Sensory disturbance may be numbness or hypoaesthesia (a term that does not have a correlate in many languages), pain, pins and needles (paraesthesiae), heightened sensation (hyperaesthesia), prolonged painful responses (hyperpathia) or abnormal unpleasant sensations perceived from innocuous stimuli (allodynia) or combinations (e.g. a 'painful numbness'). Abnormal sensations are often described in colourful terminology such as 'like walking on shards of broken glass' or sponges or as if limbs 'were wrapped in cotton wool', '...hot boots' or '...gripped in a vice'. Pain may have a number of qualities that can help the physician. For example, lancinating or shooting pain often associates with large fibre involvement and in the context of an apparent inherited neuropathy may suggest an abnormality in the *SPTLC-1* or *SPTLC-2* genes (see Autosomal dominant CMT2). Burning or stinging pain associates with small fibre involvement. The site of onset and subsequent progression help to differentiate the length dependent sensory neuropathy from the patchy multiple mononeuropathy or dermatomal radiculopathy.

**Table 10.1** (b) Innervations. Lower limb. The bold type indicates the predominant innervation of the muscle where that exists.

	Muscles innervated	Spinal roots
Femoral nerve	Iliopsoas	<b>L1, L2</b> , L3

	Peroneus longus	L5, S1
Peroneus brevis	L5, S1	

Weakness may be described in terms of handicaps ('I can no longer run for a bus' or 'I can no longer do up my zip fastener') or disability ('My foot flaps' or 'I cannot lift my arms'). The pattern of such deficits helps to point to polyneuropathy, multiple mononeuropathies or radicular involvement. Weakness should always be differentiated from fatigue.

Autonomic disturbances may be missed through lack of recognition of their importance (diarrhoea or bladder dysfunction) or social embarrassment (impotence) by the patient, often compounded by a doctor's unwillingness to enquire. More than infrequent postural hypotension with presyncope or syncope is seldom innocuous. Nocturnal diarrhoea, urinary hesitancy or urgency, impotence and reduced sweating or tearing often require a proactive line of questioning and should be taken seriously if answered in the affirmative.

The tempo of symptom onset is definitive in some conditions and highly useful in the diagnosis of others. In the inflammatory neuropathies accurate determination of the time to the nadir of a first episode distinguishes between Guillain-Barré syndrome (GBS), subacute and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) and subsequently determines the selection of treatment. Likewise, a progressive sensory neuropathy with autonomic involvement that has evolved over 7 years is

unlikely to be amyloid or paraneoplasia. Furthermore, relapses and remissions (whether spontaneous or following treatment) may favour one diagnosis over another (e.g. CIDP over GBS or an inflammatory neuropathy over a metabolic cause).

The pattern of weakness or sensory loss is a clue to the site of pathology and often to a pathogenic mechanism. It is important to establish the pattern of involvement as symmetrical, asymmetrical, focal, multi-focal, monomelic or upper or lower limb predominant and any transition from one to another (e.g. multi-focal to symmetrical in vasculitides).

Cranial nerve involvement is important to identify as some conditions have a predilection for one or more cranial nerves (e.g. sarcoidosis and Sjögren's syndrome). Phrenic nerve and diaphragmatic involvement may be disclosed with a history of orthopnoea, early morning headaches or daytime somnolence. A failure to recognise this may lead to a silent and unnecessary death.

Parts of the history, which at first sight may not seem relevant either to the patient or the doctor, are sometimes more important than the reported symptom complex. Other concurrent or previous diseases should not necessarily be assumed at face value and should be chased down and checked. For example, a diagnosis of 'asthma', so often reported, when established as relatively recent in an older person may give the clue to Churg-Strauss syndrome or if misattributed to lung disease may give the clue to cardiac involvement in amyloidosis.

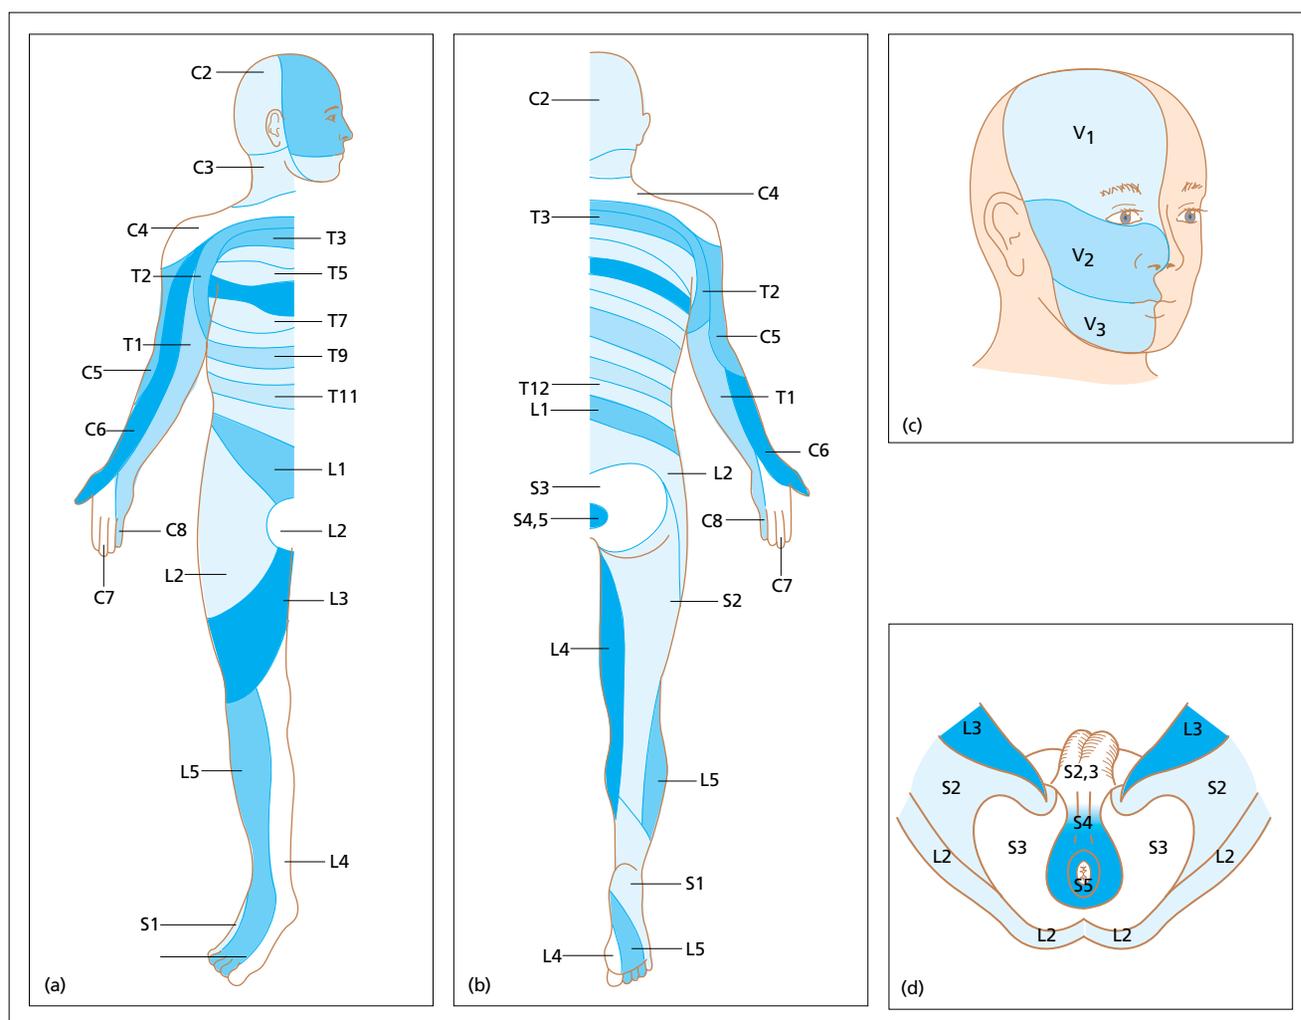

An extensive multi-generational family history including details such as consanguinity, non-paternity, early infant death or adoption is crucial to identifying reduced penetrance or recessive disorders. In genetic disorders, careful probing of early and developmental history will often establish a relevant history of symptoms pre-dating the apparent onset of the condition (lack of interest in sport or numbness of the feet after wearing high heels) by a decade or more.

In all situations, exposures to other agents through sex, travel, insect, animal, toxin or drug exposures, should be sought. A systematic and thorough search for other systemic clues should be made, enquiring about skin and nails, joints, sicca symptoms, weight loss and appetite, masses, eyes and other body systems not covered by previous enquiry.

### Examination

On inspection the examiner is looking for classic deformities such as pes cavus (Figure 10.9) or other indicators of diagnosis such as amputations, ulceration, wasting (or prominent lack of wasting in conditions with conduction block), trophic skin changes and fasciculations. Tremor usually occurs in demyelinating disease. Thickened nerves (Figure 10.10; Table 10.2) may be visible, but should be sought and palpated for. Common sites are the ulnar, superficial radial, greater auricular, sural and peroneal nerves.

Examination of the gait can identify both subtle abnormalities of the PNS such as mild distal weakness, or associated features (e.g. ataxia or dystonias). Romberg's sign is of limited use but may be illuminating in sensory neuronopathies. Tone is usually normal or apparently 'reduced'. A careful and correctly performed quantitative motor examination (O'Brien 2010) is crucial to identify the pattern of root, plexus, nerve or muscle and CNS involvement. Some neuropathies are predominantly or entirely motor (Table 10.3) but most will involve both motor and sensory modalities. Reflex loss may be variable and may evolve (e.g. GBS). Careful documentation of sensory loss in each modality using vibration, proprioception, pain, temperature or tickle and light touch may again illuminate disease patterns and pathogenesis. These may be the only findings in some purely sensory neuropathies (Table 10.4).

**Figure 10.6** Dermatomes. (a) Anterior dermatomes, (b) Posterior dermatomes, (c) Trigeminal divisions, and (d) perineal dermatome. Source: O'Brien 2000. Reproduced with permission of The Guarantors of Brain.

A subsequent general examination should be thorough but tailored and include close inspection of fundi, skin, nails, joints, testes, breasts and a search for palpable nodes or organomegaly as well as a structured systems examination.

### Scores

The quantification of the examination findings by their incorporation or translation into one of the many available scoring systems is useful for documenting levels of impairment, disability and handicap at a point in time and following patients over the course of their disease or treatment. The use of standardised and validated scales is also useful in combining and comparing data in clinical trials. Commonly used scales are the MRC Scale (for assessment of power; Chapter 4), the Overall Neuropathy Limitation Score, the new Rasch-Built Overall Disability Score (R-ODS), the Modified Rankin Scale, the 10-metre walk time, the Walk-12 and the SF36.

### Neurophysiology

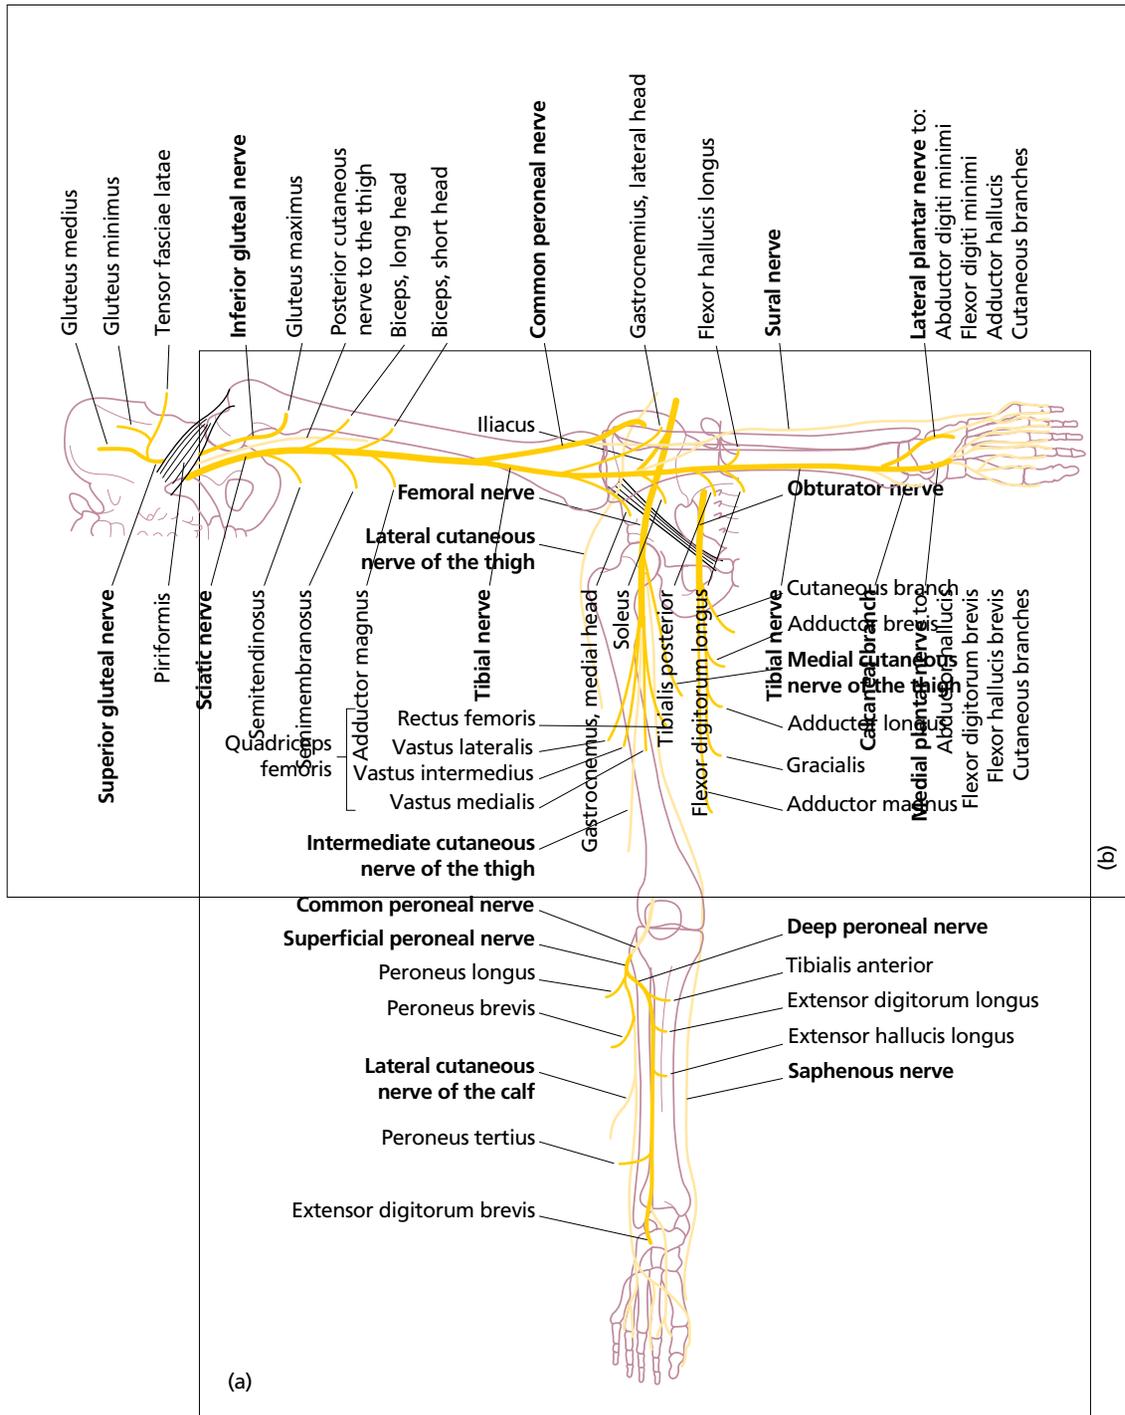

A neurophysiological examination should be regarded as an extension of the clinical examination (Chapter 4). If it is not performed by the examining physician then it should be performed with detailed communication between the neurologist and

neurophysiologist to ensure that problems and specific issues can be addressed and clarified. Conduction block may be particularly difficult to identify.

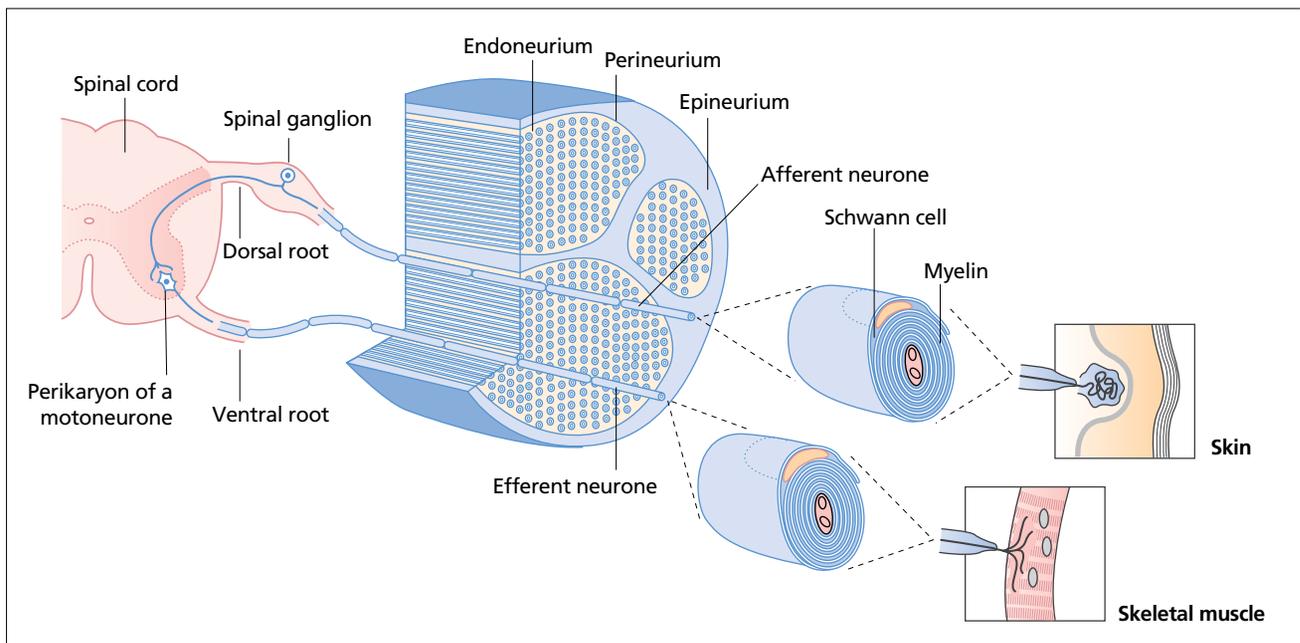

### Nerve biopsy

A nerve biopsy should be requested and performed only after careful consideration of the other options available to achieve a diagnosis. Biopsies are generally of sensory nerves, and usually a sensory nerve identifiably and recently affected; a neurophysiologically normal nerve should not be biopsied. The biopsy should be performed with informed patient consent; complications, especially of biopsy site pain, are not infrequent. The nerve biopsy should be performed by someone competent and experienced, as crush or diathermy artefact is easily caused and may render the biopsy uninterpretable. At least 4 cm should be excised for examination.

Staining and examination should again be carried out in consultation with a trained neurohistopathologist, preferably with specialist interest in peripheral nerve disease. Generic and specific tinctoric and immunohistochemical stains can be used to identify or exclude suspected pathologies and special preparation of parts of the specimen for electron microscopy or teased fibre studies should be requested and discussed beforehand.

**Figure 10.7** Nerves of the lower limb: (a) anterior aspect and (b) posterior aspect of the lower limb, their cutaneous branches and the muscles that they supply. Source: O'Brien 2000. Reproduced with permission of The Guarantors of Brain.

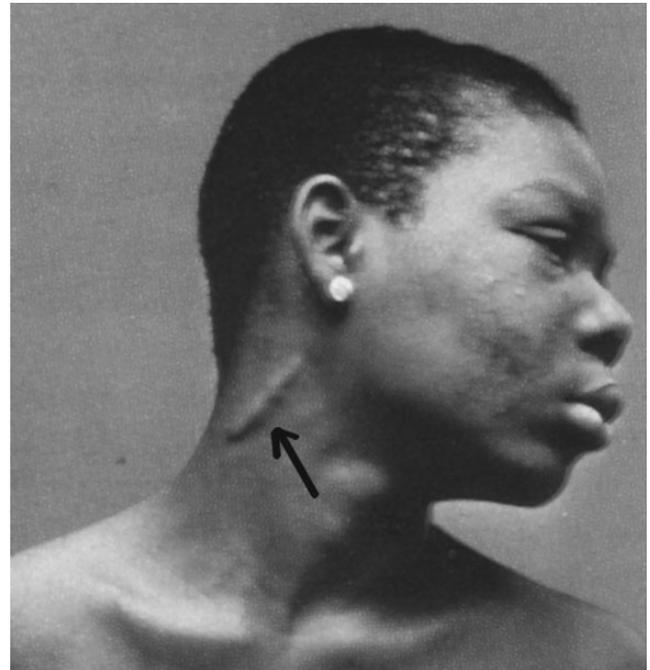

**Figure 10.8** Cross-section of nerve diagram. Axons are associated with Schwann cells which in some cases elaborate myelin. Neurones are gathered in fascicles limited by a perineurial sheath. The endoneurium also contains supporting stromal cells endoneurial vessels and, in health, low numbers of immune cells including resident macrophages and mast cells. Fascicles are grouped into nerves limited by the epineurium.

**Figure 10.9** The typical lower limb appearances of CMT1A with distal wasting, pes cavus and clawed toes.

### Inherited neuropathies

The inherited neuropathies can be divided into those in which the neuropathy is the sole or primary part of the disease and those in which the neuropathy is part of a more widespread neurological or multi-system disorder (Table 10.5). The first group includes Charcot-Marie-Tooth disease (CMT). CMT is the most common inherited neuropathy affecting approximately 1/2500 in the Caucasian population, and usually presents with a length dependent motor and sensory neuropathy. Most of the other neuropathies in this group are either genetically related to CMT (e.g. hereditary neuropathy with liability to pressure palsies) or can

**Figure 10.10** Thickened nerves. Source: Forbes 1993. Reproduced with permission of Elsevier.

present in a similar fashion (e.g. hereditary sensory neuropathy [HSN] and distal hereditary motor neuropathy [HMN]). This group also includes hereditary neuralgic amyotrophy (HNA) which presents with recurrent brachial plexus lesions and familial

Friedreich's ataxia
Spinocerebellar ataxias
Miscellaneous

amyloid polyneuropathy (FAP), a disease in which neuropathy (often including autonomic neuropathy) is the cardinal feature although other systems can be involved (e.g. heart).

The second group is a very large varied group of disorders that usually also involve the CNS (e.g. leukodystrophies, spinocerebellar ataxias) or where systems other than the nervous system are significantly involved (e.g. mitochondrial disorders and porphyrias). Many of these disorders have been covered elsewhere in this book and will not be dealt with in this chapter which concentrates on the first group where the neuropathy is the sole or primary part of the disease.

Although this classification is still very useful, next generation sequencing (NGS) techniques has identified genes that normally cause a complex neurological syndrome which includes neuropathy such as some forms of spinocerebellar ataxia, hereditary spastic paraparesis and mitochondrial diseases, but which can occasionally present with just a neuropathy and be diagnosed as CMT. This needs to be kept in mind in the evaluation of these patients.

The autosomal spinal muscular atrophies (SMA) and hereditary motor neurone disease is covered elsewhere in this chapter.

