow can be defined and calculated using prescribed methodologies. The first approach is to identify a candidate flow based on channel morphology, such as the bank-full discharge. A second approach is to select a discharge based on a specified recurrence interval discharge, typically between the 1- and 3-year events in the annual maximum series. The third approach is analytical and involves calculating the effective discharge.

### 6.4.1 Bank-Full Discharge

Based on both theoretical and empirical arguments, bank-full discharge is generally recognized as being the moderate flow that best fits Wolman and Miller's (1960) dominant discharge concept for rivers in dynamic equilibrium. Leopold et al. (1964) proposed that the bank-full discharge was responsible for channel maintenance and form, and therefore that it was equivalent to the channel-forming discharge. Dury (1961) also suggested that the channel-forming discharge is approximately equal to the bank-full discharge and Dunne and Leopold (1978) concluded that their maintenance discharge corresponded to the bank-full stage. Field identification of bank-full discharge is, however, problematic (Williams 1978). It is usually based on identification of the minimum width-to-depth ratio (Wolman 1955; Pickup and Warner 1976), together with the recognition of some discontinuity in the nature of the channel, such as a change in sedimentary or vegetative characteristics. Nixon (1959) defined the bank-full state as the highest flood of a river that can be contained within its channel without spilling water on the river floodplain. Wolman and Leopold (1957) defined

the bank-full stage as the elevation of the active floodplain. Woodyer (1968) suggested that bank-full discharge corresponds to the elevation of the middle bench of rivers having several overflow surfaces. Schumm (1960) defined bank-full stage as the height of the lower limit of perennial vegetation, primarily trees. Similarly, Leopold (1994) states that bank-full stage is indicated by a change in vegetation, such as herbs, grasses, and shrubs. Finally, the bank-full stage is also defined as the average elevation of the highest surface of the channel bars (Wolman and Leopold 1957). Harrelson et al. (1994) provide explanations of field methods for determining bank-full discharge using vegetation, gradation of bank materials, and elevation of sedimentary features. Although several criteria have been identified to assist in field identification of bank-full stage, ranging from vegetation boundaries to morphological breaks in bank profiles, considerable experience is required to apply these in practice, especially on rivers that have in the past undergone aggradation or degradation.

#### 6.4.2 Specified Recurrence Interval Discharge

Problems and subjectivity in the field identification of bank-full elevation and discharge make it attractive to use an objectively defined discharge such as a specific recurrence interval flow. This recurrence interval flow can, in turn, be related to the bank-full elevation (Table 6-2). Wolman and Leopold (1957) suggested that the bank-full frequency has a recurrence interval of 1 to 2 years. The most often quoted recurrence interval is 1.5 years. Dury (1973) concluded that the bank-full discharge is approximately 97% of the 1.58-year discharge, or the most probable annual flood. Hey (1975) showed that for three British gravel-bed rivers, the 1.5-year flow in an annual maximum series passed through the scatter of bank-full discharges measured along the course of the rivers. Richards (1982) suggests that, in a partial duration series, bank-full discharge equals the most probable annual flood, which has a 1-year return period. Leopold (1994) concludes that most investigations have found that the recurrence interval for bank-full discharge ranges from 1.0 to 2.5 years. However, there are many instances where the bank-full discharge does not fall within this range. For example, Williams (1978) showed that for 35 floodplains in the United States the recurrence interval of bank-full discharge varied between 1.01 and 32 years, and found that only about one-third of those streams had a bank-full discharge with a recurrence interval between 1 and 5 years. In a similar study, Pickup and Warner (1976) determined that bank-full recurrence intervals ranged from 4 to 10 years on the annual series.

If a specified recurrence interval flow is used to estimate the channel-forming discharge, a range of 1 to 3 years should be used. However, because of the uncertainties discussed above, it is recommended that discharges in this range be compared to the bank-full stage in the field to verify that they do have morphological significance.

**Table 6-2 Recommended Frequencies for Bank-Full Discharge (after Soar 2000)**

Discharge frequency	Recommended by
1 to 5 years	Wolman and Leopold (1957)
1.5 years	Leopold et al. (1964); Hey (1975); Leopold (1994)
1.58 years	Dury (1973, 1976); Riley (1976)
1.02 to 2.69 years	Woodyer (1968)
1.01 to 32 years	Williams (1978)
1.18 to 3.26 years	Andrews (1980)
1 to 10 years, 2 years	USACE (1994)
2 years	Bray (1973, 1982)

#### 6.4.3 Effective Discharge

The effective discharge is defined as the increment of discharge that transports the largest fraction of the annual sediment load over a period of years (Andrews 1980). The effective discharge incorporates the principle prescribed by Wolman and Miller (1960) that the channel-forming or dominant discharge is a function of both the magnitude of sediment-transporting events and their frequency of occurrence. An advantage of using the effective discharge is that it is a calculated value that integrates the discharge and sediment-transport regimes of the stream.

Equivalence between bank-full and effective discharges for natural alluvial channels that are in regime has been demonstrated for a range of river types (sand, gravel, cobble, and boulder-bed rivers) and in different hydrological environments, if the flow regime is adequately defined and the appropriate component of the sediment load is correctly identified (Andrews 1980; Carling 1988; Hey 1997). However, Benson and Thomas (1966), Pickup and Warner (1976), Webb and Walling (1982), Nolan et al. (1987), and Lyons et al. (1992) report that the effective and bank-full discharges are not always equivalent. This suggests that the effective discharge may not always be a direct surrogate for the channel-forming flow or the bank-full discharge.

Although the effective discharge is straightforward conceptually, and has been used for many years, many engineers have expressed concerns that the effective discharge calculations do not yield reasonable results in some instances. These problems may be attributable to data limitations, insufficient understanding of the morphology of the stream, or improper calculation procedure. To minimize these uncertainties a standardized procedure for the determination of the effective discharge has been developed and is outlined

in the following paragraphs. This procedure is intended to help investigators avoid many of the potential problems that the authors have experienced in the calculation of effective discharge. Interested readers are referred to Biedenharn et al. (2000a) for a more detailed discussion of effective discharge calculation.

The method most commonly adopted for determining the effective discharge is to calculate the total load (tons) transported by the range of flows over a period of time by multiplying the frequency of occurrence of selected discharge classes (number of days) by the median magnitude of the sediment load (tons/day) transported by that class of flows. Although this approach has the merit of simplicity, the accuracy of the estimate of the effective discharge is clearly dependent on the calculation procedure adopted. The basic inputs required for calculation of effective discharge are (1) flow-duration data and (2) sediment transport as a function of stream discharge.

The first step in an effective discharge calculation is to group the discharge data into classes and determine the number of events occurring in each class during the period of record. This is usually accomplished from a flow-duration curve, which is a cumulative distribution function of measured discharges. A flow-duration curve shows the percentage of time a specific discharge is equaled or exceeded during the period of record, for which the curve was developed. From the flow-duration curve, the number of days that discharges within the specified class interval occurred can be calculated. The three critical components that must be considered in developing a flow-duration curve are the time base, the number of class intervals, and the period of record.

Conventionally, values of mean daily discharge are used to compute the flow-duration curve. Although this is convenient and uses readily available mean daily flow data that are published by the U.S. Geological Survey (USGS), it can, in some cases, introduce bias into the calculations. Mean daily values underestimate the influence of the high flows that occur within the averaging period and overestimate the significance of the low flows. On large streams such as the Mississippi River, the use of mean daily values is acceptable because differences between mean daily and daily peak discharges are negligible. However, on flashy streams, the time from the flood peak to base flow may be only a few hours, so mean daily flow cannot adequately describe the hydrograph. Missing flood peaks and associated high sediment loads can result in the effective discharge being underestimated. Rivers with a high flashiness index, defined as the ratio of the instantaneous peak flow to the associated daily mean flow, are most affected.

To avoid this problem it may be necessary to increase the temporal density from 24 h (mean daily) to 1 h, or even 15 min, especially on flashy streams. This will ensure that the hydrograph is adequately described, enabling a more representative effective discharge to be determined.

Class intervals should be arithmetic and must be of equal width. It has been demonstrated that the use of logarithmic or non-equal-width arithmetic classes introduces systematic bias into the calculation of effective discharge (Soar 2000; Soar and Thorne 2001). However, interested readers should review Holmquist-Johnson (2002) for guidance in calculating effective discharge for conditions under which equal-width class intervals are not usable. The selection of class interval may influence the calculated effective discharge. There are no definitive rules for selecting the most appropriate interval and number of classes. Yevjevich (1972) stated that the class interval should not be larger than  $s/4$ , where  $s$  is an estimate of the standard deviation of the sample. For hydrological applications he suggested that the number of classes should be between 10 and 25, depending on the sample size. Hey (1997) found that 25 classes with equal, arithmetic intervals produced a relatively continuous flow-frequency distribution and a smooth sediment-load histogram with a well-defined peak, indicating an effective discharge that corresponded exactly with bank-full flow. However, in the authors' experience, 25 classes may not always produce satisfactory results. It is recommended that in difficult cases the number of intervals be increased, but not to the extent that individual classes have zero events or only one event.

The period of record must be sufficiently long to include a wide range of morphologically significant flows, but not so long that changes in the climate, land use, or runoff characteristics of the watershed produce significant changes with time in the data. If the period of record is too short, there is a significant risk that the effective discharge will be inaccurate because of the occurrence of unrepresentative flows. A reasonable minimum period of record for an effective discharge calculation is about 10 years, with 20 years of record providing more certainty that the range of morphologically significant flows is fully represented in the data. Records longer than 30 years should be examined carefully for evidence of temporal changes in flow and/or sediment regimes.

The next step in the determination of the effective discharge is to develop a sediment-rating curve that relates the sediment transport and discharge. The sediment-rating curve can be developed from observed, measured sediment loads or using a computational procedure. Effective discharge is very sensitive to the slope of the sediment-discharge relationship.

The sediment load that is responsible for shaping the channel should be used in the calculation of the effective discharge. The suspended sediment load reported by USGS publications usually includes a portion of the bed-material load and most of the wash load. If measured suspended-sediment data are used for the effective-discharge calculation, then the fine sediment load, consisting of particles not found in appreciable quantities in the bed, should be omitted. If the bed load in the stream is only a small percentage of the total bed-material load, it may be acceptable to use only the measured suspended bed-material load in the

effective discharge calculations. However, if the bed load is a significant portion of the load, it should be calculated using an appropriate sediment-transport function and then added to the suspended bed-material load to provide an estimate of the total bed-material load. If bed-load measurements are available, which seldom is the case, observed data may be used.

Once the fines have been removed from the data set, a sediment-rating curve is developed from the concentration data by plotting sediment load (concentration times discharge) against discharge, and then calculating a best-fit regression curve through the data, or, as required in some cases, multiple segments of best-fit regression.

The discharges used to generate the bed-material load histogram are the arithmetic mean discharges in each class of the flow-frequency distribution. The bed-material transport rate for each discharge class is found from the rating curve equation. This load is multiplied by the frequency of occurrence of that discharge class to find the total amount of bed material transported by that discharge class during the period of record. Care should be taken to ensure that the time units in the bed-material load rating equation are consistent with the frequency units for the distribution of flows. The results are plotted as a histogram. The bed-material load histogram should display a continuous distribution with a single mode (peak). If this is the case, the effective discharge corresponds to the mean discharge for the modal class (that is, the peak of the histogram). If the modal class cannot be identified readily, the peak of a smooth curve drawn through the tops of the histogram bars can be used to estimate the effective discharge by interpolation.

#### 6.4.4 Overview

All three approaches to estimating the channel-forming flow or dominant discharge (bank-full estimate, discharge of a selected return period, and effective discharge) present challenges. The selection of the appropriate method will be based on data availability, the physical characteristics of the study stream, the level of study, and time and funding constraints. It is recommended that all three methods be used and the results cross-checked to reduce the uncertainty in the final estimate of the channel-forming flow. If the effective discharge method is used, then it is recommended that the standardized procedure presented here be followed.

### 6.5 RELATIONSHIPS IN RIVERS

Given the evident complexity of fluvial processes and their interactions with channel morphology, it is perhaps surprising that the characteristic forms adopted by alluvial rivers are limited in number and frequent in occurrence. For example, the planforms of meandering rivers display clear similarity in their proportions. Brice (1984) suggested that the similarity of meanders accounts for the fact that, if scale

is ignored, all meandering rivers tend to look alike in plan view. It is the familiar and almost ubiquitous nature of the forms and features displayed by alluvial streams of different sizes, in widely varying landscapes, that makes these complex systems amenable to description by relatively simple empirical relationships. For example, relationships developed by Williams (1986) illustrate how Brice's recognition of the similarity of meanders may be expressed quantitatively through empirical relationships relating the geometric properties of channel meander to one another (Table 6-3).

Similarly, in regime theory the concept that the width, depth, slope, and planform of a river are adjusted to a channel-forming discharge is expressed numerically in simple power-law equations. The *Stream Corridor Restoration Manual* (FISRWG 1998) provides the selected summary of regime equations reproduced in Table 6-4.

Independent of regime theory, Leopold and Maddock (1953) compiled important statistical equations linking various channel dimensions to discharge using USGS gauging records. These equations, termed *hydraulic geometry relationships*, describe how width, depth, velocity, and other hydraulic characteristics vary both with stage at a station and with changing bank-full discharge downstream for some streams in the United States. The hydraulic geometry relationships are of the same general form as the regime equations of Kennedy (1895):

$$\begin{aligned} W &= a Q^b \\ D &= c Q^f \\ V &= k Q^m \end{aligned}$$

where  $W$  = channel width,  $Q$  = discharge,  $D$  = depth, and  $V$  = velocity. Later versions of these hydraulic geometry relationships (listed in Table 6-5) add the median bed sediment size ( $D_{50}$ ) to improve the predictive power of the equations, and appear in the following format:

$$\begin{aligned} W &= k_1 Q^{k_2} D_{50}^{k_3} \\ D &= k_4 Q^{k_5} D_{50}^{k_6} \\ S &= k_7 Q^{k_8} D_{50}^{k_9} \end{aligned}$$

The relationships presented here are only a small sample of those available in the literature. Regime relationships are empirical, which means that the relationships are derived from observed physical correlations and are strictly only applicable to the data sets from which they were derived. In this regard, Rinaldi and Johnson (1997) are correct to point out the inappropriateness of using simple regression equations in the design of meander restorations when fluvial processes and channel morphology in the project stream differ manifestly from conditions in the rivers used to develop the equations. In practice, hydraulic geometry and other empirical relationships may be widely and usefully applied, provided that conditions in the study watershed are similar to those in the watersheds for which the equations were developed. However, even under ideal conditions these equations remain incomplete representations of the factors that actually

influence channel form. For example, many popular hydraulic geometry equations express the stable width solely as a function of bank-full discharge. Intuitively, it would be expected that the width of a channel with sandy banks would be greater than that of an equivalent stream with clay banks. Indeed, Schumm's relationship between width-to-depth

ratio ( $F$ ) and the silt-clay weighted percentage in the channel perimeter ( $M$ ) confirms this expectation empirically. If Schumm's relationship is valid, a width equation based only on discharge cannot fully account for observed width variability. Clearly, the generation of reliable results through application of simple and imperfect morphological relations

relies heavily on good insight and sound judgment on the part of the individual responsible for their application.

A misapplication of empirical relationships was lampooned by Mark Twain (1944) in *Life on the Mississippi*. Describing the Mississippi River cutoffs of which he had knowledge, he conceived a simple empirical relationship between river shortening and time, and then used it to predict the historical and future lengths of the Mississippi River, concluding that:

Geology never had such a chance, nor such exact data to argue from! In the space of 176 years, the Lower Mississippi has shortened itself 242 miles. That is an average of a trifle over one mile and a third per year. Therefore, any calm person, who is not blind or idiotic, can see that in the Old Oölitic Silurian Period, just a million years ago next November, the Lower Mississippi River was upwards of 1,300,000 miles long, and stuck out over the Gulf of Mexico like a fishing rod. And by the same token, any person can see that 742 years from now the Lower Mississippi will be only a mile and three-quarters long, and Cairo and New Orleans will have joined their streets together, and be plodding comfortably along under a single mayor and a mutual board of aldermen. There is something fascinating about science. One gets such wholesale returns of conjecture out of such a trifling investment of fact.

The primary points of this passage are that, no matter what their basis in fact and observation, empirical relationships cannot be extrapolated either backward or forward in time, and engineers must avoid falling into the trap of designing a project based solely on "... wholesale returns of conjecture out of a trifling investment of fact."

## 6.6 CHANNEL STABILITY AND INSTABILITY

In designing river enhancement and channel rehabilitation projects the design engineer must recognize that rivers are dynamic systems, and must consider both the existing and possible future channel morphologies in the design. The problem is compounded when engineering interventions are planned, because the future morphology of the channel depends not only on the natural, or autonomous, evolution of the system, but also on channel response to construction, operation, and maintenance of the project. For this reason, it is important for the design engineer to acquire a broad understanding of the current stability status of the project reach and the extended channel network and to use this understanding to predict the type and extent of adjustments to the fluvial system likely to be triggered by the project. The capability to predict system response to the proposed works is vital to ensure that the selected enhancement or rehabilitation measures will work in harmony with both existing and future river conditions. The concept of channel stability status (which incorporates instability) builds on the

basic geomorphic principles introduced previously and may be applied to the river at system and local scales.

### 6.6.1 System Stability

The geomorphic concept underpinning stability assessment in rivers is that over time the cross-sectional dimensions and longitudinal slope of the channel of an alluvial stream adjust so that the channel is able to convey the discharges of water and sediment supplied from upstream with no net change in hydraulic geometry or planform. On this basis, a stream may be classified as either *stable* or *unstable*, depending on whether the channel has adjusted or is still adjusting to the flow and sediment regimes. Mackin (1948) expressed the stability concept in his definition of the *graded stream*:

A graded stream is one in which, over a period of years, slope is delicately adjusted to provide, with available discharge and with prevailing channel characteristics, just the velocity required for the transportation of the load supplied from the drainage basin. The graded stream is a system in equilibrium.

By definition, a graded stream does not have to have a channel that is static or fixed, and it may exhibit temporary morphological changes in response to the impacts of extreme events. Alluvial channel morphology is certain to be affected by major floods or protracted periods of low water, but provided that the time for moderate events to restore the graded morphology (termed the *recovery time*) is shorter than the return period for the extreme event (*recurrence interval*), the channel may be considered to be dynamically stable. The key attribute of a graded stream is that fluvial processes operating under formative flows tend to restore channel morphology to the graded condition following disturbance, rather than perpetuating or amplifying the changes imposed by the extreme event. A term commonly used for this type of stability is *dynamic equilibrium*.

The concept of dynamic equilibrium is inherent in a widely applied (and often misapplied), qualitative relationship for adjustment in alluvial streams proposed by Lane (1955):

$$QS \sim Q_s D_{50}$$

where  $Q$  = water discharge,  $S$  = slope,  $Q_s$  = bed-material load, and  $D_{50}$  = median size of the bed material. This relationship is commonly visualized as *Lane's balance* (Fig. 6-10). Mackin's explanation of how a graded stream responds to changes in the controlling variables is easily illustrated by Lane's balance, which shows how a change in any of the four driving variables will tend to produce a response in the others such that equilibrium is restored. When a channel is in dynamic equilibrium, it has adjusted these four variables so that the sediment transported into the reach is also transported out, without aggradation or degradation.

It should be noted that the map coordinates of a graded stream may change through time as the river reworks the

Fig. 6-10. Lane's balance (Rosgen 1996, with permission from Wildland Hydrology).

floodplain through meandering or braiding, provided that the reach-averaged values of width, depth, slope, and planform geometry are time-invariant. Indeed, meandering provides an important mechanism for an alluvial stream to adjust the slope relatively quickly and without transferring the large amounts of (relatively coarse) bed sediment necessary to alter slope materially through aggradation and degradation. Viewed in this context, changes in channel length achieved through meander extension and cutoff represent a natural adjustment mechanism, and planform changes do not necessarily indicate disequilibrium. When natural cutoffs occur, the river may be obtaining additional length elsewhere through meander growth, with the net result being that the overall reach length, and therefore slope, remains unchanged.

In nature, few rivers actually attain a graded condition because the driving variables change through time. The concept still has value, however, because it provides an indication of the likely trend of channel evolution over engineering time scales, which are generally less than about 50 years. Although it is a mistake to assume that a river will be stable or unchanging over this period, the concept of dynamic equilibrium gives useful clues regarding the rates and types of adjustment that may be expected as the channel evolves toward a graded condition. Also, the proximity of the system to a graded condition gives an indication of how the river will respond to engineering interventions and, particularly, how sensitive it is to being destabilized. Finally, the geomorphic concept of the stable channel is valuable in that it establishes a reference point for the definition and treatment of morphological instability on a variety of scales.

### 6.6.2 Channel Instability

Channel instability is defined as temporal change in the hydraulic geometry, long profile, or planform pattern of a channel

because of inequality between the supply and removal of sediment. Instability is, in a broad sense, inherent in the natural action of rivers in changing the landscape by eroding, transporting, and depositing sediment. In fact, the situation where sediment input exactly matches sediment output (dynamic stability) is actually a special case that can strictly occur only in subreaches of a fluvial system and that cannot persist for long periods.

Instability may result when the flow of water and transfer of sediment through a drainage network is disrupted or significantly perturbed. The fluvial system initially responds to disequilibrium by adjusting channel morphology in ways that tend to restore the previous equilibrium or graded condition. If stability is restored through a process-response that returns channel morphology to the predisturbance configuration (or something essentially similar), then the adjustments involved are restricted to the immediate vicinity of the disruption and, by definition, constitute *local instability*. However, if the magnitude of the change in driving variables is large, or the river is sensitive to destabilization because of channel characteristics (high stream power, easy availability of sediment, high erodibility of bed and bank materials, or absence of geologic or artificial controls) or proximity to a geomorphic threshold, then morphological adjustments can take the channel toward a new equilibrium configuration different from the predisturbance morphology. Under these circumstances, *system instability* propagates throughout the channel network and may spread into the watershed or even into neighboring systems.

### 6.6.3 Local Instability

Local instability refers to channel changes that result from adjustments to a fluvial system inherent in the maintenance of a dynamically stable configuration. There are three common causes of local instability. The first is channel response to temporary variations in discharge or sediment flux. Typically, discharge variations occur seasonally, or result from longer periods of above-average or below-average precipitation, whereas sediment input varies because of pulsing of sediment between storage and transport reaches or shifts in upstream channel alignment. The second cause is the series of adjustments that occur when channel morphology is altered by, and subsequently recovers from, the impact of a rare event such as a flood, drought, wildfire, or earthquake. The third cause is disruption of fluvial forms or processes associated with human activity or construction of infrastructure in or around a channel that triggers the channel changes necessary to accommodate the impacts of that disturbance within the existing, dynamically stable condition. Local instability is not symptomatic of significant disequilibrium in the system, but this does not mean that the processes of bed scour, bar deposition, and bank erosion associated with local instability are limited to a single location or that their consequences are negligible.

A good example of local instability is bankline movement due to planform evolution in a meandering river. Whereas the reach-averaged dynamically stable parameters of hydraulic geometry and slope remain steady, individual bends in a meandering river grow, migrate, and are abandoned. On average, channel lengthening through bank erosion along the concave bank in growing meander bends is offset by cutoffs at other bends as part of the natural meandering process. Under these circumstances, problems associated with bank erosion at a bend are amenable to local bank protection works, provided that the hydraulic geometry and slope of the reach are not significantly altered. However, it should be kept in mind that the channel may respond to stabilization of one bend through accelerated morphological activity in adjacent free bends. Hence, care must be taken to ensure that management of local instability at one location does not transfer or concentrate this natural process elsewhere in a way that is detrimental to the dynamic stability of the system.

The causes of local instability are not limited to the channel. This type of instability can also be triggered by activities in surrounding riparian and floodplain areas. For example, a reach of stream may display local channel widening due to trampling and overgrazing by cattle, while upstream and downstream reaches are not directly affected and are able to remain dynamically stable. In this situation, a local management solution, based on restriction of access by fencing, construction of suitably reinforced access ramps at water points, and reinstatement of the regime width, is all that is needed to alleviate a site-specific problem. Site-specific instability problems may respond satisfactorily to design alternatives developed using reference reach techniques.

In practice, however, it is not always easy to establish whether a local instability problem results from and is amenable to a local solution or is symptomatic of more serious, system-scale impacts and adjustments. Even if the engineer suspects that local instability results from adjustments of the fluvial system to channel instability, human activities, or catchment land-use changes, they may lack the authority or resources to address off-site and nonpoint causes. Under these circumstances, the engineer may have to modify the adopted solution by constructing a local structure with the capability to continue functioning successfully even when system-driven channel adjustments have significantly altered local conditions. For example, local bank stabilization may be required at the outside of a migrating bend on a river that is predicted to degrade in the future because of system instability downstream. Ideally, the system-scale problem (degradation) should be addressed directly using one or more grade control structures, but this may be institutionally or financially unfeasible. Recognition that the problem is not entirely local is nonetheless still valuable, as it allows the engineer to determine the degree of additional toe scour protection necessary to ensure that the bank protection measures can withstand the additional bed

lowering associated with degradation during the design life of the project.

#### 6.6.4 System Instability

Adjustments involved in system instability typically involve *aggradation* (increasing bed elevation), *degradation* (decreasing bed elevation), or *planform metamorphosis* (abrupt alteration from one planform pattern to another). The response of an alluvial stream to an episode of system instability is, in detail, unique to that stream and the circumstances and timing of the events responsible for destabilization. Although channel evolution models (discussed later in the section on stream classification) have been developed to characterize commonly observed styles and sequences of adjustment in unstable systems, there is no generally applicable model for process-response to system instability.

Serious engineering and river-management problems often result from channel instability and may include endangerment of bridges, buildings, roads, and other infrastructure, undermining of pipeline and utility crossings, accelerated bed and bank erosion, loss of valuable environmental habitat, and increased sediment loads that adversely impact flood control and navigation channels, water quality, reservoir areas, and wetlands. Figure 6-11 illustrates some common consequences of system instability.

The causes of system instability can be grouped into three categories: downstream factors, upstream factors, and basin-wide factors.

**6.6.4.1 Downstream Factors** The stability of a fluvial system can be affected significantly by changes to downstream base level. *Base level* refers to the downstream limit of the channel network, the elevation of which defines the datum for measurement of potential energy in the system upstream. In subcritical flow, the water surface elevation at the downstream limit of the channel controls the longitudinal water surface profile for a stream. Similarly, the bed elevation at the downstream limit of the system represents the origin of the thalweg profile. It follows from these facts that changes in base level have strong potential to trigger system instability.

Base-level lowering, due to engineering interventions such as meander cutoffs or channelization (Fig. 6-12), triggers process-response by locally steepening the slope and increasing bed-material transport capacity. As capacity exceeds supply, the bed scours to make up the supply deficit as the channel adjusts through degradation. This adjustment may generate only local instability if armoring stabilizes the bed or a geological control prevents significant bed lowering. However, if unchecked by a local channel response or control, a wave of degradation migrates upstream through the system as a headcut or knickpoint. If degradation triggers bank instability, then a wave of channel widening may follow the headcut, generating further morphological adjustments and additional sediment input

(a) Bed and Bank Instability

**Fig. 6-11.** Consequences of system instability: (a) bed and bank instability, (b) formation of gullies in floodplain, (c) damage to infrastructure, and (d) excessive sediment deposition in lower reaches of watershed.

**Fig. 6-12.** Channelized stream and abandoned old channel.

to the channel. As the degradational wave moves upstream, the zone of increased slope and additional sediment production moves with it. Sediment supply to the downstream reaches, coupled with local slope reduction due to

upstream bed lowering, then triggers aggradation, which also migrates upstream through the system. Subsequently, sediment output and bed elevation at the downstream limit of the system display damped oscillation until, following a number of cycles of degradation/aggradation, the long profile is adjusted to the new base level and stability is restored.

**6.6.4.2 Upstream Factors** The stability of a fluvial system can also be significantly affected by changes to upstream reaches that alter the downstream discharge or sediment supply. The flow regime and sediment load together constitute the two main driving variables responsible for forming and maintaining the channel, and it is no surprise that the stability of an alluvial river may well be disturbed by changes in one or both of these factors. Upstream factors are often affected by engineering and river-management projects. River regulation by a dam or diversion structure is a common cause of downstream channel adjustment that serves to illustrate the types and complexity of system response that may result from such changes.

Channel response downstream of a dam or diversion structure depends on the way the works are constructed and operated. When the structure is built, sediment supply downstream may be elevated by disruption of the channel and floodplain during construction. This may increase supply over transport capacity, inducing an initial adjustment through aggradation. However, this response will be absent if appropriate sediment-control measures are applied on site. Once the works are complete, process-response downstream will depend on the balance of changes in the water and sediment regimes. Following closure of the dam or diversion, sediment is trapped in the pool upstream from the structure. Sediment-free water released from the structure then scours the bed downstream, generating degradation in the first few kilometers below the dam. Initially, the flush of sediment produced drives aggradation further downstream, but as the channel slope immediately downstream of the dam flattens, sediment output decreases, and the leading edge of the zone of degradation migrates downstream to re-erode recently deposited sediment and sends it further downstream as an aggradational wave. This river response to closure of a dam has been observed in many rivers, and yet this pattern of adjustment is by no means universal. To explain why, it is necessary to consider the other morphological responses that may dominate adjustment of the fluvial system. For example, if the bed downstream of the dam includes a widely graded, coarse-grained fraction, bed armoring may limit degradation and stabilize the bed at a slope *steeper* than that prior to dam construction. The same effect may result from the presence of a geological control, whereas widening with limited reduction in bed level may be triggered if the channel banks downstream of the dam are close to the critical height for mass instability (Thorne and Osman 1988). If regulation by the dam significantly reduces the magnitude or frequency of sediment-transporting flows, degradation may be limited or negligible, and if a reduction in the competence of the main stream is coupled with the input of a substantial sediment load from unregulated tributaries, aggradation may occur downstream of the dam, where degradation was expected (Biedenharn 1984). The point of citing these examples is to demonstrate that morphological response to change in one or more upstream factors is complex and difficult to predict. The specific attributes of system instability and channel response depend not only on the magnitude of changes imposed on the flow regime and sediment loads, but also on the sensitivity and boundary conditions of the downstream channel network.

**6.6.4.3 Basin-Wide Factors** In morphological studies, flow regime and sediment load are often cited as the independent variables controlling channel form and process. In reality, these variables are not truly independent, but depend in turn on the characteristics of the watershed, including factors such as climate, rainfall-runoff relationship, natural vegetation, land use, and resource management. Even if upstream and downstream factors remain constant, changes in the watershed may trigger instability in the fluvial system

that leads to widespread morphological adjustments. For example, urbanization can increase peak flows and reduce sediment delivery to the channel network. These changes would reinforce one another (see Lane's balance in Fig. 6-10) to drive marked degradation in the channel draining the urbanized area, with morphological impacts migrating upstream and downstream through the system by slope adjustment and sediment transmission, respectively. Afforestation of the headwaters of a stream could produce very different morphological adjustments, depending on whether fluvial processes respond more strongly to decreases in runoff (due to increased consumptive use in the watershed) or elevated sediment delivery (due to erosion along forestry roads and ditches). In practice it is even more difficult to predict the morphological response of a fluvial system to basin changes than to upstream changes. In attempting to develop the capability to predict channel response to basinwide changes, engineers and river managers should make every effort to familiarize themselves with the geography of the basin, processes operating in the fluvial system, sedimentary features, and channel morphology. This knowledge, together with application of conventional hydrologic, hydraulic, and sediment-transport analyses, represents the best current option for regional sediment management and channel stabilization in a changing watershed.

## 6.7 CHANNEL CLASSIFICATION

The existence of a few distinctive channel forms provides the rationale for morphological classification of channels. The relationships linking channel form to fluvial process suggest that the morphological classification of a channel may allow the morphologist to infer process from classified channel form. The first step in classification is to identify whether the channel is either alluvial or nonalluvial. An *alluvial* channel is "self-formed" in that the bed and banks are composed of material transported by the river under present flow conditions. The channel is therefore free to adjust dimensions and location in response to changes in flow and sediment load. Conversely, a *nonalluvial river* is neither self-formed nor free to adjust. Examples of nonalluvial rivers include bedrock-controlled channels and streams flowing over very coarse glacial deposits.

Many classification schemes rest on channel planform pattern and stem from Leopold and Wolman's (1957) classification of channel planforms as straight, meandering, or braided. In this respect, the diagram produced by Brice (1975) is notable because it builds on earlier schemes to cover a wide range of commonly observed planforms and has proved useful in engineering geomorphic studies (Fig. 6-13). Schumm (1981; 1985) recognized an even broader range of channel patterns, although the basic straight, meandering, and braided patterns are still recognized within his classification of 14 basic patterns (Fig. 6-14).

Degree of Sinuosity	Degree of Braiding	Degree of Anabranching
1 1-1.05	0 <5%	0 <5%
2 1.06-1.25	1 5-34%	1 5-34%
3 >1.26	2 35-65%	2 35-65%
	3 >65%	3 >65%
Character of Sinuosity	Character of Braiding	Character of Anabranching
A Single Phase, Equiwidth Channel, Deep	A Mostly Bars	A Sinuous Side Channels Mainly
B Single Phase, Equiwidth Channel	B Bars and Islands	B Cutoff Loops Mainly
C Single Phase, Wider at Bends, Chutes Rare	C Mostly Islands, Diverse Shape	C Split Channels, Sinuous Anabranches
D Single Phase, Wider at Bends, Chutes Common	D Mostly Islands, Long and Narrow	D Split Channel, Sub-parallel Anabranches
E Single Phase, Irregular Width Variation		E Composite
F Two Phase Underfit, Low-water Sinuosity		
G Two Phase, Bimodal Bankfull Sinuosity		

Fig. 6-13. Channel Pattern classification devised by Brice (after Brice 1975).