### Charcot–Marie–Tooth disease and related disorders

CMT disease is a group of neuropathies that are clinically and genetically heterogeneous (Table 10.6). They are also referred to as hereditary motor and sensory neuropathies (HMSN) although CMT is now the more commonly used term. CMT is characterised clinically by distal muscle wasting and weakness, reduced reflexes, impaired distal sensation and variable foot deformity, and neurophysiologically by a motor and sensory neuropathy. There is a wide variation in the age of onset and the severity of CMT, the variation depending to a large extent on the underlying genetic defect. CMT is a motor and sensory neuropathy that is closely related to two other rarer inherited neuropathies: the hereditary sensory neuropathies (HSN) also called the hereditary sensory and autonomic neuropathies, (HSAN; Table 10.7) that either only involve sensory nerves or where sensory involvement predominates, and

the hereditary motor neuropathies HMN, (Table 10.8) in which there is only motor involvement. These three disorders (CMT, HSN and HMN), often collectively termed CMT, and related disorders represent a continuum from pure motor neuropathy (HMN) through to motor and sensory neuropathy (CMT) and to sensory predominant and pure sensory neuropathy (HSN). Some recently described causative genes for axonal CMT also cause forms of distal HMN. Certain forms of CMT and HSN are very difficult to distinguish clinically. Therefore, the same phenotypes may be caused by different genes and the same gene may cause different neuropathy phenotypes. Technology is now advanced enough using NGS techniques to allow the rapid screening in an individual patient of all genes identified so far. Therefore, classification systems (Table 10.6, Table 10.7 and Table 10.8) based on clinical features including neurophysiology and neuropathology as well as the genetic cause, when known, is the most useful current classification for the practising clinician. The rate of discovery of new causative genes for CMT and related disorders has increased dramatically with the advent of NGS techniques with over 75 causative genes now reported (Figure 10.11). The genes listed in Table 10.6, Table 10.7 and Table 10.8 although comprehensive currently will need constant updating as new genes are identified. Despite this long list of causative genes, multiple studies in the United Kingdom, United States and northern European countries have shown that mutations in four genes (*PMP22*, *GJB1*, *MPZ* and *MFN2*) account for over 90% of patients receiving a genetic diagnosis. It is beyond the scope of this chapter to discuss all types of CMT; a general overview and the phenotypes of most frequent types are given.

### An approach to the diagnosis of CMT and related disorders

**1** *Is the neuropathy hereditary?* When a patient attends with an obviously affected family member or there is a positive family history, a genetic neuropathy is likely. Unfortunately, many patients are from small sibships (especially in the United Kingdom, United States and northern Europe) and extensive family histories are often not available. Furthermore, rates of non-paternity in Western societies are reported to be approximately 10% and *de novo* dominant mutations are not uncommon in CMT. Factors that may help the clinician decide that the neuropathy in 'sporadic' patients is hereditary include:

- A long, slowly progressive history.
- The presence of foot deformity such as pes cavus in an adult patient (Figure 10.9).
- The absence of positive sensory symptoms in patients with clear sensory signs.
- In the dominant demyelinating forms of CMT (CMT1), neurophysiology can be very useful in distinguishing hereditary from acquired neuropathies, as the motor conduction velocities are usually uniformly slow in the common hereditary neuropathies.

**2** *Classifying the neuropathy.* Is the neuropathy most compatible with CMT, hereditary neuropathy with liability to pressure palsies (HNPP), HSN or distal HMN?

- CMT is numerically the most likely diagnosis.
- CMT is a motor *and* sensory neuropathy although the patient may not have sensory symptoms and sometimes no sensory signs (the most sensitive sensory sign is a reduction in distal vibration sensation).
- Because distal HMN (Table 10.8) can be indistinguishable clinically from CMT it is often necessary to perform a neurophysiological examination to differentiate between these two conditions. The sensory action potentials (SAPs) should

**Table 10.6** Classification of Charcot–Marie–Tooth (CMT) disease.

Type	Gene / locus	Specific phenotype
<b>Autosomal dominant CMT1 (AD CMT1)</b>		
CMT1A	Dup 17p (PMP22) PMP22 (point mutation)	Classic CMT1 Classic CMT1 / DSD / CHN (rarely recessive)
CMT1B	MPZ	CMT1 / DSD / CHN / CMT2 (rarely recessive)
CMT1C	LITAF	Classic CMT1
CMT1D	EGR2	Classic CMT1 / DSD / CHN
CMT1F	NEFL	CMT2 but can have slow MCVs in CMT1 range ± early onset severe disease (rare AR CMT2 cases described)
CMT1 plus	FBLN5	CMT1 plus macular degeneration, cutis laxa / HMN
<b>Hereditary neuropathy with liability to pressure palsies (HNPP)</b>		
HNPP	Del 17p (PMP-22) PMP-22 (point mutation)	Typical HNPP Typical HNPP
<b>Autosomal recessive CMT1 (CMT4 / AR CMT1)</b>		
CMT4A	GDAP1	CMT1 or CMT2 usually early onset and severe / vocal cord and diaphragm paralysis described (rare AD CMT2 families described)
CMT4B1	MTMR2	Severe CMT1 / facial / bulbar / focally folded myelin
CMT4B2	SBF2	Severe CMT1 / glaucoma / focally folded myelin
CMT4B3	SBF1	CMT1 / focally folded myelin
CMT4C	SH3TC2	Severe CMT1 / scoliosis / cytoplasmic expansions
CMT4D (HMSNL)	NDRG1	Severe CMT1 / gypsy / deafness / tongue atrophy
CMT4E	EGR2	CMT1 / DSD / CHN phenotype
CMT4F	Periaxin	CMT1 / more sensory / focally folded myelin
CMT4G (HMSN Russe)	HK1	Severe early onset CMT1; gypsy
CMT4H	FGD4	Classic CMT1
CMT4J	FIG4	CMT1 / predominantly motor / progressive
CCFDN	CTDP1	CMT1 / gypsy / cataracts / dysmorphic features
CMT4	SURF1	CMT1 / lactic acidosis / abnormal brain MRI / cerebellar ataxia
AR CMT1	PMP22 (point mutation)	Classic CMT1 / DSD / CHN
AR CMT1	MPZ	CMT1 / DSD / CHN / CMT2
<b>Autosomal dominant CMT2 (AD CMT 2)</b>		
CMT2A	MFN2	Classic CMT2 / more progressive / optic atrophy (rarely recessive)
CMT2B	RAB7	CMT2 with predominant sensory involvement and sensory complications
CMT2C	TRPV4	CMT2 with vocal cord and respiratory involvement / congenital distal SMA
CMT2D	GARS	CMT2 with predominant hand wasting / weakness or distal HMN5
CMT2E	NEFL	CMT2 but can have slow MCVs in CMT1 range ± early onset severe disease (rarely recessive)
CMT2F	HSPB1	Motor predominant CMT2 or distal HMN2B

Table 10.6 (continued)

Type	Gene / locus	Specific phenotype
CMT2I	MPZ	Late onset CMT2
CMT2J	MPZ	CMT2 with hearing loss and pupillary abnormalities
CMT2K	GDAP1	Classic CMT2 (dominant); severe CMT2 (recessive)
CMT2L	HSPB8	Motor predominant CMT2 or distal HMN2A
CMT2M	DMN2	CMT2 or intermediate CMT / cataracts / ophthalmoplegia / ptosis
CMT2O	DYNC1H1	Motor predominant CMT2 / learning difficulties
CMT2P	LRSAM1	CMT2 (can be recessive)
CMT2Q	DHTKD1	CMT2
CMT2	MARS	Late onset CMT2
CMT2	HARS	CMT2
HMSNP	TFG	CMT2 with proximal involvement
SPG10	KIF5A	CMT2 / hereditary spastic paraparesis
CMT2	MT-ATP6	CMT2 / ptamidal signs / relapsing
<b>Autosomal recessive CMT2 (AR CMT2)</b>		
CMT2B1	LMNA	CMT2 proximal involvement and rapid progression described / also causes muscular dystrophy / cardiomyopathy / lipodystrophy
CMT2B2	MED25	Classic CMT2
CMT2H	GDAP1	CMT2 or CMT1 usually early onset and severe / vocal cord and diaphragm paralysis described (rare AD CMT2 families described)
AR CMT2	LRSAM1	Classic CMT2
AR CMT2	TRIM2	Early onset CMT2
AR CMT2	HADHB	Early onset CMT2
AR CMT2	C12 or f65	CMT2 plus optic atrophy / pyramidal signs
<b>X-linked CMT</b>		
CMTX1	GJB1	Males CMT1 (patchy NCV); females CMT2
CMTX4 (Cowchock syndrome)	AIFM1	CMT2; infantile onset, developmental delay, deafness, learning difficulties
CMTX5	PRPS1	CMT2; deafness, usually optic atrophy
CMTX6	PDK3	CMT2
<b>Dominant intermediate CMT (DI-CMT)</b>		
CMTD1B	DNM2	Intermediate CMT or CMT2; cataracts; ophthalmoplegia; ptosis
CMTDIC	YARS	Intermediate CMT
CMTDID	MPZ	Intermediate CMT
CMTDIE	INF2	Intermediate CMT; focal segmental glomerulosclerosis; end-stage renal failure
CMTDIF	GNB4	Intermediate CMT

CMTR1B	KARS	Intermediate CMT; learning difficulties; vestibular Schwannoma
PRI-CMT	PLEKHG5	Intermediate CMT; SMA
<b>Hereditary neuralgic amyotrophy</b>		
	SEPT9	Recurrent neuralgic amyotrophy

AD, autosomal dominant; AR, autosomal recessive.

**Table 10.7** Classification of the hereditary sensory neuropathies (HSN/HSAN).

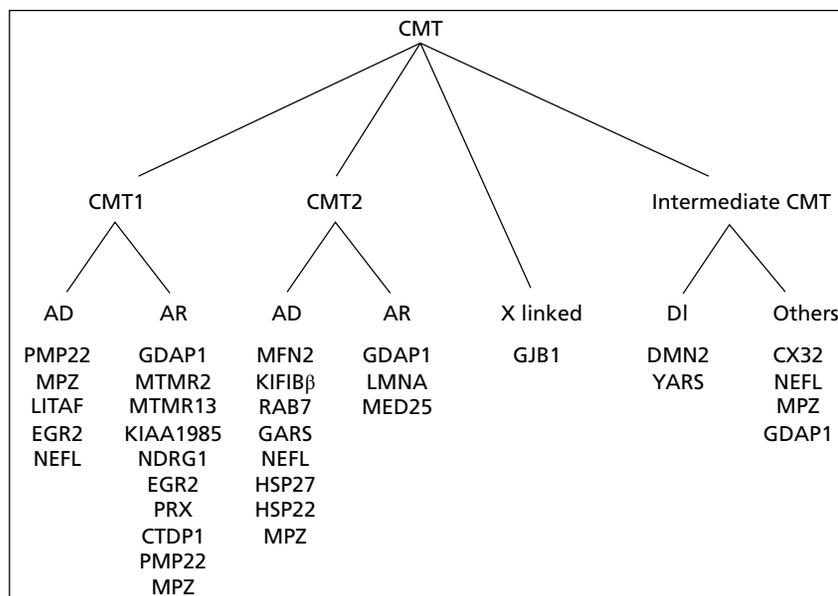

Type	Inheritance	Gene/locus	Specific phenotype
HSN1A	AD	SPTLC-1	Mainly sensory, sensory complications Occasionally motor early, males more severe
HSN1C	AD	SPTLC-2	Mainly sensory, sensory complications Occasionally motor early
CMT2B	AD	RAB7	Sensorimotor, sensory complications
HSN1D	AD	ATL1	HSN with sensory complications/hereditary spastic paraparesis
HSN1E	AD	DNMT1	HSN; deafness; dementia
HSN2A	AR	WNK1	HSN with severe sensory complications, mutilations
HSN2B	AR	FAM134B	HSN with sensory complications
HSN2C	AR	KIF1A	HSN with sensory complications
HSN2D	AR	SCN9A	Congenital insensitivity to pain (dominant mutations paroxysmal extreme pain disorder; primary erythralgia; small fibre neuropathy)
HSN3	AR	IKBKAP	Familial dysautonomia or Riley–Day syndrome Prominent autonomic, absence fungiform papillae of the tongue
HSN4	AR	NTRK1	Congenital insensitivity to pain with anhidrosis (CIPA) with severe sensory involvement, anhidrosis, mental retardation Unmyelinated fibres mainly affected
HSN5	AR	NGFB	Congenital insensitivity to pain, minimal autonomic No mental retardation Mainly unmyelinated fibres affected
HSN6	AR	DST	HSAN
HSN	AR	CCT5	HSN with spastic paraplegia
HSN	AD	PRNP	HSAN; autonomic dysfunction; dementia
HSAN	De novo dominant	SCN11A	HSAN

AD, autosomal dominant; AR, autosomal recessive.

**Table 10.8** Classification of the distal hereditary motor neuropathies (distal HMN).

Type	Inheritance	Gene/locus	Specific phenotype
HMN 2A	AD	HSPB8	Classic distal HMN/CMT2F
HMN 2B	AD	HSPB1	Classic distal HMN/CMT2L
HMN2C	AD	HSPB3	Classic distal HMN
HMN	AD	SETX	Distal HMN with pyramidal features
HMN	AR	DNAJB2	Classic distal HMN
HMN5A	AD	BSCL2	Upper limb predominant; Silver syndrome; occasional mild sensory
HMN5A	AD	GARS	Upper limb predominant; occasional early onset
HMN5B	AD	REEP1	Predominant hand wasting; pyramidal signs
HMN6	AR	IGHMB2	Spinal muscle atrophy with respiratory distress (SMARD1), infantile onset respiratory distress
HMN7A	AD	SLC5A7	Adult onset, vocal cord paralysis
HMN7B	AD	DCTN1	Adult onset, vocal cord paralysis/facial weakness
SMAX3	X-linked	ATP7A	Classic distal HMN
SMALED	AD	DYNC1H1	Congenital; contractures; lower limb predominant; cortical migration defects; learning difficulties
SMALED	AD	BICD2	Congenital; contractures; lower limb predominant; late pyramidal signs
HMN	AD	TRPV4	HMN; scapular winging; vocal cord paralysis; can be congenital
HMN	AD	AARS	Classic distal HMN
HMN	AD	HINT1	Distal HMN; neuromyotonia
HMN	AD	FBOX38	Distal HMN with calf predominance

AD, autosomal dominant; AR, autosomal recessive.

always be involved (reduced or absent) in CMT and normal in distal HMN.

- The neuropathy of HNPP is usually easily distinguished from CMT as the patient normally has a history of recurrent pressure palsies but may later accumulate neurological deficits. The neurophysiological findings are usually patchier in HNPP than in the common forms of CMT1.
- Most forms of HSN (Table 10.7) have more sensory and in some forms autonomic involvement and less motor involvement than CMT. The presence of neuropathic pain makes HSN1 secondary to *SPTLC* mutations more likely and is a useful differentiating feature.
- Additional features such as upper motor neurone signs can be found in certain forms of CMT, HSN and distal HMN.

### Charcot–Marie–Tooth disease

CMT disease is the most common of the hereditary neuropathies. The classification of CMT is in a state of constant flux reflecting the rapid advances in the identification of the underlying causative genes. Despite the rapid genetic advances the most useful method of classification for clinicians is a combination of clinical presentation, neurophysiology and inheritance pattern combined with the causative gene when known (Table 10.6).

CMT is classified as either demyelinating (CMT1) if the median (or ulnar) nerve motor conduction velocity (MCV) is <38 m/s or axonal (CMT2) if the median MCV is >38 m/s (Table 10.6). The concept of an intermediate form of CMT with median MCVs in the intermediate range (25–45 m/s) has been around since the 1970s and although sometimes out of favour it can be helpful in directing genetic diagnosis.

The inheritance pattern may not be clinically obvious until a genetic diagnosis has been established as *de novo* dominant mutations, autosomal recessive (AR) mutations and other factors may obscure it. In most UK, north European and US populations where there are few consanguineous marriages, about 90% of cases of CMT are either autosomal dominant (AD) or X-linked; the ethnic background of the population should always be taken into account.

### Autosomal dominant CMT1

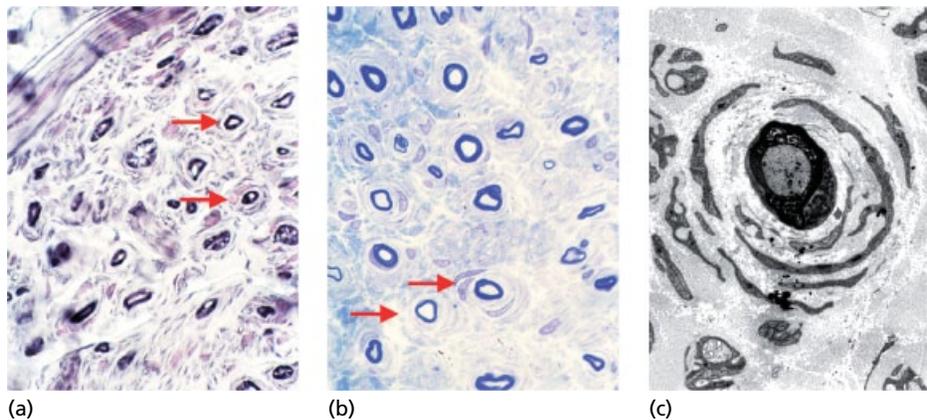

**Classic CMT1** The most common form of CMT in most populations is AD CMT1; patients usually present with a 'classic CMT' phenotype in the first two decades with motor symptoms in the lower limbs, for example difficulty walking or foot deformity. On examination, they have evidence of distal wasting and weakness and hyporeflexia affecting the lower limbs to a greater extent than the upper limbs. Distal sensory loss and foot deformity are frequent findings. Neurophysiologically, the median MCVs are <38 m/s and the SAPs are either reduced or absent. Nerve biopsies are no longer necessary to make the diagnosis but if performed show a demyelinating neuropathy with classic onion bulbs (Figure 10.12).

If there is a clear family history of AD inheritance, or if the patient is apparently 'sporadic', then the most likely diagnosis is CMT1A secondary to a duplication of the peripheral myelin protein 22 gene (*PMP22*). In a European population this duplication accounts for 70% of all CMT1 cases. Point mutations in the *PMP22* gene can also cause CMT1A but a wider spectrum of phenotypes is described with these.

CMT1B is less common and is caused by mutations in the myelin protein zero gene (*MPZ*). Patients may present with the classic CMT1 phenotype but are more likely to present with either a more severe, early onset form of CMT1 or a much milder, late onset form of CMT with median MCVs in the axonal range. As a result patients with *MPZ*-related CMT can be classified as CMT1, intermediate CMT or CMT2, depending on the MCVs.

Mutations in *EGR2* and *LITAF* are very rare and account for fewer than 1% of cases each and have no particular distinguishing features. Mutations in *NEFL* (neurofilament light polypeptide) were originally described as a cause of CMT2. Some patients with *NEFL* mutations have median MCVs in the demyelinating range and so patients with *NEFL*-related CMT can be classified as CMT1, intermediate CMT or CMT2, depending on the MCVs.

**Severe CMT1 (HMSN III, Dejerine–Sottas disease, congenital hypomyelinating neuropathy)** The severe cases of CMT1 used to be called HMSN III in older classifications and were subdivided into Dejerine–Sottas disease (DSD) and congenital hypomyelinating neuropathy (CHN) depending on the underlying pathology. They

**Figure 10.12** Charcot–Marie–Tooth type 1a with formation of onion bulbs. (a) Paraffin section (transverse) shows concentric formations (arrows) with a reduction of fibre density. The interstitial space is widened, indicating an oedema with a mucoid component. (b) Semithin resin section (toluidin blue) confirms the abundant presence of onion bulbs (arrows). (c) Electron microscopy of the same nerve with concentric arrangement of Schwann cells around myelinated axons. The Schwann cells appear as plump, elongated and rounded stacks, separated by longitudinally oriented collagen fibres (light grey).

usually present in the first decade with very slow MCVs and a more severe neuropathy than classic CMT1. It was thought that most of these cases were recessive but we now know they are usually secondary to *de novo* dominant mutations in the three genes that commonly cause AD CMT1 (*PMP22*, *MPZ*, *EGR2*). Mutations in these three genes, which cause the DSD/CHN phenotype, can also occasionally be inherited in an AR fashion (Table 10.6). Some of the other genes that cause recessive CMT1 can present with a similar phenotype (see Autosomal recessive CMT1 and Table 10.6).

**Hereditary neuropathy with liability to pressure palsies** HNPP is an AD condition usually caused by a deletion of the same portion of chromosome 17 as is duplicated in CMT1A. Point mutations in *PMP22* can also rarely cause HNPP. Most patients with HNPP present with episodic recurrent pressure palsies, although atypical presentations have been described. Diagnostically, an important point is that although patients may present with only one nerve clinically involved at a particular time, there is always a more generalised patchy demyelinating neuropathy neurophysiologically. Screening for the chromosome 17 deletion is therefore not warranted in isolated pressure palsies that do not have electrophysiological abnormalities outside the clinically involved nerve.

**X-linked CMT1** The X-linked form of CMT1 is caused by mutations in the gap junction  $\beta 1$  gene (*GJB1*) which codes for connexin 32. This is the second most common form of CMT. Over 300 mutations have been described in *GJB1*. Males are more severely affected than females. The MCVs in affected males are usually in the demyelinating range. Conversely, the MCVs in the females are usually in the axonal range but can be in the demyelinating range. Connexin 32 related CMT is therefore another form of intermediate CMT.

Patients (especially males) can have a rather patchy neuropathy both clinically and neurophysiologically with less uniform conduction slowing, differences in conduction velocities between nerves (e.g. ulnar and median) and more pronounced dispersion than that seen with AD CMT1. This can lead to difficulties in diagnosis in patients without a family history and occasionally to patients being diagnosed with CIDP, leading to unnecessary immunosuppressive therapy. CNS involvement is occasionally seen and is usually mild (extensor plantars, mild deafness, abnormal brainstem evoked potentials). A useful clue diagnostically is that abductor pollicis brevis is usually more wasted, weaker and has a lower compound muscle action potential (CMAP) than the first dorsal interosseous (the so-called split hand syndrome).

**Autosomal recessive CMT1** In communities where consanguinity is high AR CMT may account for 30–50% of all CMT cases. There are now 15 genes described that can cause AR CMT1 (including the three genes *PMP22*, *MPZ* and *EGR2* that more commonly cause AD or *de novo* dominant CMT1). AR CMT1 is also commonly called CMT4 and the various forms are classified as CMT4A, CMT4B, etc.

Unfortunately, there is no one gene that is a major cause of AR CMT1/CMT4 which makes the diagnosis difficult for the clinician presented with a patient with presumed AR CMT1/CMT4.

Although no one algorithm is suitable for the diagnosis of AR CMT1/CMT4, there are some clinical indicators that can be used to aid diagnosis. These indicators are still pertinent in the era of NGS as often more than one variant is identified in multiple candidate genes in a patient and clinical features are invaluable in helping decide the most likely causative gene.

**1** As a general rule, AR forms of CMT have an earlier onset and are more severe than AD cases. They usually start as a length depend-

ent neuropathy but are more likely to progress to involve the proximal muscles and to result in loss of ambulation than AD patients. Associated clinical features, the ethnic background of patients and specific neuropathological features can aid the diagnosis (Table 10.6).

**2** Neurophysiology may be difficult, as in severe cases all the nerves may be inexcitable although proximal nerves such as the axillary and facial nerves can sometimes be studied. In the cases where neurophysiology is not useful, nerve biopsies can be particularly helpful. Biopsy is also more useful in AR CMT1/CMT4 in general than in AD CMT1 as specific features in nerve biopsies may make a particular genetic diagnosis more likely (e.g. cytoplasmic processes in CMT4C). This is the major diagnostic use for nerve biopsy in genetic neuropathies.