Knighton (1998) related Schumm's 14 patterns to investigations by Carson (1984a; 1984b); Knighton and Nanson (1993); and Nanson and Knighton (1996). Knighton (1998) noted that the patterns in Fig. 6-14 are related to the classification by the type of sediment load (Schumm 1976): bed load, mixed load, and suspended load. Types 1 through 5 are bed load streams, Types 6 through 10 are mixed load streams, and Types 11 through 14 are suspended load streams. Carson (1984a; 1984b) specified two types of wandering, gravel-bed rivers. The first is characterized by very rapid bend migration and frequent chute cutoffs of point bars, similarly to Type 3. A second wandering type is similar to Type 14, with vegetated islands separating most of the channels. Knighton and Nanson (1993) point out that coarse-grain, anastomosing channels do exist. Therefore, despite the variety of channel patterns that have been investigated and discussed, a continuum of channel patterns does exist and these patterns

are controlled by the interaction of a series of continuous variables. Figure 6-14 suggests some of the variables that should be considered, such as sediment size and transport mechanism, whereas Bledsoe's (1999) logistic threshold approach indicates that specific stream power and sediment size are also important (Fig. 6-2).

In parallel with the development of his morphological classification, Schumm (1977) considered of the type of sediment load being transported by the stream, the percentage of silt and clay in the channel bed and banks, and the stability of the channel to describe the morphology associated with stable conditions and the morphological changes expected in response to instability through aggradation or degradation (Table 6-6). For purposes of this classification system, a stable channel complies with Mackin's definition of a graded stream in that slope is adjusted to supply just the sediment transport capacity necessary to convey the sediment load supplied from upstream. An unstable stream may be either *degrading* (eroding) or *aggrading* (depositing). It is very important to remember that the work on which this classification was based was conducted in the Midwestern United States during the second half of the 20th century. Extrapolation or transfer of the classification or related implications to other times and places should, therefore, be done cautiously.

Other, more ambitious stream classifications have been developed by Neill and Galay (1967); Rundquist (1975); and Rosgen (1994). These classifications go well beyond a description of channel form to include description of land use and vegetation in the basin, geology of the watershed, hydrology, channel bed and bank materials, sediment concentration, channel pattern, and channel stability.

Rosgen (1994) presented a stream classification system similar to the earlier Rundquist (1975) system. Rosgen (1996) included classification of valley type and introduced an entrenchment ratio, defined as the ratio of the width of the flood-prone area to the surface width of the bank-full channel. Table 6-7 is a summary of delineative criteria for broad-level classification from Rosgen (1994). Each of the stream types can be associated with dominant bed material types as follows: bedrock—1, boulder—2, cobble—3, gravel—4, sand—5, and silt/clay—6.

Through modification of Fig. 6-14, Fig. 6-15 attempts to combine some of the concepts of Schumm and Rosgen. Schumm's classification system depends heavily on his Midwestern experience, whereas Rosgen's experience began in steep mountain streams. In addition, Schumm's (1977) classification does not specifically include incised channels, which are included in Rosgen's (1994) F and G classes. Figure 6-15 includes Rosgen's C, D, DA, and E classes, and could be expanded to include all of Rosgen's (1994) classes. The point of Fig. 6-15 is to demonstrate that moving from class to class is a somewhat predictable morphological response that manages energy, materials, and channel plan-form to reestablish the balance between the local capacity of

**Fig. 6-14.** Channel classification based on pattern and type of sediment load (Schumm 1981, with permission from SEPM [Society for Sedimentary Geology]).

**Table 6-6** Classification of Alluvial Channels (Schumm 1977, with permission from S. Schumm)

Mode of sediment transport and type of channel	Channel sediment ( <i>M</i> ) (%)	Bedload (percentage of total load)	Channel stability		
			Stable (graded stream)	Aggrading (excess sediment discharge)	Degrading (deficiency of sediment discharge)
Suspended load	>20	<3	Stable suspended-load channel. Width/depth ratio <10; sinuosity usually >2.0; gradient, relatively gentle	Depositing suspended load channel. Major deposition on banks cause narrowing of channel; initial streambed deposition minor	Eroding suspended-load channel. Streambed erosion predominant; initial channel widening minor
Mixed load	5-20	3-11	Stable mixed-load channel. Width/depth ratio >10, <40; sinuosity usually <2.0, >1.3; gradient moderate	Depositing mixed-load channel. Initial major deposition on banks followed by streambed deposition	Eroding mixed-load channel. Initial streambed erosion followed by channel widening
Bed load	<5	>11	Stable bed-load channel. Width/depth ratio >40; sinuosity usually <1.3; gradient, relatively steep	Depositing bed-load channel. Streambed deposition and island formation	Eroding bed-load channel. Little streambed erosion; channel widening predominant

the channel to convey water and sediment and the discharge and supply of sediment from upstream.

Thorne et al. (1997) point out that many classification systems fail to account for dynamic adjustment or evolution of the fluvial system. Downs (1995) developed a compre-

hensive system that incorporates the classifications of Brice (1975) and Brookes (1981) and builds on their earlier work by linking observed trends and patterns of adjustment to the fluvial and sediment processes responsible for driving channel change (Fig. 6-16). Adjustment-based classifications such

**Fig. 6-16.** Downs's channel classification, based on trends and types of morphological change (modified from Downs 1995).

as that of Downs differ fundamentally from morphology-based schemes in that each system requires the observer to determine the current stability status of the channel and the nature of channel adjustment processes. Because data may not be available to document change, these schemes require sound judgment on the part of the engineer, who must infer processes and trend of adjustment from channel form.

Although any conceivable morphological channel classification will oversimplify the variability of channel patterns in nature, the underlying concept of a continuum of channel patterns that is related to a limited number of controlling variables remains valid. The opportunity and challenge for the river engineer is to develop and refine associations between channel pattern characteristics and controlling variables and to use these relationships with care and caution to predict the manner in which pattern will change in response to alteration of controlling variables. Schumm (1976) points out that major alterations in pattern change, which he terms channel metamorphosis, may be triggered by a relatively minor change in a controlling variable, if the existing pattern is near a geomorphic threshold.

## 6.8 CHANNEL EVOLUTION MODELS

Numerous geomorphological studies have used data developed from different locations to infer landform development

through time, commonly employing a technique termed location-for-time substitution. This technique assumes that by observing channel form as one moves downstream along a channel, the effect of physical processes at one location through time can be predicted; that is, changing location is substituted for changing time. This technique was used to develop a channel evolution model (CEM) for Oaklimer Creek, an incised stream in northern Mississippi (Schumm et al. 1984). Simon and Hupp (1987) later developed a similar model of channel evolution based on their observations of incised streams in western Tennessee.

The CEM (Fig. 6-17) consists of five channel-reach types, which describe the evolutionary phases typically encountered in an incised channel. These evolutionary phases range from strong disequilibrium to a new state of quasi-equilibrium. Quasi-equilibrium implies that the system is not static and changes through time, but over a period of years the average condition is one of stability. The model is based on the assumption that moving downstream through the system is equivalent to remaining in place and monitoring changes due to the passage of time. The response at any given location in the channel can then be predicted from the morphology of downstream channel locations.

The channel reach types in the CEM are labeled I through V and are assumed to occur consecutively in the downstream direction. The CEM assumes that each channel type will occur in turn at a given location as the channel evolves. The CEM

channel types are shown in Fig. 6-17. Type I reaches are located upstream of the actively degrading reach and have not yet experienced significant bed or bank instabilities. These reaches are generally characterized by U-shaped cross sections with little or no recently deposited sediment stored in the channel bed.

Type II reaches are encountered immediately downstream of Type I reaches. Bed degradation is the dominant process in the Type II reach. Type II channels are over steepened reaches where the sediment transport capacity exceeds the

sediment supply. Although the channel is actively degrading in a Type II reach, the bank heights ( $h$ ) do not exceed the critical bank height ( $h_c$ ), and therefore, reach-scale geotechnical bank instability is not encountered.

As bed degradation continues, the bank heights and angles continue to increase. When the bank heights exceed the critical bank height for stability in the Type III reaches, mass failures (geotechnical instability) begin. The dominant process in the Type III reach is channel widening. In places, the Type III reach may continue to be slightly degradational.

Fig. 6-17. Incised channel evolution sequence (after Schumm et al. 1984).

However, the reduced sediment transport capacity resulting from longitudinal channel slope decrease combined with increased sediment supply from upstream due to instability and from bank failures within the reach often results in the initiation of sediment deposition on the channel bed.

Type IV reaches are downstream of the Type III reaches and represent the first manifestation of the incising channel returning to a new state of dynamic equilibrium. In the Type IV reach, geotechnical bank instabilities and channel widening may continue, but at a much reduced rate. The sediment supply from upstream (Type III) exceeds the sediment transport capacity, resulting in aggradation of the Type IV channel bed. The Type IV reach is also characterized by the development of *berms*, which are depositional features along margins of the overwidened channel. These berms represent the beginning of a new inner channel with dimensions adjusted to the flow and sediment regime.

Type V reaches represent a state of dynamic equilibrium, with a balance between sediment transport capacity and sediment supply. Bank heights in the Type V channel are generally less than the critical bank height, and therefore, reach-scale geotechnical bank instability ceases. However, local bank failures can still exist as part of the meander process, or as the results of constrictions, obstructions, or other local factors. The berms that were initiated in the Type IV reach have now become colonized by riparian vegetation, forming a compound channel within the larger incised channel. The equilibrium channel of Type V is of a compound shape, with a smaller inner channel bounded by a narrow floodplain. The original floodplain of the Type I channel is now a terrace.

The channel evolution model addresses the channel stability status within a system context. Dynamic equilibrium in a Type V reach simply implies that system stability has been attained. A Type V reach may exhibit considerable erosion that is part of the natural meander process or some other local process, yet still be classified as being in dynamic equilibrium.

The primary value of the CEM sequence is to underpin identification of the evolutionary state of the channel from field reconnaissance. The morphometric characteristics of the channel reach types can also be correlated with hydraulic, geotechnical, and sediment-transport parameters (Harvey and Watson 1986; Watson et al. 1988). The evolution sequence provides an understanding that although reaches of a stream may differ markedly in appearance, the channel form in one reach is associated with those in adjacent and remote reaches by an evolutionary process. Form, process, and time relate dissimilar reaches of the stream linked to complex response and connectivity in the water and sediment-transfer systems.

## 6.9 GEOMORPHIC ASSESSMENT

Given the significance of fluvial geomorphology to engineering and management of rivers, the problem remains of gathering the data and qualitative information necessary to

characterize and define channel form, process, and stability status in the project river. A thorough geomorphic assessment of the river and watershed is required. Unfortunately, many engineers charged with the design of river projects either fail to fully appreciate the importance of geomorphic assessments, or lack the education or training background to perform them adequately.

Geomorphic assessment is an essential part of the design process for schemes ranging from local bank protection through reach-scale habitat enhancement to master planning for water resource management in an entire watershed. The aims of geomorphic assessment are to provide the baseline information necessary to characterize process-form interactions in the river, identify control points and problem reaches, and support division of the system into geomorphically distinct subreaches that may be individually classified with respect to morphology. Once the system has been characterized and classified, the engineer may assess the stability status on a reach-by-reach basis and predict the medium- and long-term autonomous evolution under a do-nothing scenario. This provides a baseline against which to assess the morphological responses of the project reach and wider system to the proposed engineering, rehabilitation, or water resources project.

Perhaps the most important step in any geomorphic assessment is ensuring that the scope and content match the project goals, authority, channel and watershed characteristics, and available resources. There is no standardized or “cook-book” approach, but over the past two decades a number of assessment schemes have been developed, and these provide valuable guidance based on direct experience (Simons et al. 1982; Schumm et al. 1984; Richardson and Huber 1991; Schall and Lagasse 1991; Shirole and Holt 1991; Robinson and Thompson 1993; Biedenbarn et al. 2000b). Typically, existing geomorphic assessment techniques may be subdivided into procedural steps dealing with

1. Assembly of existing and archived data/information in a desk study;
2. Establishment of current channel forms and sediment features through stream reconnaissance and field surveys;
3. Geomorphic analysis and interpretation of historical and contemporary information;
4. Stream classification and assessment of stability status at reach scale;
5. Prediction of past and future morphological evolution and response to proposed project; and
6. Integration of results into engineering design to optimize performance.

For more detailed reviews of practical and procedural issues in geomorphic studies and assessment, the reader is referred to articles by Thorne (1998; 2002).

The results of geomorphic assessment are rarely clear-cut. More often the individual elements of the assessment produce outcomes that are equivocal or even contradictory.

For example, the specific gauge record for a hydrological station may indicate that stages for a given discharge have decreased significantly, whereas the few available repeat cross sections from the same period show variations in bed topography but no evidence for discernible change, and stream reconnaissance indicates that the channel is hydraulically connected to its floodplain. The specific gauge record may suggest that the channel has degraded, but there may be a lack of supporting evidence from resurveyed cross sections and stream reconnaissance that the channel bed and floodplain levels are mutually-adjusted. In these situations, a level of confidence must be assigned to morphological conclusions based on different components of the assessment, based on the quantity, quality, and reliability of the data and the assessor's experience in applying the techniques involved. It may then be possible to reconcile apparently contradictory results by weighing the levels of confidence associated with each one. It is emphasized that sound judgment, based on insight and experience, is essential for accurate geomorphic assessment.

Obviously, geomorphic assessment alone can never provide a proper basis for engineering analysis or design. It is, however, of value when combined with computational and analytical methods for stable channel design. The wider contribution provided by geomorphic assessment is to establish the system context and framework within which the designer may

1. Select hydrodynamic and sediment transport equations appropriate to the stream and conditions;
2. Design stable channel dimensions that mimic natural channel forms and diversity while meeting project goals;
3. Use computer models matched to the alluvial setting and incorporating existing geologic and artificial controls to predict morphological response of the channel system to proposed rehabilitation measures;
4. Integrate environmental features effectively into morphological and engineering aspects of the project;
5. Anticipate maintenance requirements and optimize the design to ensure that the benefits are sustainable; and
6. Consider and propose the scope of post-project appraisal (PPA) and monitoring regime necessary to establish the strengths and weaknesses of project performance.

Geomorphic assessment alone is not sufficient to guarantee that a project will perform adequately with regard to morphological and environmental goals, but it is a valuable and necessary component of the integrated channel design process that is essential to ensure long-term sustainability in river engineering and management projects.

## 6.10 CLOSURE

Fluvial geomorphology, analytical river mechanics, and sound engineering judgment together provide the founda-

tions for sound river engineering, rehabilitation, and management. Insights and understanding provided by geomorphic principles and identification of causal links between channel form, fluvial processes, and connectivity of the river system can be invaluable in the design of river projects and management strategies. This is the case not only because the engineering geomorphic approach is consistent with environmental goals such as minimizing negative impacts and maximizing biodiversity, but also because solutions that recognize and deal with the causes rather than the symptoms of channel problems represent better engineering. Many engineering stabilization and rehabilitation projects have failed not as the result of deficient hydraulic or structural design, but rather because the significance of geomorphology to the project and the project to geomorphology has not been identified and accounted for in the design. Experience is accumulating that engineering designs guided by knowledge of the fluvial system are able to avoid having to attempt to "tame the river," instead working with the river to produce schemes that have lower long-term maintenance requirements. Engineering-geomorphology thereby opens the door to cost-effective, sustainable solutions that do not commit future generations to heavy and expensive maintenance.

## NOTATION

*The following symbols are used in this paper:*

$A$	=	area;
$A$	=	meander amplitude (Leopold et al. 1964);
$A$	=	bank-full cross-sectional area (in Table 6-3, from FISRWG 1998);
$AR^{2/3}$	=	conveyance;
$a$	=	coefficient;
$B$	=	meander belt width (in Table 6-3, from FISRWG 1998);
$b$	=	exponent;
$b_n$	=	Manning $n$ (in Table 6-5, from FISRWG 1998);
$c$	=	coefficient;
$D$	=	depth (from Kennedy 1895);
$D$	=	bank-full mean depth (in Table 6-3, from FISRWG 1998);
$D_x$	=	given sediment size;
$D_{50}$	=	median size of the bed material (from Lane 1955);
$D_{54}$	=	bed material (in Table 6-5, from FISRWG 1998);
$d$	=	average depth of the channel;
$dm$	=	maximum depth;
$F$	=	width-to-depth ratio (from Schumm 1977);
$f$	=	exponent;
$h$	=	bank height;
$h_c$	=	critical bank height;

$K$	=	channel sinuosity (in Table 6-3, from FISRWG 1998);
$k$	=	coefficient;
$L$	=	meander wavelength (Leopold et al. 1964);
$L_b$	=	along-channel bend length (in Table 6-3, from FISRWG 1998);
$L_m$	=	meander wavelength (in Table 6-3, from FISRWG 1998);
$M$	=	channel sediment;
$M$	=	weighted percentage silt-clay in the channel perimeter (from Schumm 1977);
$M$	=	percentage of bank materials finer than 0.074 mm (Table 6-5, from FISRWG 1998);
$m$	=	exponent;
$n$	=	number;
$P$	=	wetted perimeter;
$P$	=	sinuosity;
$Q$	=	discharge (from Kennedy 1895);
$Q$	=	water discharge (from Lane 1955);
$Q_s$	=	bed-material load (from Lane 1955);
$Q_x$	=	bed-material transport rate in $\text{kg s}^{-1}$ at water discharge $Q$ (Table 6-5, from FISRWG 1998);
$R$	=	hydraulic radius;
$R_c$	=	loop radius of curvature (in Table 6-3, from FISRWG 1998);
$r_c$	=	radius of curvature;
$r_c/w$	=	radius of curvature to width ratio;
$S$	=	slope (from Lane 1955);
$S$	=	estimate of the standard deviation of the sample (from Yevjevich 1972);
$V$	=	velocity (from Kennedy 1895);
$W$	=	width (from Schumm 1977);
$W$	=	channel width (from Kennedy 1895); and
$W$	=	bank-full width (in Table 6-3, from FISRWG 1998);
$w$	=	width;
$w/d$	=	width-depth ratio;
$\theta$	=	arc angle;
$\pi$	=	pi.

## CHAPTER 7

### ***Streambank Erosion and River Width Adjustment***

*James E. Pizzuto and the ASCE Task Committee on Hydraulics,  
Bank Mechanics, and Modeling of River Width Adjustment*

#### **7.1 INTRODUCTION**

Many different methods are available to describe river channel morphology and morphological adjustments for river engineering purposes. Available approaches range from equations that predict the regime or graded morphology of equilibrium channels to mathematical models that simulate channel changes in time and space. Most mathematical models, however, neglect time-dependent channel-width adjustments and do not simulate processes of bank erosion or deposition. Although changes in channel depth caused by aggradation or degradation of the riverbed can be simulated, changes in width cannot. For prediction of the behavior of natural streams, this is a significant limitation, because channel morphology usually changes with time, and adjustment of both width and depth (in addition to changes in planform, roughness, and other variables) is the rule rather than the exception (Leopold et al. 1964; Simon and Thorne 1996). As a result, our ability to model and predict changes in river morphology and their engineering impacts is limited. This is unfortunate, because width adjustments can seriously impact floodplain dwellers, riparian ecosystems, and bridge crossings, bank protection works, and other riverside structures through bank erosion, bank accretion, or bankline abandonment of the active river channel.

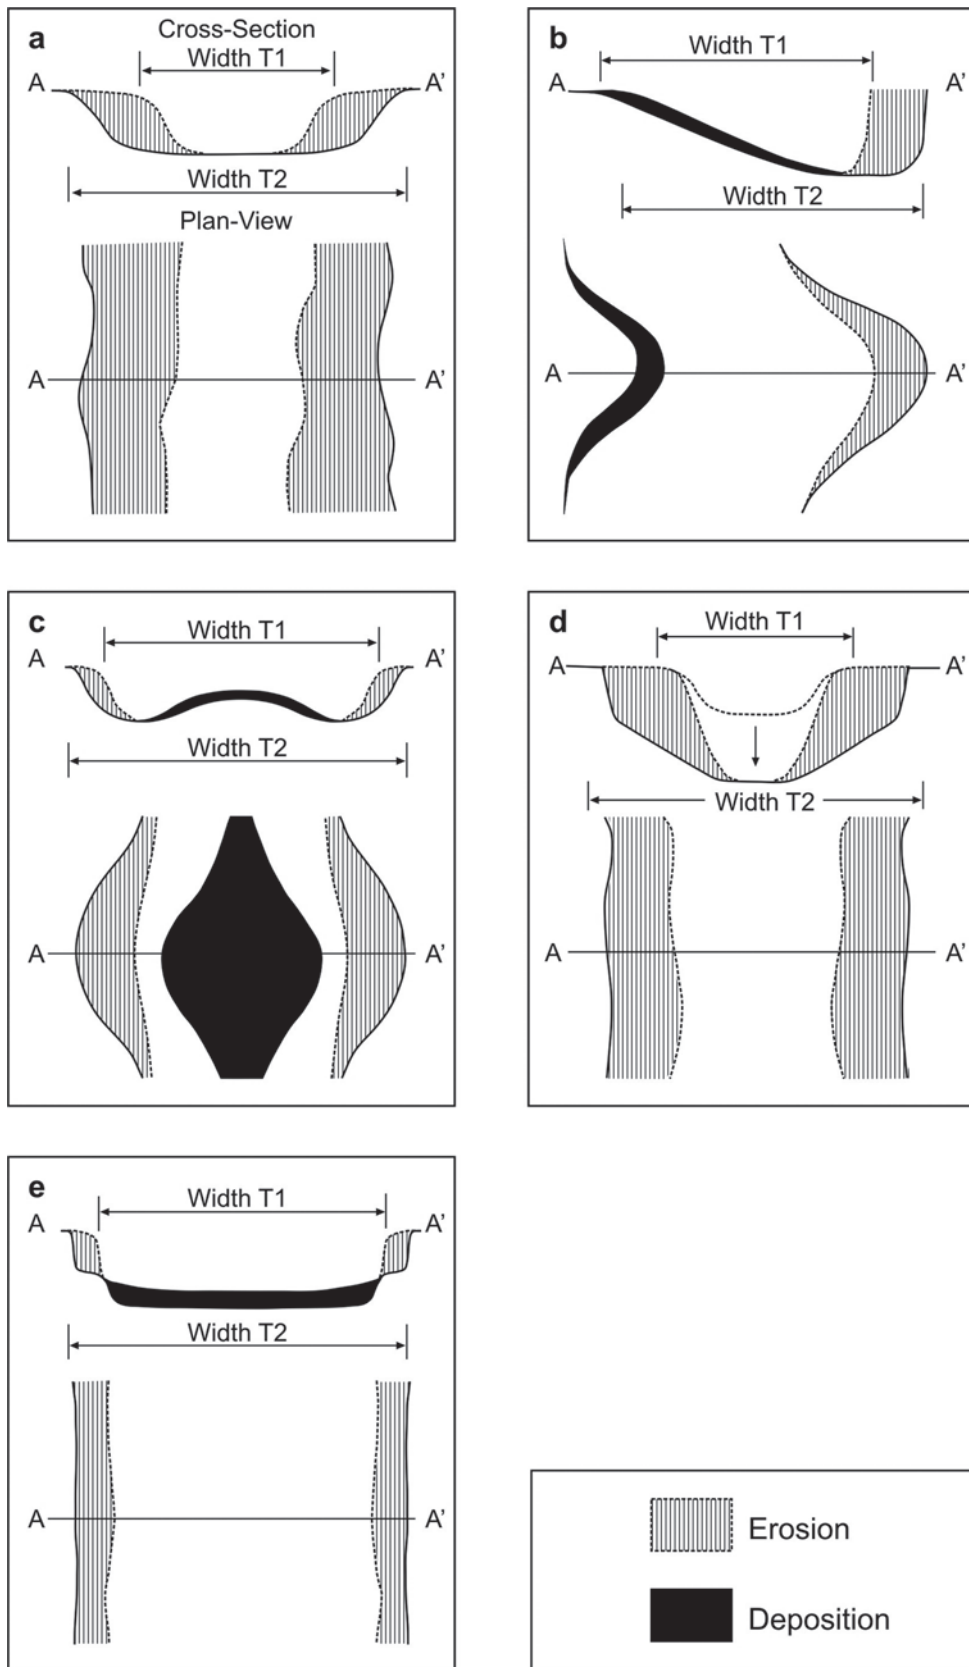

In this chapter, methods for assessing processes of bank erosion and river width adjustment are reviewed. Most of this chapter was originally written by the ASCE Task Committee on Hydraulics, Bank Mechanics, and Modeling of River Width Adjustment (1998a; 1998b), which was chaired by Dr. Colin R. Thorne.

#### **7.2 GEOMORPHIC CONTEXT OF RIVER WIDTH ADJUSTMENT**

River width adjustments have varied causes and occur in different geomorphic settings (Figs. 7-1 and 7-2). Widening

can occur by erosion of one or both banks without substantial incision (Fig. 7-1a) (Everitt 1968; Burkham 1972; Hereford 1984; Pizzuto 1994). Widening in sinuous channels may occur when outer bank retreat exceeds the rate of advance of the opposite bank (Fig. 7-1b) (Nanson and Hickin 1983; Pizzuto 1994). In braided rivers, bank erosion by flows deflected around growing braid bars is a primary cause of widening (Fig. 7-1c) (Leopold and Wolman 1957; Best and Bristow 1993; Thorne et al. 1993). In degrading streams, widening often follows incision of the channel when the increased height and steepness of the banks cause them to become unstable (Fig. 7-1d). Bank failures can cause very rapid widening under these circumstances (Thorne et al. 1981a,b; Little et al. 1982; Harvey and Watson 1986; Simon 1989). Widening in coarse-grained, aggrading channels can occur when flow acceleration due to a decreasing cross-sectional area, coupled with current deflection around growing bars, generates bank erosion (Fig. 7-1e) (Simon and Thorne 1996).

Processes of channel narrowing are equally diverse (Fig. 7-2). Rivers may narrow through the formation of in-channel berms, or benches at the margins (Fig. 7-2a) (Pizzuto 1994; Moody et al. 1999) (Fig. 7-3). The growth of berms or benches often occurs when bed levels stabilize following a period of degradation and can eventually lead to the creation of a new, low-elevation floodplain and establishment of a narrower, quasi-equilibrium channel (Woodyer 1975; Harvey and Watson 1986; Simon 1989). Encroachment of riparian vegetation into the channel often contributes to the growth, stability and, in some cases, to the initiation of berm or bench features (Hadley 1961; Schumm and Lichty 1963; Harvey and Watson 1986; Simon 1989). Narrowing in sinuous channels occurs when the rate of alternate or point bar growth exceeds the rate of retreat of the cut bank (Fig. 7-2b) (Nanson and Hickin 1983; Pizzuto 1994). In braided channels, narrowing may result when a marginal anabranch is abandoned (Fig. 7-2c) (Schumm and Lichty 1963). Sediment is deposited in the abandoned channel until it merges into the

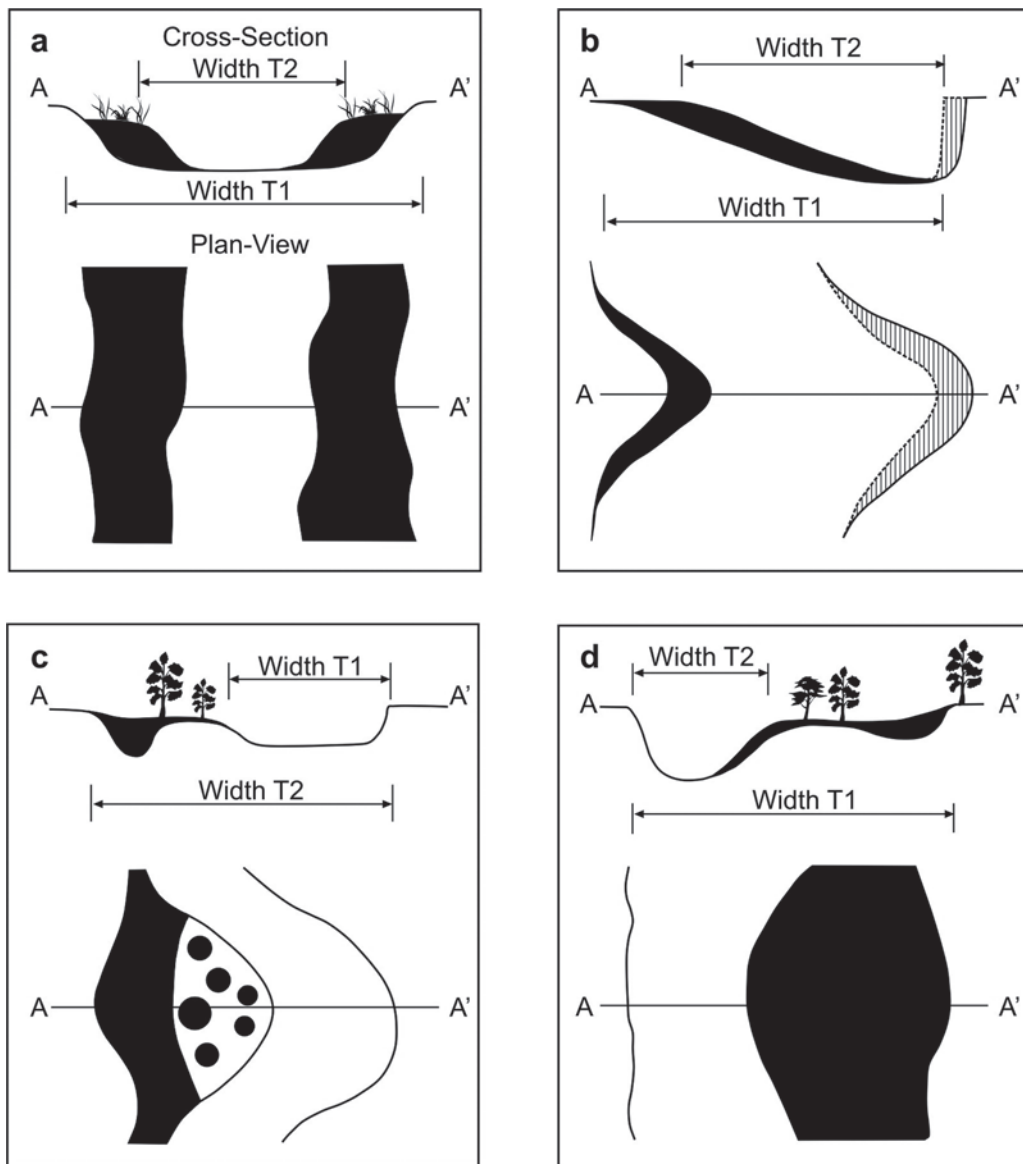

**Fig. 7-1.** Geomorphology of channel widening: (a) channel enlargement by bank erosion without incision; (b) erosion of outer bank in sinuous channel at faster rate than accretion on bar opposite; (c) deflection of flows by growing braid bar; (d) bank failure and retreat due to mass instability following channel incision; (e) bank erosion due to flow acceleration and deflection in aggrading channel (ASCE Task Committee on Hydraulics, Bank Mechanisms and Modeling of River Width Adjustment 1998a, with permission from ASCE).

floodplain. Also, braid bars or islands may become attached to the floodplain, especially following a reduction in discharge (Fig. 7-2d). Island tops are already at about floodplain elevation and attached bars are built up to floodplain elevation by sediment deposition on the surface of the bar, often in association with the establishment of riparian vegetation. Attached islands and bars may, in time, become part of the floodplain bordering a much narrower, often single-threaded channel (Williams 1978; Nadler and Schumm 1981).

If the flow regime and sediment supply are quasi-steady over periods of decades or centuries, then a river may

adjust its morphology to create a metastable equilibrium form (Schumm and Lichty 1965). Such rivers are described as being graded or in regime (Mackin 1948; Leopold and Maddock 1953; Wolman 1955; Leopold et al. 1964; Ackers 1992). Although the width of an equilibrium stream may change due to the impact of a large flood or some other extreme event, the stable width is often eventually recovered following such perturbations (Costa 1974; Gupta and Fox 1974; Wolman and Gerson 1978). Unfortunately, predicting the time-averaged morphology of equilibrium channels remains a difficult problem, despite years of effort

**Fig. 7-2.** Geomorphology of channel narrowing: (a) channel reduction by berm or bench formation; (b) accretion on advancing bar at faster rate than erosion of bank opposite; (c) abandonment of marginal anabranch in braided channel; (d) closure of marginal channel when braid bars or island becomes attached to floodplain (ASCE Task Committee on Hydraulics, Bank Mechanisms and Modeling of River Width Adjustment 1998a, with permission from ASCE).

**Fig. 7-3.** Five examples of channel narrowing by floodplain formation along Powder River in southeastern Montana based on surveyed cross sections in 1978 and 1996 (solid lines). Surveys in 1978 were done after a 25–50-year flood that widened the channel. The hachured areas represent net erosion, and the solid black areas represent net deposition (from Moody et al. 1999).

(Ackers 1992; White et al. 1982; Ferguson 1986; Bettess and White 1987).

Many rivers, however, cannot be considered to have equilibrium channels, even as an engineering approximation. These rivers display significant morphological changes, including width adjustments, when viewed over decades or centuries. For example, some rivers in arid and semiarid regions of the American West change their morphologies

drastically as the volume of annual precipitation, frequency of flood events, and other factors vary stochastically (Schumm and Lichty 1963; Everitt 1968; Burkham 1972; Osterkamp and Costa 1987). Because these streams vary so dramatically, they cannot be considered as graded or regime channels (Stevens et al. 1975) but are perpetually enlarging rapidly in response to a period of relatively high discharges, or contracting during periods of less than

average runoff (Schumm and Lichty 1963; Stevens et al. 1975; Pizzuto 1994).