**3** Specific phenotypes in AR CMT1 (CMT4) are recognised:

- CMT4A secondary to mutations in *GDAP1* is usually an early onset progressive neuropathy and can be associated with diaphragmatic and vocal cord involvement. Mutations in *GDAP1* can also cause AR CMT2 and even more rarely AD CMT2, making *GDAP1*-related CMT another intermediate form of CMT.
- Nerve biopsies showing focally folded myelin are characteristic of CMT4B1 (*MTMR2* mutations), CMT4B2 (*SBF2* mutations) and CMT4B3 (*SBF1* mutations) although this finding has also been described with *MPZ* mutations and in CMT4F secondary to periaxin mutations.
- Severe and early scoliosis is seen with CMT4C secondary to mutations in the *SH3TC2* gene. Patients with mutations in this gene also have characteristic nerve biopsy features including basal membrane onion bulbs and multiple cytoplasmic processes of the Schwann cells of unmyelinated axons.
- Three forms of AR CMT1 are largely confined to patients of Balkan Romany origin. CMT4D secondary to *NDRG1* mutations is characterised by a demyelinating neuropathy with a high incidence of deafness. Tongue atrophy has also been described in this form of CMT. Another form of AR CMT1 seen in this Romany population is CCFDN (congenital cataract, facial dysmorphism and neuropathy syndrome) secondary to *CTDP1* mutations. The third form of CMT in this population, HMSN Russe, is caused HK1 mutations.
- A phenotype ranging from a severe DSD type phenotype to a milder neuropathy with mainly sensory involvement is seen in CMT4F secondary to periaxin mutations.
- *FIG4* mutations (CMT4J) cause a severe and progressive demyelinating phenotype; patients can develop a rapid increase in weakness with acute denervation in one or more limbs mimicking an acquired inflammatory neuropathy. Although the acute denervation and rapidity of the evolution of weakness in these cases has also been described to mimic motor neurone disease, the slow conduction velocities and accompanying sensory involvement help to distinguish between these two diseases.

To summarise, although there are many different genes identified as causing AR CMT1 careful phenotyping of the patients together with consideration of the ethnic background can help guide the genetic diagnosis.

**Autosomal dominant CMT2** The true prevalence of CMT2 is not known. However, any adult presenting with a long-standing mild axonal neuropathy without an obvious family history and where an acquired cause has not been identified may have CMT2 but this is difficult to prove. Nineteen causative genes for AD CMT2 have been described (Table 10.6). These still account for less than 50% of

the total cases of AD CMT2 and, until all the causative genes for CMT2 are identified, we will not know the true prevalence of this condition.

Autosomal dominant CMT2 can broadly be divided into three different groups by phenotype which can be helpful in establishing the causative gene.

- 1 Most patients with AD CMT2 present with the 'classic CMT' phenotype, clinically indistinguishable from AD CMT1. The neurophysiology revealing an axonal sensorimotor neuropathy distinguishes between the two. Nerve biopsies are rarely performed in patients with AD CMT2 as a non-diagnostic axonal neuropathy is usually described. Many patients with the classic CMT2 phenotype do not have a genetic diagnosis although some have mutations in Mitofusin 2 (*MFN2*), the gene that accounts for approximately 20% of all cases of AD CMT2 in all populations tested so far. Patients with mutations in *MFN2* often present early and with a more severe phenotype with fairly rapid progression to proximal muscle involvement and loss of ambulation. Occasionally, patients may have brisk reflexes. Furthermore, approximately 20% of the mutations are *de novo*, explaining why so many of these patients have normal parents. Mutations in *MFN2* also cause axonal CMT with optic atrophy (HMSN VI in previous classifications). In patients with classic AD CMT2 and no mutation in *MFN2*, both *MPZ* and *NEFL* should be screened as they can cause this phenotype. Other genes listed in Table 10.6 are rare causes of the classic CMT2 phenotype.
- 2 The second phenotype seen with AD CMT2 has much more sensory involvement than is usually seen with CMT. These patients have been described as having an 'autosomal dominant inherited neuropathy with prominent sensory loss and ulceromutilating features'. They were originally classified as CMT2B. Presentation is in the second or third decade with typical motor CMT features but also severe sensory complications including ulcerations, osteomyelitis and amputations. The causative gene for CMT2B is *RAB7*. The presentation of these patients is also very similar to patients with HSN1 secondary to mutations in the *SPTLC-1* or *SPTLC-2* genes (Table 10.7; i.e. different genes, same phenotypes). Patients with *SPTLC-1* or *SPTLC-2* mutations usually have less motor involvement at presentation and also lancinating pain, an unusual feature in hereditary neuropathies. Sometimes conduction velocities can be in the demyelinating range in patients with *SPTLC-1* or *SPTLC-2* mutations and males are often more severely affected than females. There remain other families with this phenotype who do not have mutations in either *SPTLC-1*, *SPTLC-2* or *RAB7*, suggesting other unidentified genes can also cause this phenotype.
- 3 The third phenotype seen with AD CMT2 is a motor predominant phenotype where there is very little sensory involvement. Some patients with this phenotype have a typical length dependent motor predominant neuropathy with lower limbs more affected than upper limbs. Two genes, *HSPB1* and *HSPB8*, can cause this phenotype and these are of additional interest as they more commonly cause a purely motor phenotype, distal HMN type 2 (Table 10.8; i.e. same gene, different phenotype). A characteristic feature of the neuropathy associated with *HSPB1* and *HSPB8* is that ankle plantar flexion is usually affected early and is as severely affected as ankle dorsiflexion, unlike classic CMT where ankle dorsiflexion is involved much earlier and to a greater extent than ankle plantar flexion. Some patients with the motor predominant form of AD CMT2 have more more upper limb than lower limb involvement, classified as CMT2D. Patients were originally described presenting with wasting and weakness

of the small muscles of the hand (onset can also be unilateral and misdiagnosed as thoracic outlet syndrome) with much later involvement of the distal lower limb muscles. Interestingly, as with mutations in *HSPB1* and *HSPB8*, some of these patients had no sensory involvement and were classified as distal HMN type 5 (Table 10.8). CMT2D and distal HMN 5 have now been shown to be allelic with two causative genes identified for this phenotype, *GARS* and *BSCL2* although there are patients with this phenotype without mutations in either of these genes. Mutations in the *BSCL2* gene can also cause Silver's syndrome (spastic legs and distal amyotrophy of the upper limbs). Another interesting gene that cause either CMT2 or a hereditary motor neuropathy (which can be associated with scapular winging or congenital onset) is *TRPV4*. Vocal cord palsy is common with *TRPV4* mutations.

**Autosomal recessive CMT2** There are 10 causative genes known for AR CMT including AR CMT2 due to homozygous or compound heterozygous mutations in *MFN2* and *NEFL*, which more commonly cause AD CMT2. All forms of AR CMT2 are rare and the causative genes are listed in Table 10.6 but a few warrant further mention as they have interesting phenotypes.

Mutations in lamin A/C (*LMNA*) cause AR CMT2A. Moroccan and Algerian families were reported with this phenotype. Most patients present in the second decade with a severe CMT phenotype including proximal muscle involvement although some patients have been reported with a milder phenotype. Lamin A/C mutations have been associated with a wide spectrum of phenotypes including Emery–Dreyfuss muscular dystrophy, cardiomyopathy, Dunnigan-type familial partial lipodystrophy and many others.

The second form of AR CMT2, AR CMT2B, was described in a Costa Rican family and the gene for this type is *MED25*. The phenotype of AR CMT2B is milder than seen with the other AR CMT2 genes and is more like classic CMT2. Another rare AR cause of the classic CMT2 phenotype are mutations in *LRSAM1*. As shown in Table 10.6, *LRSAM1* mutations can also cause AD CMT2.

Mutations in *GDAP1* have been described above as a cause of AR CMT1 (CMT4A) but they can also cause AR CMT2 with a similar severe early onset phenotype which can include vocal cord paresis.

A characteristic feature of AR CMT2 secondary to mutations in *HINT1*, which has been described as an important cause of AR CMT2 in a number of European countries, is a high incidence of neuromyotonia. Some patients have no sensory involvement and are classified as having distal HMN.

**X-linked CMT2** X-linked CMT2 is very rare and can be caused by mutations in *AIFM1*, *PRPS1* and *PDK3*. As seen in Table 10.6, there are commonly associated clinical features such as deafness.

**Dominant intermediate CMT** It is increasingly recognised that many forms of CMT can present with MCVs in the intermediate range as discussed earlier. These include patients with X-linked CMT resulting from *GJB1* mutations, patients with AD CMT caused by *MPZ* or *NEFL* mutations and patients with AR CMT caused by *GDAP1* mutations. In addition to these forms of intermediate CMT, a number of genes have recently been described including *DNM2*, *YARS*, *GNB4* and *IFN2* that cause CMT with intermediate MCVs and these have been classified as dominant intermediate CMT (Table 10.6). Mutations in *IFN2* cause an unusual form of CMT associated with renal failure resulting from focal segmental glomerulosclerosis.

### Hereditary sensory neuropathy

HSN is much rarer than CMT but a number of causative genes for these disorders have been identified (Table 10.7). Generally, these disorders are characterised by prominent sensory and in some cases autonomic involvement and less motor involvement than CMT. The sensory involvement can be severe and result in mutilating injuries. Education of the patients to try to prevent these complications is crucial. Many patients with HSN have not had a genetic cause identified but phenotypes associated with specific genes include:

- HSN1A secondary to *SPTLC-1* and HSN1C secondary to *SPTLC-2* mutations have already been mentioned. This disease is more appropriately termed HSN than HSAN as there is usually no autonomic involvement. Mutations in *ATL1* which more commonly causes a spastic paraparesis can also cause HSN1.
- Mutations in *DNMT1* cause an unusual form of HSN1 (HSN1E) with associated deafness and dementia.
- Mutations in the prion protein, *PRNP*, have also been described to cause a sensory and autonomic neuropathy with dementia in two families.
- All other forms of HSN are rare. HSN2 is an early onset, AR, severe sensory neuropathy with prominent sensory complications and is caused by mutations in a number of genes including *WNK1*, *FAM13B4* and *KIF1A*.
- HSAN3 (Riley–Day syndrome) is a distinct autosomal recessive neuropathy seen in Ashkenazi Jews and characterised by mainly autonomic involvement but it also involves the PNS, particularly the sensory nerves. The causative gene is the *IKBKAP* gene. Presentation is often in infancy or childhood with poor feeding, swallowing difficulties and recurrent chest infections.
- HSAN4 and HSAN5 are both AR neuropathies characterised by congenital insensitivity to pain. HSN4 (also called congenital insensitivity to pain with anhidrosis [CIPA]) presents with a severe sensory neuropathy, anhidrosis and mental retardation and is caused by mutations in the *NTRK1* gene, a receptor for nerve growth factor. HSN5 is similar but without the mental retardation or significant anhidrosis. This phenotype has been described with both *NTRK1* mutations and also with *NGFB* mutations. A recent development in the hereditary sensory neuropathies has been the identification of homozygous mutations in the gene (*SCN9A*) for the voltage-gated sodium 1.7 channel (NA<sub>v</sub>1.7) in a form of HSAN resembling type V and termed HSN2D or channelopathy-associated insensitivity to pain.

### Distal hereditary motor neuropathy

The distal hereditary motor neuropathies (dHMNs) are a complex group of disorders (Table 10.8) also referred to as distal spinal muscular atrophies (distal SMA). Forms that resemble CMT have been discussed earlier. Like HSN, many patients with HMN have not had a genetic cause identified but phenotypes associated with specific genes include the following.

- Distal HMN2 is the classic form of AD distal HMN and is caused by mutations in the *HSPB8* (*HMN2A*) and *HSPB1* (*HMN2B*) genes. These patients present with classic CMT (but as described above with more ankle plantar flexion weakness) but without any sensory involvement.
- Mutations in *GARS* and *BSCL2* cause distal HMN5 as previously described and this phenotype can also be caused by mutations in *REEP1*, which usually causes a spastic paraparesis.
- Distal HMN6 is an unusually severe AR form of distal HMN that presents in infancy with respiratory and distal limb involvement (called spinal muscle atrophy with respiratory distress type 1 [SMARD1]) and is caused by mutations in the *IGHMBP2* gene.

- Mutations in dynactin (*DCTN1*) or *SLC5A7* cause distal HMN7, which is characterised by vocal cord paralysis and progressive weakness and atrophy of the face, hands and legs. Missense mutations in senataxin (*SETX*) can cause a form of distal HMN with pyramidal features. Nonsense mutations in the same gene cause autosomal recessive ataxia oculomotor apraxia type 2 (AOA2).
- A rare X-linked form of HMN due to mutations in the *ATP7A* gene (which also causes the severe infantile onset developmental disorder, Menkes disease and its milder variant, occipital horn syndrome) has been described.
- A form of hereditary motor neuropathy which has been called spinal muscle atrophy with lower extremity predominance (SMALED) is due to mutations in two genes, *DYNC1H1* and *BICD2*, which give a distinct phenotype of almost exclusive involvement of the distal and proximal lower limb muscles which is usually congenital and non-progressive. Some patients with mutations in *DYNC1H1* also have learning difficulties and some with mutations in *BICD2* develop mild spasticity in later life.

### Hereditary neuralgic amyotrophy

HNA is an autosomal dominant condition caused by mutations in the *SEPT9* gene and characterised by recurrent episodes of typical brachial neuritis. The attacks are characterised by pain, weakness and sensory disturbance in the brachial plexus distribution. These attacks are indistinguishable from sporadic brachial neuritis but are recurrent, often starting in childhood.

### Importance of a genetic diagnosis in CMT and related disorders

Our ability to identify the genetic causes of CMT and its related disorders in patients has been revolutionised by the advent of NGS which allows large number of genes to be screened simultaneously either by disease-specific panels, whole exome or whole genome sequencing. In inherited neuropathies, the major challenge is validating identified mutations as pathogenic as multiple variants are usually identified, most causative genes for inherited neuropathies are ubiquitously expressed and there are very few functional tests available in inherited neuropathies to prove a particular mutation in a specific gene is the cause of the neuropathy. Careful phenotyping remains a crucial step in validating identified mutations.

An accurate genetic diagnosis is extremely important for these patients. There are obvious benefits including diagnostic testing for other family members, accurate genetic counselling and prognosis, predictive and antenatal testing but an accurate diagnosis also prevents patients from having unnecessary and invasive diagnostic tests, for example nerve biopsies and lumbar punctures. In certain situations where inflammatory neuropathies are being considered a genetic diagnosis can prevent a trial of potentially dangerous immunosuppressive therapy.

The era of treatment for genetic neuropathies is here. The first therapeutic trials in CMT have been completed (ascorbic acid for CMT1A, which were unfortunately negative) and more are planned. Drug discovery programmes are actively hunting for new therapeutics and although some of these may be mechanism driven, it seems likely that other developments (at least at the trial stage) could now be gene-specific, making the case for an accurate genetic diagnosis even more convincing.

### Familial amyloid polyneuropathy

Familial amyloid polyneuropathy (FAP) is an AD condition first described in Portugal in 1952. The amyloidoses are characterised by deposition of a fibrillar  $\beta$ -pleated protein in the extracellular space of many organs. Only AL (light chain) amyloidosis and FAP cause a

generalised neuropathy with autonomic involvement. AL amyloid is discussed later. Within the familial amyloidoses there are more than 30 proteins that can form amyloid deposits but there are only four different forms of FAP classified by the constituent amyloid-forming protein: transthyretin (TTR), apolipoprotein A-1 (Apo A-1), gelsolin and beta-2 microglobulin (one family).

### Transthyretin-related familial amyloid polyneuropathy

**Clinical features** The cardinal clinical features of TTR-related FAP are a sensory motor peripheral neuropathy usually with autonomic involvement, a cardiomyopathy and to a lesser extent vitreous involvement. Other systems can be involved. Over 100 mutations in TTR have been described, the most common of which is the index Met30 point mutation. Clinical features do not always correlate well with a specific mutation.

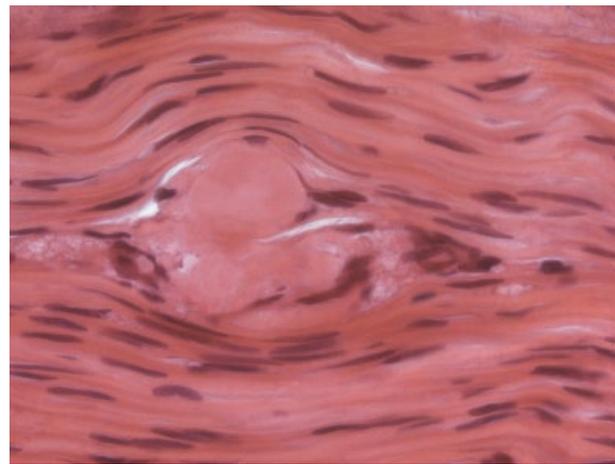

Patients with TTR Met30 usually present with painful dysaesthesia in the lower limbs progressing to a severe mixed polyneuropathy. Early there is greater small fibre susceptibility giving rise to lack of pain and temperature sensation, but eventually all sensory modalities are involved. Mutilating injuries can occur. Later motor involvement is universal, with upper limb involvement occurring months to years after lower limb manifestations. Carpal tunnel syndrome (CTS) as a presenting feature is rare in TTR Met30. Autonomic involvement occurs frequently and can be severe and early.

Neurophysiological studies confirm an axonal neuropathy although SAPs may be normal early in the course of the disease, reflecting the mainly small fibre involvement. Cardiac involvement is common, presenting as an arrhythmia, heart block or heart failure, and amyloid deposition results in abnormal echocardiographic appearances. Vitreous involvement is more common in Swedish than Portuguese TTR Met30 patients and may be the presenting feature. Kidneys and, more rarely, pulmonary or bone involvement also occur.

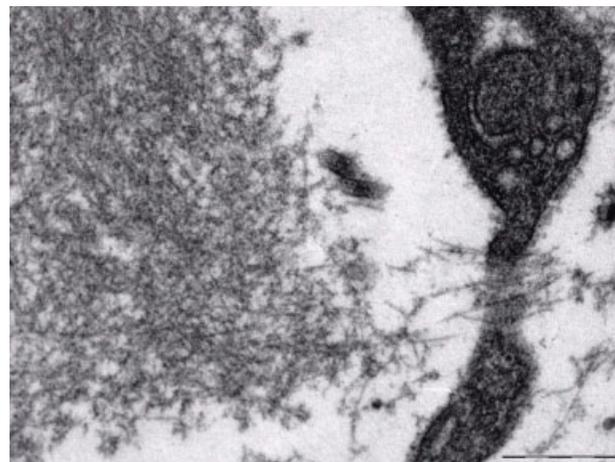

Other common mutations include TTR Tyr 77 and TTR Ala 60. FAP TTR Tyr 77 has a high incidence of CTS but absent vitreous involvement. FAP TTR Ala 60 is mainly seen in patients of Irish descent and typically presents in the sixth decade with more prominent small and large fibre sensory loss than TTR Met30. Cardiomyopathy is a major and commonly a presenting feature.

CNS involvement in FAP TTR is very rare and, although postmortem studies have shown leptomeningeal amyloid deposition, this is usually asymptomatic. Oculoleptomeningeal amyloidosis (OLMA) is associated with TTR point mutations. The clinical features vary even within a kindred and include vitreous opacities, progressive dementia, stroke, subarachnoid haemorrhage, ataxia, hydrocephalus, seizures, spasticity and episodes of fluctuating consciousness often with focal neurological signs. The hallmarks of the CNS disease are meningeal enhancement of the brain and spinal cord on magnetic resonance imaging (MRI) and a raised cerebrospinal fluid (CSF) protein.

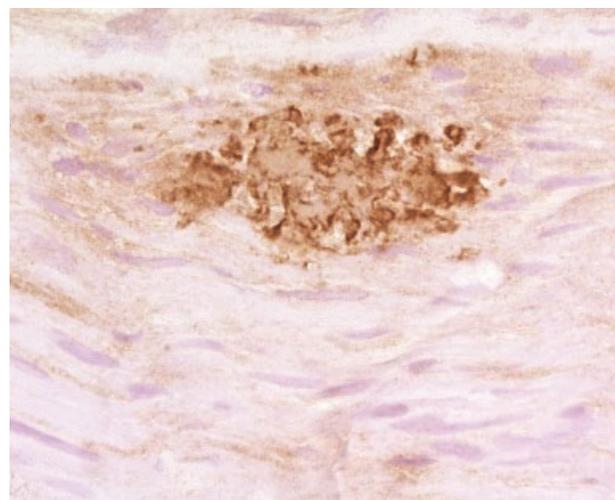

**Pathology** The pathological changes in the PNS are similar in FAP and AL amyloidosis. The amyloid in the PNS appears as extracellular, amorphous, eosinophilic deposits, which are found both diffusely in the endoneurium and epineurium and surrounding endoneurial and epineurial blood vessels. They are also present in sensory and autonomic ganglia. In milder cases there is predominant loss of small myelinated and unmyelinated axons; at later stages larger myelinated fibres are also lost. The pathology is predominantly one of axonal degeneration with some regenerative activity. Segmental demyelination has also been described. Congo red staining has apple green birefringence under polarised light and under electron microscopy (EM) rigid 10–15 nm fibrils are seen (Figure 10.13).

(a)

(b)

(c)

**Figure 10.13** Amyloid neuropathy. (a) Haematoxylin and eosin stained paraffin section with a large amyloid deposition in the endoneurium, displacing normal structures. The nerve is severely depleted of large myelinated axons. (b) Electron microscopy of the same nerve, visualising amyloid fibrils. (c) The amyloid is composed of transthyretin (determined by immunohistochemistry).

**Diagnosis** The most important step in the diagnosis of TTR-related FAP is having a clinical suspicion. It should always be considered in patients with a family history and a neuropathy and/or cardiomyopathy, CTS or vitreous deposits. The diagnosis should also be considered in patients with an unexplained small fibre neuropathy especially with autonomic involvement or a cardiomyopathy regardless of family history. Neurophysiologically, the neuropathy is an axonopathy and has no specific features.

The diagnosis of amyloid can be made by direct examination of biopsy material from rectum, peripheral nerve, heart, subcutaneous fat or other tissue depending on the presentation. Congo red staining with apple green birefringence under polarised light is the primary examination. A number of methods for Congo red staining are available, some more effective in some tissues than others. Immunohistochemistry with monoclonal antibodies against TTR or the  $\lambda$  or  $\kappa$  light chains differentiates TTR amyloid from light chain amyloid but the method is neither 100% sensitive nor specific. Light chains should be sought by immunofixation in urine and serum if AL amyloid is suspected and the antibodies to TTR are negative. The use of mass spectrometry to identify the constituent amyloid protein looks promising and is more sensitive than immunohistochemistry but is not yet widely available.

Sequencing of the TTR gene is widely available for genetic testing and confirmation of a histopathological diagnosis. Predictive testing remains difficult because of uncertainties about the penetrance of certain mutations.

Once the diagnosis is made the extent and stage of the disease must be assessed and iodine-123 labelled serum amyloid protein scan is a useful tool to help with this, especially if liver transplantation (see Treatment) is being considered.

**Treatment** Ninety per cent of TTR is produced in the liver. Until the early 1990s the treatment of TTR-related FAP was limited to symptomatic treatments and rehabilitative measures. Since then liver transplantation has been used in the treatment of TTR-related FAP. More than 2000 liver transplants have been performed for patients with TTR-related FAP worldwide. The consensus is that liver transplantation halts or slows the progression of TTR-related FAP in most Met30 patients. The 5-year survival is now 82%. There is concern that patients with mutations other than Met30 do not do as well.

Although liver transplantation has been a major advance in the treatment of TTR amyloidosis, it is associated with a significant mortality and other safer and more effective treatments are being developed:

- Drugs that stabilise TTR in the tetrameric state and prevent its dissociation into amyloidogenic monomers. Two drugs, tafamidis and diflunisal, with this action have been introduced in clinical use in some countries although both are still undergoing further efficacy evaluation studies.
- TTR gene silencing strategies to inhibit the production of wild type and mutant TTR. Trials are currently ongoing for both antisense oligonucleotides and small interfering RNA strategies.
- Monoclonal antibodies against serum amyloid protein (SAP) to increase the clearance of amyloid deposits are also in development.

**Prognosis** The average life expectancy for patients with untreated TTR-related FAP is about 10 years but varies with ethnicity, mutation and treatment. This figure is likely to improve further as newer genetic and chemotherapeutic treatments are developed.

### Apolipoprotein A-1 related FAP

One type of FAP, originally described in an Iowa kindred, has been shown to be associated with deposition of a variant apolipoprotein A-1. The phenotype is similar to that of FAP TTR Met30 except for a higher incidence of renal amyloidosis and severe gastric ulcer disease.