Other nonequilibrium rivers may be actively adjusting to changes in flow regime and sediment supply (Andrews 1986; Madej 1977; Smith and Smith 1984), changing valley slope (Patton and Schumm 1975), succession of riparian vegetation (Hadley 1961; Graf 1978), climate change (Schumm 1968; Knox 1983; Hereford 1984), watershed land-use change (Hammer 1972), neotectonic valley floor tilting (Burnet and Schumm 1983; Schumm and Winkley 1994), or sea-level rise (Brammer et al. 1993). The resulting width adjustments can occur at various rates and in different temporal sequences. For example, Hammer (1972) suggested that rivers of southeastern Pennsylvania adjust to the impacts of urbanization in less than 5 years, but Andrews (1986), Jacobson and Coleman (1986), and other researchers have documented disruptions in river morphology that persisted for more than a century.

Width adjustments not only encompass a variety of time scales; they are also accomplished by a wide range of fluvial processes and geotechnical mechanisms associated with varying discharge, climatic, and environmental conditions. Bank erosion processes provide a useful example. Wolman (1959) noted that significant bank erosion on Watts Branch in the Maryland Piedmont occurred more than 10 times per year during relatively small but frequent flow events. However, scientists working elsewhere report that significant bank erosion has been caused mostly by large floods with recurrence intervals of decades or centuries (Williams and Guy 1973; Costa 1974; Gupta and Fox 1974; Gardner 1977; Osterkamp and Costa 1987). In other cases, bank retreat has been found to be almost entirely unrelated to flow stage and intensity but correlated with precipitation events and ground-water levels that generate erosion through sapping or piping (Brunsdon and Kesel 1973; Ullrich et al. 1986; Hagerty 1991). Thus, identifying the dominant erosion processes and failure mechanisms and selecting the appropriate discharge or climate events to be included in either conceptual or mathematical models of width adjustment remain very difficult tasks.

These examples indicate that channel changes involving width adjustment occur in a wide variety of geomorphic contexts, that width adjustment will usually be accompanied by changes in other morphological parameters such as channel depth, roughness, bed-material composition, riparian vegetation, energy slope, and channel planform, and that the processes responsible for width adjustments are diverse. Furthermore, adjustment processes display a variety of spatial patterns and operate over a wide variety of time scales. Because of this diversity, it is unlikely that a single method can be developed to predict the trends and rates of width adjustment for all rivers. Therefore, engineers must establish the morphological context of width adjustment and identify the major processes and mechanisms involved before selecting appropriate methods for analysis, modeling, and solution

of width adjustment problems. This is best achieved through systematic field observation and monitoring.

## 7.3 FACTORS INFLUENCING BANK EROSION AND WIDTH ADJUSTMENT

### 7.3.1 Cause and Effect: The Influence of Scale

Causes of bank erosion and width adjustments can be viewed at several different spatial scales. Bank erosion, for example, may occur because high discharges cause increased shear forces on the banks. However, the high discharges themselves may be a result of changes in land use or climatic changes that are controlled by processes external to a particular river reach. Channel enlargement caused by urbanization provides a useful example (Hammer 1972). Impervious surfaces throughout the watershed generate increased runoff (Leopold 1968), which in turn causes bank erosion and increases in channel width and cross-sectional area.

It is important for engineers to understand both local and larger-scale causes of bank erosion and width adjustment. In some cases, bank protection or other small-scale engineering structures may provide the best solution to a bank erosion problem. In other cases, however, trying to mitigate erosion at a particular reach may be futile and wasteful because the problem is ultimately caused by land use practices throughout a watershed.

The following discussion of factors influencing bank erosion and width adjustment focuses on local processes that may affect individual river cross sections. However, the broader context of the entire watershed should always be considered in trying to understand and solve bank erosion and width adjustment problems.

### 7.3.2 Fluvial Hydraulics

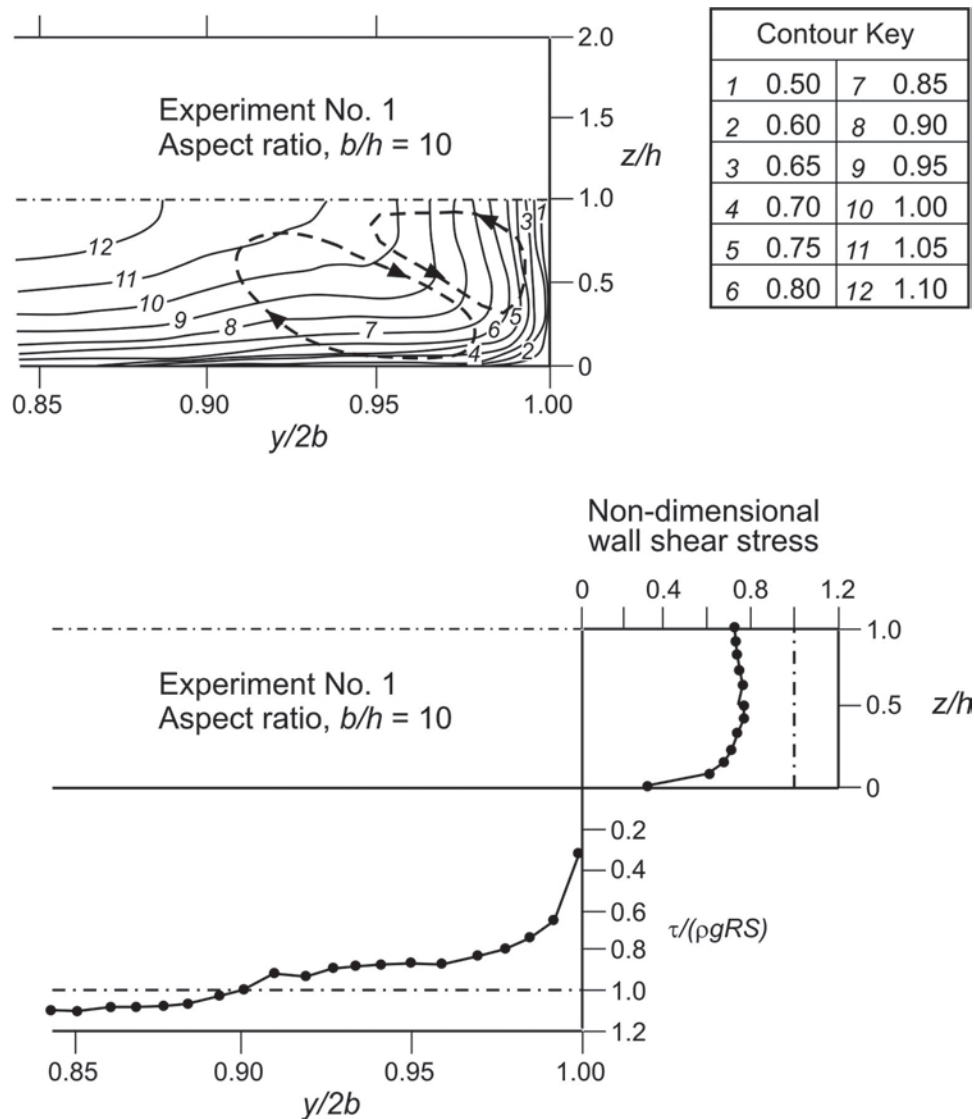

**7.3.2.1 Introduction** The flow of water and sediment in rivers is described by Newton's laws, which are straightforward until turbulence is encountered. The simplified, one-dimensional (1D) St. Venant equation is commonly applied in river engineering because the flow can be considered to occur predominantly in the downstream direction. An appropriate rigid boundary resistance law is then usually adopted to relate the conveyance capacity to the geometry (see, for example, Keulegan 1938; ASCE Task Committee on Friction Factors in Open Channels 1963; Chow 1959; Cunge et al. 1980; and Yen 1993). For alluvial channels the resistance law must also take into account the additional energy losses arising from bed forms and sediment transport (Engelund 1966; Alam and Kennedy 1969; Garde and Ranga-Raju 1977; White et al. 1982; van Rijn 1984). For meandering channels, additional resistance terms are required for form drag due to channel curvature (Nelson and Smith 1989a).

A 1D representation is simple but is inadequate to define the processes and the mechanics of river width adjustment.

A three-dimensional (3D) formulation is better, but 3D models are so complex to solve that they are of little value except in the most well-funded of projects. A two-dimensional (2D) representation (depth integration of 3D equations) can be solved more readily, but it is still limited because it is not strictly applicable in the near-bank zone and does not give any motion in the vertical direction. Vertical motion is particularly important at river bends, where most bank erosion and bar deposition occur. However, a 2D formulation is still frequently used because it yields useful information about the lateral variation of most of the important hydraulic parameters that impact bank erosion and accretion. A detailed review of aspects of channel hydraulics that directly influence width adjustment is given here. A broader river of

river and floodplain hydraulics is given elsewhere by Knight and Shiono (1995).

**7.3.3.2 Cross-Sectional Shape** The shape of a river cross section influences the isovel, secondary flow, and boundary shear stress distributions in a number of ways. A typical example (Fig. 7-4) is a rectangular cross section in a straight river with vertical banks. The data are from a rectangular duct experiment with an equivalent open-channel width/depth ratio of 20. Even in this relatively wide case the isovels and boundary shear stress distribution indicate the presence of secondary flow cells and 3D effects in the near-bank zone, which in this case is 15% of the channel width. Fig. 7-5 shows isovels and boundary shear stresses for flow in a narrow trapezoidal channel with an aspect ratio of 1.5. In this case the narrowness

**Fig. 7-4.** Typical influence of vertical riverbank on velocity and boundary shear stress in wide rectangular channel (Rhodes and Knight 1994, with permission from ASCE).

**Fig. 7-5.** Typical relationship between boundary shear stress distribution, secondary currents, and primary velocities in trapezoidal channel. The Froude number  $F = 3.24$ , width/depth = 1.52. (Adapted from Knight et al. 1994. Copyright John Wiley & Sons Limited. Reproduced with permission.)

of the channel causes the flow in the entire cross section to be influenced by 3D flow structures, unlike the case shown in Fig. 7-4. In the wide-channel case, flow in the central region is almost 2D, provided that  $y/2b < 0.85$ , and for this condition standard boundary layer distributions may be assumed for velocity and Reynolds stress. However, even in a wide ( $B/H > 20$ ) channel, although it may be acceptable to ignore bank effects for many hydraulic and geomorphic analyses, the bank still influences the flow in the near-bank zones sufficiently to require that the resulting 3D flow structures be accounted for in models of width adjustment.

Secondary flow cells may be generated by anisotropic turbulence (stress-induced secondary currents) or streamwise curvature (skew-induced secondary currents) and are always present in any turbulent flow along a channel with a noncircular cross section, such as a natural river channel (Einstein and Li 1958; Liggett et al. 1965; Tracy 1965; Perkins 1970; Melling and Whitelaw 1976; Chiu and Hsiung 1981; Naot and Rodi 1982; Nezu 1993; Meyer and Rehme 1994). In straight channels, stress-induced secondary velocities are usually small, typically being 1 to 2% of the primary velocity. Modeling these weak motions is especially difficult in complex cross sections such as those of natural rivers. In meandering channels, skew-induced secondary velocities may be as great as 10 to 20% of the primary flow, and they are known to affect the distributions of primary velocity and bed-shear stress significantly (Bathurst et al. 1979; Ikeda and Parker 1989; Nelson and

Smith 1989a; 1989b; Shiono and Muto 1993; Knight and Shiono 1995).

River engineers are often concerned with the parameters at the channel boundary. A depth-averaged form of the streamwise equation of motion of flow in a straight channel is given by Shiono and Knight (1988; 1991) as

$$\rho g H_{s_0} - \frac{1}{8} \rho f U_d^2 \left( 1 + \frac{1}{s^2} \right)^{1/2} + \frac{\partial}{\partial y} \left( \rho \lambda H^2 \left( \frac{f}{8} \right)^{1/2} U_d \frac{\partial U_d}{\partial y} \right) = \frac{\partial}{\partial y} [H(\rho UV)_d] \quad (7-1)$$

where

- $\rho$  = water density;
- $g$  = acceleration due to gravity;
- $H$  = water depth;
- $U$  = streamwise velocity;
- $V$  = cross-stream velocity;
- $y$  = lateral distance across the channel;
- $S_0$  = streamwise channel slope;
- $s$  = local channel side slope of the banks; and
- $U_d$  = depth-averaged mean velocity, defined by

$$U_d = \frac{1}{H} \int_0^H U dz \quad (7-2)$$

Three coefficients,  $f$ ,  $\lambda$ , and  $\Gamma$  are introduced to deal with the local friction factor, dimensionless eddy viscosity, and secondary flow parameter, defined respectively by

$$\tau_b = \frac{f}{8} \rho U_d^2 \quad (7-3a)$$

$$\bar{\tau}_{yx} = \rho \bar{\epsilon}_{yx} \frac{\partial U_d}{\partial y} \quad (7-3b)$$

$$\bar{\epsilon}_{yx} = \lambda U_* H \quad (7-3c)$$

$$\frac{\partial H(\rho UV)_d}{\partial y} = \Gamma \quad (7-3d)$$

where

$\bar{\epsilon}_{yx}$  = depth-averaged eddy viscosity; and  
 $\tau_b$  = local boundary shear stress.

Equation (7-1) governs lateral distributions of  $U_d$  or  $\tau_b$  across the channel width, provided that appropriate values of  $f$ ,  $\lambda$ , and  $\Gamma$  are specified for each boundary element. Applications of this model to both in-bank and over-bank flow are described in Shiono and Knight (1990) and Abril (1995).

The depth-mean apparent shear stress  $\tau_a$  acting on a vertical plane in the streamwise direction of a river cross section may be determined by laterally integrating (7-1) to give

$$\tau_a = -\frac{I}{H} \int_0^y \left[ \rho g H S_0 - \tau_b \left( 1 + \frac{I}{s^2} \right)^{1/2} \right] dy \quad (7-4)$$

A comparison between (7-1) and (7-4) illustrates that the depth-averaged apparent shear stress has two distinct components, one arising from depth-averaged secondary flow motion and the other from turbulent Reynolds stresses. It is this apparent shear stress that is often required in sediment transport models, because it links the local boundary shear stress at a point on the wetted perimeter with the streamwise resolved weight force and the resultant net stress. Some values of  $\tau_a$  are shown in Fig. 7-6 for trapezoidal channels with roughened banks and width/depth ratios between 4 and 10.

Significantly, the right-hand side of (7-1) contains a depth-averaged secondary flow term. This term is often ignored in stream-tube models and in some eddy viscosity/width-adjustment models (Wark et al. 1990; Darby and Thorne 1992; James and Wark 1994; Kovacs and Parker 1994). However, this term is, in fact, important, as is well illustrated by the examples of Knight and Abril (unpublished paper 1996) using benchmarked experimental data from the U.K. Flood Channel Facility (Knight and Sellin 1987; HR Wallingford 1992).

From the point of view of sediment transport, although it is known that the entrainment and motion of grains may be correlated with turbulent bursts and sweeps (Jackson 1976b; Raudkivi 1995), inclusion of burst and sweep phenomena in a practical model of width adjustment is at this stage premature, owing to our lack of knowledge concerning all the details of coherent structures in the boundary layer close to the bed (Tehrani 1992; Ashworth et al. 1996). As a result, one of the flow parameters still most closely associated with sediment motion is the local time-averaged boundary shear

**Fig. 7-6.** Lateral variation of depth-averaged apparent shear stress  $\tau_a$  for trapezoidal channels with roughened walls and smooth bed (ASCE Task Committee on Hydraulics, Bank Mechanisms and Modeling of River Width Adjustment 1998a, with permission from ASCE).

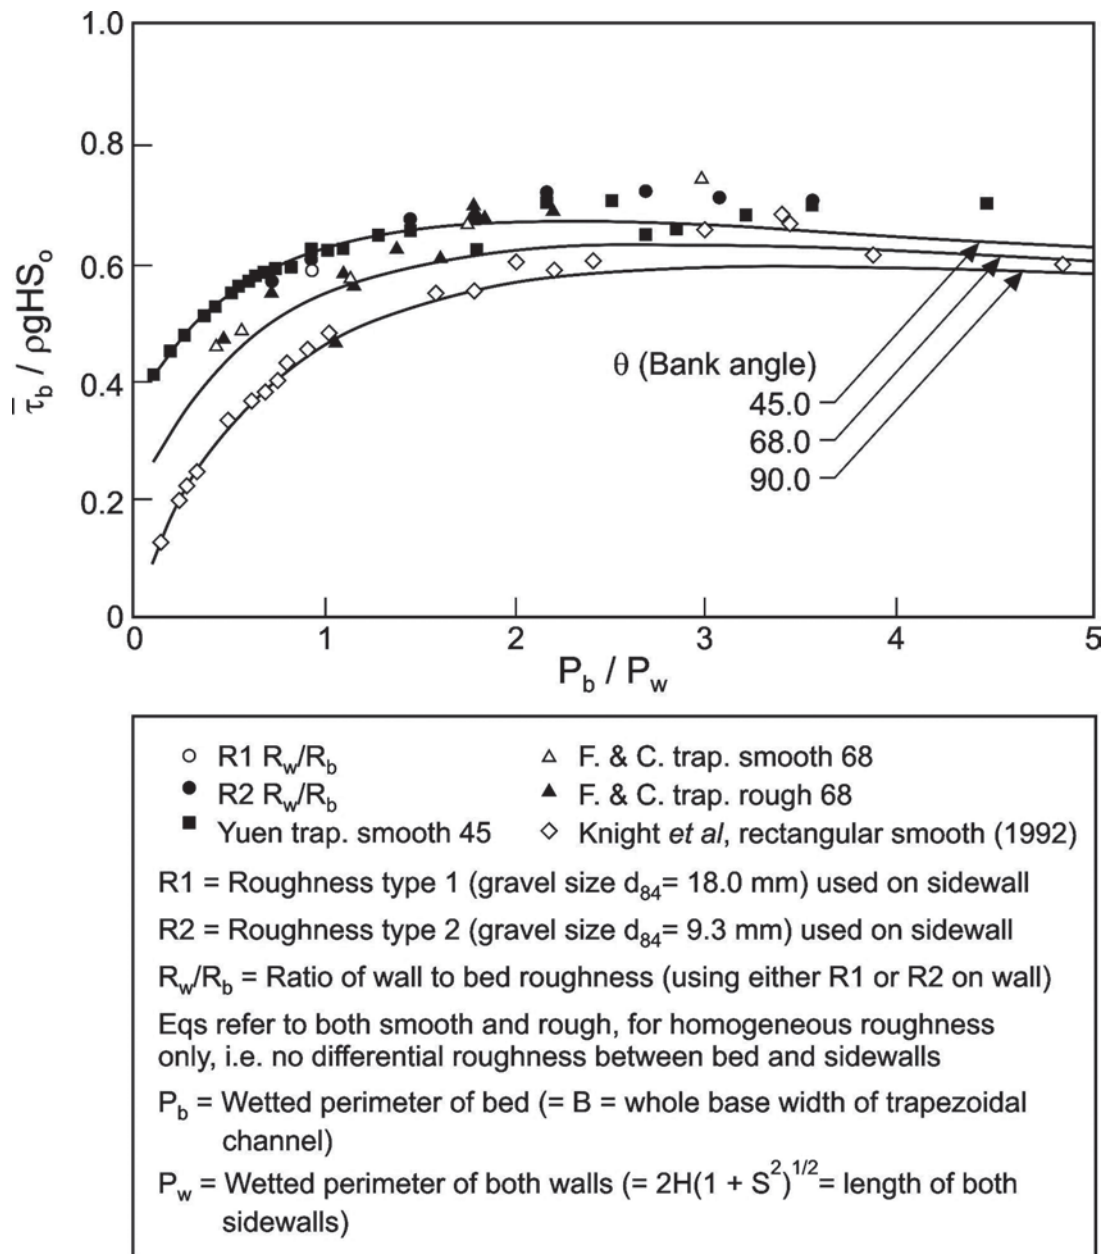

stress. Many researchers have attempted either to predict or to measure the lateral distribution of local time-averaged boundary shear stress around the wetted perimeters of channels of various shapes and the longitudinal distribution of local boundary shear stress over sand dunes or in channel reaches. These studies have usually been conducted at laboratory scale using, for convenience, rectangular, trapezoidal, or lenticular cross sections (Engelund 1964; Lundgren and Jonsson 1964; Knight et al. 1994; Rhodes and Knight 1994), and only a few studies have been undertaken in the field at

full scale (Bathurst et al. 1979; Dietrich and Whiting 1989; Nece and Smith 1970).

Although the applicability of laboratory-based work to field situations is limited, most previous studies of the relevant hydraulic processes have been carried out under carefully controlled laboratory conditions. Figures 7-7 and 7-8 illustrate how the average wall or bank stress  $\tau_w$  and bed shear stress  $\tau_b$  vary for uniformly roughened trapezoidal channels (side slope angles of 45°, 68°, and 90°) and how they compare with simple exponential equations. These data

**Fig. 7-7.** Average wall shear stress  $\tau_b/\rho g H S_o$  for smooth and rough trapezoidal channels with different side-slope angles (ASCE Task Committee on Hydraulics, Bank Mechanisms and Modeling of River Width Adjustment 1998a, with permission from ASCE).

**Fig. 7-8.** Average wall shear stress  $\tau_b/\rho g H S_o$  for smooth and rough trapezoidal channels with different side-slope angles (ASCE Task Committee on Hydraulics, Bank Mechanisms and Modeling of River Width Adjustment 1998a, with permission from ASCE).

all relate to in-bank flows. Similar plots and equations are available for the maximum stresses on the bed and banks, together with their locations, for both uniformly and non-uniformly roughened channels. High differential roughness may occur in engineered channels (with portions of the wetted perimeter especially rough due to riprap) or in natural channels (with banks that are significantly rougher than the bed due to dense riparian vegetation).

Because lenticular shapes more closely approximate the shape of natural alluvial channels they have often been the

focus of river studies (Lundgren and Jonsson 1964; Ikeda 1981; Kovacs and Parker 1994). Five methods for determining the local boundary shear stress were reviewed by Lundgren and Jonsson (1964), with the area method being found to be most suitable for general use. Distributions of boundary shear stress based on a particular lenticular shape (Fig. 7-9) are shown for all five methods in Fig. 7-10. The way in which a noncohesive riverbank might be eroded into an equilibrium shape under the action of these distributions of applied shear stress is illustrated in Figs. 7-11 to 7-13 (Kovacs and

**Fig. 7-9.** Cross section used in numerical example (circular) (ASCE Task Committee on Hydraulics, Bank Mechanisms and Modeling of River Width Adjustment 1998a, with permission from ASCE).

Parker 1994). In these sketches the lateral distribution of streamwise boundary shear stress is of special significance because those regions of the cross section in which the stress is above the transport threshold will become active with regard to bed-material transport and will form the active width. The resulting cross-sectional shapes for straight alluvial channels under both threshold and mobile bed conditions have also been the subject of much investigation. However, it should

be noted that, because the discharge and sediment supply in natural rivers are highly variable, the actual channel cross-sectional shape is constantly responding to changing stage bed forms and flow resistance. Hence, it is only possible to predict medium-term (5–10 years) time-averaged, cross-sectional shapes.

For over-bank flows in straight and meandering channels, considerably fewer experimental data are found with regard to both velocity and boundary shear stress (Knight and Demetriou 1983; Knight et al. 1989, 1990; Tominaga and Nezu 1991; Ackers 1992; Knight et al. 1992; Ackers 1993; Sellin et al. 1993; Tominaga and Nezu 1993). In general terms, for straight channels with floodplains the boundary shear stresses under over-bank flows vary in a more complex way than those for in-bank flows, with stresses in the main river channel decreasing because of the influence of the slower floodplain flows. Conversely, the floodplain boundary shear stresses rise above their expected 2D values because of the effect of the faster flowing, main river flow. Interaction between channel and floodplain flows results in some localized and complex effects in the vicinity of the

main channel riverbanks. These features are discussed by Knight and Cao (1994) in relation to large-scale experimental studies and by Knight and Shiono (1995) in relation to the relative importance of the three terms in (7-1).

The redistribution of boundary shear stress within the cross section during over-bank flow also has a profound effect upon sediment transport rate, as shown by Ackers (1992) and Abril (1995). It will consequently also have an effect on bank adjustments that occur when the river overflows its bank.

**Fig. 7-12.** Sketch of distribution of shear stress  $\tau_b$  and lateral bed slope  $\tan \omega$  along perimeter of straight channel cross section during development of stable profile (ASCE Task Committee on Hydraulics, Bank Mechanisms and Modeling of River Width Adjustment 1998a, with permission from ASCE).

**7.3.2.3 Longitudinal Changes** Unlike artificially constructed channels, river channel cross sections are not generally uniform trapezoids. Consequently, width, depth, slope, and planform change significantly in the streamwise direction. Some schematization of the natural river is therefore necessary before a numerical model is constructed (Samuels 1990), and inevitably some streamwise averaging of cross-sectional area, hydraulic radius, energy gradient, mean boundary shear stress, etc. must be performed. This is potentially a source of error in any representation of the channel hydraulics and

**Fig. 7-13.** Shear stress distribution in state of dynamic equilibrium (ASCE Task Committee on Hydraulics, Bank Mechanisms and Modeling of River Width Adjustment 1998a, with permission from ASCE).

must be treated with appropriate care (McBean and Perkins 1975; Cunge et al. 1980; Laurenson 1986). Samuels (1989; 1990) used perturbation analysis of the steady-flow equation to show that weighting the friction slope toward the upstream section gives considerably improved accuracy. For example, the longitudinal spacing between channel cross sections may be doubled if weighting coefficients are used rather than the arithmetic mean, with the same accuracy in water levels being achieved. However, the correct representation of the energy gradient or water-surface slope is difficult to achieve in natural channels where width, pool-riffle sequences (especially in gravel-bed rivers), and pool-crossing geometry (in sinuous rivers) introduce marked channel variability. In these cases, channel schematization, even using a weighting technique, may be inadequate. Further work is needed on the derivation of representative reach-averaged parameters and their significance in 1D models.

In meandering alluvial rivers, the boundary shear stress distribution, bed topography, bed load transport rate, and channel cross-sectional shape all vary considerably over the meander wavelength due to flow curvature effects. Field data (Dietrich and Smith, 1983, 1984, and many others) indicate that the near-bed flow and bed load transport along the outside bank of a meander bend are directed toward the inside bank (Fig. 7-14), leading to the development of a deep pool along the outside of the bend. On the inside bank, shoaling of the flow over the point bar causes the near-bank velocity to be directed toward the outside bank. Because the development of the pool can increase the effective height of the outside bank, scour on the outside of meander bends is an important hydraulic process that promotes bank erosion. Smith and McLean (1984) and Nelson and Smith (1989a; 1989b) have developed effective numerical models for computing flow and transport processes in meander bends, although these models are not accurate close to the bank itself because lateral momentum diffusion terms in the governing equations are neglected.

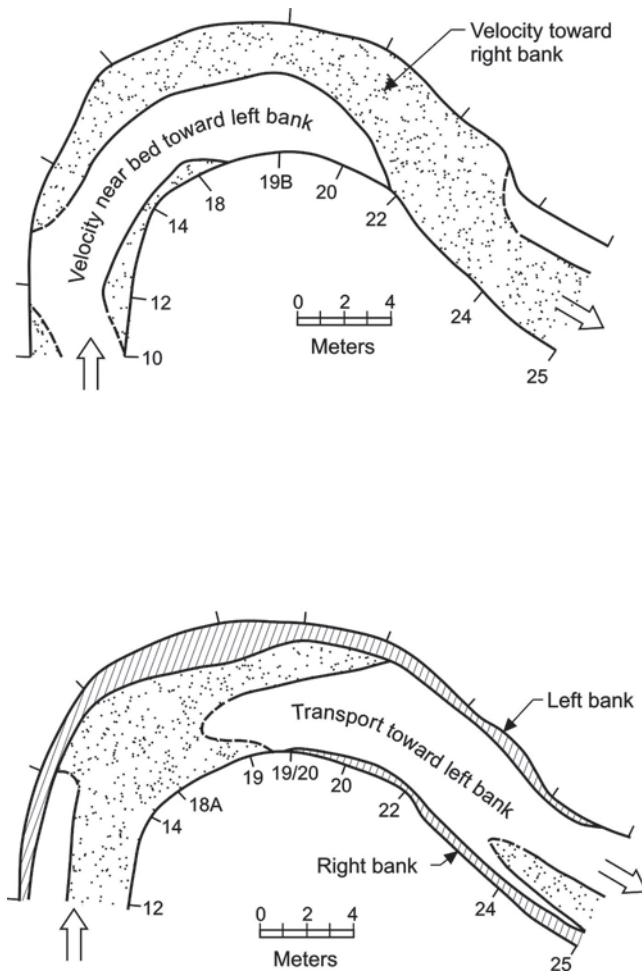

In overbank flows on meandering rivers, hydraulic processes are extremely complex and difficult to predict. Laboratory studies (Tominaga and Neza 1991; Sellin et al. 1993; Tominaga and Neza 1993; Wark et al. 1994; Knight and Shiono 1995) show that new flow structures are introduced during over-bank flow, and field studies (Fukuoka 1993; 1994; Lawler 1993a; 1993b) indicate that over-bank flows are strongly influenced by local morphological features.

**7.3.2.4 Near-Bank Zone** Knowledge of the velocity, boundary shear stress, secondary flows, and turbulence structure close to a riverbank is required before fluvial processes can be linked to channel-width adjustment. The preceding sections have highlighted current difficulties in predicting the details of near-bank hydraulics, even for relatively simple prismatic channels, whether flowing in-bank or over-bank. The 3D nature of near-bank flow leads to nonlinear distributions of Reynolds stresses normal to the boundary and velocity profiles that are not logarithmic (Knight and Shiono 1990; Shiono and Knight 1991; Meyer and Rehme 1994;

Knight and Shiono 1995). The effect of these flow complexities on boundary shear stress distributions in the vicinity of riverbanks has been illustrated by Knight and Cao (1994).

At present, no simple formulas exist to characterize the lateral distribution of local time-averaged boundary shear stress around the wetted perimeter of a natural channel, although Figs. 7-7 and 7-8 give some guidance, and experimental data, such as those shown in Figs. 7-4 and 7-5, indicate how local values may vary about the cross-sectional mean. Consequently, boundary shear stresses in the near-bank zone either have been estimated from trends established experimentally, such as those shown in Figs. 7-4 to 7-10, or else have been obtained from turbulence models, of which the nonlinear  $k$ - $\epsilon$  ( $k$  is the turbulent kinetic energy and  $\epsilon$  is the turbulent dissipation rate) and large-eddy simulation models are probably the most appropriate (Rodi 1980; Nezu and Nakagawa 1993; Thomas and Williams 1995; Younis 1996). Assuming that these local values are known, Figs. 7-11 to 7-13 show how the boundary shear stress and bed load region are often conceptualized in a typical width adjustment model (Ikeda and Izumi 1991; Kovacs and Parker 1994; Knight and Yu 1995). It should be remembered, however, that although the boundary shear stress is arguably one of the more important connecting links between the flow field and the distributions of erosion (or scour), deposition, and channel change (Breusers and Raudkivi 1991), it is not necessarily the dominant parameter responsible for bank erosion or width adjustment. Process dominance also depends on the geomorphic context within which width adjustment is taking place, the channel type (Fukuoka et al. 1993), and location within the watershed (Lawler 1992).

**7.3.2.5 Adjustment of Channel Boundaries in Near-Bank Zone** The adjustment of alluvial channel boundaries is usually related to spatially averaged hydraulic parameters, such as boundary shear stress, streamwise stream power, and energy gradient, together with data defining the net sediment supply to the system and the bank material properties (Molinas and Yang 1986; Hasegawa and Mochizuki 1987; Chang 1988a, 1988b; Hasegawa 1989; Wiele and Paola 1989; Pizzuto 1990; Lawler 1993a; Parker 1995). The variability of channel morphology and complexity of the turbulent flows described earlier might suggest that a probabilistic approach is more suitable than the deterministic treatments described previously. Whichever approach is selected, the same key hydraulic parameters are still likely to be included in process equations or functions and should be represented as faithfully as possible, despite some implicit longitudinal smoothing of localized flow structures or morphological features. The appropriate inclusion of 3D phenomena in either a 1D model or a depth-averaged model is still awaited and is likely to be derived from detailed 3D numerical simulations (ASCE Task Committee on Turbulence Models in Hydraulic Computation 1988; Li and Wang 1994a,b; Thomas and Williams 1995; Younis 1996). However, even allowing for future advances in representing the 3D flow,

**Fig. 7-14.** Top: direction of flow near the bed in a meander bend determined using current meter data (Dietrich and Smith 1983). Bottom: direction of bed load transport in a meander bend. The shaded area represents bed load transport toward the right bank, whereas the clear area denotes bed load transport toward the left bank. The dashed lines indicate uncertainty as to correct position of the boundary between fields. Diagonal lines define the area occupied by submerged bank and immobile gravel (Dietrich and Smith 1984).

a comprehensive theoretical framework for determining the equilibrium form of stable alluvial channels still needs to be developed before attempting to simulate changes from the equilibrium profile.

Identification of the junction point between active (eroding) and inactive (noneroding) elements of the bank, together with characterization of the erosion front that moves this point, appears to be crucial to quantifying width adjustment. Hydraulic conditions at the active-inactive junction are especially difficult to determine with precision, even for in-bank flows. Near-bank hydraulic conditions for over-bank flows are strongly influenced by secondary flow structures close to the banks and must be represented carefully through the correct use of local friction factors, eddy viscosities, and depth-averaged secondary flow values. For this purpose,

the depth-averaged approach described earlier is worthy of further study. Although this approach still has major drawbacks, a need still exists for calibration of specific channel shapes, and no details of vertical motion are available from the process equations.