### Gelsolin-related FAP

Gelsolin amyloidosis was first described in a Finnish kindred. This usually presents in the thirties with corneal lattice dystrophy caused by amyloid deposition in the corneal branches of the trigeminal nerve. This is followed by a progressive cranial neuropathy. The facial nerve is the most common cranial nerve involved with the upper fibres as manifested by forehead muscle weakness initially being affected. Other cranial nerves may also be affected including the vestibulocochlear, hypoglossal and trigeminal with varying clinical manifestations. Peripheral nerve and autonomic involvement is usually mild.

The fibril protein in this type of amyloidosis is an abnormal fragment of a plasma protein, gelsolin, a calcium-binding protein that fragments actin filaments.

### Beta-2 microglobulin FAP

A single family is described with an Asp76Asn mutation in beta-2 microglobulin and an otherwise classic presentation of FAP. More commonly, beta-2 microglobulin causes a dialysis related amyloid manifesting as carpal tunnel syndrome.

### Acquired neuropathies

The acquired peripheral nerve diseases are a diverse group of conditions with a variety of pathogenic mechanisms. Some are primary peripheral nerve disorders affecting a single system. Many are disorders with multi-system dysfunction such as the neuropathies associated with diabetes, autoimmune diseases or toxic exposures. The inflammatory neuropathies, in their various guises, constitute the largest group of peripheral nerve disorders.

### Inflammatory neuropathies

The inflammatory neuropathies (Table 10.9) are a diverse group of peripheral nerve disorders linked by their presumed immune-mediated pathogenesis. They are characterised pathologically by inflammatory infiltration of the peripheral nerves associated with destruction of myelin and/or axons. The inflammatory neuropathies are typified by the idiopathic demyelinating neuropathies, both acute and chronic, and the closely related neuropathies associated with paraproteinaemia. However, vasculitic, infectious and parainfectious, paraneoplastic and, more recently, diabetic plexopathy are included. Some of these may be thought of as primary disorders of the PNS (e.g. GBS and CIDP) and others secondary to a systemic immune process with subsequent involvement of the peripheral nerves (e.g. the neuropathy associated with vasculitis and the connective tissue diseases).

### Acute neuromuscular weakness and the inflammatory neuropathies

Acute neuromuscular weakness can be caused by disease of muscle, neuromuscular junction, peripheral nerve, roots or the CNS. The distinction between these sites of pathology can largely be made on clinical grounds, with supportive investigations where necessary (Chapters 4 and 20).

**Table 10.9** Inflammatory neuropathies.

<b>ACUTE</b>
<b>Guillain-Barré (GBS) variants</b>
Acute inflammatory demyelinating polyradiculoneuropathy
Acute motor axonal neuropathy
Acute motor sensory axonal neuropathy
Fisher syndrome and other regional variants

A differential diagnosis of acute inflammatory neuropathies exists (Table 10.9). By far the most common of these is GBS. The acute infectious neuropathies (poliomyelitis, diphtheria, HIV, tick paralysis) are dealt with in Chapter 9 and paraneoplastic neuropathies in Chapter 21.

### Guillain–Barré syndrome and its variants

GBS is the most common cause of acute neuromuscular weakness in the developed world following the near eradication of polio, but certainly occurs worldwide. The incidence is about 1–2/100 000 population. There is no sex difference. It affects all ages including children and infants but is more frequent in older age groups. In some populations a seasonal variation in the incidence is reported coinciding with the seasonal incidence of predisposing infections (Table 10.10). In Europe and the United States, GBS is synonymous with acute inflammatory demyelinating polyradiculoneuropathy (AIDP) as axonal variants only occur in 3–5% of cases. However, axonal forms are far more common in China, Japan and Mexico (see Variants of GBS).

**Symptoms and signs** The diagnosis of GBS remains a clinical one, supported by investigations which may be normal in the early stages of disease. Patients present with a progressive ascending sensorimotor paralysis with areflexia, affecting one or more limbs and reaching a nadir in less than 4 weeks. Patients who progress beyond this time or present with ‘recurrent GBS’ are reclassified into subacute or chronic inflammatory demyelinating neuropathies (SIDP/CIDP, see Chronic inflammatory demyelinating polyradiculoneuropathy). Pain, cranial nerve involvement and autonomic disturbances with

arrhythmias and labile blood pressure are often features. Papilloedema may occur, which if unrecognised and untreated may lead to blindness. A clinical diagnosis of GBS should be questioned if there is persistent asymmetrical weakness, bladder or bowel involvement or a sensory level suggestive of spinal cord pathology. Furthermore, the presence of a known toxin, HIV, diphtheria, tick exposure or neoplasia broadens the differential. In the first few days the examination may be normal and reflexes retained. However, some patients may progress to tetraparesis and require ventilation in as little as 48 hours and vigilance for either scenario is important. Functional variants exist with acute pure autonomic failure, pure sensory neuropathy and pure ataxic neuropathy described. Recognised regional variants (Table 10.9) are associated with particular serum antiganglioside antibodies (see Antiganglioside antibodies). The differential diagnosis of acute GBS is summarised in Chapter 20.

### Investigations

**Cerebrospinal fluid** In GBS the CSF is acellular or should contain  $<10$  cells/mm<sup>3</sup>. Ten per cent of patients have cell counts of 10–50 cells/mm<sup>3</sup> but these do not persist for more than a few days. Cell counts  $>50$  cells/mm<sup>3</sup> should stimulate a search for an alternative diagnosis. Note that intravenous immunoglobulin (IVIG) can stimulate an aseptic meningitis and may provoke increased cell counts (as well as falsely raised CSF protein levels). CSF protein is usually raised for 4–6 weeks but may be normal in the first 7 days of illness and may also remain normal in a greater proportion of the regional variants (e.g. Fisher syndrome) than typical GBS. CSF pressure is typically normal but raised levels of CSF pressure and protein contribute to papilloedema.

**Nerve conduction studies** In the correct clinical context, abnormalities of nerve conduction studies suggestive of patchy proximal and distal demyelination are highly suggestive of GBS. Nerve conduction tests may be normal in the first few days of illness. Typical changes of slowed motor nerve conduction velocities, with prolonged F-wave and distal motor latencies with largely preserved amplitudes are typical. Conduction block may be demonstrated. Early on the lower limb sensory nerve action potentials are relatively preserved but they are later lost and electromyographic (EMG) evidence of denervation may emerge. Inexcitable nerves are common in severe cases and are unhelpful in diagnosis. Axonal changes without evidence of slowing are found in acute motor axonal and acute motor and sensory axonal neuropathies (AMAN and AMSAN) and these may indicate a worse prognosis.

**Blood tests** Blood tests are unhelpful in the context of the diagnosis of GBS. However, they importantly serve to exclude major biochemical disturbances that may mimic GBS, identify coexistent disorders that may complicate treatment (e.g. renal failure and IVIG), and point to conditions that may cause a GBS-like illness (systemic lupus erythematosus [SLE], HIV, malignancy). All patients should have urea and electrolytes, calcium, magnesium, liver and thyroid function, full blood count, erythrocyte sedimentation rate (ESR), vitamin B<sub>12</sub> and folate and antinuclear antibodies (ANA) checked.

Ten per cent of patients will have abnormal liver function tests, possibly the result of viral (Epstein–Barr virus [EBV] or cytomegalovirus [CMV]) hepatitis. Hyponatraemia occurs in a proportion of patients caused both by syndrome of inappropriate antidiuretic hormone (SIADH) or an excess of atrial natriuretic factor.

**Antiganglioside antibodies** Antiganglioside antibodies are frequently requested but seldom help in diagnosis. They are sometimes found more commonly associated with one or other of the regional GBS variants. In the acute neuropathies only IgG antibodies are of relevance. IgG anti-GQ1b antibodies are found in 90–95% of cases of Fisher syndrome and also a substantial proportion of cases of GBS with ophthalmoplegia. Anti-GD1a and anti-GalNAcGD1a antibodies are associated with AMAN. IgG anti-GM1 antibodies associate with more severe disease. Anti-GM2 antibodies sometimes follow CMV infection and seem to be associated with a predominantly sensory neuropathy. Ganglioside species share epitopes and therefore more than one antiganglioside activity is commonly found.

**Campylobacter stool testing and serology** Serological testing with acute and convalescent serum may confirm seroconversion following infection with any of the infectious agents implicated in GBS causation. Stool should also be cultured for *Campylobacter* species. Its identification also has public health implications.

**Lung function testing and monitoring** Forced vital capacity (FVC) should be measured and recorded immediately on presentation and at least every 4 hours thereafter (more frequently if necessary) until the patient has begun to recover. Elective intubation should be considered if the FVC falls below 15 mL/kg. A fall in FVC of one-third between erect and supine indicates diaphragm weakness.

**Cardiac monitoring** A 12-lead ECG should be recorded and the patient monitored for arrhythmia and blood pressure fluctuations until clinically stabilised and improving.

**Nerve biopsy** Sural nerve biopsy is seldom helpful as much of the pathology in GBS is proximal to any intended biopsy site and changes may take days to weeks to develop. In severe, unusual cases or cases unresponsive to treatment sural nerve biopsy may be helpful to exclude alternative diagnoses.

**Variants of GBS** AMAN and AMSAN form a spectrum of axonal GBS. Although responsible for only 3–5% of cases of GBS in the western hemisphere, axonal variants may constitute up to 50% or more of GBS cases in China and Latin America. Here GBS occurs in seasonal summer outbreaks and is closely associated with *Campylobacter jejuni* infection. Anti-GD1a, GalNAcGD1a and GM1 antibodies occur frequently. The pathology involves direct macrophage attack on the axolemma resulting in profound axonal degeneration.

Limited and regional variants of GBS are shown in Table 10.9. Individual variants are rare but the combined incidence rate of all variants is about 7–13% of the incidence of GBS. Fisher syndrome, the triad of ataxia, areflexia and ophthalmoplegia, is the most common variant accounting for between one-third and half of variant cases. There is a frequent association with *C. jejuni* infection and up to 95% of cases are associated with anti-GQ1b antibodies. Fisher syndrome seldom progresses to require supportive or therapeutic treatment. Occasionally, a Fisher/GBS overlap syndrome or GBS with ophthalmoplegia may progress to full-blown weakness and thus it should be monitored and treated like GBS.

Other limited and regional variants are rare. The pharyngo-cervico-brachial variant involves predominantly the bulbar and upper limb musculature with weakness and areflexia but sparing

the lower limbs. Anti-GT1a antibodies (sometimes cross-reacting with GQ1b) are often found. The pathophysiology is predominantly axonal. Paraparetic lower limb variants have been described as having pure motor and pure sensory or sensory ataxic forms. Acute dysautonomia has more recently been recognised in this group of conditions. It presents with profound postural hypotension and impaired sweating, impotence and bladder and bowel dysfunction. Antibodies to the nicotinic, preganglionic acetylcholine receptor have been described associated with this condition which improves with immunotherapy.

**Pathogenesis** The infectious agents associated with GBS probably all display ganglioside-like epitopes on their surface. Humoral and cellular immune responses to these epitopes cross-react with gangliosides displayed on nerve cells, resulting in an immunological attack.

The pathogenic hallmark of typical GBS is macrophage-mediated attack of either the Schwann cell or the axolemma resulting in demyelination or axonal degeneration. The BNB becomes inflamed and leaky allowing for the ingress of activated T cells, IgG and complement. IgG and activated complement is found on actively degenerating cells. The inflammatory milieu stimulates up-regulation of MHC Class II receptors and antigen presentation by endoneurial cells including Schwann cells, promoting endoneurial damage.

### Treatment

#### General treatment (Chapter 20)

- 1 Respiratory monitoring is essential. Elective endotracheal intubation may be life-saving with early conversion to tracheostomy for comfort and prevention of complications.
- 2 Cardiac monitoring in a high dependency unit setting should be performed in all patients while the diagnosis is being confirmed and until recovery begins. Arrhythmias and blood pressure fluctuations should be treated appropriately. Persistent or severe bradyarrhythmias may require the insertion of a pacemaker.
- 3 Anticoagulation (low molecular weight heparin), pressure stockings and calf massage devices as prevention against deep venous thrombosis (DVT) should be used routinely.
- 4 Fluid balance, nutrition and electrolyte monitoring should be carried out. A nasogastric tube may be necessary for feeding, which may need to be supplemented. Hyponatraemia is more often brought about by excess atrial natriuretic factor (ANF) (with loss of salt and water) than SIADH (dilutional through retention of water).
- 5 Physiotherapy should start immediately with hand and foot splints to prevent contractures.
- 6 Excellent nursing care of the paralysed patient prevents many complications associated with immobility and recumbency (pneumonia, pressure sores, DVT) and should be the central point of all care. Detection and treatment of issues related to pain, emotion, continence, nutrition and mouth care are crucial.

**Specific treatment** Plasma exchange was the first GBS treatment shown to have substantial benefit. It halves the time on ventilation, hastens recovery and improves outcome at 1 year if administered within 4 weeks of onset. Usually four to five 3-L exchanges are given over the course of 5–10 days. More practically, IVIG 2 g/kg over 5 days is as effective as plasma exchange and more likely to be completed as it has fewer complications. No additional benefit has been shown for following plasma exchange with IVIG. No trial has been performed to examine the benefit of a second dose of IVIG 14

days after the first in cases of minimal or delayed response, but an international study is ongoing. Patients who make an IgG increment of more than 7.5 g/L after a standard dose of 2 g/kg IVIG have a better outcome than those who have a lower increment. Steroids are not indicated in the treatment of GBS.

Pain may be severe. Treat with combinations of high-dose anti-convulsants (gabapentin, pregabalin, carbamazepine) and tricyclic antidepressants or selective serotonin re-uptake inhibitors (SSRIs), in conjunction with opiates (e.g. fentanyl). Epidural anaesthesia is sometimes helpful.

**Outcome** Despite many advances in therapeutics and intensive care, GBS remains a severe illness. Poor prognostic factors include advanced age, axonal degeneration in the context of AIDP and if the patient is ventilator-dependent or bed-bound at the nadir of the illness. Predictions of the need for ventilation and of the eventual mobility outcome can be based on scores evaluable at admission or shortly afterwards, known as mEGOS (modified Erasmus GBS Outcome Score) and EGRIS (Erasmus GBS Respiratory Insufficiency Score). Even with the best medical care 5–8% of patients die and about one-third are left with significant disability. The remainder make a good recovery and have few residual symptoms. Fatigue is an under-recognised and poorly treated residual outcome.

### Chronic inflammatory neuropathies

The chronic inflammatory neuropathies include the idiopathic and those associated with other diseases, for example the paraproteinaemias and the vasculitides (Table 10.9). Although the latter group, especially the vasculitides and paraneoplastic disorders, may present more acutely and progress more rapidly, they are included here for convenience.

### Chronic inflammatory demyelinating polyradiculoneuropathy

CIDP is an acquired, treatable, demyelinating PNS disease characterised by progressive or relapsing proximal and distal weakness of the limbs with sensory loss and/or cranial nerve involvement reaching a nadir in more than 8 weeks with absent or reduced reflexes in all limbs. Prevalence estimates vary at 1.2–7/100 000 population. Unlike GBS there are no known predisposing infections.

**Symptoms and signs** The diagnosis of CIDP is clinical, supported by electrophysiological, CSF and other tests (see Investigations) and the exclusion of other causative pathologies.

Patients with CIDP present with a progressive or relapsing limb weakness or numbness which may have an asymmetrical onset. Parasthesiae are common. Limb and back pain occurs but if prominent should stimulate a search for alternative causes especially vasculitis, lymphoma or infection. As with all demyelinating conditions a tremor may be prominent. Autonomic and bladder or bowel involvement is distinctly unusual. 'Recurrent GBS' can sometimes be classified as CIDP. Unusual forms can occur including monomelic paralysis, lower limb variants and sensory ataxic forms.

The clinical signs mirror the presentation. Proximal and distal weakness with areflexia and a distal sensory loss are normal and tremor occurs frequently. Wasting is not evident until late in untreated disease. Bulbar weakness and progression to respiratory involvement with ventilation are rare.

A careful general examination is crucial to identify systemic causes or contributing factors (e.g. malignancy, pre-existing CMT, SLE and other connective tissue diseases, diabetes or alcohol).

**Investigations** The European Federation of Neurological Sciences and the Peripheral Nerve Society have published criteria (2010) for essential and supportive investigations.

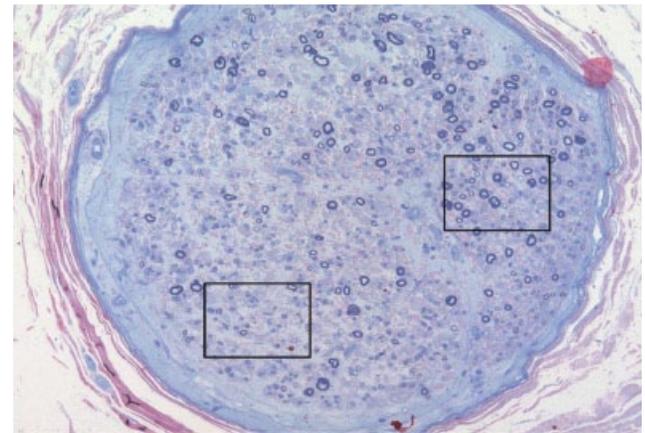

- 1 Nerve conduction studies** Clear demonstration of demyelination in at least two nerves is mandatory for a definite diagnosis of CIDP if no other supportive criteria are employed. Demyelinating features include reduced motor conduction velocity, prolonged distal motor latencies, proximal F-waves reduction or conduction block or dispersion, all in the presence of relatively preserved compound muscle action potentials are acceptable. Later in the condition axonal degeneration may supervene.
- 2 CSF** The CSF protein is raised in 90% of cases. A CSF white cell count of  $>10 \text{ mm}^3$  should prompt a search for alternative causes.
- 3 MRI** Nerve root enlargement and/or enhancement with gadolinium is often seen. Most commonly imaged areas include the cervical and lumbosacral regions. MRI findings are now included in the supportive criteria for the diagnosis.
- 4 Nerve biopsy** A diagnosis of CIDP does not usually require a nerve biopsy as the clinical presentation, neurophysiology and other less invasive paraclinical investigations are usually sufficient to make a diagnosis. Furthermore, complications include a 10–30% risk of permanent dysaesthesia at the biopsy site and other routine surgical complications of wound healing and infection. Although the sural nerve is the most commonly biopsied, a suitable nerve should be selected on the basis of symptoms and electrophysiological findings; only very rarely should an electrically 'normal' nerve be biopsied.

Biopsies contain reduced numbers of myelinated nerve fibres with evidence of active demyelination or previous onion bulb formation (Figure 10.14). Endoneurial macrophage activity is usually increased and endoneurial T cells are present in increased numbers. Unequivocal diagnostic findings in the correct clinical context are macrophage-associated demyelination on electron microscopy (EM), evidence of demyelination or remyelination in five fibres by EMG or demyelinated segments of at least 20 fibres in teased preparations.

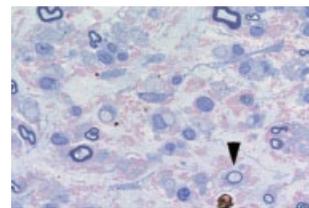

- 5 Blood tests** There are no diagnostic blood tests for CIDP. Full blood count, ESR,  $B_{12}$  and folate, urea and electrolytes, glucose, liver and

thyroid function tests, immunoglobulins, protein electrophoresis and immunofixation and ANA are normal or negative but should be requested as an initial screen to rule out other conditions.

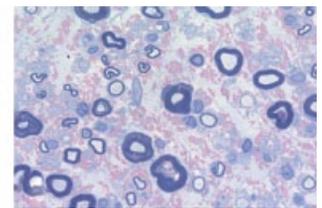

- 6 Exclusion of other conditions** Exclusion of other causative or contributing conditions is essential. Coexistent CMT disease should be considered and genetic tests requested as necessary.

(h)

(i)

**Figure 10.14** Chronic inflammatory neuropathy. (a) Patchy loss of myelinated fibres in a fascicle of the sural nerve (semi-thin resin section, toluidine blue). The left lower rectangle is shown in higher magnification in (b). (b) Close-up of the area with a significant loss of large myelinated fibres (arrowhead indicates a thinly myelinated fibre). There are several other thinly myelinated and entirely demyelinated fibres. (c) More densely populated area corresponding to the right upper rectangle in (a). (d) Endoneurial T-cells (CD8 immunohistochemical staining). (e) Most CIDPs are also characterised by a variable perivascular infiltrate as shown here (CD8 immunohistochemistry). (f) Teased fibre preparation which shows a segmental demyelination. To unequivocally identify segmental demyelination, myelinated fibres have to be identified on either end of the demyelinated stretch. (g) Close-up of demyelination, which shows a myelinated segment on the left, the end of which is indicated by the left arrowhead. This is followed by an expanded internode length, the end of which is indicated by the right arrowhead. The subsequent stretch of the axon is very thinly myelinated. (h) Electron microscopy of a demyelinated and thinly remyelinated axon. (i) Axon with almost regular myelin thickness, surrounded by concentric formations of Schwann cell laminae, also designated onion bulbs.

### CIDP variants

**Multi-focal motor neuropathy with conduction block** Multi-focal motor neuropathy with conduction block (MMNCB) is a progressive immune-mediated demyelinating motor neuropathy which often begins asymmetrically in the upper limbs. Weakness in the distribution of individual nerves, often with prominent cramps but without wasting or fasciculation, and patchy reduced reflexes are the most usual signs. Wasting and fasciculation can occur later which causes confusion with motor neurone disease. Subjective sensory symptoms can occur but no more than minor disturbance of vibration sense at the ankle is acceptable on examination. Cranial nerve or respiratory involvement are extremely rare and upper motor neurone, sphincter or marked bulbar involvement exclude the diagnosis. The prevalence of MMNCB is about 10% of that of CIDP. Men are more often affected than women.

Both IgG and IgM antibodies to ganglioside GM1 are described in the serum from 30–80% of patients, rarely as a paraprotein. CSF protein should not be raised to >1 g/L. The hallmark of the condition is the demonstration of multi-focal conduction blocks at sites other than common sites of compression. Extremely thorough neurophysiological assessment may be necessary to identify them.

MMNCB was originally described in 1988 as a subtype of CIDP but it may be a distinct entity as illustrated by its dramatically different response to immunosuppressive therapy including worsening with steroids (see Treatment of typical CIDP).

**Multi-focal acquired demyelinating sensory and motor neuropathy** Multi-focal acquired demyelinating sensory and motor neuropathy (MADSAM), previously called Lewis–Sumner syndrome, has similarities to CIDP and MMNCB. It may respond to treatment with IVIG.

**Sensory ataxic CIDP** This rare inflammatory disorder presents with profound sensory ataxia and may be caused by inflammatory involvement of the dorsal root ganglia. HIV, paraneoplasia, Sjögren's syndrome, copper deficiency and pyridoxine toxicity should be excluded.

**Distal acquired demyelinating sensory neuropathy** Many cases of distal acquired demyelinating sensory neuropathy (DADS) are associated with an IgM paraprotein.

**Chronic relapsing axonal neuropathy** Chronic relapsing axonal neuropathy (CRAN) is a rare entity that has an uncertain position in the nosology of CIDP.

**Treatment of typical CIDP** Treatment should be commenced as soon as possible in patients who warrant it after discussion of the risks and potential benefits with the patient. The first line treatments for CIDP are either oral steroids (although various regimens are used, 1 mg/kg given for 2 months and then slowly tapered is common) or IVIG (0.4 g/kg for 5 days repeated at 4–6 weeks and then as necessary according to the response). Both steroids and IVIG have been shown to be better than placebo and there is no clear difference between IVIG and steroids. Recent studies have shown that, if tolerated, steroids may produce a longer lasting remission than IVIG. Steroids should be co-prescribed with a bisphosphonate to protect against bone loss (unless contraindicated), and gastric pharmacoprotection should be considered. IVIG is a blood product and patients should be made aware of and consented

for the risks. If IVIG or steroids are contraindicated or ineffectual then plasma exchange should be considered.

Other immunosuppressants have been tried in CIDP but cyclophosphamide is the only one to have shown promise. MMNCB, MADSAM and possibly motor-predominant CIDP may deteriorate with steroids and plasma exchange and therefore steroids should be avoided in these conditions.