It is also important to know the rates at which width, depth, slope, and local morphological adjustments are made, so that errors can be assessed when an incremental series of quasi-steady-state discharges are used to simulate a hydrograph. The dominant or effective discharge responsible for forming channel morphology, although easy to define in theory, is still poorly understood and, except for work by Ackers (1992), very little attention has been paid to the influence of over-bank flows on dominant discharge. The hypothesis that in an equilibrium channel the bank-full stage corresponds to the dominant or effective discharge has some theoretical basis, but it may be a special case within a variety of associations between important features of channel morphology and a range of effective flows (Hey 1975; Thorne et al. 1993; Biedenharn and Thorne 1994). Further experimental work on equilibrium and nonequilibrium alluvial channels is required before linkages between dominant discharge, the range of effective flows, and channel morphology can be substantiated.

### 7.3.3 Bank Mechanics

The fundamental processes responsible for channel-width adjustment are fluvial erosion, fluvial deposition, and mass bank failure. The following seven topics concerned with the mechanics of bankline movement are addressed in this section: (1) bank erosion; (2) weakening of resistance to erosion; (3) bank stability with respect to mass failure; (4) basal endpoint control; (5) effects of vegetation; (6) seepage effects; and (7) bank advance.

**7.3.3.1 Bank Erosion** Water flowing in an alluvial channel exerts forces of drag and lift on the boundaries that tend to detach and entrain surface particles. To remain in place, the boundary sediment must be able to supply an internally derived force capable of resisting the erosive forces applied by the flow. The origin of these resisting forces varies according to the grain size, the size distribution, and the nature of electrochemical bonding that may exist between particles. Alluvial bank materials are formed primarily by fluvial deposition and are often stratified, with a general fining-upward sequence. Therefore, the engineering characteristics and erodibility of the bank may vary with elevation. Also, floodplain deposits typically include alluvial sands and gravels, clay plugs, and strongly cohesive backswamp deposits, so that bank material properties vary spatially over relatively short distances. Although the distribution of sustained bank retreat along the course of a river depends primarily on the distribution of boundary shear stress in the near-bank zones, outcrops of particularly resistant material may act to slow the local bank retreat rate and

to distort the fluvially driven pattern of channel planform evolution (Sun et al. 1996).

In the case of noncohesive sands and gravels, the forces resisting erosion are generated mainly by the immersed weight of the particles, although close packing of grains in imbricated patterns can also wedge particles in place, greatly increasing the critical boundary shear stress necessary for entrainment. Generally, the mobility of noncohesive bank materials can be predicted using a Shields-type entrainment function, but this must be modified to take into account the destabilizing effect of channel side slope. Also, the critical value of the dimensionless shear stress must be adjusted to allow for excessive tightness or looseness in packing of bank material particles (Thorne 1982).

Fine-grained bank materials, containing significant amounts of silt and clay, are to some degree cohesive and resist entrainment primarily through interparticle electrochemical bonding rather than through the immersed weight of the particles. When cohesive bank materials are entrained by the flow, it is aggregates of grains (such as soil crumbs or peds that have been produced by soil-forming processes) that are detached. Fluvial entrainment, therefore, requires that the local boundary shear stresses exceed the critical value to initiate motion of crumbs or peds rather than that related to the primary soil particles. Ped size and stability and interped bonding strength are not conservative soil properties, because they depend to some degree on the local history of soil development, in general, and recent antecedent conditions of wetting and drying, in particular. It follows that the conditions of incipient motion for cohesive bank materials are complex, time-dependent, and difficult to define.

A task committee (ASCE Task Committee on Erosion of Cohesive Sediments 1968) summarized early studies into the mechanics of cohesive bank erosion. The task committee recorded the results of noteworthy contributions by, among others, Smerdon and Beasley (1961) and Flaxman (1963) on channel stability in cohesive materials and Grissinger and Asmussen (1963) and Grissinger (1966) on the erodibility of cohesive soils. For example, Grissinger and Asmussen (1963) found that erosion resistance of clayey soils increased with the time that the materials were wetted. They postulated that when clay is initially wetted, the free water releases bonds between particles, but that, as free water is absorbed, the clay minerals hydrate and interparticle bonds are strengthened. This illustrates how the chemical bonding of clay particles may vary with time and the history of soil moisture changes.

A wealth of subsequent work has further addressed fundamental aspects of cohesive soil behavior, leading to important papers by Parthenaides and Passwell (1970); Kandiah and Arulanandan (1974); Arulanandan (1975); Arulanandan et al. (1975); Ariathurai and Krone (1976); Ariathurai and Arulanandan (1978); Abt (1980); Grissinger (1982)—who presents an excellent review of progress achieved up to the early 1980s; Kamphuis and Hall (1983); Parchure and Mehta (1985); Springer et al. (1985); Shaikh

et al. (1988a; 1988b); and, more recently, Annadale and Parkhill (1995) and Kranenburg and Winterwerp (1997). Space limitations preclude an in-depth review of the findings of these papers here. However, in summary it can be concluded that although critical boundary shear stresses for cohesive bank soils are extremely difficult to predict accurately (Grissinger 1982), they tend to be higher than those for noncohesive bank materials. As a result, erosion rates for cohesive banks are generally lower than those for noncohesive materials (Vanoni 1975; Thorne and Tovey 1981).

Once entrained, crumbs and peds disintegrate rapidly due to corrosion at the channel boundaries and turbulent buffeting in the flow, so that most silt- and clay-sized sediment derived from bank erosion is transported in suspension and is conventionally classified as wash load.

**7.3.3.2 Weakening of Resistance to Erosion** The erodibility of bank soils can be increased markedly by processes of weakening and weathering. The processes responsible for loosening and detaching grains and aggregates are closely associated with soil moisture conditions at and beneath the bank surface. In poorly drained soils, positive pore-water pressures act to reduce bank stability, which can lead to bank failure, particularly during rapid drawdown of the channel stage following a high flow. Conversely, rapid immersion of a dry bank can lead to slaking, which is the detachment of aggregates by positive pore pressures due to compression of trapped air.

Changes in moisture content and freezing and thawing can significantly influence the erodibility of a riverbank. Swelling and shrinkage of soils during repeated cycles of wetting and drying can contribute to cracking that significantly increases erodibility and reduces soil shear strength. Shrinkage is especially damaging to the strength of the bank when intense drying of the soil leads to desiccation cracking. Heaving due to the 9% increase in water volume on freezing (Ritter 1978) and the growth of needle ice crystals at the bank surface, followed by collapse of ice wedges and needles during thawing of soil moisture, are highly effective in increasing the susceptibility of cohesive bank materials to flow erosion (Lawler 1993b).

Temporal variability in the erodibility of bank soils due to the operation of weakening processes means that the effectiveness of a given flow event in eroding a bank depends not only on the magnitude and duration of a particular event but also on antecedent conditions (Wolman 1959).

**7.3.3.3 Bank Stability with Respect to Mass Failure** Fluvial erosion drives bank retreat directly by removing material from the bank face, but it often also causes bank retreat by triggering mass instability. The stability of a bank with regard to mass failure depends on the balance between gravitational forces, which tend to move soil downslope, and forces of friction and cohesion, which resist movement. Failure of the bank occurs when scour of the bed next to the bank toe increases the bank height, or when undercutting increases the bank angle, to the point that motivating

**Fig. 7-16.** Culmann analysis for plane slip failure. (After Thorne 1982. Copyright John Wiley & Sons Limited. Reproduced with permission.)

the failure plane, leading to the following equation to define the critical height for mass failure:

$$H_c = 4c(\sin \theta \cos \phi) / \gamma [1 - \cos(\theta - \phi)] \quad (7-5)$$

where

- $H_c$  = critical bank height;
- $c$  = cohesion;
- $\theta$  = bank angle;
- $\gamma$  = bank material unit weight; and
- $\phi$  = friction angle.

Tension cracks often develop downward from the ground surface, parallel to the bankline, behind steep banks because of horizontal tensile stress in the soil at this location (Terzaghi and Peck 1967). Tension cracks truncate the effective length of the potential failure surface, tending to destabilize the bank and reducing its stability relative to that predicted from a Culmann analysis. Cracks may occupy as much as half of the bank height, isolating a column or slab of soil, which then slides and topples forward into the channel in a toppling failure (Fig. 7-17).

Stability analyses applicable to the very steep (almost vertical), deeply cracked river cliffs associated with eroding, unstable streambanks have been undertaken by researchers in hydraulic engineering and fluvial geomorphology, but much more testing and validation is required before these models can be adopted for routine application as engineering design tools (Osman and Thorne 1988; Darby and Thorne 1996a; Millar and Quick 1997).

Cantilevered or overhanging banks are generated when erosion of an erodible layer in a stratified or composite bank leads to undermining of overlying, erosion-resistant layers. Thorne and Tovey (1981) pointed out that cantilevered banks may fail by shear, beam, or tensile collapse (Fig. 7-18). Shear failure (Fig. 7-18(a)) occurs when the weight of the cantilever block exceeds the soil shear strength, causing the overhanging block to slip downward along a vertical plane. In a beam failure, a block rotates forward about a horizontal axis within the block (Fig. 7-18(b)) when disturbing moments about the neutral axis exceed restoring moments. Tensile failure (Fig. 7-18(c)) occurs when the tensile stress exceeds the soil tensile strength and the lower part of the overhanging block falls away. Frequently, the strength of cantilever blocks is significantly increased by root reinforcement due to riparian and floodplain vegetation. Flow erosion and tensile failure occurs below the root mat, leaving root-bound cantilevers that fail subsequently by either the beam or shear mechanism.

Whether bank failure occurs by rotational slip, toppling, or cantilever collapse, the primary force tending to move the failure block is the tangential component of the weight of the block. Fluvial erosion can increase the motivating force by increasing the bank height (through bed scour next to the bank toe) or by increasing the bank slope angle (through lateral erosion of the toe and lower bank). The weight of bank material also increases with the moisture content of the soil, and failure often follows the change from submerged to saturated conditions that occurs when draw-down occurs in the channel (Rinaldi and Casagli, 1999; Simon et al. 2000).

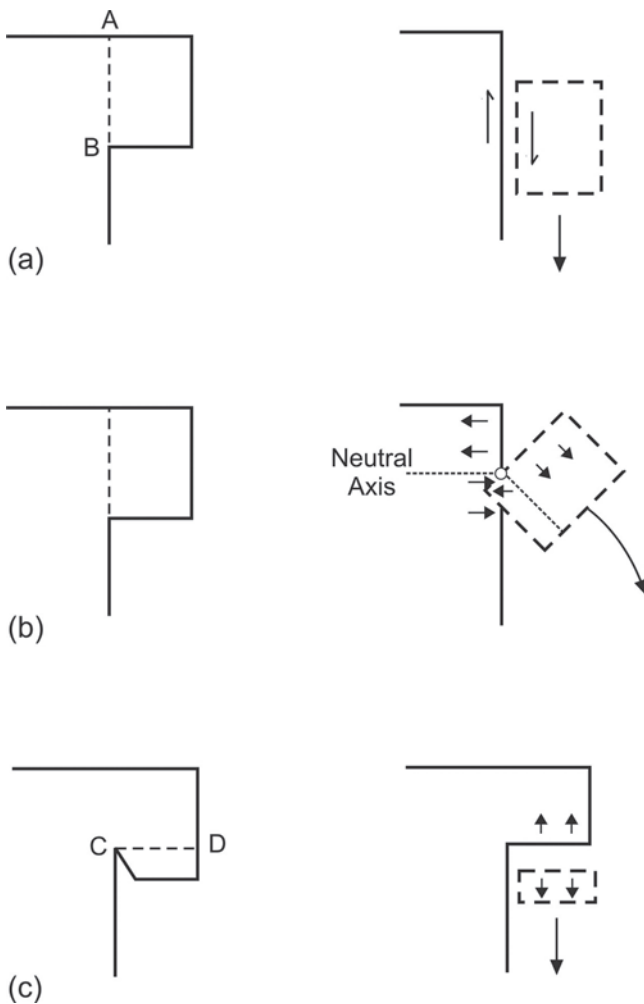

**Fig. 7-17.** Sequence (i–iv) of toppling failure on low steep stream bank. (After Thorne and Tovey 1981. Copyright John Wiley & Sons Limited. Reproduced with permission.)

Ample field evidence exists that bank failure may be triggered by any of these changes in motivating force. For example, Abam (1993) noted that bank failure in the Niger Delta, Nigeria, could often be attributed to increases in bank height and bank angle due to fluvial erosion and bed scour at the riverbanks. Abam (1993) also documented decreased bank stability due to rapidly falling water levels that led to (1) the loss of the confining pressure provided by the channel water level; (2) positive pore pressures due to poor drainage resulting from the low permeability of the soil; and (3) increases in the effective unit weight of the soil due to saturation.

**7.3.3.4 Basal Endpoint Control** Although fluvial erosion processes and geotechnical failures are controlled by different aspects of bank geomorphology, they are actually linked. The key to characterizing this link lies in recognizing that mass wasting delivers the failed material to the toe of the slope, or basal area, but does not entirely remove it from the bank profile. The removal of failed material from the basal area depends primarily on its entrainment by current and wave action, following by fluvial transport downstream. The concept of basal endpoint control explains how the medium- to long-term retreat rate of the bank is controlled by the rate of sediment entrainment and removal from the toe.

The concept of basal endpoint control was first developed by Carson and Kirkby (1972) to explain variations in hill-slope profiles. Thorne (1982) applied the concept to riverbanks, proposing that bank retreat can only be sustained when the near-bank flow is able to remove failure debris and to continue to scour the basal area. In contrast, where the flow is unable to remove all the debris, basal accumulation occurs and a berm or bench of failed material develops. This tends to protect the bank from fluvial erosion and, by acting as a buttress against gravity failures, increases bank stability. On this basis, the balance of basal supply and removal of sediment can be defined by one of the following three states of basal endpoint control:

1. *Impeded removal*—Bank failures supply debris to the base at a higher rate than it is removed. Basal accumulation results, decreasing the bank angle and height and therefore increasing stability with respect to mass failure. The rate of debris supply decreases, favoring the second state.
2. *Unimpeded removal*—Processes delivering debris to the base and removing it are in balance. No changes in basal elevation or slope angle occur. The bankline

**Fig. 7-18.** Mechanisms of cantilever failure: (a) shear failure along AB; (b) beam failure about neutral axis; (c) tensile failure across CD. (After Thorne and Tovey 1981. Copyright John Wiley & Sons Limited. Reproduced with permission.)

recedes by parallel retreat at a rate determined by the degree of fluvial activity at the base.

3. *Excess basal capacity*—Basal scour has excess capacity over the debris supply from bank failures. Basal lowering occurs, increasing bank angle and height, and therefore, decreasing stability with respect to mass failure. The rate of debris supply increases, favoring the second state.

The state of basal endpoint control is useful in explaining the medium- to long-term rates of riverbank retreat of advance. It also highlights the importance of considering the response of near-bank morphology to bank stabilization. The concept indicates that a reduction in debris supply that is due to bank stabilization may induce a state of excess basal capacity that generates very deep toe scour (Thorne et al. 1995). As pointed out by Maynard (1996), this additional scour must be properly accounted for in the design of the

stabilization works if failure due to undermining is to be avoided.

Hagerty (1991) proposed that not all sustained bank retreat depends on the state of basal endpoint control. This proposal was based on the fact that piping is a widespread cause of sustained bank retreat along the Ohio River, which is apparently independent of the state of basal endpoint control. Even though the bank toe is stable, upper bank retreat has continued unabated for many years. However, closer inspection of the relevant bank profiles indicates that the reason that the toe has been stable is that, in this regulated river, the toe is well below pool level and is thus morphologically inactive. Piping in sand layers at about the elevation of the stranded low water plane has produced a bench that represents the toe of the morphologically active bank. At this elevation, bank retreat may still be considered to be covered by the concept of basal endpoint control, with the bank profile above pool elevation almost continually in a state of unimpeded removal, due to the ability of current and wave action to remove the fine debris supplied by piping. Creation of the bench and control of the profile thus depend on the piping process in supplying debris that can easily be removed by waves and currents that would not otherwise be able to erode intact bank material.

Hagerty et al.'s (1995) detailed treatment highlights the subtlety of interactions between fluvial and mechanical processes responsible for bank retreat, and it illustrates that great care must be taken in interpreting bank processes from bank form, especially in regulated rivers.

**7.3.3.5 Vegetation Effects** The role of vegetation in affecting bank erosion and width adjustment is complex and poorly understood. Although vegetation generally reduces soil erodibility, its impact on bank stability with respect to mass failure may be either positive or negative. Hence, depending on the geomorphic context and dominance of either fluvial processes or mass failure, vegetation may produce either a net increase or a decrease in the rate of bankline shifting.

Vegetation can play an important role in limiting the effectiveness of bank erosion by detachment and entrainment of individual grains or aggregates of bank material. Compared to unvegetated banks, erosion of well-vegetated banks is reduced by one to two orders of magnitude (Carson and Kirkby 1972; Smith 1976; Kirkby and Morgan 1980). Gray and Leiser (1982) have reviewed the effects of herbaceous and, to a lesser extent, woody vegetation in reducing flow erosivity and bank erodibility and concluded that major effects include the following:

- Foliage and plant residues intercept and absorb rainfall energy and prevent soil compaction by raindrop impact.
- Root systems physically restrain soil particles.
- Near-bank velocities are retarded by increased roughness.
- Plant stems dampen turbulence to reduce instantaneous peak shear stresses.

- Roots and humus increase permeability and reduce excess pore water pressures.
- Depletion of soil moisture reduces water-logging.

Gray and Leiser (1982) also reviewed the ways that woody vegetation may affect the balance of forces promoting and resisting mass failure. Roots mechanically reinforce soil by transferring shear stresses in the soil to tensile stresses in the roots, which root strength is able to resist. However, this effect operates only to the rooting depth of the vegetation, and it does not reinforce potential failure planes that pass beneath the plant rootballs. Hence, root reinforcement is negated when bank height significantly exceeds rooting depth.

Soil moisture levels are decreased by interception on the canopy and evapotranspiration from the foliage, reducing the frequency of occurrence of the saturated conditions conducive to bank collapse. Anchored and embedded stems can act as buttress piles or arch abutments in a slope, counteracting downslope shear stresses and increasing bank stability. However, roots may also invade cracks and fissures in a soil or rock mass and thereby cause local instability by their wedging or prying action. The surcharge weight of vegetation may significantly increase motivating forces, causing destabilization of the bank, and wind loading of tall vegetation may exert an additional and potentially critical destabilizing moment on the bank.

These few examples illustrate the complexity of vegetation impacts on flow erosivity, soil erodibility, and mass stability. A recent scoping study on bank vegetation and bank protection reached the conclusion that vegetation may be either a positive or negative influence on bankline stability and retreat rate (Thorne et al. 1997). This may explain the apparently contradictory conclusions regarding the effect of bank vegetation on equilibrium channel width of, for example, Hey and Thorne (1986), who reported that stable channel width decreases as the density and stiffness of bank vegetation increase, and Murgertroyd and Ternan (1983), who found the opposite in a study of the effects of afforestation on channel form. Also, they may explain why the notable increases in the shear strength of root-permeated soils found in laboratory test soils by Waldron (1977) are not always replicated in strength measurements made in real riverbanks (Amarasinghe 1992).

As pointed out by Thorne and Osman (1988a), Darby and Thorne (1996a), and most recently, Thorne et al. (1997), a great deal of further research is necessary before vegetation effects can be properly understood and incorporated into the technical description of bank material characteristics under conditions representative of the range of environments encountered along natural streams and waterways.

**7.3.3.6 Seepage Effects** In addition to fluvial activity causing scour at the toe of the slope, grain-by-grain detachment, and mass wasting, Parola and Hagerty (1993) have identified a general class of failure mechanisms that is often

very important to bank stability. This class of mechanisms is driven by seepage within the bank.

Pore-water movement within a bank is most vigorous during and following a high-flow event. As flood waters rise in a stream, the increased hydraulic head drives seepage into the bed and banks, resulting in groundwater recharge. As the flood stage recedes, hydraulic gradients reverse, driving seepage into the stream from the banks. The distribution of inflow, movement, and outflow through the bank is seldom uniform but is, in fact, strongly influenced by the layered stratigraphy that is characteristic of alluvial banks.

Alluvial banks consisting of sand, silt, and clay layers typically have hydraulic conductivity that is much greater in the horizontal direction than the vertical. Consequently, groundwater flow occurs principally by horizontal seepage into and out of sandy layers. During bank drainage, outflowing water may entrain and remove grains from a sand layer—a process termed piping by Hagerty (1991). Piping erosion leads to undermining of overlying, less pervious layers causing those layers to deflect and distort. The most common result of this undermining is the formation of cracks in the undermined layer, where the soil is unable to support the tensile stresses created by deflection (Parola and Hagerty 1993). Mass wasting then occurs as cracking reduces the operational strength of the bank.

Another type of bank failure associated with strong seepage is gully development. Although gully development is usually regarded as resulting from surface erosion, subsurface erosion by piping may lead to subsequent collapse of the pipes to form gullies along streambanks (Harvey et al. 1985). This mode of gully formation is particularly likely in loess deposits.

Bank weakening and erosion by seepage are often overlooked by river engineers. Failure to identify subsurface piping erosion can lead to misclassification of the erosion problem and subsequent problems with bank stabilization works that are adequate to armor the bank against fluvial attack but that are likely to fail due to internal erosion driven by piping.

**7.3.3.7 Bank Advance** Bank advance occurs through sediment deposition, a process that tends to narrow the channel. Bank advance occurs in a variety of different geomorphic settings (Figs. 7-1 and 7-2), and sediment may be deposited from bed load, suspended bed-material load, wash load, or a combination of all three transport processes. Despite this diversity, however, processes of bank advance have a common result: new floodplain deposits are created as the bank advances. This suggests that bank advance should be more broadly viewed as one of several processes that create new floodplains.

In a meandering stream, bank advance may occur on point bars on the insides of the channel bends (Figs. 7-1b and 7-2b) (Sundborg 1956; Leopold and Wolman 1957; Leopold et al. 1964; Jackson 1976a, 1976b) or on concave bank benches on the outsides of channel bends. Point bars are initiated by

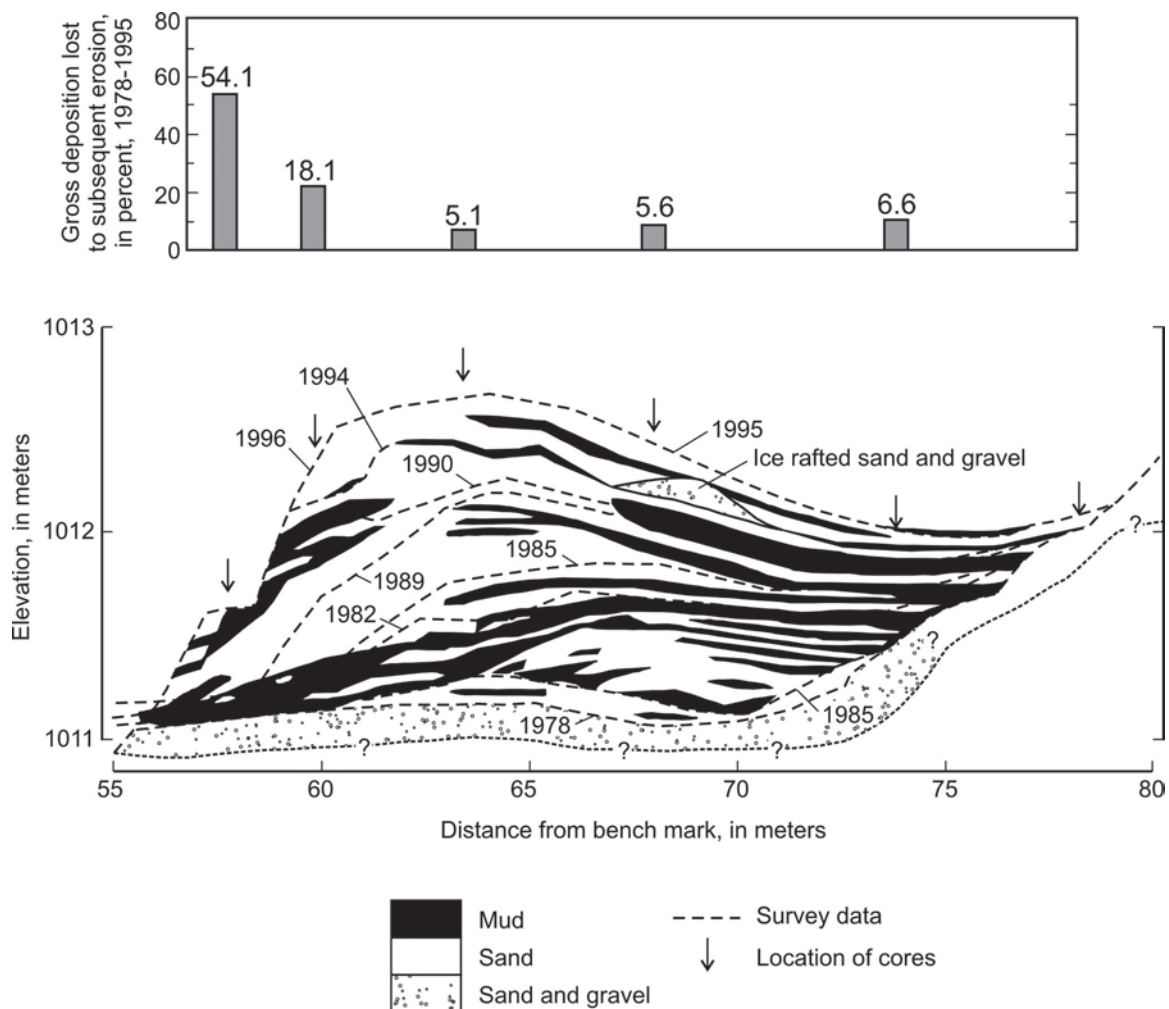

the creation of a point bar platform deposited primarily from bed load transport (Nanson 1980). The platform is the base on which develops a scroll bar of fine traction and suspended load. As the scroll bar grows, vegetation may be established, further enhancing deposition. When the scroll bar is fully developed, approximately half of the new floodplain sediment is deposited from suspension, and the other half from bed load (Nanson 1980).

Bank advance and channel narrowing can also occur by deposition of berms or benches at the margins of the channel (Fig. 7-2a). Pizzuto (1994) and Moody et al. (1999) describe the formation of new floodplain “benches” along the Powder River in southeastern Montana (Fig. 7-19). These new floodplains were formed primarily by deposition from suspension in a widened channel created by a 25 to 50 year flood in 1978. Schumm et al. (1984) and Simon (1989) described

the formation of “berms” as part of the evolution of incised channels. These authors note that as incised channels recover, the bed aggrades and berms develop on the channel margins. Harvey and Watson (1988) propose that the berms are formed from dunes left as remnant bed forms following high flows. The remnant dunes are then draped with fine-grained silts and clays from the suspended load as the flow diminishes, stabilizing the deposits. Repetition of this process eventually produces a stable berm, permanently advancing the bankline.

Bank advance may also occur as sediment is draped onto riverbanks from suspension. Taylor and Woodyer (1978) describe sand-mud couplets that increase in thickness and grain size with depth that are formed by deposition of suspended sediment on riverbanks. Taylor and Woodyer (1978) note that the bank advance process may be accelerated through sediment trapping in pioneer vegetation.

**Fig. 7-19.** Stratigraphic cross section of the flood plain at Section PR120 across Powder River near Moorhead, Montana, showing the history of bank advance from 1978 to 1996. The mud is shown as solid black areas and the sand as white areas. Some of the annual and biennial surveyed surfaces are labeled and the arrows indicate the locations of cores. Complete topographic cross sections of this site in 1978 and 1996 are presented in Fig. 7-3 (uppermost sections).

## 7.4 METHODS FOR EVALUATING BANK EROSION AND WIDTH ADJUSTMENT

### 7.4.1 Introduction

In this section, methods for evaluating bank erosion and width adjustment are described. The first method involves the development of qualitative conceptual models. The remaining methods are quantitative, involving either empirical equations or equations developed theoretically by specifying quantitative models of selected physical processes.

It is important to recognize that none of these methods apply to all rivers, and that all of the methods greatly simplify field conditions. Furthermore, the variety of different approaches available in the literature suggests that scientists who study rivers rarely agree on the best method for predicting the extent of bank erosion or deposition. As a result, the scientific knowledge required to solve practical engineering problems of bank erosion and width adjustment may not always be available. Each problem, then, will require careful study before an engineering solution can be proposed.

### 7.4.2 Conceptual Models of Channel Evolution and Processes

For a problem to be solved, it must be clearly defined. For problems of bank erosion and width adjustment, this implies understanding the processes that are acting at a particular site and their temporal and spatial context. This understanding may be developed as a "conceptual model," which could be summarized as a series of diagrams, or as a verbal description of how bank erosion and width adjustment occur at a particular site. In a very few selected cases, the conceptual model could actually be quantified and summarized by one or more equations.

The first part of this chapter summarized processes that control bank erosion and width adjustment, and some conceptual models of channel evolution were presented in Figs. 7-1 and 7-2. Here, a detailed example of a conceptual model of incised channel evolution is presented.

**7.4.2.1 A Conceptual Model for Incised Channel Evolution** Although applicable only to incised channels, the six-stage conceptual channel evolution model of Harvey and Watson (1986) has been of value in developing an understanding of watershed and channel dynamics and in characterizing whether or not a reach is stable (Fig. 7-20). The model was originally based on observations of the channel evolution of Oaklinter Creek, a tributary of Tippah River in northern Mississippi (Schumm et al. 1984). The Oaklinter sequence describes the systematic response of a channel to base level lowering and encompasses conditions that range from disequilibrium (Type I) to a new state of dynamic equilibrium (Type VI). It should be recognized that these categories are only conceptual and variation may be encountered in the field. Similar conceptual models have been

proposed by Thorne and Osman (1988a; 1988b) and Simon and Hupp (1992).

Type I reaches are characterized by sediment transport capacity that exceeds sediment supply, bank height that is less than the critical bank height, a U-shaped cross section, and small precursor knickpoints in the bed of the channel (provided that the bed material is sufficiently cohesive and little or no bed material is deposited). Width/depth ratios at bank-full stage are highly variable.

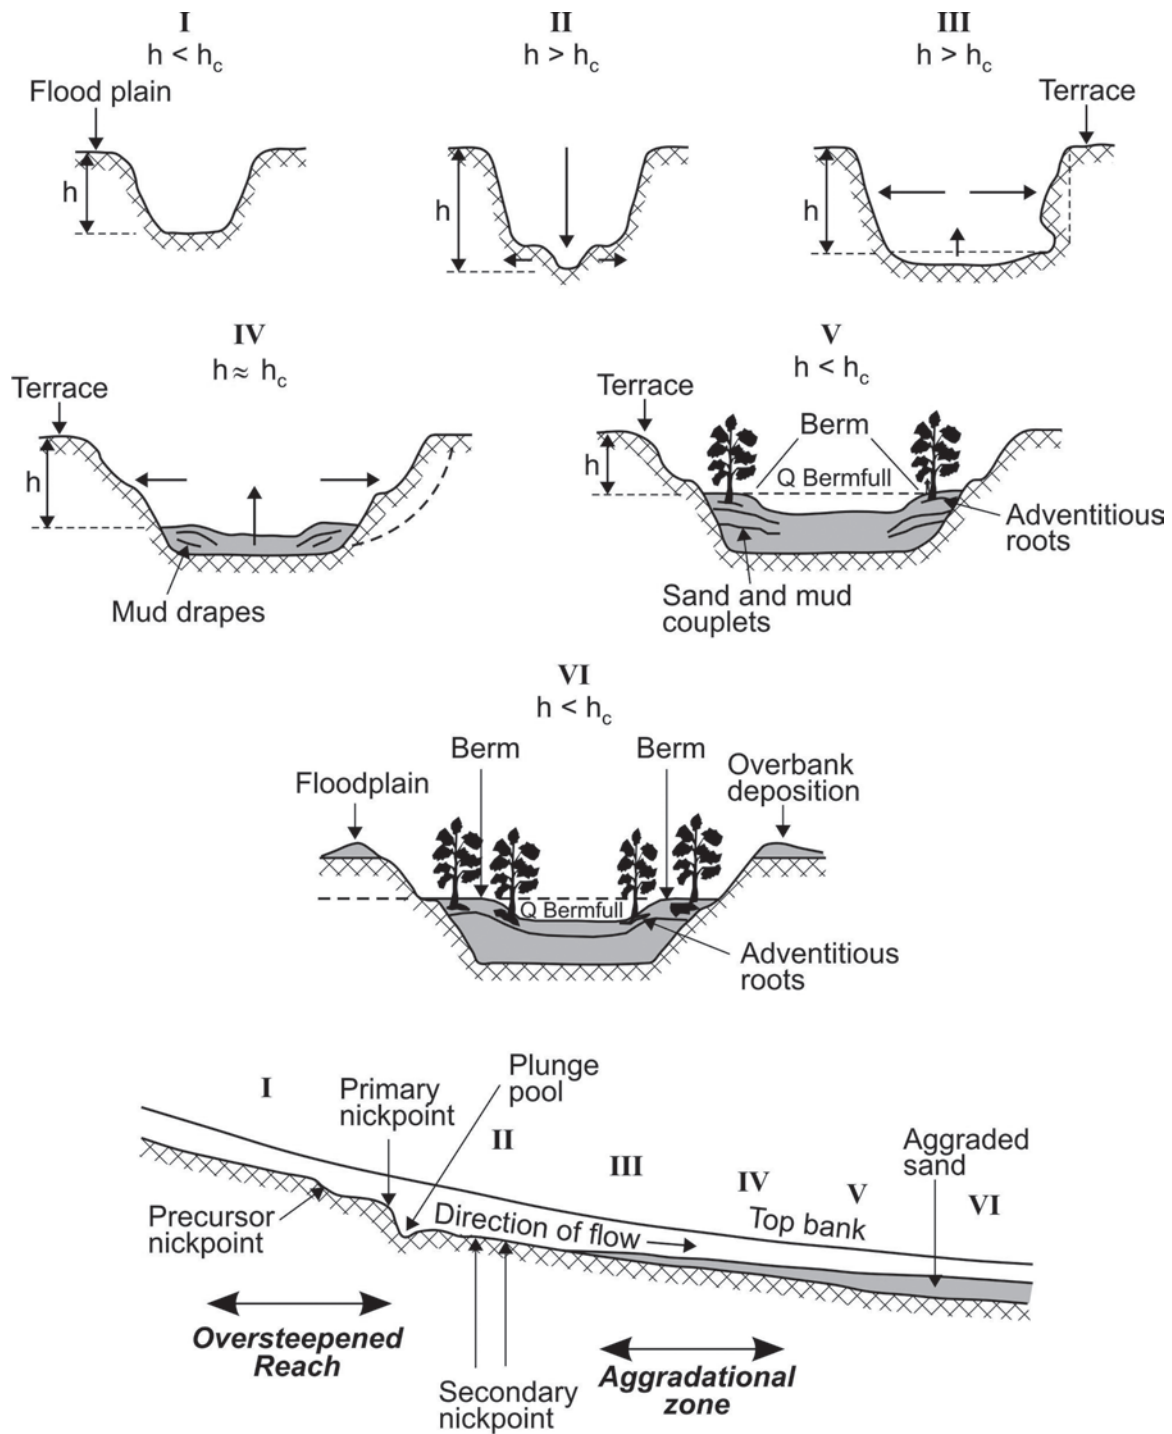

Type II reaches are located immediately downstream of the primary knickpoint and are characterized by sediment transport capacity that exceeds sediment supply, bank height that is less than the critical bank height ( $h < h_c$ ), little or no bed sediment deposits, a lower bed slope than the Type I reach, and a lower width/depth ratio than the Type I reach because the depth has increased, but the banks are not yet unstable.

Type III reaches are located downstream of Type II reaches and are characterized by sediment transport capacity that is highly variable with respect to the sediment supply, bank height that is greater than the critical bank height ( $h > h_c$ ), bank erosion that is due primarily to slab failure (Bradford and Piess 1980), bank loss rates that are at a maximum, bed sediment accumulation that is generally  $<0.6$  m but can be greater locally due to local erosion sources, and channel depth that is somewhat less than in Type II reaches.

Type IV reaches are downstream of Type III reaches and are characterized by sediment supply that exceeds sediment transport capacity, resulting in aggradation of the channel bed, bank height that approaches the critical bank height with a rate of bank failure lower than for Type III reaches, nearly trapezoidal cross-sectional shape, and width/depth ratio higher than the Type II reaches. The Type IV reach is aggradational and has a reduced bank height. Bank failure has increased channel width, and in some reaches, the beginnings of berms along the margins of an effective discharge channel can be observed. These berms are the beginning of natural levee deposits that form in aggraded reaches that were overwidened during earlier degradational phases.

Type V and VI reaches are located downstream of Type IV reaches and are characterized by dynamic balance between sediment transport capacity and sediment supply for the effective discharge channel, a bank height that is less than the critical bank height for the existing bank angle, colonization by riparian vegetation, accumulated bed sediment depth that generally exceeds 1.0 m, width/depth ratio that exceeds the Type IV reach, and generally a compound channel formed within a new floodplain. The channel is in dynamic equilibrium. Bank angles have been reduced by accumulation of berm materials. Types V and VI reaches are distinguished primarily by the possible occurrence of overbank deposition in Type VI reaches.

The primary value of the sequence is that it enables the evolutionary state of the channel to be determined from field observations that record the characteristic channel forms

$h_c$  - Critical bank height

**Fig. 7-20.** Six-stage sequence of incised-channel evolution originally used to describe the evolution of Oaklimiter Creek (ASCE Task Committee on Hydraulics, Bank Mechanisms and Modeling of River Width Adjustment 1998b, with permission from ASCE).

associated with each stage of evolution. The morphometric characteristics of the channel reach types can also be correlated with hydraulic, geotechnical, and sediment transport parameters (Harvey and Watson 1986; Watson et al. 1988a; 1988b).

**7.4.2.2 Channel Stability Diagram** The channel evolution sequence of Schumm et al. (1984) and Harvey and Watson (1986) can be viewed in terms of two dimensionless stability numbers: (1)  $N_g$  is a measure of bank stability, and (2)  $N_h$  is a measure of fluvial stability. For a channel to be stable, fluvial stability and bank stability are both essential conditions. The desirable range for long-term channel stability is for  $N_g$  to be  $<1$ , and for  $N_h$  to be  $\sim 1$ , as shown in Fig. 7-21 (Watson et al. 1988a; 1988b). Quantifying the channel evolution sequence through the use of the dimensionless parameters  $N_g$  and  $N_h$  allows stability conditions along channel reaches to be ranked during rapid assessment and reconnaissance studies.

$N_g$  is defined as any reasonable measure of bank stability expressed in terms of a factor of safety. The factor of safety represents the ratio between resisting and driving forces, such that banks are unstable for  $N_g < 1$  and stable for  $N_g > 1$ . To allow flexibility, the operational definition of  $N_g$  is tailored according to the data available during a specific study (Watson et al. 1988a, 1988b). For example,

in an initial reconnaissance of a site, the field investigator may note that banks over 3 m in height are generally unstable. In that circumstance,  $N_g$  could be the ratio of the bank height at a site divided by 3 m, which would yield  $N_g \leq 1$  for stable bank heights. With better data and analyses,  $N_g$  could be the geotechnical bank safety factor computed with full knowledge of geotechnical properties, bank angle, and materials.

Similar flexibility is built into the operational definition of  $N_h$ , which was first defined as the ratio between the desired sediment supply and the actual sediment transport capacity (Watson et al. 1988a; 1988b). However,  $N_h$  could be any reasonable ratio of parameters that could be used as surrogates for sediment transport, such as the ratio of computed (or measured) sediment transport rates for the upstream supply reach and the stream reach of interest. In an initial reconnaissance, the thalweg slope of a stable channel may be surveyed and compared with the thalweg slope of the reach of interest.  $N_h$  would equal the ratio of the slope of the reach of interest divided by the stable slope.  $N_h$  is  $>1$  for degradational reaches and is  $<1$  for aggradational reaches.

The dimensionless stability numbers,  $N_g$  and  $N_h$ , can be related to the Oaklimiter sequence, as shown in Fig. 7-21. As the channel evolves from a state of disequilibrium to a state

**Fig. 7-21.** Comparison of Oaklimiter Creek channel evolution sequence and channel stability parameters (ASCE Task Committee on Hydraulics, Bank Mechanisms and Modeling of River Width Adjustment 1998b, with permission from ASCE).

of dynamic equilibrium through the six reach types of the Oaklimer sequence, the channel progresses through the four stability diagram quadrants in a counterclockwise direction. Rehabilitation of the channel should attempt to avoid as many of the quadrants as possible to reduce the amount of channel deepening and widening.

Each quadrant of the stability diagram is characterized by geotechnical and hydraulic stability number pairs, and stream reaches that plot in each quadrant have common characteristics with respect to stability, flood control, and measures that may be implemented to achieve a project goal.

In Quadrant 1 ( $N_g < 1$ ,  $N_h > 1$ ), the channel bed may be degrading or may be incipiently degradational; however, the channel banks are not geotechnically unstable. Bank erosion is occurring only locally, and bank stabilization measures, such as riprap or bioengineered stabilization, could be applied. However, local bank stabilization would not be successful if bed degradation continued and destabilized the stabilization measures; therefore, bed stabilization measures should be considered for long-term effectiveness of bank stabilization measures. If flood control is a project goal, almost any channelization or levee construction would increase  $N_h$  and shift the value to the right. Flow control using a reservoir can address flood control capacity, which may cause other changes in channel dynamics. The designer must be aware of the channel response to imposed conditions relating to the stability factors.

Quadrant 2 ( $N_g > 1$ ,  $N_h > 1$ ) streams are unstable. The channel bed is degrading and channel banks are geotechnically unstable. Grade control must be used to reduce bed slope, transport capacity and  $N_h$ . Bank stabilization measures will fail in this quadrant because the bed is continuing to degrade, which will destabilize the foundation of the bank stabilization. Both flood control and bank stability must be considered when determining the height to which grade control should be constructed. A series of grade control structures can reduce bank height sufficiently to stabilize the banks, but a combination of lower grade control and bank stabilization may meet flood control, ecological, and stability objectives. Emplaced habitat features are subject to failure caused by degradation of the bed, bank failure, and lowering of water-surface elevations.

Quadrant 3 ( $N_g > 1$ ,  $N_h < 1$ ) is characterized by gravity-driven bank failure but without continued bed degradation. Bank stabilization could be effective without grade control emplacement, but both measures should be considered. Flow control in these two quadrants could be beneficial. Emplaced habitat features may be inundated by channel aggradation or affected by adjacent bank failure.

Quadrant 4 ( $N_g < 1$ ,  $N_h < 1$ ) is characterized by general stability. Local bank stabilization measures will be effective. As  $N_h$  decreases in this quadrant, the potential for channel aggradation-related flood control problems or inundation of habitat features will increase.

### 7.4.3 Equilibrium Approaches

**7.4.3.1 The Engineering Significance of Geomorphic Equilibrium** In section 7.2, streams that are “graded” or “in regime” are defined as those whose morphology does not change “significantly” with time due to quasi-steady supplies of water and sediment. In section 7.4.3, quantitative models of graded streams are discussed. Before these models are presented, however, it is important to understand how graded streams are defined and how they may be recognized. Streams that are “graded” are not static, and they may change their morphologies during floods or other short-term perturbations. These changes may be large enough to have important engineering consequences.

A useful conceptual model of the temporal evolution of graded streams has been proposed by Schumm and Lichty (1965), who explained how streams can change progressively with time and yet still be considered “graded.” To resolve this paradox, Schumm and Lichty (1965) defined three timescales for viewing river channels. Figure 7-22 presents these timescales using channel gradient to illustrate morphologic change, though any morphologic feature (e.g., width, depth) could be used. It is also important to recognize that the time axis of Fig. 7-22 is imprecise, and may be shorter or longer depending on the morphologic variable plotted on the y axis and the particular river system that is being investigated.

Over short periods, referred to by Schumm and Lichty (1965) as “steady time,” the channel morphology is constant, because flows large enough to change the slope are not likely to occur. Over longer periods, defined as “graded time” by Schumm and Lichty (1965), the channel morphology oscillates about a temporally steady average value. This is the classic behavior associated with graded streams. It is important to note that the morphology is not constant, but changes tend to average to zero when viewed over sufficient time. Over the longest time scale, defined by Schumm and Lichty (1965) as “cyclic time,” a drift in the morphology may be observed.

Schumm and Lichty’s (1965) conceptual model suggests that field observations over graded timescales could be used to determine if a stream is graded or not. However, because decades of measurements are typically required, such data are rarely available. As an alternative, geomorphologists and engineers often use regression equations to determine if a river’s morphology can be explained by variables such as discharge or bank sediment type that do not involve time (the power-law approach presented in section 7.4.3.2 is a typical example) (Fig. 7-23). If these regression equations explain a significant amount of the variance in the observations, streams are often considered to be graded or in a quasi-equilibrium state (Leopold and Maddock 1953; Wolman 1955; Leopold et al. 1964).

Figure 7-22 implies, however, that significant morphologic variation may still occur even if stream morphology

**Fig. 7-22.** Different time intervals and associated equilibrium in geomorphic analyses. (A) Steady time (static equilibrium). No change in channel gradient over short periods. (B) Graded time (steady-state equilibrium). Constant average channel gradient with periodic fluctuations above and below the average condition. Measurements made during intervals of steady time within the graded time period may show no change in channel gradient. (C) Cyclic time (dynamic equilibrium). Gradual lowering of the average channel gradient over long time intervals. Intervals of graded time and steady-state equilibrium exist within the cyclic time scale (Ritter 1978).

can be explained by discharge or any other variable that does not include time. Data from the Powder River watershed (Figs. 7-3, 7-19, and 7-22) present a useful example. Figure 7-23 demonstrates that the width is highly correlated with mean annual discharge in the Powder River basin. However, observations of the channel morphology of the Powder River between Moorhead and Broadus, Montana, from 1975 to 1998 demonstrate that a 25 to 50 year flood increased the channel area by an average of 62% (Pizzuto

1994). Subsequent deposition caused a substantial decrease in channel area (Moody et al. 1999). These oscillations are not large enough to invalidate Fig. 7-23, and thus the channel is in some sense graded or in regime. However, the observed temporal changes in channel form could greatly influence engineering structures, suggesting that equilibrium approaches should be used with considerable caution as design tools.

**7.4.3.2 Regime Theory: A Power-law Approach** The initial approach to predicting equilibrium channel form was based on empirical methods developed from field observations and regression equations and applied to the design of stable canals. The first regime relation was proposed by Kennedy (1885) over a century ago. Several regime relations followed, and these have been repeatedly refined and enhanced. The regime equations attributed to Lindley (1919), Lacey (1920), Simons and Albertson (1963), and Blench (1969) are probably the most widely known.

Although regime equations are extensively used by engineers, with successful outcomes, they suffer several shortcomings, including the facts that they are not dimensionally homogeneous and that their validity is limited to the basins and data from which they were derived. More sophisticated regime relations have been proposed by employing computers to obtain regression equations based on much larger data sets (Brownlie 1981a; 1981b). Most work, including that previously cited, pertains to sand-bed streams, but equivalent regime relations have also been proposed for gravel-bed streams; reviews are presented by Bray (1982) and Hey and Thorne (1986). More recently, semianalytical work by Julien and Wargadalam (1995) has attempted to refine the regime approach within a framework based on the governing principles of open channel flow.

Geomorphologists have used data from natural streams and laboratory flumes to develop power-law hydraulic geometry relations between channel top width, average depth, average velocity, and bank-full discharge (Leopold and Maddock 1953); Fig. 7-23 is an example. The exponents in these relations exhibit surprising universality, particularly the one for channel width, which has been found to be  $\sim 0.5$  for rivers with widely varying flow regimes and sediment characteristics located in different physiographic regions of the world. However, the regression coefficients are found to vary significantly from one locality to another, which renders power-law hydraulic geometry relations inappropriate as tools for general design purposes.

The relevant empirical formulas developed in these approaches, as well as others that are not mentioned here due to lack of space, are described in detail in standard river mechanics books (e.g., Garde and Ranga-Raju (1977) and Simons and Senturk (1992)) and earlier review papers (e.g., Ferguson (1986)).

**7.4.3.3 Extremal Hypothesis Approach** The last two decades have seen the proliferation of approaches that employ an extremal hypothesis as part of their formulation for predicting channel morphology. Equations for sediment

**Fig. 7-23.** Relationship between mean annual discharge and width for the Powder River watershed in Wyoming and Montana (Leopold et al. 1964). The shaded region represents the variation in width documented by cross sections from 1977 to 1991 (Pizzuto 1994).

transport and alluvial friction are combined with a third relationship to determine channel width and to predict regime or equilibrium conditions. This third relationship has frequently been expressed in terms of the maximization or minimization of a parameter, such as stream power, energy dissipation rate, or sediment concentration. Extremal hypotheses have been introduced by Chang (1980); Yang et al. (1981); Yang and Song (1986); Bettess and White (1987); Chang (1988a); Yang (1992); Chiu and Abidin (1995); and Millar and Quick (1997), among others. An extremal hypothesis, based on stream power, also forms the basis of the analytical approach of White et al. (1981) to the river regime and the Wallingford tables for the design of stable channels (White et al. 1981).

The theoretical justification for such hypotheses and the relationships between them are still not entirely clear. Also, when extremal hypotheses are applied, a clear understanding is required of the physical constraints presented by geological or other boundary conditions on the evolution of a channel toward a form that minimizes its rate of energy expenditure. The predictions based on such methods, however, provide global, if not exacting, agreement with a wide range of observations.

**7.4.3.4 Tractive Force Methods** Tractive force methods employ the basic laws of mechanics to obtain expressions that specify the geometry of stable channel cross sections. This approach was initiated in the late 1940s by the U.S. Bureau of Reclamation, and it resulted in the threshold channel theory (Glover and Florey 1951; Lane 1955). The theory

is based on a fluid momentum balance that is used to obtain the local boundary shear stress and a stability criterion for the sediment particles that make up the channel perimeter. It assumes that the channel is straight, that secondary flow is negligible, and that sediment is noncohesive and does not vary within the channel. Most importantly, the tractive force approach assumes that the channel morphology is adjusted so that sediment across the perimeter of the cross section is at the threshold of motion. Under these conditions, sediment is neither eroded nor deposited at any point on the cross section. When these assumptions are satisfied, a cosine profile is predicted for the stable cross section (Fig. 7-24).

A threshold channel does not allow for bed-load transport. Diplas (1990) and Parker (1979) showed that the Glover and Florey method cannot be extended to generate channels capable of transporting sediment while they maintain threshold banks. This result is contrary to numerous observations from natural streams and flume experiments, which attest to the possible coexistence of a mobile bed and

**Fig. 7-24.** Comparison between threshold channel profile obtained from momentum-diffusion model and cosine profile (adapted from Vigilar and Diplas 1997, with permission from ASCE).

stable banks. Parker (1978b) overcame this inconsistency by employing the momentum balance of Lundgren and Jonsson (1964), which accounts for lateral turbulent diffusion of downstream momentum. Due to the complexity of the corresponding differential equation, his solution was limited to the flatbed region, whereas the bank geometry was solved as a first-order solution, yielding a cosine profile. Thus, Parker (1978b) was able to reconcile the existence of sediment movement within a stable channel. Ikeda et al. (1988) extended the results of Parker (1978b) to include sediment heterogeneity, and Ikeda and Izumi (1990) considered the effect of bank vegetation, whereas Parker (1978a) and Ikeda and Izumi (1991) examined the influence of suspended load on channel dimensions.

The tractive force model, in the form proposed by Parker, was recently refined by Diplas and Vigilar (1992). The main differences from the previous work were that the governing equations were solved numerically and the bank geometry was not assumed, but became part of the solution. As a result, the threshold channel shape turned out to be different from a cosine curve, having a greater top width and center depth (Diplas and Vigilar 1992; Vigilar and Diplas 1994; 1997; 1998). For the example shown in Fig. 7-24, the longitudinal slope is 0.00081, the value of the critical Shields parameter is 0.056, and the sediment is semiangular, with  $D_{50} = 45$  mm and  $D_{90} = 75$  mm. The cross-sectional area of the threshold channel and the water discharge that it conveys are more than

twice those for a cosine channel under the same conditions. This is attributed to the role of momentum diffusion, which results in decreased stresses in the central region of the channel (thus allowing a deeper flow) and increased stresses in the upper bank regions (forcing banks to assume gentler slopes to prevent erosion). Knowledge of the local topography, the sediment size and shape, and the value of the critical Shields parameter uniquely determine the dimensions of a threshold channel and its discharge.

In the case of a channel with stable banks and a mobile bed, the bank profiles change with the width of the flatbed section (Fig. 7-25) (Vigilar and Diplas 1997; 1998). However, beyond an aspect ratio of 12, which is typical of natural streams, the bank profile remains constant, and the channel is termed "wide." The stable channel dimensions and bed load transport capacity can be determined for known local bed slope, sediment size and shape, value of the critical Shields parameter, and water discharge. If the bed load discharge is specified, the channel bed slope becomes part of the solution.

It is important to recognize, however, that tractive force methods do not accurately represent channels where sediment is deposited on the banks or eroded from the banks. For these conditions (which represent the majority of natural channels), only a few preliminary mechanistic models of equilibrium channels are available (Parker 1978b; Pizzuto 1984).

**Fig. 7-25.** Bank profiles generated by momentum-diffusion model for different values of flatbed width of channel (ASCE Task Committee on Hydraulics, Bank Mechanisms and Modeling of River Width Adjustment 1998a, with permission from ASCE).

#### 7.4.4 Empirical Methods Based on Field Observations

In many cases, an existing theory or model may not be available to predict rates of bank erosion, deposition, or width adjustment at a particular site. However, field observations may be used to develop empirical equations that may be used for prediction. Although such empirical equations typically have little or no generality, they may provide useful short-term predictions if future conditions are similar to those used to develop the empirical equations.

Rates of bank retreat are predicted by two different methods. One involves using maps, aerial photographs, or historical surveys to determine past rates of bank erosion. For prediction, these rates may simply be extrapolated into the future to provide an estimate of the future position of the eroding bank. Another method involves developing an empirical equation that includes one or more physical parameters that control rates of bank erosion. Figure 7-26 illustrates a correlation between rates of bank retreat and velocity near the bank (Pizzuto and Meckelnburg 1989) based on field observations of bank retreat from the Brandywine Creek in southeastern Pennsylvania (the values of the near-bank velocity were obtained using the flow model of Ikeda et al. 1981). The regression equation represented by the best-fit line, although only valid at the study site, could provide accurate predictions of the future positions of the retreating bank.

**Fig. 7-26.** Relationship between rate of bank retreat and near-bank velocity for a meander bend of the Brandywine Creek in southeastern Pennsylvania (after Pizzuto and Meckelnburg 1989).

#### 7.4.5 Numerical Width Adjustment Models

Fixed-width numerical morphological models are now commonly used in engineering practice to obtain predictions of the extent of scour and fill of a bed in response to changes in the independent variables of flow and sediment discharge. The status of fixed-width numerical morphological modeling has been reviewed by Fan (1988).

Fixed-width numerical models are limited in applicability to cases where width adjustments in the prototype channel are not significant. To address this deficiency, a number of attempts to account for time-dependent width adjustments in numerical morphological models have been made. It should be recognized at the outset that each of these models is in some way limited. Twelve numerical width adjustment models based on various approaches to representing the governing processes of flow, flow resistance, sediment transport, and bank mechanics are reviewed in Table 7-1. A promising numerical width adjustment model described by Nagata et al. (2000) was published after the following analysis was completed.

**7.4.5.1 Fluvial Hydraulics and Hydrodynamics** A number of approaches have been used to estimate the flow field in the computational domains of the various numerical models (Table 7-2). Despite their undoubted significance, over-bank flows are excluded from all of these approaches. The approaches are based on simplifications of the governing

flow momentum and continuity equations and are therefore limited in validity to the particular conditions defined in making the simplifying approximations. Additionally, each approach requires an estimate of the friction factor, which is usually either specified by the user or calculated using an empirically calibrated roughness equation. The friction factor estimate may or may not be allowed to vary through space and time (Table 7-2). Each of the flow resistance equations in Table 7-2 is, strictly speaking, valid only for the physical conditions corresponding to the data originally used to derive it. None of the reviewed models account for the effects of vegetation on flow.

The water-routing submodel of the FLUVIAL-12 model (Chang 1988a; 1988b) computes the water-surface elevation and energy gradient at each cross section by solving 1D versions of the flow momentum and continuity equations. For steady flow, the standard step method is employed, whereas solution procedures suggested by Fread (1971; 1974) and Chow (1973) are followed for unsteady-flow routing. A correction for flow resistance due to secondary flow effects in curved channels is made (Chang 1988a). Osman (1985), Alonso and Combs (1986), and Borah and Bordoloi (1989) developed similar approaches to flow routing in their morphological models. Unlike FLUVIAL-12, these methods also neglect secondary flows and are applicable to steady flows only, though unsteady flows are approximated through the use of a stepped hydrograph with discharge constant in any one time step. The 1D flow-routing methods provide estimates of cross-sectionally averaged flow parameters

<sup>b</sup>Quasi2D models refer to those models that simulate lateral variation of bed topography through use of multiple 1D stream tubes.

and are unable to resolve near-bank boundary shear stresses sufficiently accurately to estimate fluvial erosion of bank materials.

Various attempts to account for the lateral variation of flow fields in natural channels have been made. Both the GSTARS (Molinas and Yang 1986; Yang et al. 1988) and modified BRI-STARS (Simon et al. 1991) models employ quasi-two-dimensional (quasi-2D) flow-routing procedures based on the stream tube approach. Stream-tube-based approaches are limited because they normally exclude lateral momentum exchange processes due to secondary flows and lateral shear induced by bank friction, and they are limited to steady flows. These approaches are also expected, therefore, to have low predictive ability for near-bank-zone applications.

Darby and Thorne (1996c) adopted a quasi-2D method in which lateral distributions of flow velocity and boundary shear stress were estimated at each cross section via numerical solution of a version of the flow momentum and continuity equations in which lateral shear stress terms were retained (Wark et al. 1990). The method is valid for steady, uniform flow but was applied in conjunction with a gradually varied 1D flow-routing model solved using the standard step method (Chow 1973) to estimate longitudinal variations in water-surface elevations and energy gradients at each of the modeled sections. The flow submodel employed by Darby and Thorne provides an improved representation of the flow field compared to 1D and stream-tube flow-routing methods. However, the validity of this method is limited because secondary flows are neglected (the approach was intended for straight channels only).

The 2D depth-averaged flow submodel of RIPA (Mosselman 1992) is based on differential equations expressing the conservation of mass and momentum of water. This model includes a correction for the deformation of the flow field due to secondary flow, but the influence of lateral shear on near-bank flows is neglected. Wiele (1992) included both terms in his flow submodel.

The flow submodels employed by Pizzuto (1990) and Kovacs and Parker (1994) model the distribution of fluid-induced boundary shear stress on gently curved riverbanks in straight channels. The methods are valid for steady, uniform flows; they include lateral shear stress terms but ignore momentum transfer by secondary currents. Both methods are only valid where bed and bank curvature is small.

In the CCHEBank model (Li and Wang 1993; 1994a,b), the flow field is computed using CCHE3D (Wang and Hu 1990), an advanced 3D hydrodynamic model, which can simulate unsteady free surface turbulent 3D flow fields in open channels. Secondary flows and lateral shear stress terms are also included in the model. This 3D flow model has the fewest simplifying approximations of the models reviewed here and, therefore, has the greatest potential for successfully modeling near-bank flows. However, simplifying assumptions are still required in the eddy viscosity closure

model, and the flow model is also subject to the limitations of the method used to specify the friction factor.

**7.4.5.2 Sediment Transport and Continuity** Methods of sediment routing in each of the 12 models reviewed here are summarized in Table 7-3. Sediment routing is accomplished by relating sediment transport at each computational node to the flow field and physical properties of the bed material there. An empirically calibrated sediment transport equation is used to estimate the sediment flux field. Some models offer users the choice of specifying a particular equation from a menu. Spatial differences in sediment flux so estimated determine the evolution of the bed topography through solution of the sediment continuity equation.

The models are uniformly limited in validity to conditions corresponding to those originally used to calibrate the available sediment transport equation. Even within these constraints, and optimistically assuming that the flow field has been predicted accurately, sediment flux predictions are prone to order-of-magnitude errors (Gomez and Church 1989; Yang and Wan 1991).

A particular limitation of width adjustment modeling applications is that most sediment transport equations are valid only for bed surfaces inclined at low angles ( $\sin \theta < 0.1$ ), though in noncohesive channels such equations are applied in bank regions that are often inclined at angles close to the angle of repose (typically  $35^\circ$ ). The vertical bed load transport equation developed by Kovacs and Parker (1994), and included in their bank erosion model, is the only model reviewed here that accounts for the effects of large bed slopes ( $\sin \theta > 0.1$ ).

In some models, sediment sorting is handled through the use of mixed (active) layer theory. Accurate prediction of the bed-material grain-size distribution throughout the model simulation is important if the flow resistance and sediment transport submodels are to have any chance of continuing to predict the flow and sediment-transport fields with acceptable accuracy throughout the simulation. Research has indicated that bed-material grain-size adjustments in unstable rivers are as important as adjustments in gradient, depth, or width (Hoey and Ferguson 1994). Ability to account for the transport of heterogeneous sediment mixtures is particularly important in the context of width-adjustment models, because the grain-size distribution of eroded bank materials is often quite different from that of the original bed material. Summary information regarding the mixed layer scheme employed in each of the models is provided in Table 7-3.

The wide ranges of potential grain sizes frequently involved in the width-adjustment process also dictate that both bed load and suspended-sediment fluxes must be accounted for in width-adjustment modeling. Table 7-3 summarizes the capabilities of the various sediment-routing submodels with respect to this issue.

In each model, changes in bed elevation resulting from spatial differences in the predicted sediment flux field are computed through numerical solution of the sediment continuity equation. The sediment continuity equation is usually simplified by neglecting either the longitudinal or transverse sediment-flux difference terms (Table 7-3). These simplifications limit the validity of these models; it can be shown that both streamwise and transverse sediment-flux differences are, in fact, equally significant in controlling near-bank bed topography changes (Darby and Thorne 1992).

One-dimensional sediment-routing procedures (Table 7-3) neglect transverse sediment fluxes and require various assumptions concerning the distribution of predicted changes in bed elevation across the channel cross section. In this context, the most important areas are the near-bank zones, because predicted changes in bed elevation directly influence the stability of the banks and, hence, the predicted widening or narrowing rates. For example, Osman (1985) assumed that the bed level change is distributed evenly over the entire cross section. In contrast, Alonso and Combs (1986) and Borah and Bordoloi (1989) utilized various assumptions to distribute the scour and fill more realistically across the section. Alonso and Combs (1986) accounted for nonuniform sediment deposition across the channel cross section using relations describing the lateral flux of suspended sediments proposed by Parker (1978a). No method of accounting for nonuniform distribution of erosion is described.

To address this issue, quasi-2D approaches have been proposed (Table 7-3). Simon et al. (1991) proposed a quasi-2D sediment-routing model based on the stream-tubes concepts employed in the GSTARS model. Darby and Thorne (1996c) divided each modeled cross section into three (one central and two near-bank) segments. This was done to provide more refined estimates of bed topography evolution in the near-bank zones. Each near-bank segment extended a distance of two bank heights from the base of the bank. In contrast to the quasi-2D approaches, fully 2D solutions of the sediment continuity equation (Table 7-3) provide higher definition, though not necessarily more accurate, estimates of bed topography changes in the near-bank zones.

**7.4.5.3 Riverbank Mechanics** A summary of methods of modeling bank mechanics in each of the reviewed models is provided in Table 7-4. None of these methods accounts for the impacts of riparian vegetation.

**7.4.5.3.1 Retreat and Advance Processes** Processes of bank retreat and advance may occur together or separately at different locations and times along the same reach of a river. Modeled rates of bank advance and retreat on both banks at a single section determine the rate of width adjustment. Bank advance processes, that is, processes of bank deposition and channel narrowing, are excluded by most of the modeling approaches reviewed here.

Fluvially controlled processes of bank retreat are essentially twofold. Fluvial shear erosion of bank materials results in progressive incremental bank retreat. Additionally,

increases in bank height due to near-bank bed degradation or increase in bank steepness due to fluvial erosion of the lower bank may act alone or together to decrease the stability of the bank with respect to mass failure. Bank collapse may lead to rapid, episodic retreat of the bankline. Depending on the constraints of the bank material properties and the geometry of the bank profile, banks may fail by any one of several possible mechanisms (Thorne 1982), including planar (e.g., Lohnes and Handy (1968)-, rotational (e.g., Bishop (1955)-, and cantilever (e.g., Thorne and Tovey (1981)-type failures. A separate analysis is required for analysis of bank stability with respect to each type of failure.

Nonfluvially controlled mechanisms of bank retreat include the effects of wave wash, trampling and grazing by livestock, and piping- and sapping-type failures (e.g., Hagerty 1991; Ullrich et al. 1986) associated with stratified banks and adverse groundwater conditions. Nonfluvial processes leading to bank retreat are excluded from all of the models reviewed here.

**7.4.5.3.2 Fluvial Entrainment of Bank Materials** For models of noncohesive bank erosion, hydraulic shear erosion of the banks is implicitly simulated through application of the sediment-transport submodel in the near-bank zone. Comparatively little is known about the mechanics of cohesive-bank fluvial entrainment. Excess-shear-stress formulations are difficult to apply because the value of shear stress required to entrain the bank particles varies widely and is influenced by diverse processes (Grissinger 1982). For example, processes such as frost heave or desiccation, which result in weakening of the intact material, may exert a more dominant control on observed rates of fluvial erosion than the intensity of the near-bank flow (Lawler 1986).

It is important to include a method of predicting the hydraulic shear erosion of cohesive bank materials in width-adjustment modeling because erosion directly influences the rate of retreat of the banks, and it also steepens the bank profiles and promotes retreat due to mass bank instability. Approaches that exclude analysis of fluvial erosion of bank materials (Table 7-4) are therefore somewhat limited. Widening models that attempt to account for fluvial erosion of cohesive bank materials (Table 7-4) utilize empirically based methods, such as that of Arulanandan et al. (1980), which was reviewed extensively by Osman and Thorne (1988). Borah and Dashputre (1994) and Darby and Thorne (1996b) have, however, suggested that these methods are subject to serious shortcomings.

**7.4.5.3.3 Cohesive- and Noncohesive-Bank Stability Analyses** Despite the fact that natural riverbanks are liable to failure by a number of specific mechanisms of bank collapse, most cohesive bank-width-adjustment modeling approaches (Table 7-4) have been based solely on analysis of planar failures.

The mass-wasting algorithms developed by Osman (1985) and reported in Osman and Thorne (1988) account for the bank profile geometry associated with natural, eroding

riverbanks that are destabilized through a combination of lateral erosion and bed degradation. These algorithms are employed in most of the cohesive bank approaches listed in Table 7-4. Previous stability analyses were restricted to a simple bank geometry and excluded the effects of lateral fluvial erosion on the bank profile (Lohnes and Handy 1968; Little et al. 1982).