**Outcome** CIDP is a chronic progressive or relapsing disease. About 80% of patients will respond to treatment. Where patients fail to respond to treatment an occult paraprotein should be sought annually.

Over half (54%) of patients require assistance to walk or are bed-bound at some stage of their illness; 13% of patients require assistance to mobilise or are bed-bound at any one time. Over 50% require continuous treatment to maintain stability.

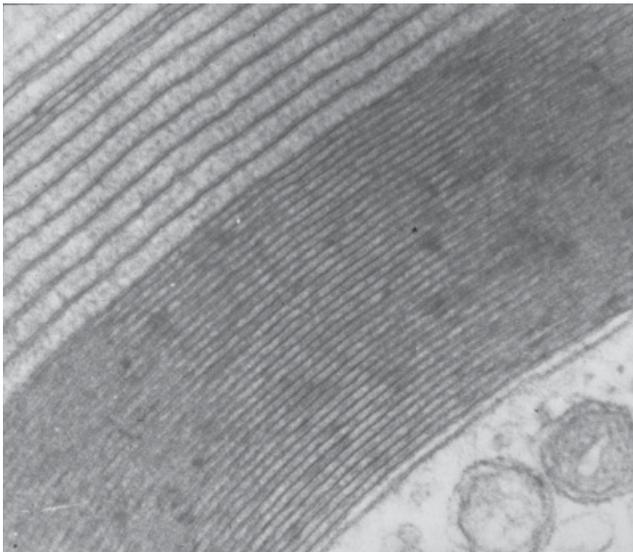

### Paraproteinaemic neuropathies

Neuropathies associated with a paraprotein occur more often than by chance alone. The prevalence of a paraprotein in the serum at the age of 50 is approximately 1%, rising to 3% aged 70. Some 30–70% of patients with a paraprotein have a demonstrable peripheral neuropathy. Conversely, of a group of patients with no other identifiable cause for their neuropathy, 10% have a paraprotein. Most neuropathies are associated with 'benign' paraproteinaemias (monoclonal gammopathies of undetermined significance [MGUS]). Although IgG paraproteins account for 61% of all paraproteins, IgM MGUSs are over-represented in association with neuropathies and in many the MGUS is thought to be implicated in causation. Neuropathies associated with malignant gammopathies are more often caused by compressive lesions, direct infiltration or amyloidosis.

If a paraprotein is discovered in the serum it should be fully investigated with a full clinical examination, search for urine light chains, a skeletal survey and a bone marrow aspirate and trephine to establish whether it is benign or malignant. The differential diagnosis of gammopathies associated with neuropathy is shown in Table 10.9.

**Neuropathies associated with IgM paraproteins** The neuropathy associated with IgM paraproteins is most frequently demyelinating. About 50–70% of the paraproteins react with the peripheral nerve epitope displayed by myelin-associated glycoprotein (MAG). A  $\kappa$  light chain is most frequent although IgM $\lambda$  anti-MAG paraproteins do occur. The clinical picture associated with anti-MAG antibodies is relatively homogeneous. A slowly progressive distal sensorimotor neuropathy with a variable degree of ataxia and prominent tremor is typical. Men are affected more than women, with a mean age of onset of 59 years. The neurophysiological features are demyelination with characteristic prominent distal slowing. Nerve biopsy (not required for diagnosis) shows characteristic widening of the myelin lamellae (Figure 10.15).

There is good evidence to indicate that anti-MAG IgM paraproteins are pathogenic, although it is likely that the current assays are highly sensitive and pick up a subgroup of non-pathogenic antibodies. The evidence for the pathogenesis of other IgM paraproteins is less robust even though other serum activities to specific epitopes are reported. Thus, when IgM paraproteins occur in conjunction with otherwise CIDP-like or axonal neuropathies the neuropathies are treated according to their non-gammopathy related features (see Treatment of paraproteinaemic neuropathies).

**Figure 10.15** Widely spaced myelin. The normal myelin lamellae are tightly compacted and have a periodicity in electron microscope preparations of 12–15 nm. In the demyelinating neuropathy associated with IgM paraprotein that has activity against MAG (anti-MAG PDPN) the intraperiod line becomes split giving an overall periodicity of 30–40 nm. There is a suggestion of material within the widened spaces, possibly immunoglobulin M.

**Neuropathies associated with IgG and IgA paraproteins** The neuropathy associated with an IgG or IgA paraprotein is most often a chronic symmetrical predominantly sensory neuropathy similar to CIDP, but the presentations are much more heterogeneous than for IgM. People with IgG and IgA MGUS neuropathy often have less weakness and relatively more sensory involvement, both clinically and neurophysiologically, than do people with idiopathic CIDP. Electrophysiologically the neuropathies are either demyelinating or axonal/mixed neuropathies in approximately equal numbers. Debate continues about whether a patient with an IgG MGUS and otherwise typical CIDP justifies a separate diagnosis.

**Neuropathies associated with lymphoma/CLL/Waldenström's macroglobulinaemia** Neuropathy may be the presenting feature of a malignant gammopathy. A progressive painful neuropathy is common. Axonal and demyelinating large fibre and small fibre involvement occur. Several pathogenic mechanisms have been described including direct antibody attack on the nerves, immunoglobulin deposition, cryoglobulinaemic vasculitis, cold agglutinin activity, amyloid deposition, increased serum viscosity and ischaemia and direct infiltration by malignant cells (neurolymphomatosis).

**POEMS syndrome** Polyneuropathy, organomegaly, endocrinopathy, M-protein and skin changes constitute the POEMS syndrome, a rare haematological paraneoplastic disorder in which the cytokine vascular endothelial growth factor (VEGF) is strongly implicated in the pathogenesis. All five clinical features are not always present at presentation. The minimal criteria to establish the diagnosis are the presence of a demyelinating and axonal polyneuropathy associated with an IgA or IgG monoclonal gammopathy, the light chain being almost always  $\lambda$ , as well as one other major criterion (Castleman's disease, osteosclerotic bone lesion(s) or a raised plasma VEGF) and at least one secondary minor criterion; endocrinopathy (excluding

diabetes), skin change (glomeruloid haemangiomas are specific to POEMS), organomegaly, generalised oedema, papilloedema or thrombocytosis/polycythaemia. A number of associated features are also recognised including (but not limited to POEMS) weight loss, low  $B_{12}$ , diarrhea, clubbing, restrictive lung disease. Ultrastructural identification of uncompacted myelin lamellae on the peripheral nerve biopsy is also a strong argument in favour of the diagnosis.

**Cryoglobulinaemic neuropathy** See Vasculitic neuropathies.

**Neuropathies associated with multiple myeloma, solitary myeloma and other malignant plasma cell dyscrasias** The neuropathies associated with a malignant plasma cell dyscrasia are heterogeneous. They should be managed in conjunction with a haematologist.

**Treatment of paraproteinaemic neuropathies** Because the neuropathy associated with paraproteinaemia is often mild and only slowly progressive treatment may not be required. The level of paraprotein and the neuropathy should be monitored as there is a risk of approximately 1% per year of malignant transformation of the B-cell clone which is greater in the first few years after identification. Treatments are aimed at reducing the amount or activity of antibody in the serum. IVIG has short-term benefit in IgM paraproteinaemic neuropathies. Rituximab is showing promise as an effective treatment. Plasma exchange, steroids, chlorambucil, azathioprine, cyclophosphamide,  $\alpha$ -interferon, fludarabine and cladribine have all been used with variable success. For IgG and IgA paraproteinaemic neuropathies those with a slowly progressive distal axonal polyneuropathy tended to show a poor response to immunotherapy. Patients with a sensorimotor demyelinating neuropathy tend to respond better. In POEMS syndrome, specific treatment of osteosclerotic bone lesions may improve the other features of the syndrome, especially the neuropathy. Autologous bone marrow transplantation has been effective in some.

**Acquired amyloid neuropathy** In AL (light chain) amyloidosis the constituent amyloid protein is derived from monoclonal immunoglobulin light chains secondary to multiple myeloma, malignant lymphoma or Waldenström's macroglobulinaemia, or to a non-malignant immunocyte dyscrasia. Amyloid develops in approximately 15% of patients with myeloma and less frequently in other malignant B-cell disorders.

The amyloid is more commonly derived from  $\lambda$  than  $\kappa$  light chains.

**Clinical features** The incidence of AL amyloidosis is 5.1–12.8 per million. Light-chain amyloidosis occurs predominantly in later life, two-thirds between the ages of 50 and 70. It may present with non-specific symptoms such as malaise, fatigue and weight loss or with system specific symptoms, the most common being nephrotic syndrome, congestive cardiomyopathy, peripheral neuropathy (sometimes with autonomic involvement) and hepatomegaly. Associated features include purpura, oedema, hepatosplenomegaly and macroglossia.

Patients with neuropathy present with an acquired length dependent sensory loss with prominent small fibre involvement. Pain is often burning, especially nocturnally, or lancinating stabs. Autonomic involvement including distal limb anhidrosis, orthostatic hypotension, difficulty in voiding urine, and erectile and ejaculatory difficulty tends to be an early manifestation. Diarrhoea and

gastroparesis may be prominent but whether this is related to direct gut wall or autonomic infiltration is uncertain.

On examination, nerves may be thickened, pain and temperature are selectively involved and autonomic involvement is often evident (including pupillary involvement).

**Pathology** The pathological features of AL amyloidosis are similar to those already described in the section above on pathology of transthyretin-related FAP.

**Diagnosis** Histological confirmation of amyloid deposition in nerve, rectum, abdominal fat or other tissue with Congo red is described above. Immunohistochemical staining for  $\lambda$  or  $\kappa$  light chains has a sensitivity of only 50%.

Once the diagnosis of AL amyloidosis is made it is necessary to screen for a paraprotein. Protein electrophoresis will detect a paraprotein in serum or urine in about 50% of patients where it is present. Immunofixation of serum and urine should be routinely performed and quantification of free light chains detects abnormality in 92% of patients. If all of the above techniques are used the sensitivity is 99%.

Bone marrow aspirate with a trephine biopsy and detailed systemic investigation should then be undertaken to assess the degree of other organ involvement, especially renal, cardiac and gastrointestinal. A serum amyloid protein scan identifies and quantifies tissue deposits in many tissues but not peripheral nerve.

**Treatment of amyloid neuropathy** Symptomatic treatments for pain, autonomic symptoms and the neuropathy can be tried as outlined above for TTR-related FAP. Extensive cardiac or renal involvement may merit organ transplantation. Chemotherapeutic regimens of different intensity are available to treat patients diagnosed at different stages of their disease. It is very important that patients are treated by centres with expertise in amyloidosis as regimes are continually being researched and updated.

**Prognosis** Prior to recent advances in treatment a median survival time of 35 months for patients with acquired amyloid peripheral neuropathy compared to 16 months for those without neuropathy was typical although longer survival is reported. Death was usually because of involvement of systems other than the peripheral nerves.

With treatment the outcome is better; a recent review reported that 22% of patients survived more than 10 years.

### Vasculitic neuropathies

The vasculitic neuropathies are uncommon but are some of the most devastating but treatable peripheral neuropathies. The principal pathology is vascular inflammation in the vessels of the vasa nervorum with fibrinoid necrosis and occlusion of the vessel leading to nerve infarction. The early recognition, diagnosis and appropriate treatment can prevent considerable morbidity. They can be classified into systemic or non-systemic and then into primary or secondary causes (Table 10.9).

**Symptoms and signs** Sequential progressive painful sensorimotor mononeuropathies presenting over days or weeks is typical of the presentation of vasculitis. Lower limb nerves tend to be affected first. Progression to confluence occurs, especially in polyarteritis nodosa (PAN) and Wegener's granulomatosis, and more slowly in some of the secondary vasculitides. Systemic involvement may present as fever, weight loss, myalgia, fatigue and night sweats or as organ-specific symptoms of rash, wheeze or shortness of breath, haematuria and arthritis or arthralgias.

### Primary vasculitides

- 1 Eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome)** Up to 80% of patients with Churg–Strauss syndrome present with a neuropathy. Fever, pulmonary infiltrates, late onset asthma, skin rash and eosinophilia are often all present. Antineutrophil cytoplasmic antibody (ANCA) is positive in up to 70%.
- 2 Granulomatosis with polyangiitis (Wegener's granulomatosis)** This is a midline necrotising vasculitis associated with a positive c-ANCA in 90% of patients. A neuropathy occurs in up to 40% of patients and may be confluent.
- 3 Polyarteritis nodosa** True PAN is rare. It affects muscular arteries and arterioles only and is ANCA negative. Neuropathy occurs in 75% of cases and presents quite frequently as a painful symmetrical picture. Hepatitis B infection is often associated and implicated in the genesis.
- 4 Microscopic polyangiitis** This is an overlap syndrome in which neuropathy occurs in 50–60% of cases. p-ANCA is often positive.

### Secondary vasculitides

- 1 Rheumatoid arthritis (RA)** The most common neuropathy associated with RA is a slowly progressive distal symmetric sensory neuropathy, many of which are asymptomatic. This is not vasculitic. Vasculitic neuropathies occur more often in late seropositive disease.
- 2 SLE** This may present with a multiple mononeuropathy with vasculitis on nerve biopsy. However, a CIDP or GBS-like illness also occurs.
- 3 Infection** Hepatitis C is strongly associated with the presence of type II (mixed) cryoglobulinaemia. This may cause a painful asymmetric multiple mononeuritis. The treatment is that of hepatitis C with ribavirin and interferon, although there are a number of case reports of vasculitis occurring in association with treatment per se. Vasculitis is directly attributable to HIV in <1% of cases. More frequent is a vasculitis secondary to coexistent hepatitis B, CMV or lymphoma.

### Non-systemic vasculitides

- 1 Non-systemic vasculitic neuropathy** usually has a more subacute or chronic course, but again with multiple mononeuropathies. Systemic symptomatic features are absent, except occasionally weight loss or fevers. No other organ involvement is identified on investigation. The prognosis and response to treatment are more favourable than with systemic forms.
- 2 Diabetic lumbosacral plexopathy (diabetic femoral neuropathy, Bruns–Garland syndrome, diabetic amyotrophy).** There remains controversy about the classification of this entity but it seems to be a form of monophasic vasculitis.

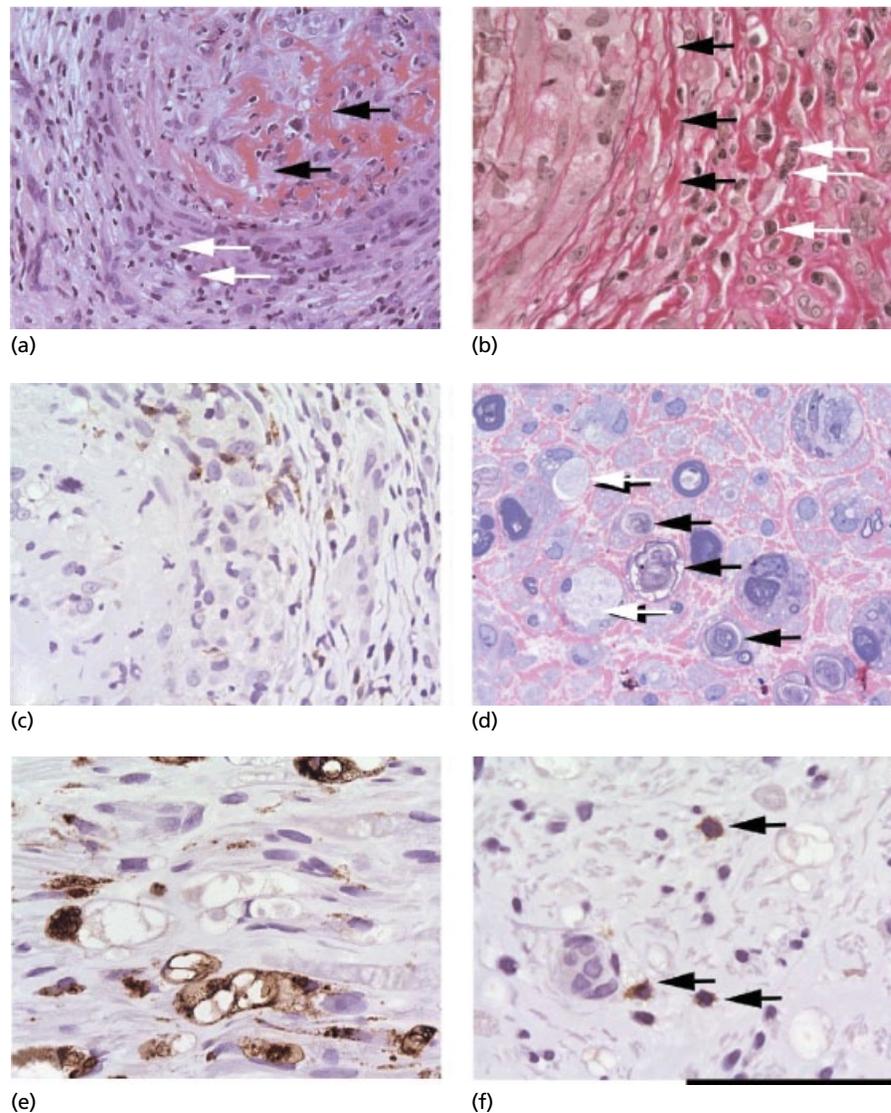

### Investigation of vasculitic neuropathies

- 1 Haematological and biochemical investigation** Routine investigations should include full blood count, ESR, urea and electrolytes, C-reactive protein (CRP), liver and thyroid function, glucose (+/- HbA1c), ANA, ANCA, rheumatoid factor and RA latex, complement, serum protein electrophoresis and immunofixation, cryoglobulins (transfer to the laboratory at 37°C), hepatitis B and C. Consider requesting anti-ENA (extractable nuclear antigen), anti-CCP (cyclic citrullinated peptide), serum ACE (angiotensin converting enzyme), HIV testing and Lyme serology. The urine should be examined for red cell casts and Bence-Jones proteinuria.
- 2 Radiology** A chest X-ray should be performed.

- 3 CSF is not usually helpful in vasculitic neuropathies. It could be performed to rule out differentials including HIV, carcinomatosis, lymphoma and Lyme disease if these are relevant.
- 4 *Neurophysiology* Patchy asymmetric sensorimotor axonal damage is typically found with evidence of acute or subacute denervation on EMG. Demyelinating neuropathies are sometimes found but should point to alternative or additional pathologies.
- 5 *Nerve biopsy* Patients with vasculitis are likely to need treatment with high dose, potentially toxic immunotherapies for a considerable time. A biopsy-proven diagnosis can usually only be made before treatment commences and it will reassure both physician and patient about their treatment. A biopsy of skin, liver, kidney

or lung might be an alternative. If a nerve biopsy is performed, a recently affected sensory nerve should be selected. Biopsy of the superficial peroneal nerve and the underlying peroneus brevis muscle increases the chances of diagnosis over biopsy of the superficial peroneal nerve alone.

Patchy axonal fibre loss with active axonal degeneration is frequently seen in vasculitides. The diagnostic hallmarks of T-cell infiltration into vessel walls with destruction of the elastic lamina and fibrinoid necrosis with vessel occlusion (Figure 10.16) are seen less frequently. Biopsies should be carried out by an experienced surgeon and interpreted by a histopathologist with specific experience in peripheral nerve disease.

**Figure 10.16** Vasculitis and severe axonal neuropathy in a peripheral nerve. (a) Fibrinoid necrosis (black arrow) of a medium-sized vessel. The vessel wall is densely infiltrated by inflammatory cells (white arrows). (b) Van Gieson elastica staining to visualise the distended and infiltrated vessel walls (red, black arrows) and interdispersed lymphocytes (white arrows). (c) CD8 immunohistochemical staining to visualise T-cells in the vessel walls. (d) Semi-thin resin sections on a transverse section of the adjacent nerve. Black arrows show acutely degenerating axons. White arrows indicate macrophages with the characteristic fine granular bright cytoplasm and peripheral small dark nucleus. (e) CD68 immunohistochemical staining to visualise digestion chambers and macrophage in the acutely degenerating nerve. (f) Accompanying occasional T-cell infiltrates in the affected nerve. This is regarded as a bystander effect to the overall inflammatory disease and should not be regarded as primary inflammation. Scale bar: A = 160 µm; b, e = 90 µm; c = 110 µm; d, f = 50 µm.

**Treatment** The vasculitides are a treatable group of disorders. Because of the ischaemic pathology, missing the opportunity to treat early may result in permanent irrecoverable peripheral nerve lesions. Randomised controlled trial evidence for specific therapeutic regimens in vasculitic neuropathy does not exist.

**Non-virus-associated vasculitis** Treatment is usually required, except in mild or non-progressive cases (usually non-systemic vasculitic neuropathy) and usually urgently. The key to treatment is the initial induction of remission followed by a maintenance phase. Oral steroids at a dose of 1–2 mg/kg or pulsed methylprednisolone (monthly courses 1 g/day for 3–5 days with 1 mg/kg oral prednisolone between) are usual. Wegener's granulomatosis and microscopic polyangiitis often require a more aggressive treatment course than Churg–Strauss or the non-systemic vasculitides. However, each case should be judged on its merits. Furthermore, there is good retrospective evidence that the addition of additional agents to the remission regimen improves the rate of remission, disability at 1 year and the rate of relapse even in non-systemic vasculitis. Cyclophosphamide is the most commonly used agent. Oral cyclophosphamide (2 mg/kg/day) was traditionally used; however, many clinicians now prefer to use monthly pulsed intravenous cyclophosphamide (10–15 mg/kg, maximum 1 g per dose and modified by age and renal function) with prehydration and MESNA cover for 6 months because of its reduced side effect profile (CYCLOPS regimen).

Many agents have been used for maintenance which usually covers the tail of oral steroids and continues to 2 years depending upon outcomes and patient tolerance. Methotrexate, azathioprine, mycophenolate and leflunomide have all been shown to be beneficial in case reports. Rituximab is useful in cryoglobulinaemic and lymphoma-associated vasculitis and demonstrated to be effective in other primary vasculitides (Rituxvas trial).

**Virus-associated vasculitis** Hepatitis B associated PAN responds to a short (2-week) induction course of steroids followed by 6 months of antiviral treatment, either interferon-2 $\alpha$  or lamivudine. Hepatitis C cryoglobulin associated vasculitis is treated with pegylated interferon-2 $\alpha$  with ribavirin, although neuropathy has on occasion been induced when this regimen is used to treat hepatitis C alone. Plasma exchange is traditionally used alongside the treatment for both viruses to clear circulating immune complexes but is of no demonstrable benefit.

**Outcome** Untreated vasculitis has a very poor outcome. In most types of vasculitis induction and maintenance treatment is associated with partial or complete recovery in about 50% of patients over months to years. Non-systemic vasculitis has much the best prognosis in terms of remission and low rates of recurrence.

## Other acquired peripheral nerve disorders

### Endocrine disorders

**Diabetes** Neuropathies occur extremely frequently in association with diabetes and, after leprosy, diabetes is the most common cause of neuropathy worldwide. Many neuropathies are asymptomatic or minor. Most occur later in the course of the disease; the prevalence of neuropathy is 50% after 25 years. The risk of neuropathy increases with duration of disease, poor control, height, male sex and with other cardiovascular risk factors constituting the 'metabolic syndrome'. Diabetic neuropathies can be classified as in Table 10.11.

**Table 10.11** Classification of diabetic neuropathies.

Distal symmetric sensory neuropathy (DSSN)
Autonomic neuropathies
Vasculitic plexopathies and thoracolumbar radiculopathies (amyotrophies)
Focal and multifocal mononeuropathies
Small fibre neuropathy
Acute reversible hyperglycaemic neuropathy
Insulin neuritis and hypoglycaemic neuropathies
Neuropathies associated with diabetes (e.g. CIDP)

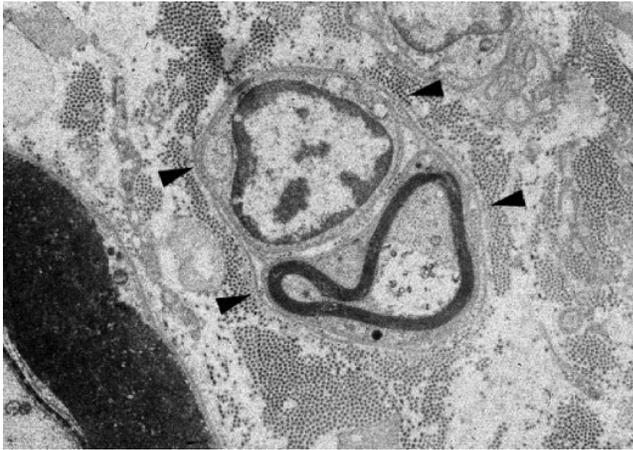

CIDP, chronic inflammatory demyelinating polyradiculoneuropathy.

**Figure 10.17** Charcot joint in a foot secondary to recurrent severe vasculitic neuropathy. The second phalanx has been amputated and a new vasculitic ulcer is present on the sole of the foot.

**Distal symmetric sensory neuropathy** Distal symmetric sensory neuropathy (DSSN) is the most common of the diabetic neuropathies. It presents with a slowly progressive 'glove and stocking' sensory loss which may be painful. Small fibre symptoms may also be present. With severe neuropathy, neuropathic Charcot joints may be present (Figure 10.17).

It is rarely necessary to perform a sural nerve biopsy on someone with apparently uncomplicated DSSN. Many of the biopsy features are non-specific but reduplication of basement membranes (Figure 10.18) and other endothelial alterations are commonly found.

**Figure 10.18** A diabetic nerve demonstrating reduplication of the basal lamina (arrows) around a Schwann cell and myelinated nerve fibre.

The pathophysiology is poorly understood but relates to prolonged periods of hyperglycaemia increasing flux through the polyol pathway. Increased metabolic and oxidative stresses result in advanced glycated end-products in nerve.

There is no effective treatment but progress of the neuropathy can be largely arrested with aggressive diabetic control, although this is only achieved in about 25% of patients. Pain can be treated with antiepileptic and antidepressant medication.

**Autonomic neuropathies** These occur in both type 1 and 2 diabetes but are often most severe in type 1. Diabetes is the most common cause of autonomic neuropathy in the West. Up to 75% of men have impotence. Gastrointestinal motility disorders are common with constipation and nocturnal diarrhoea. Subclinical cardiovascular autonomic involvement is common with sympathetic and parasympathetic cardiac denervation demonstrated by fixed high heart rates. Postural hypotension is demonstrable in more than 40% of patients but is seldom symptomatic.

**Vasculitic plexopathies** The most common plexopathy is the diabetic lumbosacral plexopathy (also known as diabetic femoral neuropathy, diabetic amyotrophy, lower limb asymmetric motor neuropathy or Bruns–Garland syndrome). Patients present with asymmetric aching pain in the buttock, hip or thigh followed by progressive weakness and wasting affecting the hip flexors and quadriceps. The knee jerks are lost but sensory loss is unusual unless there is a coexistent DSSN. Patients describe a progressive history of asymmetric leg ache or pain followed by weakness and wasting, mostly in the femoral compartment. Usually, dramatic weight loss and the appearance of diabetes or worsening of its control are prominent. Cervical plexopathies and thoracolumbar radiculopathies have also been described. These probably have the same pathogenesis.

Nerve conduction studies show radicular neurogenic changes in the quadriceps muscles. Pathological studies have suggested that this is a microvasculitis.

Regaining tight control of the diabetes is the basis of treatment. Both IVIG and pulsed intravenous and oral steroids have been anecdotally been said to be of benefit. However, spontaneous recovery (which is sometimes complete) may occur over 18–24 months without any treatment.

**Focal and multi-focal mononeuropathies** Individual mononeuropathies including CTS and peroneal neuropathies are more common in diabetes than in the healthy population because nerves are more susceptible to the mechanical effects of compression.

Cranial nerve palsies, most commonly pupil-sparing ‘microvascular’ IIIrd nerve palsies, are not uncommon. The VIIth and VIth nerves may also be affected.

**Small fibre neuropathy** See Small fibre neuropathies.

**Acute reversible hyperglycaemic neuropathy** In patients with uncontrolled hyperglycaemia, an uncomfortable mainly lower limb sensory neuropathy can develop acutely. Nerve conduction is slowed. The symptoms resolve with reversal of the hyperglycaemia.

**Insulin neuritis** Rarely, an acute painful neuropathy may develop after the introduction of insulin, leading to rapid normalisation of glycaemic control. There is scant evidence to support a pathology but a pre-existing diabetic neuropathy may be unmasked with sudden relative hypoglycaemia. Prognosis is good if insulin therapy is continued.

**Neuropathies associated with diabetes (e.g. CIDP)** CIDP, but not GBS, was thought to occur more commonly in diabetics than the otherwise healthy population although this epidemiological association may not be correct from more recent studies. Severe proximal and distal diabetic neuropathy should be investigated for supra-added CIDP.

**Hypoglycaemia** Recurrent and severe hypoglycaemia, as occurs in insulinoma, results in a distal symmetric sensorimotor neuropathy. Distal painful paraesthesiae are usually prominent. Correction of the hypoglycaemia by treatment of the insulinoma results in improvement of the sensory symptoms but not the motor.

**Hypothyroidism** Frank hypothyroidism is associated with a sensory axonal neuropathy in a substantial number of cases. CTS occurs frequently as a presenting feature.

**Acromegaly** Unrecognised and untreated acromegaly is now unusual. Most commonly weakness is caused by myopathy. Carpal tunnel syndrome is common as are other entrapment neuropathies partly through hypertrophy of nerves. A distal predominantly sensory axonal neuropathy also occurs.

### Toxic, nutritional and metabolic peripheral neuropathies

**Toxic neuropathies** Peripheral nerve is relatively sensitive to the effects of systemic toxins (Chapter 19). The number of implicated drugs, chemicals and neurotoxins are too numerous to discuss each individually (Table 10.12). The reader is referred to <http://neuro.muscular.wustl.edu> for a discussion of individual toxins.

If toxin exposure is suspected a full history and examination should be performed and a sample of the toxin should be retrieved if possible. Serum and urine specimens should be collected and, for acute poisoning, an acute poisons unit consulted.

Most toxins cause axonal neuropathies, some of which have either a motor or sensory predominance. Far fewer toxins cause demyelination (e.g. amiodarone or bortezomib). Frequently, the severity of the neuropathy is dose related. Removal of the source of the toxin may result in recovery which may be complete. Some agents, for example taxol, ‘coast’ (i.e. the neuropathy tends to

**Table 10.12** Toxic neuropathies. After <http://www.neuro.wustl.edu/neuromuscular>.

Axonal				
Sensory	Sensory and motor	Motor	Demyelinating	Mixed

Platinum analogues	Spanish toxic oil			
Propafenone	Taxol			
Pyridoxine	Tetrodotoxin			
Statins	Thallium			
Thalidomide	Trichloroethylene			
	Tri-ortho-cresyl phosphate			
	Vacor (PNU, a rat poison)			
	Vinca alkaloids			

continue to worsen) for several weeks or months after removal of the toxin. Heavy metal poisoning may require specific treatment (e.g. lead, mercury and thallium) and toxins (e.g.  $\alpha$ -latrotoxin, botulinum toxin) may benefit from antitoxin therapy. Prolonged supportive therapy in ITU may be required (e.g. botulism, tick paralysis).

**Nutritional** Vitamin deficiencies occur through inborn errors of metabolism (e.g. vitamin E deficiency, methylcobalamin deficiency; Chapter 19), limited dietary intake (vegan/vegetarian diet, alcoholism) or failure of absorption (post-ileal resection, pancreatic failure, coeliac disease). Deficiencies may therefore be isolated or combined. Neuropathies are invariably axonal, some associated with pain or ataxia and many with CNS involvement. Replacement of deficient vitamins by supplementation or providing an alternative metabolite can halt and sometimes improve the neuropathy.

#### *Multi-vitamin malabsorption syndromes*

- 1 Coeliac disease** Coeliac disease is associated with a typical length-dependent sensory neuropathy, sometimes with pain. As well as the systemic disease features, coeliac has also been associated with seizures, ataxia, myopathy, headaches and vitamin A deficient night-blindness. Causation is difficult to prove except in the latter.
- 2 Inflammatory bowel disease** Occasionally, a neuropathy occurs proportionate to the severity of the illness. Vitamin B<sub>12</sub> deficiency through terminal ileal malabsorption is common.
- 3 Cuban epidemic neuropathy** (Strachan's syndrome) Strachan's syndrome was described in prisoners of war. Cuban epidemic neuropathy occurs in patients of Afro-Caribbean origin and is very similar. It is thought to be caused by deficiencies in B vitamin and sulphur compounds. It typically occurs between 25 and 65 years of age with no sex predominance. Risk factors include tobacco and cassava consumption. The neuropathy is distal, axonal, sensory and often painful and occurs with an optic neuropathy presenting as central scotomata. Early treatment with B and multi-vitamin preparations can lead to resolution of the neuropathy although visual field defects may persist.
- 4 Postgastroplasty/gastreectomy** Patients may become malnourished through severely reduced dietary intake, diversion, bypass or resective procedures and sometimes vomiting. Copper and selenium deficiency may occur. Polyneuropathy, mononeuropathies (especially CTS), radiculopathies and myelopathies are all described.

#### *Vitamin deficiencies* (Chapter 19)

- 1 Vitamin B<sub>1</sub>** (beri-beri) presents with an acute or chronic length dependent sensorimotor axonal neuropathy primarily affecting the legs. Burning feet with lancinating pains are common as is autonomic involvement in severe disease. Wernicke-Korsakoff syndrome, cerebellar degeneration and cranial nerve palsies also occur as well as the systemic features of beri-beri (heart failure, oedema and weight loss).
- 2 Pyridoxine** (vitamin B<sub>6</sub>) In excess, pyridoxine typically causes a neuropathy/neuronopathy syndrome. Deficiency causes a length-dependent polyneuropathy. Users of isoniazid, penicillamine and hydralazine as well as alcoholics, the elderly and the malnourished are all at risk and should receive appropriate supplements.
- 3 Vitamin B<sub>12</sub>** The causes of B<sub>12</sub> deficiency are legion and all neuropathy blood profiles could include the measurement of B<sub>12</sub> and folate. Symptoms are compounded by central and peripheral involvement. Deficiency may be long-standing and chronic.

Nitrous oxide dental anaesthesia may unmask it. Typically, large fibre modality distal sensory loss begins first and motor involvement occurs later. Corticospinal tract involvement may lead to pyramidal weakness and extensor plantar responses. Treatment with vitamin B<sub>12</sub> may stabilise or improve the neuropathy but seldom improves the central involvement.

- 4 Vitamin E** Deficiency states cause a distal axonal neuropathy associated with cerebellar and posterior column involvement. Plantar responses may be extensor.

#### **Metabolic neuropathies**

**Porphyrias** Acute intermittent porphyria (AIP), coproporphyria, variegate porphyria and  $\delta$ -amino-levulinic dehydratase porphyria cause neurological syndromes (Chapter 19). The most common is AIP.

AIP typically occurs in attacks, affecting women more than men. Abdominal pain and constipation reflect the sympathetic and parasympathetic involvement which can cause great management difficulties with additional cardiovascular instability. The neuropathy is motor and sensory and may be severe enough to result in respiratory failure and require ventilation.

Nerve conduction studies typically show axonal degeneration with denervation and small sensory potentials.

Treatment of attacks is with haem arginate or haematin and supportive measures to treat pain, constipation and weakness (including ventilation).

**Uraemic neuropathy** Renal failure, uraemia and dialysis are all associated with a multi-factorial neuropathy. Up to 60% of patients have a subclinical neuropathy. Symptoms and signs are of a length dependent sensory axonal neuropathy occasionally with pain and prominent itching. Recovery from renal failure or renal transplantation may improve or reverse the symptoms.

#### **Critical illness neuromyopathy**

The existence of a severe critical illness neuropathy in the absence of a myopathy is controversial (Chapter 20). Most patients who have a period of intensive care will develop a mild distal sensory neuropathy and some limb weakness of unknown cause. However, some patients have a severe proximal and distal weakness, sometimes affecting ventilation and weaning because of a myosin loss myopathy. This is most common in sepsis, dialysis-dependent renal failure and as a consequence of severe and prolonged ITU admission. On examination patients may be profoundly weak (including neck flexors), have absent reflexes and they often have distal sensory loss. Small compound muscle action potentials (CMAPs) are found on electrophysiology because of muscle inexcitability rather than axonal loss. Myosin is depleted in muscle biopsy specimens. Treatment is supportive.

#### **Small fibre neuropathies**

Small fibre neuropathies (SFN) are an increasingly recognised and symptomatically troublesome group of disorders with diverse causation. There are no studies of the epidemiology of SFN. This is largely because of the lack of a satisfactory definition for SFN and standardised methods of investigation and detection. A reasonable definition is a neuropathy characterised by positive (spontaneous or stimulus-induced) or negative sensory symptoms caused by dysfunction of A $\delta$  or C fibres with or without autonomic abnormalities as assessed by specific neuropathological or electrophysiological tests. Asymptomatic small fibre involvement also occurs.

**Table 10.13** Small fibre neuropathies.

<b>Idiopathic</b>
Idiopathic small fibre neuropathy

Familial amyloid polyneuropathy
Familial burning beet
<b>Systemic amyloidosis</b>

EBV, Epstein–Barr virus; HAART, highly active antiretroviral therapy; MGUS, monoclonal gammopathies of undetermined significance; SLE, systemic lupus erythematosus.

The list of causes of SFN is increasing (Table 10.13). Unfortunately, perhaps 50% or more small fibre neuropathies have no identifiable cause. Recently up to one-quarter of patients with idiopathic small fibre neuropathy have been shown to have mutations in the *SCN9A* gene encoding the voltage gated sodium channel NaV<sub>1.7</sub>.

**Symptoms** SFN most often presents with positive sensory symptoms of pain (often burning, pricking or aching) in the feet. Sometimes the

symptoms also affect the upper limbs. Pain may be spontaneous or stimulus evoked. It is often worse at night, may interfere substantially with sleep and can be relieved temporarily by walking or immersing the feet in cold water. Lancing pain and paraesthesiae are usually indicative of additional large fibre involvement.

An association with restless legs syndrome is not uncommon. Significant autonomic disturbances are uncommon in idiopathic small fibre neuropathy and most often mild. Prominent orthostatic hypotension, faecal urgency, diarrhoea (especially nocturnal) and incontinence, urinary difficulties, impotence and sweating abnormalities should all prompt a search for diabetes, amyloid, vasculitis or a hereditary cause.

**Signs** The allowable clinical signs in SFN vary between experts in the field. Usually there is reduced temperature and pain sensation in the feet. Otherwise there should be no muscle wasting or weakness, deep tendon reflexes should be present and bedside vibration and proprioception should be normal.

**Investigation** Causation should be sought with appropriate blood tests and chest X-ray. Genetic testing for mutations in *SCN9A* should be considered (many polymorphisms exist). Standard nerve conduction tests are normal. Thermal threshold testing (especially warm thresholds which correlate well with intra-epidermal nerve fibre densities) is an effective method to confirm the diagnosis. Other tests are being developed (contact heat evoked potentials, laser evoked potentials, measurement of cutaneous silent periods and axon reflex flare responses) but are yet to be fully validated or widely used. Skin biopsy is a useful, largely painless, site specific and minimally morbid procedure to quantify intraepidermal nerve fibre density with high diagnostic efficiency and predictive value. Sural nerve biopsy does not form part of the investigation of SFN.

**Treatment** No treatments are yet available to treat or reverse SFN. Treatment is largely symptomatic and trials of gabapentin, pregabalin, sodium valproate, topiramate and opiates all demonstrate some benefit. Tricyclic antidepressants, duloxetine, oxcarbazepine and others are often tried. Enzyme replacement is helpful for the SFN in Fabry disease. Erythropoietin has shown promise in limited *in vitro* studies.

### Idiopathic axonal neuropathy

Despite best practice the cause of at least 25% of neuropathies remain undiagnosed. These are largely a group of slowly progressive but usually non-disabling axonal and SFN. Careful history-taking, examination and sometimes the ability to examine 'unaffected' relatives improves diagnosis. It is to be hoped that over the coming years many of these conditions will be diagnosed more successfully.

### Focal and compressive neuropathies

Focal neuropathies are the result of local damage to individual nerve trunks. They may be single or multiple; the occurrence of more than one pressure palsy should stimulate a search for a predisposing cause. Damage occurs most frequently because of compression, usually as the nerve passes through a tissue tunnel (bone, ligament, aponeurosis, muscle), or against an underlying surface at an exposed site (e.g. the peroneal nerve as it passes around the head of the fibula). Compression may also occur with prolonged abnormal postures (e.g. radial paralysis in the 'Saturday night palsy'). Diabetes, HNPP and alcohol overuse render nerves susceptible to the effects of otherwise non-damaging pressure.

The pathogenesis of focal compressive nerve dysfunction is probably multi-factorial and in experimental studies the mechanisms of acute and chronic compression have been shown to differ. At sites of acute compression endoneurial fluid, axonal contents and subsequently myelin are squeezed down the pressure gradient at the edge of the compression, resulting in nerve intussusception and subsequently Wallerian degeneration. In chronic compression, focal demyelination is found with alterations in nodal structure suggestive of a 'myelin slippage' secondary to stretching. In addition, endoneurial ischaemia may occur and contribute to focal pathology. The transperineurial venous plexus may be easily compressed as it obliquely exits the perineurium resulting in increased endoneurial tissue pressures, reduced blood flow and alteration in the endoneurial metabolic microenvironment. Over the longer term, impaired axonal transport may result in reduced distal trophic support. Furthermore, a nerve that becomes tethered at a site of inflammation can become further damaged; the inability of the nerve to glide during limb movement results in more nerve stretching.

Compression palsies cause signs in the motor and sensory distribution distal to the site of compression. Symptoms may occur both proximal and distal to the site. The reader is referred to diagrams of neuromuscular innervation at the beginning of this chapter (Figure 10.3, Figure 10.4, Figure 10.5 and Figure 10.6). The most common focal neuropathies affect the median (CTS), ulnar and

common peroneal nerves. Many other nerves may be affected producing a variety of syndromes, many with colloquial names; e.g. orator's [anterior interosseous] and claw [ulnar] hand, waiter's tip and Saturday night [radial] palsies in the upper limb and toilet seat [sciatic], strawberry and turnip picker's and hoeing [peroneal] palsies in the lower limb). These are not always entirely 'typical' as anatomical variations may vary muscle and cutaneous innervation (e.g. Martin-Gruber anastomoses between median and ulnar nerves). Lesions of any other individual nerve trunk are possible and result in motor and/or sensory signs in the distribution of their innervation. The most common are the lateral cutaneous nerve of the thigh (resulting in meralgia paraesthetica), sciatic, radial, long thoracic, 'tarsal tunnel' (distal tibial [posterior] and peroneal [anterior] neuropathies) and femoral neuropathies.

History, examination and investigation follow similar principles to those already described. These are outlined with their colloquial terminology in Table 10.14. For more detailed descriptions the reader is referred to specialised texts.

### Median nerve compression and carpal tunnel syndrome

Median nerve compression between the flexor retinaculum of the wrist and the bones of the carpus is referred to as carpal tunnel syndrome (CTS) and is the most common of the median compression palsies. The prevalence has been estimated at more than 6% of the population.

**Table 10.14** Other focal neuropathies.

Colloquial terminology	Sites of compression	Weakness	Sensory loss
<b>UPPER LIMB</b>			
<b>Median nerve</b>			
Carpal tunnel syndrome (CTS)	Wrist (carpal tunnel)	Opponens pollicis, abductor pollicis brevis, flexor pollicis brevis, lumbricals	Palmar skin of thumb, digits II, III (and lateral IV)
Circle sign	Anterior interosseous nerve (below elbow)	Flexor pollicis longus and flexor digitorum profundus (median) – the circle sign	None
Orator's hand	Bicipital aponeurosis (elbow), or ligament of Struthers (above elbow)	Median innervated flexors (profundus/superficialis) and pollicis + pronators quadratus and teres	Palmar + CTS loss
<b>Ulnar nerve</b>			
Guyon canal syndrome	Guyon canal at wrist	Interossei and abductor digiti minimi (variable)	Distal superficial ulnar (variable)
'Claw hand'/tardy ulnar palsy/cubital tunnel syndrome	Elbow	As above + flexor carpi ulnaris, flexor digitorum profundus (ulnar)	Medial surface of palm and digits V and IV
<b>Radial nerve</b>			
Waiter's tip palsy	Upper arm/axilla	Triceps (strong in proximal lesions), brachioradialis, wrist and finger extensors	Superficial radial territory of hand (snuff box)
Tourniquet palsy			
Saturday night palsy			
Crutch palsy (sometimes with ulnar and median = triad neuropathy)			

(continued)

Table 10.14 (continued)

Colloquial terminology	Sites of compression	Weakness	Sensory loss
Wartenberg syndrome	Wrist	None	
Cheiralgia paraesthetica			
<b>Axillary nerve</b>	Axilla or humeral head	Deltoid	Skin over deltoid
<b>Suprascapular nerve</b>			
Pitcher's neuropathy	Suprascapular notch or ligament	Supra- and infraspinatus weakness (often painful)	None
<b>Long thoracic nerve</b>			
Rucksack palsy Long thoracic neuropathy	Shoulder or lateral thoracic wall	Serratus anterior	None
<b>Brachial plexus</b>			
Neurogenic thoracic outlet syndrome	C7 transverse process, anterior scalene muscle, fibrous band	C8 root > T1 root hence thenar > hypothenar muscles	Ulnar border of hand, forearm and arm
<b>LOWER LIMB</b>			
<b>Sciatic nerve</b>			
Toilet seat palsy	Gluteal compression	Hamstrings and all muscles below knee	Tibial and common peroneal territories (latter more common if partial)
Yoga paralysis	Sciatic notch	May also involve superior/inferior gluteal nerve	? + posterior cutaneous nerve of thigh
Catamenial sciatica (with endometriosis)			
<b>Peroneal nerve</b>			
Strawberry picker's, (olive) harvester's, turnip picker's, hoeing or clergyman's palsy	Popliteal fossa, lateral fibular head and fibular tunnel	Tibialis anterior, extensor hallucis longus, extensor digitorum and peronei	Lateral lower leg and dorsum of foot

Fractured humerus
Elbow dislocation
Direct trauma
Anatomical compression
Supracondylar ligament/spur
Biceps aponeurosis
Pronator teres
Tumours and masses
Angiography/venepuncture

Compression in the more proximal upper limb occurs more rarely. Median nerve compression in the axilla usually co-occurs with radial and ulnar nerve compressions and is most commonly caused by traumatic or surgical injury, or unusual compressive forces (e.g. crutches or heavy sleep through intoxication). In the upper arm trauma is the most common insult and the median nerve may be affected in isolation. At the elbow the median nerve is susceptible to numerous injuries (Table 10.15). Compression at the elbow or more proximally is easily clinically identifiable as it leads to inability to pronate the forearm and flex the distal phalanx of thumb and index finger (orator's hand). Numbness affects the palm as well as the distal fingers.

### Carpal tunnel syndrome

CTS is 3–8 times more common in women than men. It most commonly affects both hands, usually the dominant hand first. There are many recognised causes of CTS (Table 10.16). Numbness, paraesthesiae and pain in the hand and sometimes in the more proximal arm, often occurring at night, are the most common presenting complaints. When the pain is intermittent, shaking the hand or wrist relieves the symptoms and is a relatively reliable sign of compression at the wrist. The provocative tests of median nerve compression include Tinel's sign in which a light tapping over the nerve elicits tingling in the sensory distribution of the nerve or Phalen's test when the patient holds their wrists in complete and forced flexion to reproduce the symptoms. If not treated, these sensory symptoms become permanent and weakness and wasting of the thenar eminence may become apparent.