The Osman-Thorne stability analysis is, however, subject to two main limitations (Simon et al. 1991). First, it does not include the effects of pore-water pressure and hydrostatic confining pressures. Second, the analysis constrains the failure plane to pass through the toe of the bank, excluding the possibility of secondary, upper-bank failures. Such failures are fairly common (Thorne et al. 1981a,b; Simon and Hupp 1992).

Simon et al. (1991) employed a bank stability analysis designed to account explicitly for hydrostatic and pore-water pressure effects on bank stability, while relaxing the assumption that the failure plane must pass through the toe of the bank. This enables bankline adjustments in response to secondary, upper-bank failures to be simulated. Conversely, Simon et al. (1991) excluded the effects of fluvial erosion on the bank profile that were accounted for in the Osman-Thorne (1988) stability analysis.

Darby and Thorne (1996a) accounted for two specific mechanisms of bank erosion and retreat, using the stability analyses proposed by Osman (1985) for rotational failure mechanisms and Osman and Thorne (1988) for planar failure mechanisms. Consideration of both rotational and planar failures, the failure mechanisms being discriminated on the basis of lower predicted factor of safety, represents the first attempt to account for the possibility of multiple failure mechanisms. This is important, because the shape of the failure surface is largely determined by the failure mechanism, and the failure surface forms the new bank profile following mass failure. Because stability of the bank is sensitive to the shape of the bank profile, predicting the correct failure surface is important in ensuring that predictions of bank stability and retreat continue to be accurate throughout a model simulation that includes several consecutive bank failures. However, the range of specific mechanisms of bank collapse included by Darby and Thorne (1996c) is still small compared to the number of potential failure mechanisms that may occur in nature.

For noncohesive riverbanks, models of widening have been proposed by Wiele and Paola (1989); Pizzuto (1990); Kovacs (1992); Wiele (1992); Li and Wang (1993; 1994a,b); and Kovacs and Parker (1994). These approaches can be subdivided into two categories. First, Pizzuto (1990) and Li and Wang (1993; 1994a,b) simulate the bank erosion mechanism using a heuristic procedure (a similar approach is also adopted by Nagata et al. [2000]). When bank slope exceeds the angle of repose of the boundary materials, a slumping model is employed such that a failure surface inclined at the angle of repose is projected to the flood-plain surface.

Sediment above the failure plane is moved downslope, forming a deposit with a linear upper surface.

The second approach is characterized by the work of Kovacs and Parker (1994). Their vectorial bed load equation and bank erosion models represented considerable advances in modeling noncohesive sediment transport. Kovacs and Parker (1994) realized that the fundamental problem of previous analyses was that the bed-load formulations employed were valid only at angles much less than the angle of repose, but it is the entrainment and transport of noncohesive sediment particles on steep slopes that is precisely the problem of interest. To avoid this problem, Kovacs and Parker (1994) formulated a vectorial bed load transport equation (Parker and Kovacs 1993) for coarse-sediment transport that was applicable to slopes up to the angle of repose in both the streamwise and transverse directions. Kovacs and Parker (1994) applied the vectorial bed load transport equation to simulate the widening observed by Ikeda (1981) in his laboratory experiments. According to their approach, widening is initiated when bank erosion along the lower part of the bank causes the local slope of the upper bank to exceed the angle of repose of the sediments. A discontinuity in slope is created between the over-steepened upper bank and the lower part of the bank; this discontinuity migrates up the bank with a characteristic velocity, widening the channel as it propagates. Using their bed load transport equation and an integral form of the sediment continuity equation, Kovacs and Parker (1994) derived a rigorous expression for the propagation velocity of the discontinuity in slope, allowing them to reproduce the widening rates observed by Ikeda (1981).

Further development of their methods is needed before they can become a practical design and simulation tool. In particular, the bank erosion and transport models need to be coupled with a sophisticated 2D or 3D flow model to account for complex hydraulics found in natural rivers. Furthermore, the method should also be extended to account for mixtures of varying grain sizes before it can be widely applied to field conditions.

**7.4.5.3.4 Homogenous and Heterogenous Bank Structures** The physical properties of natural riverbanks are frequently characterized by great spatial variability in their vertical structure and distribution. Many banks are composed of multiple sediment horizons, often featuring a fine-grained cohesive layer above a noncohesive granular layer. Despite this, all of the bank stability analyses employed in the models reviewed here assume that banks are characterized by a homogeneous vertical structure. Additionally, some models (Table 7-4) do not represent spatial variation in the physical properties of bank materials, either along the banks in the streamwise direction, or extending into the flood plain.

**7.4.5.3.5 Longitudinal Extent of Mass Failure** Most of the reviewed analyses assume that the volume of bank sediments delivered to the channel per unit reach length, required as a source term in the sediment continuity

equation, is equal to the product of the unit failure volume of bank material and the reach length. Application of bank stability analyses without consideration of the actual longitudinal extent of the failure can result in serious overestimation of this source term in the sediment continuity equation, propagating errors in estimated bed and bank adjustments throughout the entire simulation. Darby and Thorne (1996b) attempted to account for the longitudinal extent of mass failures within modeled reaches. Darby and Thorne suggested that the volume of sediment supplied within a modeled reach should be equal to the unit volume (per unit channel length) supplied by mass-wasting processes multiplied by the product of the length of the modeled reach and the probability of failure occurring at the computational node. Darby and Thorne suggested that the measurable statistical variations in bank material properties along the reach (Simon 1989) could be substituted into the deterministic Osman-Thorne bank stability equations to obtain the probability of failure using the procedure of Huang (1983). Darby and Thorne's approach is a tentative first step toward solving this important problem.

#### **7.4.5.4 Interaction of Fluvial Hydraulics and Bank Mechanics**

**7.4.5.4.1 Approaches Based on Extremal Hypotheses** Two numerical models that use extremal hypotheses to simulate width and other channel adjustments are the FLUVIAL-12 (Chang 1988a,b) and GSTARS codes (Molinas and Yang 1986; Yang et al. 1988). FLUVIAL-12 and GSTARS assume that changes in cross-sectional area determined from the sediment-routing module represent an overall change in area that may be applied to both the bed and the banks. The total area is distributed over the cross section by first calculating the magnitude of width adjustment, and then distributing the computed area over the bed and banks. Width corrections at each cross section are computed assuming that the stream power for the reach moves toward uniformity (FLUVIAL-12) or toward a minimization of energy dissipation rate (GSTARS), in accordance with the extremal hypothesis that forms the basis for each of these approaches. However, banks composed of cohesive sediments are not accounted for in any of the (noncohesive) sediment-transport equations used in the sediment-routing module. This procedure is not obviously applicable, therefore, to channels with banks composed of cohesive sediments.

FLUVIAL-12 and GSTARS also add entrained bank materials into the bed-material transport scheme simplistically: The bank-material size distribution is transferred instantaneously to the bed-material active layer. Although this is reasonable for noncohesive sediments, the processes of cohesive bank-material breakdown are not yet known. The authors of the two models provided no information on how both cohesive and noncohesive bank sediments were distributed across the channel section following mass failure.

Independent of their capability to predict changes in channel width, FLUVIAL-12 and GSTARS are both char-

acterized by another limitation. Only an overall estimate of the total change in channel width in any time step is made by the extremal hypothesis, and therefore the extent of advance and/or retreat of the left and right banks individually is unknown. Distributions of changes in total width between left and right banks are specified by the user.

**7.4.5.4.2 Geofluvial Approaches** In contrast to approaches based on extremal hypotheses, other methods have been developed that are based on coupling flow- and sediment-routing models with bank-erosion and mass-wasting algorithms. Such approaches are here termed "geofluvial" and focus on treating bankline adjustments mechanistically. Critical issues concern the need to

1. Predict accurately, in channels with the complex topography characteristic of natural rivers, the boundary shear stress distribution in each of the near-bank zones;
2. Determine the corresponding sediment flux field over the entire channel width;
3. Use the boundary shear stress distribution to determine the rate of fluvial particle-by-particle erosion on both banks, whether composed of cohesive or noncohesive materials;
4. Estimate the stability of the updated bank geometries and determine the volume (if any) of bank sediments delivered to the channel;
5. Characterize the exchanges of sediment between the banks and the bed material to satisfy conservation of sediment mass in channels that either are undergoing width adjustments, or are laterally migrating with stable width.

Topic 5 is the main focus of concern in this section. In geofluvial approaches, interactions between fluvial hydraulic and bank processes are modeled based on a solution of the sediment continuity equation. A given bed topography describes the geometry of the bank profile. Estimates of the sediment flux field and stability of the banks with respect to mass failure are then obtained. If a bank is unstable, then the width of the simulated failure block(s) determines the magnitude of bankline retreat during a time step. The volume of material involved in the failure, determined by the geometry of the failure surface, controls the bank-material input term in the sediment continuity equation, which is solved to determine the bed topography in the subsequent time step.

To couple the flow- and sediment-routing and bank-mechanics submodels in this way, an overall estimate of the failure-block volume is, in itself, insufficient. Precise details of the mechanics by which the failed bank materials are transferred down the failure surface are needed, because the lateral distribution of failure products determines the magnitude of the bank-material inflow term at each computational node. In addition, information regarding the physical properties (size, density, and cohesion) of the disturbed bank material at each

node is required so that the fluvial transport of these materials can be calculated in subsequent time steps.

No empirical information regarding the processes of, and controls on, the lateral distribution and physical status of bank material following fluvial entrainment or mass failure is currently available, either for laboratory or natural channels. Empirical information is not available regarding the fluvial transport of heterogeneous mixtures of disturbed bank and bed material. Conceptually, the lateral distributions and physical status of failed bank materials are determined by the geometry of the failure surface and channel-bed topography, the physical characteristics of the undisturbed bank materials, and the hydraulics of the flow.

In light of these difficulties, a distinction can be made between mechanistic widening models applicable to cohesive and noncohesive bank materials. For noncohesive banks, at least the physical status (size, density, and cohesion) of disturbed noncohesive bank materials is known, because these values are identical to those of the undisturbed bank materials. In contrast, disturbed cohesive bank materials may have physical properties distinct from those of intact bank materials, particularly if the failure products become immersed in the flow.

For noncohesive banks, two main approaches to estimating the lateral distribution of bank failure products can be identified. Pizzuto (1990) and Li and Wang (1993; 1994a,b) employed schemes such that, when the bank slope exceeded the angle of repose, a heuristic slumping model was employed in which a failure surface inclined at the angle of repose was projected to the floodplain surface. Sediment above the failure plane was translated downslope, forming a deposit with a linear upper surface. The highest point of the deposit was the lowest point of the failure plane. The deposit extended downslope until its value equaled the volume eroded. Wiele (1992) and Kovacs and Parker (1994) employed an approach in which the sediment continuity equation was manipulated to treat the bank erosion products as a transverse sediment flux. This approach is more consistent with a grain-by-grain noncohesive bank erosion mechanism, whereas the former approach is more consistent with slumping or toppling mechanisms of bank failure (Wiele 1992).

For cohesive banks, geofluvial approaches assume that failed bank materials are instantaneously deposited close to the toe of the bank. Failure products are distributed uniformly across the near-bank flow segments defined by Simon et al. (1991) and Darby and Thorne (1996c). Mosselman (1992) stated that failure products were distributed evenly across the near-bank computational cells. Borah and Bordoloi (1989) used a linear distribution function based on local sediment transport capacity. Osman (1985) and Alonso and Combs (1986) did not specify exactly how bank failure products were distributed in their models, other than stating that they were deposited close to the toe.

Some mechanistic approaches (Osman 1985; Alonso and Combs 1986; Borah and Bordoloi 1989; Mosselman 1992)

assume that the banks are composed of a fraction of cohesive material ( $\omega$ ) that becomes wash load after being eroded and a fraction of noncohesive materials ( $1 - \omega$ ) with the same properties as the bed material. The sediment-transport submodels employed in these approaches are then directly applied to compute transport rates for noncohesive sediment.

Simon et al. (1991) proposed a conceptual model where failed bank materials are considered to represent bank material, bed material, bed-material load, or wash load, according to the physical properties of the failed materials and the hydraulic properties of the flow. The approach they present is perhaps best regarded as a conceptual framework from which to proceed. Application of the existing approach is currently hindered by two limitations. First, Simon et al. (1991) did not allow the possibility of bed-material load being deposited on the banks, thus excluding the possibility of fluvially controlled bank-accretion and channel-narrowing mechanisms. Second, no information is yet available on how to predict the physical properties of the failed bank materials that are significant with respect to fluvial transport processes.

Darby and Thorne (1996c) assumed that undisturbed cohesive bank material failure blocks tended to disaggregate into disturbed aggregates of some measurable size range during mass failure. Darby and Thorne noted that these disturbed aggregates, though composed of cohesive particles, were themselves large enough to behave as noncohesive sediment particles. Darby and Thorne went on to suggest a criterion to discriminate whether or not the failure block would disaggregate, based on energy dissipated during mass failure and internal resistance of the failure block. Darby and Thorne used the criterion to hypothesize that steep planar failures would tend to result in disaggregated blocks delivered to the basal region of the bank as noncohesive sediment clasts, whereas shallower rotational failures would tend to remain as intact blocks of bank materials. Knowledge of the size and density of deposited sediment assumed to behave as noncohesive sediment particles allowed standard sediment-transport analyses for heterogeneous sediment (Rahuel et al. 1989) to be applied to the failed bank material aggregates deposited as bed material in the near-bank sediment-routing segments. No means of predicting the size of the disturbed bank material aggregates was suggested by Darby and Thorne.

**7.4.5.5 Testing and Application of Numerical Models** The capabilities, predictive abilities, scope, limitations, and usefulness of the various numerical models are now summarized. Tables 7-2 to 7-5 indicate that the reviewed models are limited in terms of the range of conditions to which they may be applied, as determined by the limitations of the assumptions in the hydraulic, flow-resistance, sediment-transport, and bank-erosion modules used in each model.

**7.4.5.5.1 Tests with Laboratory Data** The reviewed models applicable to noncohesive bank materials (Pizzuto

1990; Wiele 1992; Li and Wang 1993; 1994a,b; Kovacs and Parker 1994) have been tested with a common data set obtained from a laboratory study (Ikeda 1981). Results from these studies are shown in Fig. 7-27. However, assessment of the relative performance of these models is not attempted here because some small, but significant, differences are found in the numerical values of coefficients used by each of the aforementioned authors. Specifically, the critical dimensionless Shields stress is assumed to be 0.03 by Li and Wang (1993; 1994a,b) and Pizzuto (1990), 0.035 by Kovacs and Parker (1994), and 0.038 by Wiele (1992), respectively. The value of the internal angle of friction of the boundary material (which also influences the dynamic Coulomb friction coefficient) was assumed to be 33° by Pizzuto (1990) and 40° by the other authors.

Although a direct comparison of the relative performance of each model is not appropriate, Fig. 7-27 can be used to provide some insight into the capabilities of each of the individual models. The Kovacs and Parker model (Fig. 7-27(a)) resulted in predicted cross sections with cross-sectional areas larger than those measured in reality. Pizzuto's (1990) (Fig. 7-27(b)) model provided close agreement between simulated and measured channel shapes throughout the extent of the simulation. Wiele's (1992) model (Fig. 7-27(b)) underpredicted measured widening rates, presumably reflecting the relatively high Shields stress and friction-angle values selected by that author. Finally, Li and Wang (1993; 1994a,b) obtained overpre-

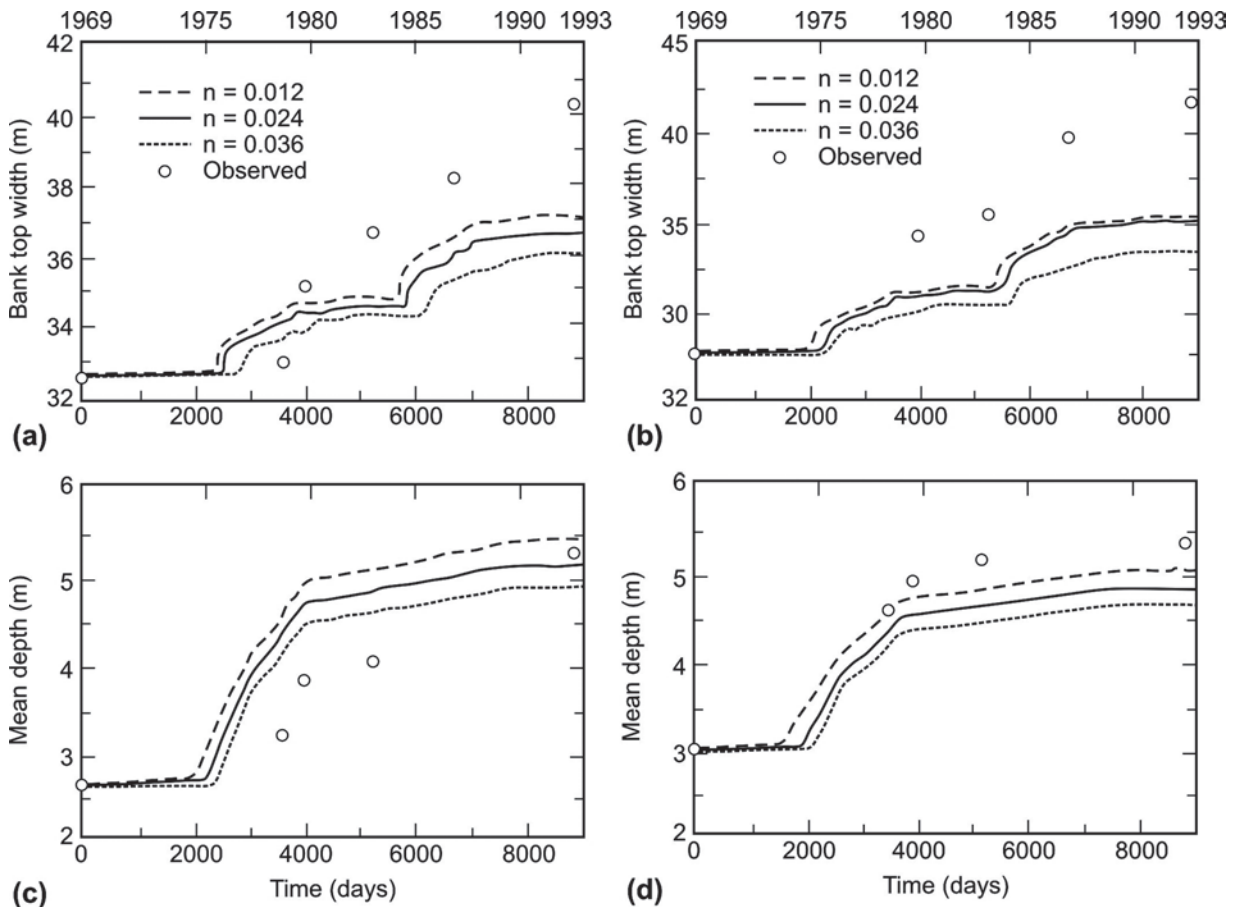

dictions of widening compared to the observed channel changes (Fig. 7-27(d)).

**7.4.5.5.2 Field Testing** Those authors who have attempted to test their models with field data have tended to calibrate the adjustable model parameters to improve agreement between predicted and observed data. Authors also tend to characterize their results using qualitative terminology such as "reasonable agreement" and "acceptable results." In these circumstances, it is futile to attempt to summarize and compare the accuracy of those models, particularly because the same source data set has not been used to test each analysis. For calibrated testing analyses, the reader is referred to the source material. Borah et al. (1982) and Borah and Dashputre (1994) tested components of the Borah and Bordoloi (1989) model, whereas Chang (1988a,b), Yang et al. (1988), Mosselman (1992), and Wiele (1992) fully reported both the development and testing of their codes.

One model (Darby and Thorne 1996c) has been applied with unadjusted calibration parameters (Darby et al. 1996) (Fig. 7-28.). Model calibration parameters were not adjusted from the values set during the course of the model development. Although the model appeared to be able to replicate the observed sequence of channel adjustment, and the magnitudes of simulated and observed widths and depths agreed within ±10% of each other overall, simulated widening rates were underpredicted by a factor of 3 (Darby et al. 1996). Darby et al. (1996) attributed this poor result to limitations of the Osman and Thorne (1988) mass-wasting algorithm.

## 7.5 PROCEDURE FOR APPROACHING WIDTH-ADJUSTMENT PROBLEMS

The wide range of geomorphic and engineering contexts associated with width adjustment makes it essential that practicing engineers adopt a broad and rational approach to such problems. Such an approach can be used to analyze the majority of problems that arise with the assurance that important factors are not overlooked, appropriate analytic techniques are applied, and effective engineering solutions are selected. The procedure proposed here (Fig. 7-29) is based on amassing and utilizing a wide range of information. Although each case is unique, the proposed procedure should have a number of elements that are relevant for the majority of situations.

### 7.5.1 Step 1: Problem Identification

Width-adjustment problems may be associated with a range of river engineering and societal activities. Questions to consider are the following:

1. Does the problem arise from a natural response?
2. Does it involve channel response to existing engineering works?
3. Does it require the prediction of channel response to proposed engineering works?

In all cases, it is necessary to formulate the problem in terms of whether it is existing or predicted, who or what is affected, and what level of analysis and response is appropriate. The aim of successful problem identification is to select a cost-effective engineering approach that will solve the problem.

### 7.5.2 Step 2: Field Data Collection

In all cases, visits to the site and river reaches upstream and downstream are essential. Particular attention should be paid to identifying channel characteristics, bank conditions, bank materials, the extent of existing or expected bank problems, the nature of the flow, the nature of the bed materials, the presence and nature of any vegetation, and the presence and

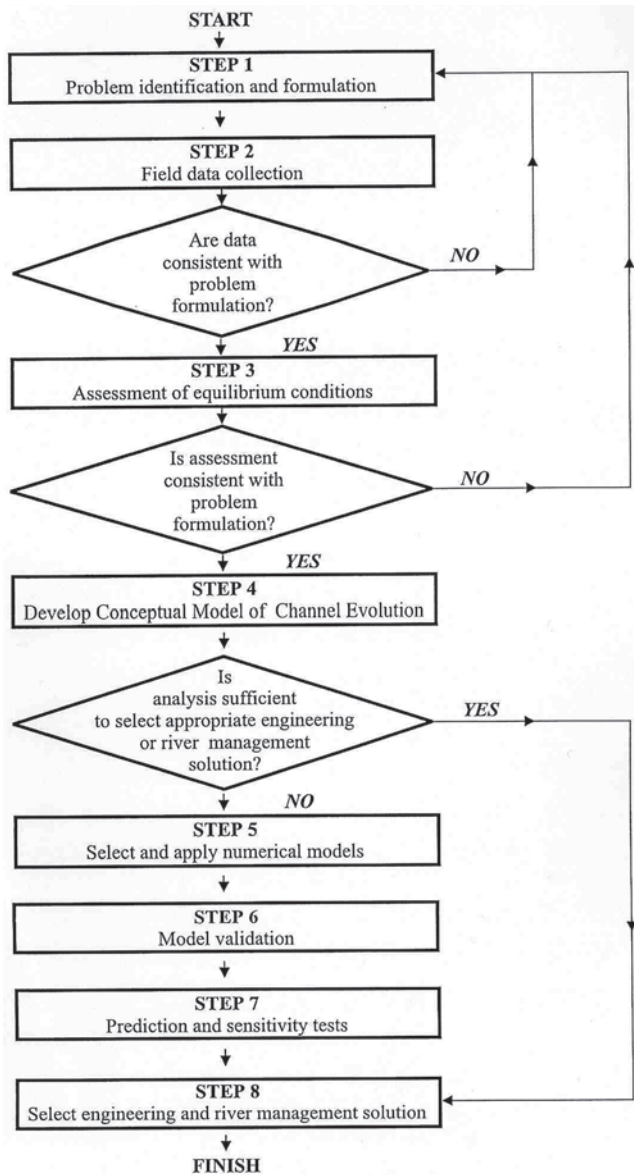

Fig. 7-29. Proposed procedure for identifying, analyzing, and modeling width-adjustment problems.

condition of any engineering structures. Stream reconnaissance techniques are described by, among others, Kellerhals et al. (1976); Thorne (1992); and Downs and Brookes (1994).

In all cases, it is necessary to identify the nature and extent of the width-adjustment problem that may arise. Where there have been width changes in the past, both reaches that have been subject to change and reaches that are stable should be examined.

Depending on the number of existing data available, it may be necessary to mount a specific data-gathering campaign. Data are needed to assess the equilibrium morphology of the channel and, in some cases, to understand the nature of the problem. If the use of numerical models is

warranted, field measurements will always be needed. Data requirements for numerical modeling studies are discussed further in Appendix I.

### 7.5.3 Step 3: Assessment of Equilibrium Morphology

As a first step, the equilibrium morphology of the channel should be estimated using methods described in section 7.4.3. Of the methods discussed in section 7.4.3, regime theory is probably the most reliable, but field data near the particular field site will be needed to determine the necessary empirical coefficients and exponents.

Once predictions of the equilibrium morphology are available, the predicted morphology should be compared with the existing morphology to provide an assessment of the current morphological status of the channel; for example, whether it is overwide, of equilibrium width, or underwide. Where the impact of proposed engineering works is being considered, the equilibrium conditions should also be compared to the proposed channel conditions.

### 7.5.4 Step 4: Developing Conceptual Models of Channel Evolution

If the channel is actively evolving under natural conditions, or is responding to engineering intervention or regulation, then simple empirical channel response or dynamic models, such as those described in section 7.4.2, should be developed and applied in an attempt to explain both existing and, if appropriate, proposed conditions. Application of such models should aid in identifying the dominant processes and trends of channel change and can form a framework for subsequent, more detailed modeling.

### 7.5.5 Step 5: Application of Numerical Models

If the complexity and severity of the width adjustment problem merit numerical modeling, a hierarchical modeling approach will usually be appropriate. Initially a 1D model should be applied to the study reach to provide the overall setting of any additional detailed modeling. If appropriate, to provide a more detailed assessment of width adjustment, it may be necessary to apply 2D or 3D models to the whole or part of the study reach. Selection of numerical models appropriate for this purpose may be guided by the comments provided in this paper. At present, models of width adjustment are still undergoing active development, so selecting a useful model is not a simple task.

### 7.5.6 Step 6: Model Validation

The numerical model results should be validated. This will nearly always require an extensive program of field observations.

### 7.5.7 Step 7: Model Prediction

The numerical models should be applied to existing conditions and also used to assess the impacts of any proposed works. Model predictions should include a sensitivity analysis of the results to the various parameters specified in the model. Particular attention should be paid to parameters that either are difficult to determine or exhibit significant spatial or temporal variation.

### 7.5.8 Step 8: Selection of Engineering or River Management Solution

On the basis of the previous steps, an appropriate plan of action should be formulated and implemented. One example of a management approach is provided by Simon and Downs (1995). They describe an interdisciplinary approach to evaluating stream-channel instability conditions on the regional or statewide scale. The regionwide studies were motivated primarily by the desire of some state transportation departments in the United States to inventory the potential for channel instability to damage bridge crossings and other transportation infrastructure. A modular procedure was developed based on (1) initial site evaluations; (2) geographic-information-system-based data input and management; (3) ranking of relative channel stability conditions; (4) identification of spatial trends; (5) ranking of socioeconomic impacts and identification of problem sites; and (6) collection of additional field data for enhanced desktop and modeling analyses of future conditions at the problem sites (Simon and Downs 1995). Based on this approach, the state transportation departments were provided with a product that enabled them to optimize repair and maintenance schedules for damaged infrastructure or infrastructure at risk from channel adjustment.

## 7.6 CONCLUSIONS

1. Width adjustments take place within a wide range of geomorphic contexts. Adjustments may occur as part of the natural evolution of the channel morphology, or they may be caused by river engineering structures, river management policies, or changes in land use in the watershed or riparian zone.
2. To understand, predict, and manage changing channel width, it is essential that civil engineers understand the geomorphic context within which width adjustment is occurring.
3. The time- and space-averaged boundary shear stress is an important parameter in predicting both equilibrium width and width adjustment. However, the lateral distribution of local values of boundary shear stress is poorly understood, especially for channels with nonuniform cross sections.

4. Improved understanding of the effects of over-bank flows on river-width adjustment processes is needed.
5. A variety of mass-failure mechanisms may be involved in bankline retreat. Care must be taken to match the slope stability analysis used to check bank stability to the critical failure mechanisms observed in the field. It is essential that engineers identify actual and potential instability mechanisms prior to selecting an engineering or management strategy for dealing with bank retreat and width adjustment.
6. The long-term rate of bank retreat or advance of the bank toe can be explained using the concept of basal endpoint control. However, seepage-driven procedures operating within a bank can lead to serious bank instability due to piping even when wave and current action at the toe is not excessive.
7. Bank advance takes place through sediment accumulation as a berm or bench in the channel and by the development of floodplains on migrating point bars. Bank advance is often accelerated by invasion of pioneer riparian vegetation.
8. Current knowledge of bank processes and flow modeling is sufficient to allow some tentative *predictions* of width adjustment to be made.
9. Analysis of equilibrium width in stable channels can be approached using (1) empirical regime methods; (2) extremal hypotheses; and (3) rational tractive force methods. These approaches are strictly limited to prediction of time-invariant width in graded or regime channels. They can be used with care to predict asymptotic values of width following disturbance of the graded or regime condition, but they cannot predict either the rate of change or intermediate width attained during dynamic adjustment of channel morphology. Tractive force methods are limited to straight channels with noncohesive banks. Despite these limitations, these methods have many useful engineering applications.
10. To date, models of river width adjustment can be divided into two broad approaches: (1) those based on extremal hypotheses, and (2) those based on the geofluvial approach. The former have been used in engineering practice more frequently than the latter, which are at present used essentially as research tools. However, geofluvial approaches have the potential to become adopted as standard engineering tools.
11. Currently, very few appropriate laboratory and field data sets are suitable for testing width-adjustment models. This has resulted in a lack of comprehensive testing and verification analyses of existing models on benchmark field and laboratory data sets.
12. At present, no single model or method exists that is applicable to all the circumstances under which width adjustments may occur.

## APPENDIX. DATA SOURCES

### 1 Equilibrium Channels

Equilibrium channel geometry measurements have been reported for at least a century. A summary of published data sources was presented by Julien and Wargadalam (1995), based on a compilation of available data by Wargadalam (1993). The data encompass measurements from 835 field channels and 45 laboratory channels that were used to test semi-theoretical downstream hydraulic geometry relationships.

Brownlie (1981a,b; 1983) published an extensive compilation of laboratory and field data. Khan (1971) reported 45 laboratory measurements of hydraulic geometry for straight, meandering, and braided reaches. Griffiths (1981) reported 136 gravel-bed river geometry measurements collected from 46 rivers in New Zealand. Of these, 84 were conducted under rigid bed conditions, whereas 52 are for mobile bed conditions. Church and Rood (1983) published a compendium of river regime data that lists 496 hydraulic geometry measurements reported in the technical literature. This data set includes measurements from rivers in Canada and the United States, which were carefully selected from 25 references published between 1955 and 1983. Hey and Thorne (1986) reported data from 62 river measurement sites from stable gravel-bed rivers in the United Kingdom. Higginson and Johnston (1988) published data from 68 sites under bank-full flow conditions from rivers in Northern Ireland. Colosimo et al. (1988) published 42 gravel-bed river measurements from streams in Calabria, Southern Italy. The range of flow parameters covered by all these data is summarized in Table 7-7.

### 2 Nonequilibrium Channels

For nonequilibrium channels, data sets that include all the parameters required to apply width adjustment models

**Table 7-7 Range of Flow Parameters Covered in Equilibrium Channel Data Set of Julien and Wargadalam (1995)**

Parameter (1)	Range (2)
Discharge	0.00018–26,600 m <sup>3</sup> /s
Channel width	0.16–1,100 m
Average flow depth	0.003–15.7 m
Mean flow depth	0.09–4.7 m/s
Channel slope	0.00004–0.08
Median grain size	0.12–400 mm
Width/depth ratio	4.2–507
Relative submergence	1.4–70,400
Froude number	0.017–4
Shields number	0.001–8.5
Grain shear Reynolds number	1.6–156,000

(Table 7-6) are comparatively rare. Laboratory experiments involving width adjustments in straight channels formed in sand were conducted by Ikeda (1981). Ikeda et al. (1988) performed similar experiments in a gravel channel. Data on width adjustment in rivers can be found in Brice (1982); Nanson and Hickin (1983); Richardson et al. (1990); and the USACE (1981). However, these reports do not contain all of the required data listed in Table 7-6. Data sets that include many of the parameters listed in Table 7-6 are generally not available in the literature. However, three data sets have been identified that are suitable for use with numerical models of width adjustment. Data for the Toutle River, Washington, are described by Simon (1992). Similarly, data from the South Fork Forked Deer River, West Tennessee, were used by Darby et al. (1996) to test the Darby and Thorne (1996c) numerical

**Table 7-6 Minimum Data Required to Apply Geofluvial-Based Numerical Width Adjustment Models**

Data Item (1)	Notes (2)
<i>(a) Time-independent data (initial conditions)</i>	
Cross-sectional surveys	Required to define initial channel morphology. Surveys are required at several sites along the prototype reach.
Bed material size distribution	Required to define the initial bed material characteristics. Data is required at each cross section.
Bank material characteristics	Measurements of cohesion, friction angle, unit weight, and particle size distribution at left and right banks of each cross section are required to define the bank-material characteristics.
<i>(b) Time-dependent data (boundary conditions)</i>	
Discharge	Value of discharge to be used in each discrete time step of the simulation
Sediment supply	Value of sediment load at the upstream boundary of the prototype reach during each discrete time step of the simulation.

model. Further information about these two data sets may be obtained through contact with the authors of these reports. Finally, data from Goodwin Creek, Mississippi, are available through contact with personnel at the USDA-ARS National Sedimentation Laboratory, Oxford, Mississippi.

## ACKNOWLEDGMENTS

Most of the text of this chapter was prepared by the ASCE Task Committee in River Width Adjustment and published in the *Journal of Hydraulic Engineering* (reprinted with permission from ASCE). The Task Committee was chaired by Colin R. Thorne of the University of Nottingham, U.K. The members of the Task Committee were Carlos Alonso, USDA-ARS National Sedimentation Laboratory; Roger Bettess, HR Wallingford, U.K.; Deva Borah, Illinois State Water Survey; Stephen Darby, University of Southampton, U.K.; Panos Diplas, Virginia Polytechnic University; Pierre Julien, Colorado State University; Donald Knight, University of Birmingham, U.K.; Lingeng Li, University of Mississippi; Jim Pizzuto, University of Delaware; Michael Quick, University of British Columbia; Andrew Simon, USDA-ARS National Sedimentation Laboratory; Michael Stevens, Stevens and Associates; Sam Wang, University of Mississippi; and Chester Watson, Colorado State University. Agnes Kovacs, Erik Mosselman, Leonardo Schippa, and Steven Wiele provided materials and discussions that aided in the preparation of the original Task Committee review papers published in the *Journal of Hydraulic Engineering*.

## CHAPTER 8

### *River Meandering and Channel Stability*

*A. Jacob Odgaard and Jorge D. Abad*

#### 8.1 INTRODUCTION

River meandering is a planform process that generates a series of bends of alternate curvature connected by straight reaches. The outer banks of the bends tend to erode, causing the channel planform to gradually shift or migrate (Fig. 1). The rate of shift depends on the properties of the surrounding material, which can vary from alluvium to rock. Depending on the surrounding material, the channel is termed either *freely meandering* or *rock incised*. Most rock-incised channels are formed by down-cutting over long periods of time (Leopold et al. 1964; Dury 1966). This chapter deals with freely meandering channels.

The planforms of freely meandering channels migrate by down-valley translation, lateral expansion, or a combination of both. Down-valley translation is essentially a longitudinal shift of the meander pattern, whereas lateral expansion is a widening of the meander pattern. This chapter presents a summary of analytical approaches to the description of this process.

The chapter starts with a brief review of historical relationships, which is then followed by a summary of recent approaches to the calculation of flow and bed topography in rivers, migration rates, and dominant meander wavelength. The chapter concludes with a brief review of technologies for channel stabilization.

The review is not inclusive. It is focused on concepts and findings that have direct bearing on river engineering practice more than on scientific discourse. As such, important contributions may have been omitted. For a more inclusive review, readers are referred to Callander (1978); Richards (1982); and Howard (1992; 1996).

#### 8.2 MEANDERING PROCESS

It is generally assumed that meandering is the result of channel instability. This assumption implies that a straight

channel is unstable and that a slight perturbation in any of its flow or boundary characteristics causes an increase in shear stress along one bank, resulting in erosion, and a decrease in shear stress along the opposite bank, promoting deposition. The result is gradual increase in channel sinuosity (ratio of channel length to valley length) with time. As the length of the channel increases, the channel slope decreases and becomes less than the valley slope.

The process of erosion and deposition results in sideways migration of the channel, which, as indicated previously, may or may not be combined with down-valley translation. Sideways migration may eventually result in a cut-off, after which the process starts over again.

Field observations have been described by, among others, Leopold and Wolman (1957); Wolman and Leopold (1957); Schumm (1963); Kondrat'yev (1968); Konditerova and Ivanov (1969); Schumm and Khan (1971, 1972); Brice (1973); Kulemina (1973); Brice (1974); Hickin (1974); Hickin and Nanson (1975); Lewin (1976); Allen (1977); Hooke (1977); Lewin and Brindle (1977); Dort (1978); Lewin (1978); Nanson (1980); Allen (1982); Beck et al. (1983b); Lewis and Lewin (1983); Nanson and Hickin (1983); Schumm (1983); Hooke (1984); Schumm (1985); Carson and Lapointe (1986); Lapointe and Carson (1986); Nanson and Hickin (1986).

The meandering process has also been demonstrated in numerous laboratory studies. An early demonstration was by Friedkin (1945). By studying the evolution of a laboratory channel from straight to meandering (Fig. 8-2), Friedkin defined some of the key variables of the process. He also made a first attempt to establish qualitative relationships between the variables.

##### 8.2.1 Meandering Criteria

A significant amount of literature suggests that this process takes place only when certain combinations of variables are in place. Data suggest that as the channel slope becomes

**Fig. 8-1.** Aerial photos of the East Nishnabotna River just south of Red Oak, Iowa: (left) October 5, 1973; (right) May 25, 1979.

steeper, there is a tendency for the river to become braided, that is, split into several channels. Leopold and Wolman (1957) analyzed data from a large number of rivers in the United States and in India and found that the threshold between the two classifications (meandering and braided) for these rivers is a function of channel slope  $S$  and bank-full discharge  $Q(\text{m}^3/\text{s})$ ,

$$S = 0.012 Q^{-0.44} \quad (8-1)$$

For a braided river,  $S$  is greater, and for a meandering river, it is less than the value given by Eq. (8-1). As indicated in Fig. 8-3, the data suggest that one and the same river can have both braided and meandering reaches.

Henderson (1963) attempted to refine Eq. (8-1) by accounting for the effect of size of bed material and proposed the relation

$$S = 0.0002 D^{1.14} Q^{-0.44} \quad (8-2)$$

Fig. 8-2. Meandering process demonstration by Friedkin (1945).

in which  $D$  = median-particle diameter in millimeters and  $Q$  = discharge in  $\text{m}^3/\text{s}$ .

Based on observations of sand-bed rivers in the United States, Lane (1957) proposed a slightly different criterion for braided and meandering rivers,

$$S = KQ^{-0.25} \quad (8-3)$$

in which  $K$  = constant. Figure 8-4 summarizes Lane's plots and shows that when  $K \leq 0.0017$  English units ( $K \leq 0.0007$  metric units), a sand-bed river will tend toward a meandering pattern, and when  $K \geq 0.01$  (0.004 metric units), it will tend toward a braided pattern. It is noted that channel slopes for these two extremes differ by a factor of nearly 6. It is also noted that many U.S. rivers fall in between these extremes.

Fig. 8-3. Threshold between meandering and braided channels (Leopold and Wolman 1957).

Fig. 8-4. Slope-discharge relationships in meandering and braided sand-bed streams (after Lane 1957).

Recently Millar (2000) showed that bank vegetation influences channel patterns and that the meandering-braiding transition slope increases with the erosional resistance of the banks. Millar's relation, which is based on theoretical analysis and curve fitting, using data from 137 rivers, reads as

$$S = 0.0002 D^{0.61} \phi^{1.75} Q^{-0.25} \quad (8-4)$$

where

$D$  = median sediment diameter for the banks and bed surface (meters);

$\phi$  = bank sediment friction angle (degrees); and

$Q$  = bank-full discharge ( $\text{m}^3/\text{s}$ ).

With no vegetation on the bank,  $\phi$  is the angle of repose for noncohesive bank sediment, which for coarse gravel is up to  $40^\circ$ . As vegetation increases,  $\phi$  increases. Millar states that  $\phi$  represents a lumped calibration parameter that probably accounts for several different processes, including reduction of near-bank velocity and shear stress, binding of the bank sediment by root networks, packing and imbrication, and cementing of the gravel clasts by interstitial fines.

These relations are just a few of the many criteria for meandering that have been proposed over the years (for a more complete summary, see Bridge 1993). Although they have been, and are still being, challenged by engineers and scientists, the relations offer some guidance to river engineers.

## 8.2.2 Meander Planform

Measurements of the dimensions of meander patterns suggest that there are relations between certain planform characteristics that are relatively consistent for a wide range of stream sizes. The planform characteristics, defined in Fig. 8-5, are wavelength  $\lambda$ , amplitude  $A$ , bank-full channel width  $b$ , and minimum radius of curvature  $r_c$ . Leopold and Wolman (1960) have suggested the following relationships between these variables:

$$L = 11.0 b^{1.01} \quad (8-5)$$

Fig. 8-5. Meander planform characteristics.

$$A = 3.0b^{1.1} \quad (8-6)$$

$$\lambda = 4.6r_c^{0.98} \quad (8-7)$$

All dimensions are in meters. These relationships imply that  $r_c \approx 2.4b$ . Leopold et al. (1964) and Zeller (1967) later confirmed these relationships in a comprehensive data analysis that included furrow meanders, meanders in glacier ice, and meanders of the Gulf Stream.

A number of theories have been proposed to explain the observed regularity of plan form. They include theories based on optimization concepts such as minimum energy dissipation and minimum variance (Langbein and Leopold 1966; Chang 1979; 1984; 1988b). For a review of these theories, readers are referred to Chang (1988a).

The consistency of these relations may suggest that the meandering process, as described in Section 8.2, is a transitional (transient) process that, as sinuosity increases, tends toward some form of planform equilibrium or order, which is disrupted only during extreme events when cutoffs occur.

The notion of a time-limited equilibrium or order has been promoted in recent studies that attempt to simulate meandering through chaotic dynamics and self-organization. These simulations show the meandering process as oscillating in space and time between a state in which the river planform is ordered and one in which it is chaotic (Stølum 1996; 1997; 1998).

### 8.2.3 Meander Migration—Bank Erosion

As indicated in the Introduction, the planforms of meanders tend to migrate. The aforementioned relations do not predict rate and direction of migration. Specific migration relations have been developed by, among others, Hickin (1974); Hickin and Nanson (1975); Hooke (1980); Brice (1982); Nanson and Hickin (1983). Their relations are in the form of measured correlations between rates of bank retreat and width or width-radius ratio.

Brice demonstrated that the rate of bank retreat increases with increasing channel width. His data consist of 43 data points from four different stream types (equiwidth, wide bend, braided point bar, braided) with rates ranging from 0.1 m/year on a 10-m-wide channel to about 9 m/year on a 600-m-wide channel. The approximate relationship is mean erosion rate in meters per year = 0.01 times channel width in meters.

An increase in erosion rate with channel width is also indicated indirectly in Hooke's (1980) data. Her plot of erosion rates versus drainage area for 11 streams in Devon, England, and 43 streams compiled from the literature covers rates from 0.05 m/year for a drainage area of 3 km<sup>2</sup> to 800 m/year for a drainage area of 1 million km<sup>2</sup>. The approximate relationship is mean erosion rate in meters per year = 0.05 times square root of drainage area in square kilometers.

Hickin and Nanson (1975) and Nanson and Hickin (1983) demonstrated that channel curvature plays an important role in determining the rate of bank retreat. They used the technique of dendrochronology to determine the relative ages of scroll bars on the floodplain of the Beatton River, Canada, and they correlated local migration rate with local radius-width ratio. Their data (Nanson and Hickin 1983) conform, approximately, to the relation

$$\begin{aligned} v_e \text{ (m/year)} &= 2.0 b/r_c \quad b/r_c \leq 0.3 \\ v_e \text{ (m/year)} &= 0.2 r_c/b \quad b/r_c \geq 0.3 \end{aligned} \quad (8-8)$$

in which  $v_e$  is the erosion rate,  $b$  is the channel width, and  $r_c$  is the radius of curvature of the channel.

Ikeda et al. (1981), in their theory of river meanders, assume that the rate of bank retreat  $v_e$  is proportional to the difference between near-bank depth-averaged mean velocity  $u_b$  and the reach-averaged mean velocity  $u$  at bank-full discharge,

$$v = E(u_b - u) = Eu'_b \quad (8-9)$$

in which  $E$  = parameter describing the erodibility of the bank material and  $u'_b$  = near-bank velocity increment. This relationship is based on the assumption that soil particles on the bank are eroded and removed by the flow whenever the near-bank velocity exceeds the reach-averaged velocity. Field data support the assumption of a linear relationship between erosion rate and near-bank velocity increment (Odgaard 1987; Hasagawa 1989; Pizzuto and Meckelnburg 1989).

By determining  $u_b$  using Engelund's (1974) second approximation, Parker (1983) and Parker and Andrews (1986) developed a convolutional relation between migration rate and curvature. For developed bend flow in a constant-radius curve, their relation reduces to

$$\frac{v_e}{r} = EA \frac{u}{b} \quad (8-10)$$

in which  $A$  is "an order-one scour factor parameterizing the role of secondary currents" (Parker 1983, p. 727). Equation (8-10) supports Hickin and Nanson's (1975) notion that the rate of channel migration is a function of width-radius ratio. Odgaard (1987) used Eq. (8-10) for analysis of stream bank erosion along rivers in Iowa.

A convolutional relationship between migration rate and curvature has also been suggested by Howard and Knutson (1984) and Furbish (1988; 1991) and has been used in several simulation models. A convolutional relationship is often

appropriate because it allows the migration rate at a given point to depend not only on the local channel curvature but also on the upstream curvatures. The merits of a con-volitional model have been discussed and demonstrated by Furbish (1991), among others.

Odgaard (1989a) has suggested that erosion rate may also be related to increase in scour depth at the bank,

$$\frac{v_e}{u} = E' \frac{d'_b}{d} \quad (8-11)$$

in which  $d'_b = d_b - d$  = near-bank depth increment. The rationale behind this relation is that as the height of the outer bank increases, the stability of the bank decreases, which is indicated by the analyses of Osman and Thorne (1988) and Thorne and Osman (1988). Hasegawa also includes near-bank depth increment as a factor in determining the rate of bank migration; however, in his equation, the effect is negative under certain conditions. Howard (1992) has suggested that the migration rate may be related to both  $u'_b$  and  $d'_b$ . Such a relationship may read

$$\frac{v_e}{u} = E'' \left( C_1 \frac{u'_b}{u} + C_2 \frac{d'_b}{d} \right) \quad (8-12)$$

in which  $C_1$  and  $C_2$  are weighting factors. The value of  $C_1$  is positive, whereas  $C_2$  may be positive, negative, or zero.

The mechanism of bank failure varies from river to river and there are cases where none of the aforementioned relationships come even close to a description of it. For example, bank failure by piping and sapping (Hagerty 1991a; 1991b), which occurs along many rivers in the midwestern states of the United States, may have little or no relationship to stream-flow variables. The same applies to bank failure triggered by vegetative growth or climate-influenced deterioration (weathering) of the bank material. A more extended description of these mechanisms can be found in ASCE (1998); Langendoen (2000); and in chapter 7 of this volume. Lawler et al. also describe bank erosion measurement techniques that are under development, including a photo-electronic erosion pin (PEEP) automatic erosion and deposition monitoring system.

### 8.3 FLOW AND BED TOPOGRAPHY IN MEANDERS

It is the dynamics of the flow in the river, in particular in bends, that determines whether the bends migrate sideways or down-valley or both.

As the flow enters a bend, the centrifugal acceleration drives the faster-moving surface current toward the outer bank and the flow near the bed toward the inner bank (secondary current). The result is a spiraling flow that produces greater depths and higher velocities near the outer bank. The channel-deepening undermines the bank, and the higher

velocity and shear stress attack it, setting the stage for bank erosion. Near the inner bank a point bar tends to form. Thomson (1876) may have been the first to suggest that this is the process that causes rivers to meander. His qualitative description of the bend flow has remained unchallenged.

There are other features of flow and bed topography in meander curves that also must be recognized. As a result of the secondary current, pressure builds along the outer bank, causing the water surface to rise or superelevate (Thomson 1876; Ippen and Drinker 1962; Yen 1965; Yen and Yen 1971). In sharp curves of the river there is a tendency for flow to separate at the point bar (Dietrich and Whiting 1989; Kawai and Julien 1996; Hodskinson and Ferguson 1998; Ferguson et al. 2003). In fact, the sharper the curve the more complex are the secondary currents and boundary shear stresses (Hey and Thorne 1975; Bathurst et al. 1979; Cheng and Shen 1983; Allen 1985; Thorne et al. 1985; Hey and Rainbird 1996; Blanckaert and Graf 2001; Blanckaert 2003). The complexity of flow is also reflected in the sediment transport. A sorting of bed sediment often occurs (Parker and Andrews 1985; Ikeda 1989; Bridge 1992; Yen and Lee 1995; Julien and Anthony 2002). Readers are referred to Chapter 3 for more details about sediment transport of mixtures.

Because, as indicated in the previous section, the rate of bank erosion may be closely related to near-bank depth and velocity, many attempts have been made over the years to relate these variables to mean-flow properties (Thomson 1879; van Bendegom 1947; Rozovskii 1957; Yen 1965; Yen 1970; Yen and Yen 1971; Apmann 1972; Yen 1972; Engelund 1974; Ikeda 1974; Engelund 1975; Hooke 1975; Ikeda 1975; Yen 1975; Bridge 1976; Bridge and Jarvis 1976; Gottlieb 1976; Kikkawa et al. 1976; Bridge 1977; Bridge and Jarvis 1977; DeVriend 1977; Allen 1978; Zimmermann and Kennedy 1978; Dietrich et al. 1979; Begin 1981; Odgaard 1981; Bridge and Jarvis 1982; DeVriend and Geldof 1983; Dietrich and Smith 1983; Falcon and Kennedy 1983; Geldof and DeVriend 1983; Parker et al. 1983; Thorne et al. 1983; Bridge 1984; Chang 1984; Dietrich and Smith 1984; Kitanidis and Kennedy 1984; Odgaard 1984; Smith and McLean 1984; Ikeda and Nishimura 1985; Parker and Andrews 1985; Struiksmas et al. 1985; Odgaard 1986a; 1986b; Parker and Andrews 1986; Dietrich 1987; Odgaard 1987; Furbish 1988; Odgaard and Bergs 1988; Dietrich and Whiting 1989; Ikeda 1989; Nelson and Smith 1989; Odgaard 1989a; 1989b; Parker and Johannesson 1989; Shimizu and Itakuru 1989; Bridge 1992; Mosselman 1995; 1998; Seminara et al. 2001; Zolezzi and Seminara 2001). Summaries have been given by, among others, Odgaard (1984) and Chang (1988a).

#### 8.3.1 Governing Equations and Sample Solution

Several attempts to relate near-bank depth and velocity to mean-flow properties are based on solving the equations for conservation of mass (water and sediment) and momentum and using a stability criterion for sediment particles on the

streambed. The attempts differ in the way the equations are reduced. As an example, Odgaard (1989a; 1989b) employs an order-of-magnitude consideration and linearization and reduces the equations to those of a damped oscillating system. He utilizes the observation, from both laboratory and field, that both  $u$  and  $d$  are essentially constant along the river channel's centerline, and that their variation in transverse direction is nearly linear over the central portion of the cross section (Fig. 8-6). Consequently, the following description is deemed appropriate:

$$\frac{\bar{u}}{\bar{u}_c} = 1 + \frac{n}{d_c} U_{tc} \quad (8-13)$$

$$\frac{d}{d_c} = 1 + \frac{n}{d_c} S_{tc} \quad (8-14)$$

in which  $S_{tc}$  = transverse bed slope at the centerline =  $(\partial d / \partial n)_c$  and  $U_{tc}$  = normalized transverse velocity gradient at the centerline =  $d_c [\partial / \partial n (\bar{u} / \bar{u}_c)]_c$ , in which subscript  $c$  = the centerline values, and overbars denote the depth-averaged values. In Fig. 8-6 the  $s$ -axis is along the channel centerline, and positive in the streamwise direction, the  $n$ -axis is perpendicular to the  $s$ -axis and positive toward the concave bank, and the  $z$ -axis is vertically upward. The velocity components (time-averaged) in the  $s$ -,  $n$ -, and  $z$ -directions are denoted  $u$ ,  $v$ , and  $w$ , respectively.

Odgaard assumes a transverse distribution of sediment transport  $q_s$  described by a power law,

$$q_s = q_{sc} \left( \frac{\bar{u}}{\bar{u}_c} \right)^M \quad (8-15)$$

in which exponent  $M$  is a function of sediment characteristics and  $q_s$  is the volumetric rate per unit width. Such a power law is often used for description of bed load transport in straight alluvial channels, where the value of  $M$  is generally between 2 and 4 (Simons and Sentürk 1977).

Fig. 8-6. Definition sketch for sinusoidal channel flow.

Odgaard is then able to reduce the equations to two ordinary differential equations,

$$\frac{dU_{tc}}{d\sigma} + a_1 U_{tc} = \frac{1}{2} a_1 S_{tc} \quad (8-16)$$

$$\frac{d^2 S_{tc}}{d\sigma^2} + a_2 \frac{d^2 U_{tc}}{d\sigma^2} + a_3 \frac{dS_{tc}}{d\sigma} + a_4 \frac{dU_{tc}}{d\sigma} + a_5 S_{tc} = a_6 \quad (8-17)$$

in which  $\sigma = s/b$  and

$$a_1 = \frac{2k^2}{m^2} \frac{b}{d_c} \quad (8-18)$$

$$a_2 = 1 - \frac{m+1}{m+2} M \quad (8-19)$$

$$a_3 = \frac{8 B \sqrt{\theta}}{\alpha \kappa F_{Dc}} \frac{m(m+1)}{m+2} \frac{d_c}{b} + \frac{2 \kappa^2 m}{(m+1)(m+2)} \frac{b}{d_c} \quad (8-20)$$

$$a_4 = \frac{2 \kappa^2 m}{(m+1)(m+2)} \left[ 1 - M \left( 1 + \frac{1}{2m} + \frac{1}{2m^2} \right) \right] \frac{b}{d_c} \quad (8-21)$$

$$a_5 = \frac{8 B \kappa \sqrt{\theta}}{\alpha (m+2) F_{Dc}} \left( 1 + \frac{2m^2}{m+1} \right) \quad (8-22)$$

$$a_6 = \frac{8}{\alpha} \frac{2m+1}{m(m+2)} \frac{d_c}{r_c} \quad (8-23)$$

in which factor  $F_{Dc}$  = particle densimetric Froude number, defined as  $F_{Dc} = \bar{u}_c / \sqrt{\Delta g D}$ .  $m$  = friction parameter, whose relationship to shear velocity  $u_*$ , Darcy-Weisbach's friction factor  $f$ , and Chezy's coefficient  $C$  is  $m = \kappa \bar{u} / u_* = \kappa \sqrt{8/f} = \kappa C / \sqrt{g}$  is in which  $\kappa$  = von Karman's constant ( $\sim 0.4$ ), and  $u_* = \sqrt{\tau_{bs} / \rho}$ ,  $\tau_{bs}$  = bed shear stress in the  $s$ -direction,  $\rho$  = density of water,  $\Delta$  = specific weight of submerged sediment =  $(\rho_s - \rho) / \rho_s$ ;  $\rho_s$  = density of sediment (for quartz sand,  $\Delta = 1.65$ ),  $B$  = transverse bed-slope factor (see Odgaard 1989a),  $\alpha$  = transverse-mass flux factor (Odgaard 1989a),  $\theta$  = dimensionless critical bed shear stress (Shield's parameter), and  $g$  = acceleration due to gravity. Typical values of  $\alpha$ ,  $B$ , and  $\theta$  are 0.4, 6, and 0.03, respectively.

By eliminating  $S_{tc}$ , using Eq. (8-16), Eq. (8-17) is reduced to

$$\frac{d^3 U_{ic}}{d\sigma^3} + h_1 \frac{d^2 U_{ic}}{d\sigma^2} + h_2 \frac{dU_{ic}}{d\sigma} + h_3 U_{ic} = h_4 \quad (8-24)$$

in which  $h_1 = a_1 + (1/2)a_1 a_2 + a_3$ ;  $h_2 = a_1 a_3 + (1/2)a_1 a_4 + a_5$ ;  $h_3 = a_1 a_5$ ; and  $h_4 = (1/2)a_1 a_6$ . The system ( $U_{ic}$  and  $S_{ic}$ ) described by these equations is a damped oscillation forced by curvature ( $h_4$ ). With given boundary conditions, the solution is readily obtained.

In fully developed bend flow, where  $d/d\sigma = 0$ , Eqs. (8-16) and (8-17) yield

$$\frac{\bar{u}}{\bar{u}_c} = \sqrt{\frac{d}{d_c}} \quad (8-25)$$

and

$$S_{ic} = H F_{Dc} \frac{d_c}{r_c} \quad (8-26)$$

in which  $H = (2m + 1)(m + 1)/[B\kappa\sqrt{\theta} m(m + 1 + 2m^2)]$ . These equations are well supported by both laboratory and field data (Kikkawa et al. 1976; Falcon and Kennedy 1983; Ikeda and Nishimura 1985; Odgaard and Bergs 1988). The composition of factor  $H$ , however, varies somewhat from author to author.

### 8.3.2 Sample Simulation of Bed Topography in Laboratory Channel

The oscillatory behavior of the flow system is illustrated by a simulation of  $S_{ic}$  in a recirculating 180° constant-radius alluvial-bend model at IIHR Hydrosience and Engineering. This model has width 2.44 m and centerline radius  $r_c = 13.11$  m. At a discharge of 0.153 m<sup>3</sup>/s, centerline values of depth, velocity, particle Froude number, and water surface slope are  $d_c = 0.15$  m,  $u_c = 0.45$  m/s,  $F_{Dc} = 6.5$ , and  $S_c = 0.00116$ , respectively; resistance parameters are  $m = 5.3$  and  $\kappa = 0.52$ ; and bed load transport  $q_s \cong 4$  g/cm/min. Flow and sediment conditions were described earlier by Odgaard and Bergs (1988) and Bergs (1989). The bend is preceded by a 20-m-long straight reach. Under such conditions,  $d^2 U_{ic}/d\sigma^2$  is negligibly small, and Eqs. (8-16) and (8-17) yield

$$\frac{d^2 S_{ic}}{d\sigma^2} + \left(a_3 + \frac{1}{2} a_4\right) \frac{dS_{ic}}{d\sigma} + a_5 S_{ic} = a_6 \quad (8-27)$$

With  $S_{ic}$  and  $dS_{ic}/d\sigma$  being zero at the beginning of the bend at  $\sigma = 0$ , the solution is

$$S_{ic} = S_{ico} - S_{ico} \sqrt{1 + \left(\frac{a'}{2\omega}\right)^2} \cos(\omega\sigma - \psi) \exp\left(-\frac{1}{2} a'\sigma\right) \quad (8-28)$$

in which  $\omega = (1/2)\sqrt{4a_5 - a'^2}$ ;  $a' = a_3 + (1/2)a_4$ ;  $\psi = \arctan[a'/(2\omega)]$ ; and  $S_{ico}$  = fully developed value of  $S_{ic}$  (Eq. (8-26)). The simulation (using values  $B = 3$ ,  $\alpha = 1$ ,  $\theta = 0.03$ , and  $M = 2.7$ ) is shown in Fig. 8-7 with measured data. The oscillation of  $S_{ic}$  is very distinct in this flow situation. The transverse bed slope is seen to overshoot its equilibrium (fully developed) value by a factor of about 1.5. A similar overshoot was measured in Struiksmat et al.'s (1985) experiments and also predicted by their model. The overshoot is associated with redistribution of flow and sediment transport in the beginning of the bend, where both  $q_n$  and  $\partial u/\partial n$  are greater than zero ( $q_n$  = volumetric bed load transport per unit width in the  $n$ -direction). A positive value of  $q_n$  is necessary there to provide the increase of sediment transport associated with the increase in velocity along the outer bank. It is apparent that the system generates such a transverse transport of sediment by locally increasing transverse bed slope beyond that of fully developed bend flow (to make the downslope gravity force component larger than the upslope drag force component). The magnitude of the overshoot is dependent on the value of  $M$ . Overshoot of "overdeepening" is also discussed by Zolezzi and Seminara (2001). Using a linear, depth-averaged flow model coupled with the Exner equation, they simulate, and obtain good agreement with, the overshoot measured by Struiksmat et al. (1985).

### 8.4 CHANNEL STABILITY

One of the critical questions from a river-engineering point of view is the extent to which a given channel alignment is prone to future changes. There is an obvious need for answers to this question. The problem is one of stability of river channel alignment.

Fig. 8-7. Measured and computed transverse bed slopes in IIHR bend model experiment.

### 8.4.1 Regime Theories

Many attempts have been made in the past to establish guidelines for assessment of channel stability. Among the guidelines are the so-called regime theories (Kennedy 1895; Lacey 1930; Blench 1952; Kellerhals 1967; Charlton et al. 1978), which are empirical techniques, used primarily for the design of stable, straight channels. These theories generally predict that channel width must be less than 6 to 10 times depth for the channel to remain stable.

Most natural channels have a width-depth ratio larger than 6 to 10, and their planforms are unstable. They consist of meanders that, as mentioned above, usually migrate by both downstream translation and lateral expansion.

### 8.4.2 Perturbation Stability Analyses

As indicated earlier, it is generally believed that meandering is the result of channel instability. Building on this assumption, many researchers have attempted to simulate the initiation of the meandering process by a perturbation stability analysis. Early attempts were made by, among others, Callander 1969; Hansen 1967; Engelund and Skovgaard 1973; Fredsoe 1978; and Parker 1976. As they progressed in sophistication, the perturbation stability analyses were also used to evaluate the stability of given channel alignments. That is, if a given channel alignment had characteristics similar to those calculated by the stability analysis, the alignment was considered "relatively stable" or "minimally destructive" in terms of bank erosion. Early alternate approaches are reviewed by Yang (1971), Chitale (1973), and Callander (1978) among others. The theory of minimum variance has also been offered as a possible cause of meandering (von Schelling 1951; Langbein and Leopold 1966; and Chang 1988a).

In a perturbation stability analysis, small traveling perturbations are introduced into the system of equations governing river flow, and their effect on channel planform is determined by calculating the rate of growth of the perturbations. The primary advantage of the perturbation stability analysis is that it allows channel planform stability to be described as a feature of the basic flow equations. Whereas the regime formulas and empirically based meander relations correlate flow and meander variables using data and simple, one-dimensional, straight-channel resistance formulas (Manning, Chezy, etc.), the perturbation analyses generally employ models that are based on the complete set of governing equations, including those of sediment transport, and describe flow and depth distributions in the channel in at least two dimensions.

Two categories of stability theories exist: (1) bar theories, which examine conditions for formation of alternating bars in straight channels, and (2) bend theories, which examine migration features of weakly meandering flows. It is the latter category that is addressed in this section. It should be noted that the two categories may in fact be related. Theoretical analyses by Blondeaux and Seminara (1983; 1985), Seminara and Tubino (1989), Parker and Johannesson

(1989), and Tubino and Seminara (1990) suggest that alternating bars may under certain circumstances trigger bend instability and lead to meandering.

Representative bend theories are those of Ikeda et al. (1981); Kitanidis and Kennedy (1984); Blondeaux and Seminara (1985); and Odgaard (1989a). These theories differ in their treatment of bank erosion and of centrifugally induced secondary flow and its effect on bed topography and primary flow. Kitanidis and Kennedy assume that the rate of bank retreat is proportional to and in phase with the secondary current, whereas the other authors assume that the rate is proportional to and in phase with the difference between near-bank and section-average velocity. Kitanidis and Kennedy account for effects of secondary current and assume that transverse bed slope has negligible effect on stability. Ikeda et al., on the other hand, consider effects of transverse bed slope and neglect effects of secondary current. Blondeaux and Seminara (1983; 1985) and Odgaard (1989a) include effects of both secondary current and transverse bed slope. In Blondeaux and Seminara's model, the secondary current is controlled by an external stress relation, whereas in Odgaard's model it is controlled by the basic flow equations. Odgaard's approach allows for phase lag between channel curvature and secondary current and thus calculates the direction of migration. None of these analyses account for convective transport of primary flow momentum by the secondary current. One reason for this is that depth averaging of the governing flow equations eliminates it; in addition, in mildly curved channels, the effect is minor.

In Odgaard's stability analysis, the bed topography is calculated based on a coupling between flow field and sediment transport. This was done in response to the findings of Struiksmä et al. (1985) and Johanneson (1988) that redistribution of sediment transport can have a significant effect on bed topography. In most other stability analyses, sediment redistribution is not considered.

### 8.4.3 Example of a Perturbation Stability Analysis

The following example illustrates the principles of stability analysis (Odgaard 1989a) based on the equations of a damped oscillating system. The stability of the system is tested by subjecting it to a channel alignment perturbation in the form of a traveling sinusoid,

$$\eta(x, t) = A(t) \sin[k(x - ct)] \quad (8-29)$$

in which  $x$  = coordinate distance along the unperturbed channel axis;  $k = 2\pi/\lambda$  is the wave number;  $A$  = amplitude;  $\lambda$  = meander wavelength;  $t$  = time; and  $c$  = celerity of sinusoid. The channel-centerline displacement  $\eta(t)$  is limited to values much smaller than the meander wavelength. The centerline curvature is then

$$\frac{1}{t_c} = -\frac{d^2\eta}{dx^2} = k^2 A(t) \sin[k(x - ct)] \quad (8-30)$$

The differential equation for  $U_{ic}$  is obtained by substituting Eq. (8-30) into Eq. (8-24). The solution, which is periodic and independent of the initial condition, is

$$U_{ic} = \frac{N b k^2 A}{\sqrt{e_1^2 + e_2^2}} \sin [k(x - ct) - \gamma] \quad (8-31)$$

in which  $N = 8\kappa^2(2m + 1)/[\alpha m^3(m + 2)]$ ;  $e_1 = h_3 - 2h_1 k^2 b^2$ ; and  $e_2 = h_2 k b - k^3 b^3$ . The phase shift between  $U_{ic}$  and the channel-axis displacement is  $\gamma = \arctan(e_2/e_1)$  ( $0 \leq \gamma \leq \pi/2$ ). The corresponding transverse bed slope is obtained by substituting Eq. (8-31) into Eq. (8-16),

$$S_{ic} = \frac{2 N b k^2 A}{\sqrt{e_1^2 + e_2^2}} \sqrt{1 + \left(\frac{b k}{a_1}\right)^2} \sin [k(x - ct) - \phi] \quad (8-32)$$

in which  $\phi = \gamma - \arctan(bk/a_1)$ .