**Examination** Compression of the median nerve at the wrist typically results in sensory disturbance on the palmar skin of the thumb, second, third and half the fourth digit and weakness of abductor pollicis brevis, opponens pollicis, first and second lumbricals and sometimes flexor pollicis brevis. There are many anatomical variations. The palmar cutaneous branch arises proximal to the flexor retinaculum and does not pass through the carpal tunnel. Occasionally, the motor branch may pierce the retinaculum and may escape compression but be damaged during surgery.

**Investigation** Nerve conduction studies are required to confirm the diagnosis as demonstration of the clinical symptoms and signs is not 100% reliable. About 5% of studies are falsely negative, but a negative study should provoke a search for an alternative diagnosis (C6/7 radiculopathy, thoracic outlet syndrome or thalamic infarction). Severely affected patients are unlikely to benefit from surgical decompression

**Table 10.16** Causes of carpal tunnel syndrome.

as there is no remaining nerve to save. Where anatomical variants or structural abnormalities of the wrist are considered MRI can be most helpful in assisting both diagnostician and surgeon. The yield from haematological and biochemical testing where no pathology is detected on thorough clinical examination is low.

**Treatment** There is evidence of variable quality that non-surgical interventions including oral steroids, ultrasound, yoga and carpal bone mobilisation are effective in the short term for symptom relief. There is no benefit from the use of non-steroidal anti-inflammatory drugs or diuretics. Nocturnal splinting can relieve the symptoms in mild disease. Local steroid injections into the carpal tunnel seems to provide short-term relief, and while this procedure is carried out widely, a needle can cause median nerve injury. Surgical decompression gives the most satisfactory relief (90–95% success) in both the short and long term (3% recurrence rate) and is associated with minimal risks. Results are better if symptoms have been present for less than 3 years. Endoscopic release has few advantages over open procedures and is more often associated with failure.

### Ulnar nerve compression

The ulnar nerve can also be damaged anywhere along its course from the brachial plexus to the hand. The most common site of damage is at the elbow. Here the nerve is exposed to trauma, pressure and stretching as it passes the medial epicondyle through the ulnar groove and then deep to the flexor aponeurosis under flexor carpi ulnaris. Other causes reflect the causes – similar to median neuropathy (Table 10.17). An extensive differential diagnosis of conditions mimicking ulnar neuropathy exists (Table 10.18).

C8/T1 radiculopathy
Thoracic outlet syndrome
Lower brachial plexus lesions (trauma/infiltration/radiation/post sternotomy)
Brachial neuritis (neuralgic amyotrophy)
Multi-focal motor neuropathy with conduction block

**Symptoms** Numbness and tingling affecting the fourth and fifth digits of the hand are the most frequent presenting complaints. Deep pain may be felt proximal to the nerve. Weakness of hand grip appears later but may be the only symptom in some. The elbow may be identified as a site of previous damage, trauma or pressure and occasionally sensitivity of the ulnar nerve at the elbow is reported.

**Signs** Accurate clinical localisation of ulnar neuropathies is essential to guide exploration and treatment. Weakness of first dorsal interosseous and abductor digiti minimi in the hand is most common. Motor branches and the distal superficial cutaneous branches all pass through Guyon's canal; signs confined only to this territory could result from compression at the wrist or more proximally. Sensory loss should not extend above the wrist; the medial cutaneous nerve of the forearm

emerges from the brachial plexus. Weakness of the flexor digitorum profundus to the fourth and fifth digits or flexor carpi ulnaris puts the lesion at the elbow or above. Involvement of the palmar skin of the medial border of the hand or the dorsal skin of the affected fingers excludes compression in Guyon's canal at the wrist. Additional weakness of median nerve innervated muscles (see Median nerve compression and carpal tunnel syndrome) suggests alternative diagnoses. The presence of a thickened nerve at the elbow suggests inflammatory, hereditary, tumour or lepromatous involvement.

**Treatment** Effective treatment of ulnar neuropathies usually involves surgical intervention. Conservative measures aimed at educating the patient to avoid leaning on the elbow, nocturnal splinting and diffusing pressure with sheepskin elbow pads may all assist. Surgery should be offered to patients who have sensory and motor signs consistent with the diagnosis, especially if there is clear worsening. Patients with sensory signs only should be closely reviewed to detect signs of progression – most will remit. In late severe cases with weakness, wasting and sensory loss surgical intervention may not be beneficial but tendon transfer procedures may help hand function. Surgical approaches involve removing compressing structures (e.g. masses) if appropriate, and thereafter releasing and mobilising the nerve to a greater or lesser extent. Transposition of the nerve is associated with greater risks of peri-operative damage and thus extensive exploration and release may often be the most appropriate intervention.

**Other ulnar neuropathies** Ulnar neuropathies at other sites are identified by careful history-taking, examination directed at ulnar nerve innervation and more widely in the neck, chest and upper limb and neurophysiological 'inching studies' (inch by inch). Imaging (both MRI and ultrasound) are more widely used to identify abnormalities in sites other than the elbow.

### Common peroneal neuropathies

Isolated lesions of the peroneal nerve are the third most common of the mononeuropathies. The common peroneal nerve is most liable to damage as it winds laterally around the knee and fibula head. It then passes through the fibular tunnel (a fibrous arch derived from peroneus longus) before dividing into superficial and deep peroneal nerves (Figure 10.7).

**Symptoms** Complete common peroneal lesions cause a foot drop with inability to evert the foot or extend the toes and a characteristic high-stepping and audibly slapping gait. The sensory loss covers the lower half of the lateral part of the leg and dorsum of the foot, sparing the sural nerve territory. The history may or may not reveal an obvious cause (Table 10.19). A history of focal pain elsewhere in the leg or other systemic symptoms should prompt a search for a local or systemic cause.

**Signs** The site of the lesion may be clear from the history or obvious site of damage from examination. However, the variability of innervations in the leg, and common occurrence of partial nerve lesions of the sciatic, lumbosacral trunk or multiple radiculopathies, means that an electrical study is often crucial for localising the site of damage and directing further investigation and treatment.

**Investigation** Nerve conduction and EMG studies enable localisation of any lesion from root (often L5) through the lumbosacral trunk and sciatic nerve to the more distal branches of the superficial and deep peroneal nerves. Although plain radiographs, CT and

DVT, deep venous thrombosis.

arteriography have diagnostic use in specific scenarios, MRI scanning has greatest utility in demonstrating intrinsic and extrinsic mass lesions (both tumours and inflammatory) of the nerve.

**Treatment** Acute trauma with nerve transection or compartment syndromes are surgical emergencies and intervention to explore and relieve pressure and/or repair the nerve is indicated. Where an episode of prolonged nerve compression is identified avoidance of further injury and watchful waiting are appropriate. Most lesions recover. Lesions that progress or fail to recover, or lesions associated with other structural abnormalities should be surgically explored.

### Plexopathies

The two major nerve plexuses are the brachial and lumbosacral. Lesions of a plexus cause complex post-ganglionic motor and sensory deficits in the distribution of part or all of the plexus. The reader is referred to the anatomical diagrams (Figures 10.3 and 10.6) to assist with identifying and localising involvement. Causes are shown in Table 10.20. Many of these are common to both plexuses. Some, for example neuralgic (brachial) amyotrophy and diabetic lumbosacral plexopathy, have a predilection for one or the other.

### Acute brachial neuritis

Parsonage and Turner described this entity also known as neuralgic amyotrophy in 1948. Typically, acute deep aching pain occurs

CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; MMNCB, multi-focal motor neuropathy with conduction block.

spontaneously and affects the neck, shoulder and upper arm in a diffuse pattern. This may last from hours to 2 weeks or more; it is sometimes exceedingly painful. This is followed by focal wasting and weakness, most commonly in the distribution of nerves originating from the upper plexus (deltoid, serratus anterior, supraspinatus and infraspinatus and biceps). Muscles in the distributions of the lower brachial plexus may also less commonly be affected. Sensory symptoms occur in about one-third of patients

and sensory signs in about two-thirds, most often sensory loss in the territory of the axillary nerve. Prolonged pain, bilateral involvement, structural or mass lesions on examination should prompt a search for an alternative cause.

The cause of brachial neuritis remains uncertain. Occasional rapid recovery and the finding of conduction block point to demyelination as an initial mechanism but clearly axonal degeneration swiftly follows. Rare pathological reports of inflammatory nerve lesions exist. Associations with immunisation, infection, trauma, surgery, pregnancy and childbirth, intravenous heroin and vasculitides point to an immune mechanism. Steroids, although sometimes

useful for pain, usually fail to alter the outcome. Other analgesics (including opioids) are usually necessary. About 90% of patients with a typical brachial neuritis will recover in 3 years. Rarely, a similar condition affects the lumbosacral plexus.

## Anterior horn cell diseases

Many motor nerve diseases principally affect the anterior horn cell body; these are usually neurodegenerative (e.g. motor neurone disease) or hereditary (e.g. spinal muscular atrophy). However, there is a broad differential diagnosis (Table 10.21).

**Table 10.21** Differential diagnosis of motor neurone disease.

<b>Bulbar weakness</b>	Charcot–Marie–Tooth diseases
Brainstem	Distal hereditary motor neuropathies
(tumour, infarction, infection, demyelination)	Muscular dystrophy – fascio-scapulothoracic
Syringobulbia	Autoimmune
Neuromuscular junction	VGKC Ab mediated disease (neuromyotonia, Isaac's syndrome, Morvan's syndrome)
Myasthenia gravis	SLE, Sjögren's syndrome
Muscle	Infective
Oculopharyngeal dystrophy	Postpolio syndrome
Others	Borrelia
Allgrove's (AAA) syndrome (achalasia, adrenal deficiency, alacrima)	Syphilitic pachymeningitis
Neuro-acanthocytosis	HIV related
Superficial siderosis	Inflammatory
Neuro-degenerative conditions	CIDP
<b>Upper motor neurone</b>	Inflammatory muscle disease (polymyositis, inclusion body myositis)
Compressive	Multifocal motor neuropathy with conduction block
Cervical spondylosis/radiculopathy	Metabolic/endocrine
Intrinsic	Hexosaminidase A deficiency
Multiple sclerosis	Metabolic muscle disease (acid maltase deficiency)
Solitary sclerosis	Thyrotoxicosis
Spinal cord tumour	Hyperparathyroidism
Degenerative	Toxins
Hereditary spastic paraparesis	Heavy metal toxicity – lead, thallium, arsenic toxicity
Infective	Konzo, lathyrism
HTLV1-related myelopathy	Radiation
Metabolic	Organophosphate toxicity
Subacute combined degeneration	Compressive
Adrenomyeloleukodystrophy	Multiple radiculopathies
Vascular	Paraneoplastic syndromes
Cord infarction/haemorrhage	<b>Neurodegenerative</b>
<b>Lower motor neurone</b>	Corticobasal degeneration
Unknown cause	Progressive supranuclear palsy
Benign fasciculation/cramps	Multiple system atrophy
Hereditary	Parkinson's disease
Spinal muscular atrophy	Huntington's disease
X-linked bulbospinal neuronopathy (Kennedy's disease)	
Benign monomelic amyotrophy (Hirayama syndrome)	

## Motor neurone disease

Motor neurone disease (MND) is a progressive neuronal degenerative disease involving the corticospinal tract, brainstem and anterior horn cells of the spinal cord that leads to severe disability and death. There is considerable variability in presentation, clinical course and prognosis. The condition is divided into several different clinical subtypes. Amyotrophic lateral sclerosis (ALS) is the most common and is characterised by upper and lower motor neurone involvement of the bulbar, upper and lower limb territories; presentation with predominantly or exclusive bulbar weakness (lower and/or upper motor neurone) is referred to as progressive bulbar palsy (PBP). In primary lateral sclerosis (PLS) there is exclusively upper motor neurone involvement and progressive muscular atrophy (PMA) involves only lower motor neurones although there is a considerable overlap between these patterns.

### Amyotrophic lateral sclerosis

The onset of ALS is usually with asymmetrical focal wasting and weakness affecting contiguous limb muscles more commonly in the upper limbs. Occasionally, there may be severe isolated wasting and weakness of individual limbs (e.g. flail arms). Other patients may present with bulbar dysfunction, progressive dysarthria and, less commonly, dysphagia. Rarely, there may be selective involvement of respiratory muscles leading to respiratory failure. ALS is characterised by the progressive development of wasting, fasciculation, cramp, weakness, spasticity, brisk reflexes and extensor plantar responses. Limb involvement is more often distal than proximal leading to weakness of the hands or bilateral foot drop. Patients may complain of clumsiness or impaired mobility. Bulbar involvement is characterised by weight loss, dysarthria, wasting, fasciculation and slow movement of the tongue, sialorrhoea and dysphagia. Patients complain of difficulty speaking or occasionally hoarseness which usually precedes swallowing difficulties. Clear fluids tend to aspirate causing the patient to cough after drinking. Hypersalivation becomes difficult to clear and leads to the development of drooling and dribbling. Pseudobulbar involvement is also associated with pathological emotional lability in which there is excessive uncontrolled laughter or crying and a brisk jaw jerk.

Fasciculation is variable but may be prominent after exercise. It is well seen in the tongue and across the back. Head droop may be an early feature because of weakness of the neck extensors and paraspinous muscles. Progressive respiratory muscle weakness may lead to exertional dyspnoea and selective diaphragm weakness will cause breathlessness on lying flat and progressive hypoventilation; examination shows paradoxical movements of the abdomen on inspiration. Increasing limb and truncal weakness causes worsening immobility and self-care. Bulbar weakness leads to increasing difficulty with communication and eventual anarthria with worsening dysphagia. Sleep disturbance is common and multi-factorial related to difficulty turning in bed, periodic limb movements, hypersalivation and inability to clear secretions, difficulty with communication, emotional lability and depression. Sensory, ocular and bladder symptoms are unusual.

### Progressive bulbar palsy

PBP is restricted to bulbar musculature at presentation and during the initial progression. The clinical pattern is usually predominantly upper motor neurone but wasting, fasciculation and palatal weakness may also be present. Subsequent spread to the cervical regions and then more generally is usual, but not inevitable, after several months. Occasionally, bulbar weakness remains isolated or the

predominant manifestation for many years, although generalised involvement usually develops eventually. PBP constitutes about 15–20% of cases of MND.

### Flail arm/leg syndrome

Progressive isolated wasting and flaccid weakness of an arm or leg may be the presenting feature in up to 10%. Upper motor neurone features develop later. This form of the condition is considerably more common in males, often below the age of 50, and carries a better prognosis than ALS.

### Primary lateral sclerosis

This is an exclusively upper motor neurone form of MND which occurs in about 10% of patients. Lower motor neurone features may develop in a minority after 5–10 years. The condition develops at an older age and may be slow in its progression. Survival for 20 years is not uncommon. Bladder symptoms are frequent but bulbar involvement often occurs later and is less severe.

### Progressive muscular atrophy

This is a heterogeneous syndrome in which there is exclusively lower motor neurone involvement. However, at least 30% of patients with PMA develop upper motor neurone signs within 18 months and progress to ALS. Patients with an exclusively lower motor neurone syndrome and disease duration of 4 years or more have a more favourable prognosis, particularly if muscle involvement is predominantly segmental.

### Cognitive involvement

Frontotemporal dementia occurs in <15% of patients with MND. It is characterised by personality change, irritability, poor insight and persuasive deficits on frontal executive tests. A milder form of executive impairment occurs in up to 20% of patients with ALS. It is associated with impaired judgement, behavioural disturbance, impulsivity and is a poor prognostic indicator.

### Other forms

The hemiplegic variant of Mills is a rare presentation with mixed upper and lower motor neurone signs occurring on one side of the body. Overlap of MND occurring with features of other neurodegenerative disease including parkinsonism and progressive supranuclear gaze palsy may occur. Facial onset sensory motor neuronopathy (FOSMN) has recently been described. Although there are marked similarities to classic bulbar onset MND, FOSMN is set apart clinically by the striking facial-onset sensory deficits with subsequent development of motor deficits, slow evolution in a rostral–caudal direction and a much better prognosis. The different forms of MND are summarised in Table 10.22.

### Aetiology

Sporadic MND is a complex disease and both genetic and environmental factors contribute to the development of the disease.

**Genetics** Between 5% and 10% of cases of ALS are familial (FALS) and most have an autosomal dominant pattern of inheritance. This is likely to be an underestimate because of incomplete recording or knowledge of family history and the possibility that some cases of sporadic MND represent familial forms with reduced penetrance.

**Table 10.22** Forms of motor neurone disease.

Genetic
Familial ALS
Brown–Vialeto–van Laere syndrome
Fazio–Londe

Sporadic MND (PBP, ALS, PMA)
PLS
Distal focal SMA
Madras form
Western Pacific form
MND and frontotemporal dementia
Multi-system atrophy
Progressive supranuclear palsy
Corticobasal degeneration
Focal onset sensory motor neuropathy
Acquired
HTLV1-associated myelopathy
HIV-associated MND
Creutzfeldt–Jakob disease
Acute poliomyelitis and post polio syndrome

ALS, amyotrophic lateral sclerosis; HSP, hereditary spastic paraparesis; HTLV, human T-lymphocyte virus; MND, motor neurone disease; PBP, progressive bulbar palsy; PLS, primary lateral sclerosis; PMA, progressive muscular atrophy; SMA, spinal muscular atrophy.

Mutations in more than 15 genes have been found to cause familial MND (Table 10.23). In approximately 20% of patients with FALS the genetic defect is a mutation on chromosome 21 in the gene for copper/zinc superoxide dismutase (*SOD1*). More than 100 mutations of the *SOD1* gene are now known. There is a small incidence of *SOD1* mutation occurring in sporadic MND. *SOD1* mutation screening is available, but counselling is essential before predictive testing can be undertaken. At present genetic screening for predictive testing is not performed routinely. Mutations in several other chromosomal loci have now been described in patients with autosomal recessive inheritance.

Patients with ALS and the C9orf72 repeat expansion are characterised by an earlier age of disease onset, cognitive and behavioural impairment, specific neuroimaging changes (i.e. non-motor cortex change on high resolution [3T] MRI and reduced grey matter volume), a family history of neurodegeneration with autosomal dominant inheritance and reduced survival. Identification of the transactive response DNA-binding protein 43 (TDP 43) as the major inclusion protein, common both to patients with ALS and frontotemporal dementia (FTD-TDP) suggests these conditions are closely related.

**Environmental factors** There is a 50–150 fold increase in the incidence of MND in the Western Pacific and other geographical clusters are described. The condition differs pathologically from sporadic ALS because dementia and parkinsonism frequently coexist. The pathological findings in these patients differ from sporadic ALS and are characterised by the presence of neurofibrillary tangles. It seems likely this form of the condition is related to a toxin, possibly from the cycad seed.

**Lymphoproliferative disease** An association between MND and lymphoproliferative disorders has been reported. PLS may rarely occur as a paraneoplastic disease associated with antineuronal antibodies.

### Diagnosis of MND

Routine haematology and biochemical screening is usually normal. Creatine kinase (CK) may be mildly or moderately elevated. Underlying lymphoproliferative, infective, endocrine, vasculitic or toxic causes should be excluded. Hexosaminidase A should be checked in the young. Genetic analysis may include *SOD1* and *SMN* in the predominantly lower motor neurone presentation.

### Investigations

Neurophysiology is essential in establishing the diagnosis and severity of MND and excluding the differential diagnoses (Tables 10.21 and 10.22). Sensory nerve action potentials (SNAPs) are normal and motor conduction velocities should be >70% of normal. There must be no conduction block. Needle EMG shows neurogenic changes of denervation and reinnervation. There is considerable variability in EMG findings and extensive sampling of bulbar, cervical, thoracic and lumbosacral muscles may be necessary. MRI is important to exclude structural or inflammatory conditions that may mimic MND. MRI may show high signal in the pyramidal tracts indicating Wallerian degeneration in patients with upper motor neurone involvement. Positron emission tomography (PET) imaging has shown cortical changes, particularly in patients with cognitive impairment.

### Incidence and prognosis

The annual incidence is 2–3/100 000 and the prevalence approximately 4–8/100 000. Males are more commonly affected than females (1.5 : 1). The incidence increases with age, with a mean age of onset of 63 years and peaks at 50 and 75 years.

The natural history of MND is variable and occasional prolonged periods of stability may occur. Patients with PBP have the worst prognosis because of the risk of aspiration with a median survival of 2–2.5 years. In ALS the mean disease duration is 3–4 years. Over 50% of patients die within 3 years but <10% survive for more than 8 years. In PLS a survival of 20 years is relatively common. In general, rapid rate of progression, early respiratory or bulbar symptoms and increasing age are adverse prognostic indicators, while exclusively upper or lower motor neurone syndromes and young age are associated with a better prognosis.

### Management

**Telling the patient the diagnosis** Diagnostic uncertainty is common during the early stages of the disease. Thus, the diagnosis is usually established 9–15 months after the first symptoms and usually two or three specialists will have been consulted, often resulting in profound anxiety and uncertainty. The communication of the diagnosis is a major and potentially devastating life event which must be handled with great sensitivity. All too often patients complain that the diagnosis has been given in a hurried, off-hand

and inappropriate manner. The diagnosis should be explained by a senior physician, in a quiet and private room, with a nurse specialist and a carer present. The patient should be provided written comprehensible information, contact telephone number or e-mail address and a follow-up appointment within a few weeks. Ongoing follow-up should be supervised by a single named doctor, in close liaison with the nurse specialist, GP and community services. The diagnosis and details of the information given to the patient and the management plan must be communicated to the GP without delay.

**Principles of management** The management of MND involves the coordination of multi-disciplinary care with a team that includes the patient's GP and primary care team, occupational and physiotherapists, clinical nurse specialists, support and social workers and the palliative care team. The supervising neurologist or physician should coordinate a continuum of care for each patient from diagnosis to the terminal phase of the disease. Each member of the team has an individual role. In the United Kingdom, the Motor Neurone Disease Association (MNDA) employs a network of regional care advisors. These individuals act as a point of contact for people with MND and their carers, and help to point to the provision of pieces of equipment such as splints and communication aids. They also provide a telephone helpline and are able to contribute to the support of relatives and carers following the death of the patient. Important websites are listed in Table 10.24.

**Pharmacotherapy** Riluzole has multiple actions which includes inhibition of glutamate release. It is the only drug that has been shown to increase survival in MND. Riluzole prolonged survival by 3 months after 18 months administration with little or no effect on functional deterioration in two clinical trials. It is usually well tolerated with occasional nausea and fatigue. The drug should be discontinued if liver function tests exceed five times the upper limit of normal. Many patients look to other possible treatments and antioxidants (vitamins C and E) and creatine are in common use despite the absence of evidence from randomised clinical trials. Acupuncture, reflexology, chiropractic manipulation and massage may contribute to the individual's personal feeling of well-being.

**Respiratory management** Respiratory impairment is common and may develop because of respiratory muscle weakness, impaired bulbar function and obstructive sleep apnoea (OSA) or defects in central control. It should be anticipated in all patients with a diagnosis of MND. Dyspnoea is caused by infection, pulmonary embolus or airway obstruction from mucus plug or inhaled

pharyngeal contents. Prompt use of antibiotics should be supplemented with physiotherapy. Annual influenza vaccination should be undertaken. Nocturnal hypoventilation and OSA present as daytime hypersomnolence, lethargy, morning headaches, poor concentration, depression, anxiety and irritability with or without snoring and restless sleep with abnormal movements.

FVC reflects respiratory muscle strength, and serial measurements may be useful in predicting the onset of respiratory failure. Non-invasive ventilation is often initiated when FVC is <50% of predicted. Isolated or selective diaphragm weakness is a particular concern and FVC should be monitored, both standing and lying – a fall of >30% indicates diaphragm weakness. Other markers of impending respiratory failure include maximal inspiratory and expiratory mouth pressures and maximum sniff nasal pressure. Nocturnal oximetry, polysomnography, diaphragmatic EMG and phrenic nerve conduction studies may provide useful additional information.