To determine  $A(t)$ , an equation is introduced that describes the rate of lateral shifting of the channel axis due to erosion of the concave bank and deposition on the convex bank. In this example, two alternatives are used. One is the relation proposed by Ikeda et al. (1981), which assumes that the rate of bank retreat is proportional to the difference between near-bank depth-averaged velocity  $u_{bank}$  and the section-averaged velocity  $\bar{u}_o$ . By using the depth-averaged centerline velocity  $\bar{u}_c$  for  $\bar{u}_o$ , the relation reads

$$v_e = E \bar{u}_c \left( \frac{\bar{u}_{bank}}{\bar{u}_c} - 1 \right) \quad (8-33)$$

in which  $v_e$  = rate of bank retreat and  $E$  = parameter describing the erodibility of the bank material. This model is labeled IKD. The other relation, which is proposed by Odgaard (1989) and labeled ODG, assumes that rate of bank retreat is linearly related to increase in scour depth at the bank,

$$v_e = E' \bar{u}_c \left( \frac{d_{bank}}{d_c} - 1 \right) \quad (8-34)$$

in which  $E'$  = erosion parameter. It follows that  $E' \cong (1/2) E$ . Because of the assumed mild curvature of the channel,  $v_e$  may be equal to the rate of change of channel alignment,  $\partial\eta/\partial t$ . The parenthetical expressions in Eqs. (8-33) and (8-34) equal  $bU_{ic}/2d_c$  and  $bS_{ic}/2d_c$ , respectively. The closing of the problem is achieved by substituting Eq. (8-29) into the left-hand sides of Eqs. (8-33) and (8-34), and Eqs. (8-31) and (8-32) into the right-hand sides of Eqs. (8-33) and (8-34), respectively. After some reduction, relationships for amplitude growth rate,  $\partial A/\partial t$ , and celerity,  $c$ , are obtained. Using the IKD bank erosion model (Eq. (8-33)), the relations are

$$\frac{1}{A} \frac{\partial A}{\partial t} = \frac{E \bar{u}_c}{b} K b k \cos \gamma \quad (8-35)$$

$$c = E \bar{u}_c K \sin \gamma \quad (8-36)$$

in which

$$K = \frac{1}{2} N \frac{b}{d_c} \frac{k b}{\sqrt{e_1^2 + e_2^2}} \quad (8-37)$$

The ODG bank erosion model [Eq. (8-34)] yields

$$\frac{1}{a} \frac{\partial A}{\partial t} = 2 \frac{E' \bar{u}_c}{b} K b k \sqrt{1 + \left(\frac{b k}{a_1}\right)^2} \cos \phi \quad (8-38)$$

$$c = 2 E' \bar{u}_c K \sqrt{1 + \left(\frac{b k}{a_1}\right)^2} \sin \phi \quad (8-39)$$

#### 8.4.4 Dominant Wavelength

It is generally assumed that the dominant wavelength is the wavelength that is associated with the conditions that yield maximum growth rate of alignment amplitude. The wave number at which the maximum amplitude growth rate occurs is termed the dominant wave number, and it is determined from the equation

$$\partial^2 A / \partial t \partial k = 0. \quad (8-40)$$

Sample calculations are shown in Fig. 8-8, which shows dominant wavelengths  $\lambda_d$  and corresponding phase shifts  $\phi_d$  and  $\gamma_d$  as a function of width-depth ratio for different friction factors, densimetric Froude numbers, and transverse bed slope factor. A value of  $M = 3$  is used. It is seen that the calculations based on the IKD bank erosion model yield a stronger dependence of wavelength on width-depth ratio than do calculations based on the ODG bank erosion model. The typical bank-full range for  $F_{Dc}$  and  $m$  are  $5 \leq F_{Dc} \leq 15$  and  $3 \leq m \leq 5$ . For width-depth ratios between 10 and 60 (the typical range), the ODG model then yields dominant wavelengths between 9 and 24 times the width, which is in agreement with data presented by Zeller (1967) and Leopold and Wolman (1957; 1960). For the same width-depth ratios, the IKD model yields wavelengths between 9 and 57 times the width, somewhat larger than those indicated by data.

The calculations based on the IKD bank erosion model yield dominant-wavelength relationships ranging from  $\lambda_d \propto d_c$  at small width-depth ratios to  $\lambda_d \propto \sqrt{b d_c}$  at large width-depth ratios. This range covers that represented by the theories of Ikeda et al. and Kitanidis and Kennedy. The IKD model yields a nearly linear dependence of  $\lambda_d$  on  $m$ , or the inverse of  $\sqrt{f}$ , which is also predicted by Ikeda et al. and Kitanidis and Kennedy. The ODG model yields a roughly linear dependence on  $m$  only at large width-depth ratios; the dependence on  $m$  is weaker at smaller width-depth ratios. For large width-depth ratios, the two analyses yield essentially the same results. The two analyses also differ in their prediction

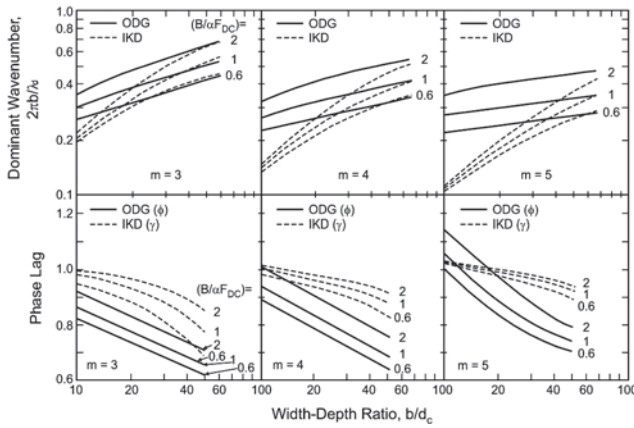

Fig. 8-8. Results of sample stability analysis: dominant wavelengths and phase shifts as functions of width-depth ratio.

of dominant phase lag, and thus of distance from crossover to first outer-bank erosion occurrence. The phase lags predicted based on the ODG model are generally smaller than those predicted when the IKD bank erosion model is used. Computed data points, obtained using the ODG model and  $M = 3$ , conform roughly to the following curve-fitted relations:

$$\frac{2\pi b}{\lambda_d} = 0.11m^{1/4} \left( \frac{B}{\alpha F_{Dc}} \right)^{0.41} \left( \frac{b}{d_c} \right)^{1/m} \quad (8-41)$$

and

$$\phi_d = 0.16(m+5) \left( \frac{B}{\alpha F_{Dc}} \right)^{0.1} \left( \frac{d}{b} \right)^{0.125m^{0.27}} \quad (8-42)$$

Within the range  $2 \leq M \leq 4$ , dominant meander wavelength and phase shift are relatively insensitive to  $M$ . For width-depth ratios between 10 and 40, a 50% increase (decrease) of  $M$  causes  $\lambda_d$  to decrease (increase) by less than 10%.

#### 8.4.5 Finite-Amplitude Meanders

In the analysis presented, it is assumed that curvature is small and that the meander wavelength is the same whether it is measured along the down-valley axis or along the channel centerline. As the process of meandering progresses, the wavelength measured along the centerline,  $L$ , becomes larger than that measured along the down-valley axis,  $\lambda$ . The ratio  $L/\lambda$  is often termed the sinuosity of the channel. Stochastic analysis, as well as field data (Langbein and Leopold 1966), indicates that a sine-generated alignment persists during the migration of many meanders. The curvature may then be written

$$\frac{1}{r_c} = \frac{1}{R_c} \sin \left( \frac{2\pi s}{L} \right) \quad (8-43)$$

in which  $R_c$  = minimum value of  $r_c$  at apex; and transverse bed slope and velocity may be obtained from the aforementioned equations with  $x$  replaced by  $s$ ,  $k$  by  $2\pi/L$ , and  $k^2 A(t)$  by  $1/R_c$ . It easily can be shown (Langbein and Leopold 1966) that  $L$  and  $R_c$  are related as

$$L = 4.4\pi R_c \sqrt{1 - \frac{\lambda}{L}} \quad (8-44)$$

#### 8.4.6 Prediction Uncertainties

This sample stability analysis shows that the description of meander migration is very sensitive to the manner in which bank erosion is related to primary flow variables. The rates of bank retreat are, of course, particularly sensitive to the values of  $E$  and  $E'$ . The direction of channel migration (lateral expansion versus downstream translation) is different depending on the bank erosion model used. There are not enough data available to determine which of the models, ODG or IKD, performs better. In fact, it is still an open question whether any of them comes even close to complete description of the relationship between flow variables and bank erosion.

In the sample analysis, the transverse bed slope factor  $B$  and the transverse-mass flux factor  $\alpha$  play significant roles. Factor  $B$  represents the bed sediment's motion-resistive properties. Its value has been reported to range from 3 to 6, possibly depending on sediment gradation. For the field cases analyzed by Odgaard (1989b), its value is about 6, which is in agreement with findings of Kikkawa et al. (1976). The transverse-mass flux factor  $\alpha$  corrects the cross-channel flows of water and sediment when these are calculated based on linear distributions of  $u$  and  $d$  in the cross-channel direction. Its value is defined by comparing the calculation (with the continuity equation) of transverse flow of water using linear  $u$  and  $d$  distributions with that computed with measured  $u$  and  $d$  distributions. A value of  $\alpha = 0.4$  is found to be reasonable for field cases.

The sediment transport relation is another uncertain element in the analysis. By using a simple power law (Eq. (8-15)), as is done in the preceding example, all sediment properties are embodied in the exponent  $M$ . Consequently,  $M$  varies from river to river. The value of  $M$  has a significant influence on transverse bed slope in accelerating bend flow, although not as dominant as that of  $B$ . In Odgaard's analysis of field data, a value of  $M = 3$  is used.

It must be kept in mind that the formulas presented in the previous example are based on linear analysis; they cannot be expected to apply to river channels with large curvature. The studies by Nelson (1988), Blanckaert and Graf (2001) and Blanckaert (2003) show that in channels with large curvature,

nonlinear terms in the flow equations can have a significant effect on the description of flow. Blanckaert (2003) demonstrates that in a large-curvature channel bend, an additional secondary flow cell develops near the outer bank. There is even a tendency for stacking of cells. Moreover, multiple point bars may develop as has been demonstrated by Whiting and Dietrich (1993a; 1993b; 1993c).

## 8.5 APPLICATIONS OF FLOW AND STABILITY RELATIONS

The flow and stability analysis in the preceding sections provides formulas and graphs for calculation of (1) rate and direction of channel migration; (2) dominant meander wavelength and phase shift; and (3) velocity and depth distributions in meandering channels.

Input consists of primary channel characteristics: slope  $S$ , width  $b$ , centerline depth  $d_c$ , median grain size  $D$ , friction factor  $f$ , and bank-erosion constants  $E$  and  $E'$ . Lateral and down-valley migration rates are then calculated by Eqs. (8-35) to (8-39), velocity and depth distributions by Eqs. (8-13), (8-14), (8-31), and (8-32), and dominant wavelength and phase lag by Eqs. (8-40) and (8-41) or Fig. 8-8.

Velocity and depth distribution in channels with arbitrary curvature are obtained by solving Eqs. (8-16) and (8-17) (or (8-24)) with appropriate boundary conditions, and by using Eqs. (8-13) and (8-14). In a constant-radius channel with a long straight approach reach, velocity and depth distributions may be calculated by Eqs. (8-28) and (8-16) together with Eqs. (8-13) and (8-14).

Two alternative bank-erosion models have been tested, the Ikeda et al. model (1981), denoted by IKD, which assumes that the rate of bank retreat is proportional to and in phase with the difference between near-bank and section-averaged velocity (Eq. (8-33)), and a model proposed by Odgaard (1989), denoted by ODG, which relates the rate of bank retreat to increase in near-bank scour depth (Eq. (8-34)).

The principal quantities and concepts are shown in Figs. 8-9(a) and 8-9(b). The figures show the paths of maximum velocity and flow depth through two consecutive meander bends. As indicated, the velocity and depth distributions respond to the change in curvature with a certain lag, which equals  $\gamma L/2\pi$  for velocity and  $\phi L/2\pi$  for depth. In the IKD bank-erosion model, it is assumed that bank erosion occurs with the same lag as velocity, whereas the ODG model assumes that bank erosion occurs with the same lag as depth. A basic assumption is that  $\lambda$  is nearly equal to  $L$ .

### 8.5.1 Numerical Example

The application of the previously given formulas is best illustrated by an example with data from a hypothetical river (Odgaard 1989b). The bank-full characteristics of the river channel are taken to be  $S = 0.0005$ ;  $b = 150$  m;  $d_c = 6$  m;

**Fig. 8-9.** Applications of flow and stability relations. Definition sketch for principal quantities and concepts: (a) utilizing IKD bank erosion model; (b) utilizing ODG bank erosion model.

$f = 0.08$  (i.e.,  $m = \kappa\sqrt{8/f} = 4$ );  $D = 1$  mm;  $\bar{u}_c = 1.72$  m/s ( $\approx \sqrt{8gSd_c/f}$ );  $M = 3$ ;  $\theta = 0.06$ ; and  $F_{Dc} = \bar{u}_c/\sqrt{\Delta g D} = 13.5$ . Transverse bed slope and mass flux factors are  $B = 6$  and  $\alpha = 0.4$ , and erosion constants are  $E = 3 \times 10^{-7}$  and  $E' = 1.5 \times 10^{-7}$ , values typical of rivers in the Midwest (Odgaard 1987).

To estimate dominant wavelength and phase lag, the graphs in Fig. 8-8 (or Eqs. (8-40) and (8-41)) are used. With  $B/\alpha F_{Dc} = 1.1$ ,  $m = 4$ , and  $b/d_c = 25$ , the ODG curve yields  $\lambda_d = 2,700$  m and  $\phi = 0.8$ , and the IKD curve  $\lambda_d = 3,500$  m and  $\gamma = 0.95$ . The phase shifts indicate that the first outer-bank erosion occurrence may occur at a distance from crossover of 0.12 to 0.15 times meander length, or slightly more. Lateral and down-valley migration rates are estimated by Eqs. (8-35), (8-36), or (8-38) and (8-39). The values of pertinent variables are listed in Table 8-1. If  $A = 200$  m, then  $\partial A/\partial t$  (ODG) = 5 m/year; and  $\partial A/\partial t$  (IKD) = 2 m/year. The variation of transverse bed slope through the meander is obtained from Eq. (8-32) with  $A = 200$  m (or, if  $L$  is given instead of  $A$ , with  $k^2 A = 1/R_c$ , and  $R_c$  obtained from Eq. (8-43))

$$S_{tc} \text{ (ODG)} = 0.071 \sin \left( \frac{2\pi s}{L} - 0.8 \right) \quad (8-45)$$

$$S_{tc} \text{ (IKD)} = 0.039 \sin \left( \frac{2\pi s}{L} - 0.8 \right) \quad (8-46)$$

and near-bank depth by Eq. (8-14) with  $n = 75$  m and  $d_c = 6$  m (or by Eq. 49 in Odgaard (1986a)). Maximum depth of scour is estimated to be 11.3 m based on ODG and 8.9 m based on IKD, and to occur at  $s/L = 0.38$  (downstream from bend apex). Migration rates of and flow and bed topography

**Table 8-1 Computation of Lateral and Down-Valley Migration Rates for Hypothetical River**

Variable	Bank erosion model	
	ODG	IKD
$kb$	0.35	0.27
$a_1$	0.50	0.50
$a_2$	-1.50	-1.50
$a_3$	1.793	1.793
$a_4$	-2.633	-2.633
$a_5$	1.074	1.074
$h_1$	1.918	1.918
$h_2$	1.312	1.312
$h_3$	0.537	0.537
$e_1$	0.067	0.257
$e_2$	0.416	0.335
$N$	0.075	0.075
$K$	0.778	0.600
$(1/A)\partial A/\partial t$	$8.0 \times 10^{-10} \text{ s}^{-1}$	$3.2 \times 10^{-10} \text{ s}^{-1}$
$c$	11 m/year	8 m/year

in channels with planform different from that of the dominant wave are computed in the same manner with  $k$  = actual wave number. Note that if  $L$  is significantly larger than  $\lambda$ , the calculations should be performed with  $k = 2\pi/L$  instead of  $2\pi/\lambda$ .

## 8.6 SIMULATION OF MEANDER EVOLUTION

Many attempts have been made over the years to develop models that can simulate the evolution or long-term behavior of a meandering river. They range from purely stochastic models to more rigorous process models.

The stochastic models include models based on the “most probable path” assumption with various degrees of simulated randomness (von Schelling 1951; Langbein and Leopold 1966; Thakur and Scheidegger 1968; Surkan and van Kan 1969; Thakur and Scheidegger 1970; Ferguson 1973; 1976; 1977; Stølum 1996; 1997; 1998). These models generally attempt to reproduce the evolution of meander patterns on a large scale with no or little consideration of local flood-plain characteristics and local sedimentary processes.

The process models attempt to reproduce the relationship between rates of migration and flow and channel variables quantitatively. The relationship is typically one of the equations listed in Section 8.2.3 or a convolutional relation between migration and curvature. The process models attempt to predict the long-term evolution of rivers, taking

into consideration flood-plain characteristics that modulate, in both time and space, the channel parameters and erosion coefficient (Parker 1982; Beck et al. 1983a; 1983b; Howard 1983; Beck 1984; Beck et al. 1984; Howard and Knutson 1984; Johannesson and Parker 1985; Parker and Andrews 1986; Parker et al. 1988; Crosato 1989; Furbish 1991; Howard 1992; Garcia et al. 1994; Mosselman 1995; Meakin et al. 1996; Sun et al. 1996; Mosselman 1998; Sun et al. 2001a; 2001b; 2001c; Lancaster and Bras 2002). A few process models are developed in which bank erosion is calculated by a separate process model that accounts for near-bank scour, bank collapse, and deposition and removal of bank material (Nagata et al. 2000; Duan et al. 2001; Darby 2002; Darby and Delbono 2002).

The simulations by Stølum (1996; 1997; and 1998) are examples of a combination of process and stochastic modeling. Stølum assumes that meander evolution is the result of two opposing processes: lateral migration, which acts to increase sinuosity, and cutoffs, which act to decrease it. Lateral migration results from bend erosion and deposition, whereas cutoffs result from local geometry. According to Stølum, these opposing processes self-organize the sinuosity into a steady state around a mean value of 3.14, the sinuosity of a circle  $\pi$ .

Recently, several attempts have been made to overcome the limitations of using a calibrated bank erosion coefficient. They include two-dimensional flow-field (mass and momentum), sediment-transport and bank erosion models (Nagata et al. 2000; Duan et al. 2001; Darby 2002; Darby and Delbono 2002).

### 8.6.1 Sample Simulations

Figure 8-10 shows a simulation by Johannesson and Parker (1985) of the evolution of Red Lake River, Minnesota. The evolution of the channel is obtained by tracking the channel migration over time. Channel width is assumed constant. It is also assumed that the channel centerline is displaced at the same rate as the bank. The migration is described by a Hickin mapping (so called in recognition of the original work of Hickin (1974)), according to which the centerline displacement is described as

$$\frac{dx_p}{dt} = v_e \sin \theta \quad (8-47)$$

$$\frac{dy_p}{dt} = -v_e \cos \theta \quad (8-48)$$

in which  $x_p$  and  $y_p$  are the coordinates of point P of the channel centerline, and  $\theta$  = local angle of centerline with x-axis. See Fig. 8-11.

A slightly modified Johannesson and Parker model was used by Garcia et al. (1994) to simulate the evolution of rivers in Illinois. In order to better determine the magnitude

Fig. 8-10. Simulation of the evolution of the Red Lake River, Minnesota, from 1954 to 1977 (from Johannesson and Parker 1985).

and characteristics of channel shifts, Garcia et al. used the computer program MEANDER, developed by MacDonald et al. (1992). MEANDER measures various components of channel shift, the most important of which is the average normal shift. It also measures sinuosity, time rate of change of sinuosity, and average rate of curvature. Figure 8-12a shows the simulation of the evolution of the Big Muddy River in Illinois (Garcia et al. 1994). Abad and Garcia (2004) have also presented a methodology for simulating the evolution of meandering streams in restoration and naturalization processes. The remeandering of Poplar Creek, Illinois, was analyzed. In this application, Kinoshita curves (Kinoshita 1961; Kinoshita and Miwa 1974; Parker et al. 1982; Parker et al. 1983; Parker and Andrews 1986; Seminara et al. 2001) were used to delineate the new channel. Figure 8-12b shows the planform migration of Poplar Creek at bank-full flow over a period of 100 years. Recently, Abad and Garcia (2006) developed a Windows-based and geographical information system-based interface for the analysis and modeling of planform migration (this program contains the models of Garcia et al. (1994) and MacDonald et al. (1992)).

## 8.7 CHANNEL STABILIZATION

Channel stabilization is an important part of floodplain management. Channels are stabilized to enhance the utility of floodplains, whether for business or recreation. Specific objectives are to (1) prevent bank erosion and loss of property, including bridges and other infrastructure; (2) enhance conveyance, in particular for floods; (3) facilitate traffic (commercial navigation and recreation); and (4) facilitate water usage (utilities, irrigation, diversion, etc.).

### 8.7.1 Strategy

The basic strategy is to stabilize the channel alignment and the channel cross section. The river should maintain a natu-

Fig. 8-11. Schematic showing migration of Point P on channel centerline.

ral alignment (a path of easy bends of reverse curvature) and have a cross section that can accommodate the river's water and sediment regime. A good practice is to find a relatively stable reach of the river, determine channel and alignment characteristics for that reach and then apply those characteristics to the reach to be stabilized.

A complementary or supplementary approach is to calculate alignment characteristics using stability theory. This approach is described in detail in the previous sections of this chapter. The approach is based on (1) equations for conservation of mass (water and sediment) and momentum and (2) a stability criterion for sediment particles on the bed. The equations are reduced to those of a damped oscillating system, which is then subjected to a traveling small-amplitude channel alignment wave. It is the growth characteristics of this wave that defines the natural alignment. This approach results in (1) planform development in terms of lateral and downstream migration rates; (2) flow and bed topography in terms of transverse gradients of depth and depth-averaged velocity; and (3) formulas for estimates of dominant meander wavelength and phase shift.

### 8.7.2 Technologies

Several technologies are available for stabilizing a channel. Reviews are given by Biedenharn et al. (1997) and Petersen (1986). The techniques range from the construction of revetments and dikes, vanes or weirs, to dredging. They function by adjusting bank resistance and/or bank erodibility and/or flow and bed topography.

**8.7.2.1 Revetments** Revetments are structures that are aligned parallel to the current. They are used most often to protect eroding banks and to form a smooth bank line. Petersen 1986 classifies revetments into the following types: (1) standard revetment with mattresses (e.g., gabions); (2) woven wooden mattresses; (3) articulated concrete mattresses; (4) standard trench-fill revetments; (5) pile revetments; and (6) stone-fill revetments. Biomattresses are also used to promote vegetation on banks.

**8.7.2.2 Dikes, Submerged Vanes, Bendway Weirs** Dikes, submerged vanes, and bendway weirs are structures placed at

an angle to a current. They are typically used for (1) fairing out sharp bends to a larger radius of curvature to provide a more desirable channel alignment (and thus stabilize concave banks); (2) closing off secondary channels and old bend ways; (3) redistributing flow within a channel cross section (for example, to constrict a channel to increase depth in certain areas or to concentrate a braided river into a single channel); and (4) protecting bridges, utility crossings, and structures along the bank.

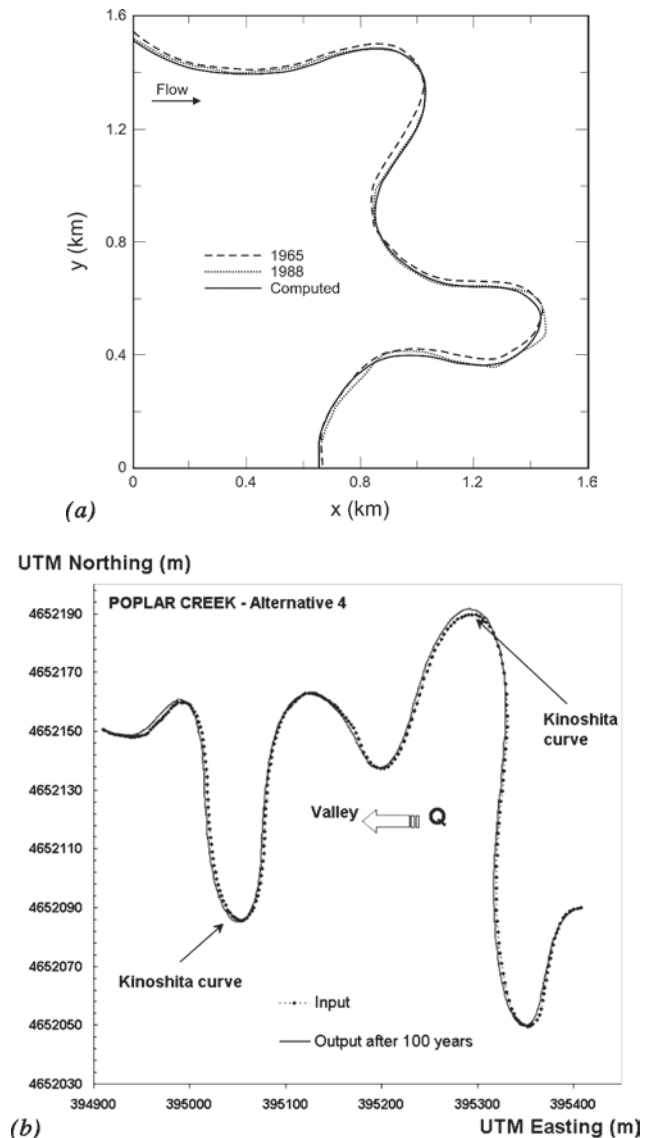

Most dikes are made with stone fill, but other materials are used. Petersen (1986) provides a comprehensive review of standard techniques. The submerged vane technique has received less coverage in the literature and will be described in more detail in a subsequent section. The technique for bendway weirs also has received little coverage so far. Made of rocks, they function like dikes. They are oriented upstream, at an angle with the bank of, typically,  $60^\circ$  to  $80^\circ$ . Reference is made to Pokrefke (1993) and U.S. Army Corps of Engineers (2002).

**8.7.2.3 Dredging** Dredging is the process of moving material from one part of a channel to another or to a disposal site on land. It is used most often for deepening or widening navigation channels or for land reclamation. This technique is also described in detail in Petersen (1986).

### 8.7.3 Submerged Vanes

Submerged vanes are small flow-training structures (foils) designed to modify the near-bed flow pattern and redistribute flow and sediment transport within the channel cross section. The structures are installed at an angle of attack  $15^\circ$  to  $25^\circ$  with the flow, and their initial height is 0.2 to 0.4 times local water depth at the design stage. The vanes function by generating secondary circulation in the flow (Fig. 8-14). The circulation alters the magnitude and direction of the bed shear stresses and causes a change in the distribution of velocity, depth, and sediment transport in the area affected by the vanes. As a result, the riverbed aggrades in one portion of the channel cross section and degrades in another (Fig. 8-15).

Vanes or panels for flow training have been discussed previously by Potapov and Pyshkin (1947); Potapov (1950, 1951); Chabert et al. (1961); and Jansen et al. (1979). However, it is only recently that efforts have been made to optimize vane design and document performance. The first known attempts to develop a theoretical design basis were those of Odgaard and Kennedy (1983) and Odgaard and Spoljaric (1986). Odgaard and Kennedy's efforts are aimed at designing a system of vanes to stop or reduce bank erosion in river curves. In such an application, the vanes are laid out so that the vane-generated secondary current eliminates the centrifugally induced secondary current, which is the root cause of bank undermining. Centrifugally induced secondary current in river bends results from the difference in centrifugal acceleration along a vertical line in the flow because of the nonuniform vertical profile of the velocity. The sec-

**Fig. 8-12.** (a) Simulation of the evolution of the Big Muddy River, Illinois (from Garcia et al. (1994)); (b) prediction of planform migration for Poplar Creek, Illinois (from Abad and Garcia (2006)).

ondary current forces high-velocity surface current outward and low-velocity near-bed current inward. The increase in velocity at the outer bank increases the erosive attack on the bank, causing it to fail. By directing the near-bed current toward the outer bank, the submerged vanes counter the centrifugally induced secondary current and thereby inhibit bank erosion. The vanes can be laid out to make the water and sediment move through a river curve as if it were straight. Figure 8-15 shows a typical layout, and Fig. 8-16 indicates the primary design variables. Field tests with this application have been conducted by Odgaard and Mosconi (1987); Fukuoka and Watanabe (1989); and others. Figure 8-17(a) shows vanes being installed in a bend of the Wapsipicon River, Iowa, in the summer of 1988 during low flow. Figure 8-17(b) shows the same bend 2 years later.

**Fig. 8-13.** Schematic of flow situation showing vane-induced circulation.

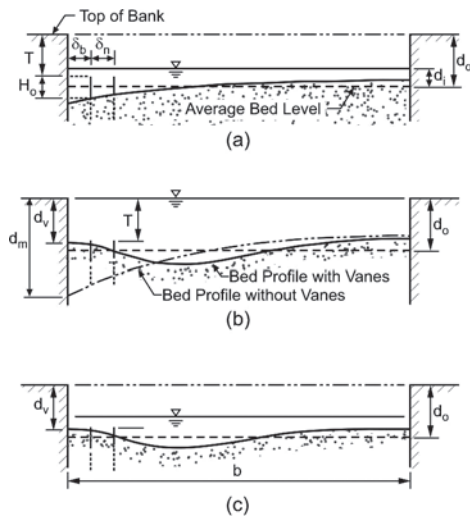

**Fig. 8-14.** Schematic showing vane-induced circulation.

**Fig. 8-15.** Layout of vane systems in a curved channel.

The technique has been further developed to ameliorate shoaling problems in rivers. This application is suggested by laboratory tests by Odgaard and Spoljaric (1986), in which vanes were laid out to change the cross-sectional profile of the bed in a straight channel. The tests showed that significant changes in depth could be achieved without causing significant changes in cross-sectional area, energy slope, or downstream sediment transport. The changes in cross-sectional average parameters are small because the vane-induced secondary current changes the direction of the bed shear stresses by only a small amount.

Further field and laboratory studies (Odgaard and Wang 1991a; 1991b; Pokrefke 1993; Wang et al. 1996; Sinha and Marelus 2000; Zijlstra 2003; Van Zwol 2004) and three-dimensional numerical modeling of the flow around vanes

## CHAPTER 9

### *Stream Restoration*

*F. Douglas Shields, Jr., Ronald R. Copeland, Peter C. Klingeman,  
Martin W. Doyle, and Andrew Simon*

#### 9.1 INTRODUCTION

##### 9.1.1 Scope

This chapter describes the application of the principles described elsewhere in this manual to a special class of engineering problems: stream restoration. Basic concepts are presented first in a qualitative discussion of “big ideas” rather than technical “how-to” guidance. This is followed by a description of how to prepare and execute a sediment studies plan for a stream restoration project. The generic approach described here may be too elaborate for small-scale, simple projects, but is less complex than needed for systemic types of restoration that aim to promote fundamental shifts in fluvial characteristics. However, some sedimentation analysis is needed for all stream restoration projects. Analytical tools useful for restoration analysis range from empirical relationships many decades old to recently developed science. References are provided in lieu of a full description of some of the analytical tools.

##### 9.1.2 Basic Concepts

**9.1.2.1 Definitions** The term “river restoration” is used to refer to a wide spectrum of activities (Table 9-1). Definition of terms is an essential starting point, because the engineer must be able to communicate clearly with project stakeholders to create realistic expectations for project outcomes. Stakeholders may prefer to call a project “restoration,” when in fact it is something else (e.g., an effort to improve aesthetics). No harm is done if everyone understands that the project will not restore a preexisting ecosystem. Whereas restoration aims to return an ecosystem to a former condition, rehabilitation and reclamation imply putting a landscape to a new or altered use to serve a particular human purpose. Restoration is not preservation, which keeps conditions in their current state, nor

is it naturalization, which targets socially desirable improvement, but not a preexisting state. True restoration may be thought of as an attempt to return an ecosystem to its historic (predegradation) trajectory (SER 2002). Although this “trajectory” may be impossible to determine with accuracy, the general direction and boundaries may be established through a combination of information about the system’s previous state, studies on comparable intact ecosystems, information about regional environmental conditions, and analysis of other ecological, cultural, and historical reference information (SER 2002). In this chapter, “restoration” refers to restoration, rehabilitation, and components of the other activities listed in Table 9-1 that lead to partial recovery of predisturbance ecosystem functions and attributes.

- In practice, river restoration projects are either targeted at entire watersheds or at reaches of channel 20 to 100 channel widths long, or more local measures to control erosion of gullies, zero-order tributaries, or single bends (Shields et al. 1999). Smaller-scale local measures are nested within reach-scale projects, whereas watershed restoration projects include reach-scale efforts and/or activities and programs designed to fundamentally impact land use and management (Williams et al. 1997). Watershed-scale actions are generally preferred from an engineering and ecological perspective because they have the greatest potential to influence fundamental causes of degradation. Fluvial processes operating at landscape or watershed scale can govern system response at smaller scales. However, economic and political factors usually dictate smaller-scale strategies for restoration projects. Local measures often used for restoration include erosion control structures (e.g., bank protection measures or grade control structures), floodplain and streambank revegetation, and habitat