Respiratory support can provide symptomatic relief and increase life expectancy. These benefits must be balanced against the demands on carers, practical problems of administration, the risk of iatrogenic problems and distressing and unwanted prolongation of life in the terminal stages of MND. Many of these difficulties can be avoided by early and careful discussion with patients and their carers. Elective ventilatory support is usually administered non-invasively (NIV), initially during sleep. NIV allows speech, oral feeding and leads to fewer respiratory infections, extends survival and improves quality of life. However, it may not be desirable in patients with severe bulbar weakness, facial abnormalities or where aspiration has already occurred. Some patients require ventilatory support for increasing periods and may choose to undergo tracheostomy. Tracheostomy carries a significant risk of complications and considerable difficulties in domiciliary management. There remains a concern that tracheostomy may lead to prolonged survival in the face of severe disability. Many patients will decide to use NIV support if their respiratory function deteriorates and is symptomatic. There has been recent interest in pacing the phrenic nerve but this technique is expensive and unproven. The provision and supervision of respiratory support should be through a specialist MND centre.

**Management of bulbar weakness** Bulbar palsy is one of the most distressing features of MND. Weakness of tongue, pharynx and facial muscles results in slow eating, choking, drooling, dysarthria and dysphonia. Sialorrhoea is generally managed with anticholinergic agents including atropine or amitriptyline taken orally, hyoscine (scopolamine) transdermally or glycopyrronium bromide subcutaneously. Side effects are common in the elderly. Antimuscarinic

agents or mucolytic agents render secretions viscid whereas  $\beta$ -blockers have been reported to reduce secretions without increasing tenacity and a saline nebuliser may also be helpful. Portable home suction devices and cough enhancement techniques are also valuable in some patients. Unilateral parotid gland irradiation and botulinum toxin injection into the duct or directly into the parotid gland have also been used although the latter may exacerbate any bulbar weakness.

**Dysphagia** The management of dysphagia requires detailed clinical assessment with videofluoroscopy or fibreoptic techniques. This must be followed by speech and language therapy advice on techniques to ease mastication and prevent aspiration (e.g. tucking chin and flexing neck forward to protect the airway).

**Nutrition** Patients with dysphagia may have inadequate calorific and fluid intake, leading to accelerated weight loss and dehydration. The initial management of dysphagia in ALS includes modification of food and fluid consistencies while ensuring maximal calorific intake. Percutaneous endoscopic gastrostomy (PEG) should be considered as an alternative or supplementary route for nutrition, hydration and medication. PEG should be undertaken before FVC falls below 50% of predicted as it is more successful, improves survival and is less complicated at this early stage. Radiologically inserted gastrostomy tubes do not require sedation or endoscopy and are preferable in patients with respiratory compromise.

**Communication** Progressive dysarthria is common and speech may become severely impaired or lost within a short time. Simple techniques for improving the intelligibility of speech include reducing background noise and facing the speaker. Writing is often an excellent alternative to speech if limb function is preserved. There are a variety of other aids ranging from pointing boards to computerised speech synthesisers, particularly using iPad applications.

**Limb dysfunction** Musculoskeletal pain is common and may respond to antispasticity agents, NSAIDs and stronger analgesics including opiates. Skin pressure pain caused by immobility may also occur. Cramps are usually nocturnal and may respond to quinine sulfate, diazepam, carbamazepine or phenytoin. Stiffness may be caused by spasticity or muscle or joint contracture. Tizanidine and baclofen may help with the pain of spasticity.

**Cognitive impairment in ALS** MND is associated with both mild frontal lobe impairment and also a more severe form of frontotemporal dementia. Cognitive impairment occurs most often in patients with pseudobulbar palsy who may show changes in character, personality and behaviour. However, this is difficult to assess because of the speech disturbance and motor retardation associated with pseudobulbar palsy, these may be exacerbated by distress, anxiety and depression. Frontotemporal dementia is characterised by disinhibition, loss of insight and social awareness, impulsivity, reduced speech output with echolalia and eventual mutism. In the late stages there may also be anxiety, agitation, apathy and even delusions. There are characteristic pathological changes including frontotemporal neuronal loss, gliosis and spongiform change.

**Psychological factors** Depression and anxiety often follow the diagnosis of MND. The drugs of choice are SSRIs. Anxiety may require

specific drug therapy. This may be short-term treatment with benzodiazepines or amitriptyline. If aggression and disinhibition occur with cognitive impairment, phenothiazines may be necessary and psychiatric support is often helpful. Emotional lability may be distressing for patient and carers and may be eased by amitriptyline or an SSRI.

**Other symptoms** Insomnia is common in MND. If sleep remains disturbed after relief of pain then amitriptyline is preferable to hypnotics for sedation. Constipation is treated by dietary modification, ample fluid intake and aperients. With severe pyramidal involvement bladder frequency and urgency may occur requiring oxybutinin.

**Terminal care** Palliative care (Chapter 26) should be introduced before the terminal stages of MND. Home care teams and day centres offer respite care in parallel with home carers. Close liaison between GP, community health care and hospice teams and palliative care physicians is essential. In the later stages of the patient's illness, regular respite and psychological support should also be available for the primary carer.

Terminal care often involves alleviating psychological distress and the symptoms of bulbar weakness and respiratory failure. Patients may experience a frightening sensation of choking because of episodes of laryngospasm. Benzodiazepines and agents to dry secretions may be helpful but laryngospasm usually resolves spontaneously. Oral, subcutaneous or intravenous morphine may be indicated to relieve dyspnoea, anxiety, pain or other distress. The effectiveness of sedatives such as diazepam, midazolam or chlorpromazine in reducing anxiety in the terminal stages outweighs any depressive action of the drugs on respiratory function.

The 'Breathing Space Kit', provided by the Motor Neurone Disease Association in the United Kingdom, contains medication that can be used by the carer, nurse or GP for the emergency treatment of acute episode of respiratory distress which often occurs in the terminal stages. These include diazepam, diamorphine, chlorpromazine and hyoscine.

Some patients wish to consider an advanced directive to record their end-of-life decisions. For the large majority who decide against life-prolonging measures including tracheostomy and invasive ventilation it is important to reassure the patient and their carers that palliative care can control symptoms in the terminal phase of the illness.

**Carers** Following the death of a patient with MND the family and carers will require bereavement support. This can be provided by the palliative care team but continuing domiciliary support may also be necessary.

### Spinal muscular atrophy

Spinal muscular atrophy (SMA) represents a group of predominantly autosomal recessive disorders characterised by degeneration of anterior horn cells and bulbar nuclei without corticospinal or sensory neurone involvement. After cystic fibrosis, SMA is the second most common autosomal recessive disease of childhood (1/6000–10 000 live births). There are four clinically distinct types (Table 10.25):

- 1 SMA type I: infantile SMA (Werdnig–Hoffmann disease)
- 2 SMA type II: intermediate SMA
- 3 SMA type III: juvenile SMA (Kugelberg–Welander disease)
- 4 SMA type IV: adult onset SMA.

**Table 10.25** Summary of spinal muscular atrophy (SMA).

Condition	Genetic association	Clinical features
SMA type I (infantile, Werdnig–Hoffman)	5q13 (SMN gene)	See text
SMA type II (intermediate)	5q13 (SMN gene)	See text
SMA type III (juvenile, Kugelberg–Welander)	5q13 (SMN gene)	See text
SMA type IV Adult onset	Variable (AR or AD)	See text
X-linked arthrogryposis multiplex (X-linked infantile SMA)	Xp11.3–q11.2	Hypotonia, areflexia, multiple congenital contractures. Death in infancy
Diaphragmatic SMA (HMN III, IV)	11q13	Distal limb weakness
SMARD (HMN VI)	1GHMB2	Diaphragm weakness, death in infancy
Distal SMA (HMN V)	7p15 (GARS)	Often sporadic, predominantly upper limb

GARS, glycyI-tRNA synthetase; HMN, hereditary motor neuropathy; SMARD, SMA with respiratory distress type 1; SMN gene, survival motor neurone gene.

### Genetics and aetiology

The most common types of SMA are associated with defects in ribonucleic acid (RNA) processing. Spinal muscular atrophy types I–III and some of type IV (95% of the total SMA cases) are associated with reductions in the product of the survival motor neurone (*SMNI*) gene (chromosome 5q11.2–5q13.3). The *SMNI* gene encodes a protein involved in RNA metabolism and the severity of the phenotype correlates with the level of SMNI protein. In the majority of patients it is functionally absent and survival depends on the expression of the *SMNII* gene.

### Clinical features

**SMA type I (infantile, Werdnig–Hoffmann)** This develops in infancy with failure to achieve a sitting posture and death by 2 years. There may be loss of fetal movements *in utero* and the baby is born floppy with a weak cry and failure to suck, swallow and achieve head control or sitting posture. Contractures develop after immobilisation and death usually occurs by 2 years as a result of respiratory failure.

**SMA type II (intermediate)** In SMA type II (intermediate SMA) muscle weakness develops after 6 months and manifests as motor development delay. Independent sitting is achieved but not walking. Kyphoscoliosis, severe contractures, skeletal deformity and respiratory muscle weakness may lead to death in early adulthood but prolonged survival is possible if respiratory involvement is limited or with appropriate ventilatory support.

**SMA type III (juvenile, Kugelberg–Welander)** SMA type III (juvenile SMA) becomes symptomatic in early childhood (<18 months) and patients achieve mobility. Fasciculation, cramps and a fine tremor are common and there is proximal limb weakness and wasting more prominent in the lower limbs. SMA III is highly variable and often stabilises. Prognosis can often be predicted by the age of onset and severity. SMA III may be compatible with normal life expectancy.

**SMA type IV (adult onset)** Adult SMA represents a heterogeneous group. The pattern of weakness symmetrical with proximal muscles

more affected than distal muscles, legs more than arms with little involvement of facial or bulbar muscles. The truncal muscles or often severely affected with involvement of the intercostals but relative sparing of the diaphragm. The distal SMAs or HMNs present with distal limb weakness. Many of these disorders are allelic with subtypes of CMT2 disease with the principal distinction being mild to moderate sensory nerve involvement in CMT2. The autosomal dominant HMN 2A–C present with distal leg followed by distal arm weakness. In contrast, patients with HMN5A present with weakness beginning in the hand muscles and subsequently spreading to the legs.

An autosomal dominant pattern of inheritance accounts for up to 30% of cases and is not associated with chromosome 5 abnormalities or known dHMN mutations. The clinical pattern is variable with onset between the third and sixth decades. There may be slowly progressive limb girdle or scapulo-peroneal weakness with difficulty climbing stairs, arising from chairs or walking which resembles limb girdle dystrophy. Respiratory muscle involvement and scoliosis are rare but there may be vocal cord impairment.

**Other forms of SMA** Severe forms of SMA associated with death in infancy include X-linked arthrogryphosis multiplex (X-linked infantile SMA) characterised by hypotonia, areflexia and multiple congenital contractures and diaphragmatic SMA (SMARD-1) in which there is gynaecomastia, congenital fractures and sensory neuropathy. Fazio–Londe disease is a form of MND limited to the lower cranial nerves starting in the second decade of life and progressing to death over 1–5 years. Brown–Violetto–Van Laere syndrome presents largely in females in the second decade with bulbar palsy and deafness. The differential diagnosis of SMA is summarised in Table 10.26.

**Kennedy's disease (X-linked spinobulbar muscular atrophy)** Kennedy's disease is of particular importance because the clinical pattern resembles MND. With a frequency of 1/50 000 per year it is not uncommon. Kennedy's disease affects males with onset in the third decade or later. It is an X-linked disorder caused by a CAG trinucleotide repeat expansion in exon 1 of the androgen receptor gene on Xp11-12. The condition is characterised by prominent oral and

peri-oral fasciculation, muscle cramps, progressive dysarthria and dysphagia and slowly progressive lower motor neurone bulbar, shoulder girdle, axial and limb weakness. Upper motor neurone signs are not seen. Sensory involvement occurs. Other features of Kennedy's disease include gynaecomastia, diabetes mellitus, testicular atrophy and infertility. Kennedy's disease progresses more slowly than conventional MND and respiratory muscle involvement is less common; patients have an almost normal life expectancy. Serum CK may be elevated and nerve conduction studies may show reduced amplitude of both motor and sensory action potentials with diffuse, predominantly chronic denervation changes on EMG. The diagnosis is confirmed by genotyping.

**Hexosaminidase-A deficiency** The most severe form of hexosaminidase-A deficiency is Tay-Sachs syndrome (Chapter 19). However, a milder form may develop in children or adults characterised by a form of SMA associated with prominent muscle cramps, tremor, dementia, cerebellar atrophy and sensory involvement.

**Monomelic amyotrophy (Hiriyama's disease)** Monomelic amyotrophy is a form of non-progressive wasting and weakness affecting the upper limbs. It is usually unilateral and occurs predominantly in men (4 : 1) with onset typically between 15 and 25. There is focal involvement of the C7, C8 and T1 myotomes often sparing brachioradialis. There is no fasciculation or sensory involvement. The condition must be distinguished from the monomelic onset of motor neurone disease, chronic asymmetrical spinal muscular atrophy, brachial neuritis, multi-focal motor neuropathy and intrinsic cervical cord lesion.

The aetiology remains uncertain. The occurrence is sporadic and insidious in onset which had led to the suggestion that it is caused by focal compression of the cervical spinal cord possibly causing focal venous ischaemia. In support, typical MRI findings with the neck flexed include flattening of the spinal cord against the C5–6 vertebral bodies, lower cervical cord atrophy, reduction in the size of the posterior cervical subarachnoid space and hyperintensity in the anterior horn cell region on T2-weighted imaging.

**Allgrove's syndrome** Allgrove's syndrome is a rare multi-system disorder characterised by achalasia, adrenal insufficiency and

alacrima. Presentation is often with severe dysphagia caused by delayed passage of food into the stomach. There may be a more generalised autonomic disturbance characterised by abnormal pupillary reflexes, reduced heart rate variability and postural hypotension. There may also be a peripheral neuropathy, pyramidal syndrome, cerebellar and cognitive impairment. Allgrove's syndrome is caused by a mutation in the *ALADIN* gene on chromosome 12q13.

### Investigation

Serum CK is often normal in SMA I–IV but elevated in Kennedy's disease, SMARD-1 and other rare forms of SMA. Neurophysiological studies show reduced CMAPs but normal conduction velocities and SAPs, except in Kennedy's disease where sensory involvement is identified in 80% of cases. EMG shows acute denervation and chronic reinnervation. Muscle biopsy is not especially helpful and shows features of acute denervation and secondary myopathic change. Genetic confirmation of mutations in the *SMN1* or androgen receptor genes is diagnostic. Mutations may not be found in some rare forms of childhood SMA and in many patients with adult onset SMA.

### Management

There is no specific treatment available for SMA. The management largely involves the treatment of musculoskeletal complications which vary with age of onset and severity.

Ventilatory support may be necessary in SMA II. Invasive respiratory support leads to improved survival in some patients. Non-invasive ventilation may be necessary if nocturnal hypoventilation develops. In HMN7B or SPSMA, particular attention must be paid to vocal cord paresis which causes stridor and eventual airway obstruction. Vocal fold tie back procedures or tracheostomy may be indicated.

Scoliosis develops if there has been paraspinous weakness prior to the growth spurt and spinal correction may be necessary to preserve mobility and ventilatory function. The provision of walking aids including braces and callipers may allow younger patients to remain ambulant for many years.

It is important to ensure early access to an experienced paediatric palliative care support team. Ventilatory support is increasingly available for infants with SMA but most families opt to withdraw support when tracheostomy and invasive ventilation are indicated.

Treatment and management for SMA has improved to such an extent that many patients are surviving into adulthood. Clinics often need to be multi-disciplinary with input from neurology, respiratory, gastrointestinal, orthotic and nursing services. Independent mobility may be lost in teenage years and appropriate wheelchair and even driving provision must be considered. Planning for further education, work, pregnancy, independent living and genetic counselling is often necessary.

### Disorders of the neuromuscular junction

Functional or structural abnormalities of the neuromuscular junction (NMJ) interfere with the transmission of neural impulses from motor nerves to muscles. In myasthenia gravis, antibodies mediate damage to the post-synaptic acetylcholine receptor. In Lambert-Eaton myasthenic syndrome, antibody-mediated block of the pre-synaptic calcium channels results in a deficit of quantal release. Congenital myasthenia is caused by defects affecting presynaptic, synaptic and post-synaptic mechanisms leading to NMJ impairment.

### Myasthenia gravis

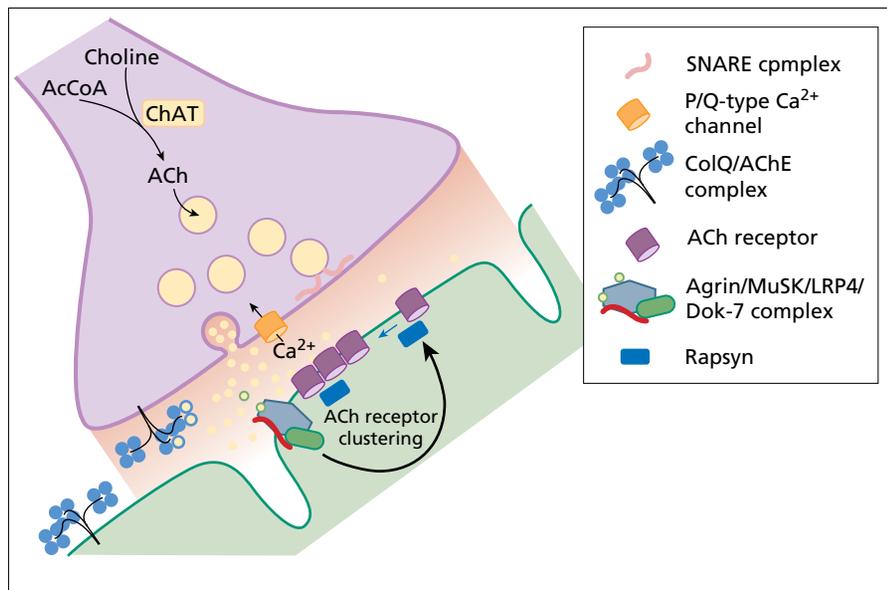

Myasthenia gravis (MG) is an autoimmune disorder caused by antibodies directed against the acetylcholine receptor (AChR) in the muscle membrane (Figure 10.19 and Figure 10.20). The serum antibody to the AChR and its interaction with the target antigen are well characterised.

The nicotinic AChR is a transmembrane glycoprotein with five subunits arranged around a central ion channel. These subunits are designated  $\alpha, \beta, \gamma, \delta$  and  $\epsilon$ , each of the two  $\alpha$  units has an extracellular acetylcholine binding site. The fetal AChR has a  $\gamma$  subunit in place of the  $\epsilon$ . The AChR ion channel is closed in the resting state and when the binding sites of both  $\alpha$ -subunits are occupied the channel

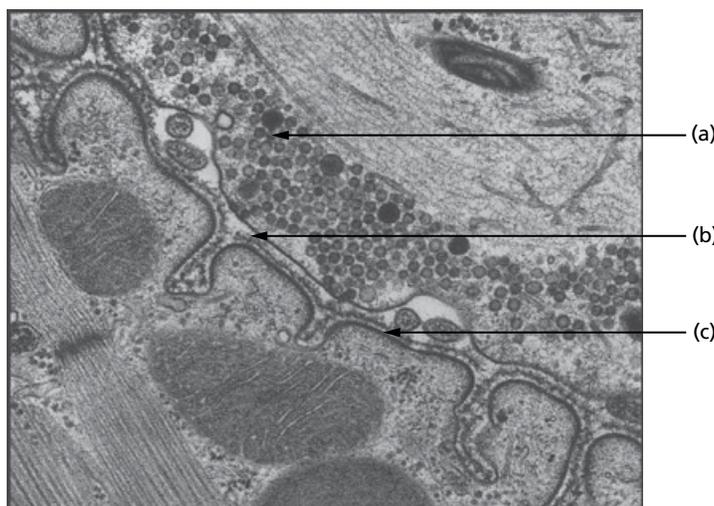

opens transiently. There is a continuous process of turnover and renewal of AChR at the NMJ; impaired transmission induces increased transcription of AChR genes, which eventually allows full recovery of the NMJ.

IgG anti-acetylcholine receptor antibodies (AChRab) of the IgG1 and IgG3 subtypes are detectable in 75% of patients with MG. These antibodies:

- Bind complement leading to destruction of the muscle end-plate.
- Bind to the receptor leading to blockade
- Cross-link muscle surface AChR increasing their rate of internalisation

**Figure 10.19** Key steps in acetylcholine (ACh) synthesis and release at the neuromuscular junction and the core pathway responsible for ACh receptor clustering. AChE, acetylcholinesterase; AcCoA, acetyl coenzyme A; ChAT, choline acetyltransferase; ColQ, AChE collagen-like tail subunit; Dok-7, downstream of tyrosine kinase 7; LRP4, low-density lipoprotein receptor-related protein 4; MuSK, muscle-specific kinase; SNARE, soluble NSF attachment protein receptor. Source: Spillane et al. 2010. Reproduced with permission of BMJ.

**Figure 10.20** Electron micrograph of a normal neuromuscular junction showing presynaptic vesicle (a), synaptic cleft (b); post synaptic membrane (c).

Loss of voltage-gated Na<sup>+</sup> channels at the end-plate leads to reduced muscle membrane depolarisation and an increase in the threshold necessary to initiate a muscle action potential.

### 'Antibody negative' myasthenia gravis – Anti MuSK antibodies

Some 20–25% of patients with MG are AChRab negative. IgG auto-antibodies to muscle-specific kinase (MuSK) can be found in >50% of these patients with either ocular or generalised MG. MuSK is a receptor tyrosine kinase expressed selectively in the NMJ of mature skeletal muscle. MuSK has a critical role in the clustering of post-synaptic proteins, including AChR during NMJ development. Anti-MuSK do not activate complement but reduce the postsynaptic density of AChRs and impair their alignment. The remaining patients, negative for both AChRab and MuSKab, are referred to as 'seronegative' although there is a conversion rate of <15%. Recently some of these patients have been shown to have 'low-affinity' AChRab.

### Clinical features

MG has a bimodal pattern of onset; it occurs most commonly in women in the second and third decade but there is a second peak of incidence in the sixth and seventh decades with men being predominantly affected. The approximate incidence is 1.5 and prevalence 15/100 000. Presentation is characterised by fatigable weakness in the ocular, cranial nerve, limb, truncal or respiratory musculature.

A number of drugs impair neuromuscular transmission and therefore precipitate or exacerbate myasthenic weakness; these are summarised in Table 10.27. D-penicillamine MG is usually mild and may remit when the drug is withdrawn; however, in others it may precipitate severe MG which proves difficult to control.

The initial manifestation is often fatigable visual blurring, diplopia and/or unilateral or asymmetrical ptosis which worsens towards the end of the day. Weakness remains localised to the ocular muscles in 15% of patients. The jaw, facial muscles, speech and/or swallow, neck, respiratory muscles and proximal limbs are all commonly affected. Selective diaphragm weakness is rare.

On examination, fatigable weakness can be demonstrated in any affected muscle by repetitive or sustained activity. Cogan's lid twitch sign is pathognomic – when the patient rapidly refixates from downgaze to the primary position, there is overshoot of the eyelid before it settles down to the ptotic position. Cooling of the eye with an ice pack may lead to improvement in ptosis but its sensitivity and specificity in myasthenia remain uncertain. The ophthalmoplegia is fatigable and often does not fit the pattern of a single cranial nerve weakness. The medial and inferior rectus and superior oblique are most commonly affected but severe and occasionally

**Table 10.27** Drugs that impair neuromuscular transmission.

Antibiotics	Aminoglycosides (gentamicin, neomycin, streptomycin)
Antiarrhythmics	Quinine, quinidine, lidocaine and β-blockers
Antiepileptics	Phenytoin
Antirheumatoid drugs	D-penicillamine Chloroquine
Competitive neuromuscular junction blocking agents used during anaesthesia	D-tubocuarine Pancuronium Depolarising agents (e.g. succinylcholine)

total external ophthalmoplegia may occur. Up to 20% of patients with MG have prominent bulbar symptoms early in the course of their disease.

Respiratory muscle weakness is demonstrated by limited chest wall movement and excessive use of accessory muscles of respiration. Weakness of the truncal musculature leads to difficulty sitting from supine while limb weakness is characterised by fatigability in a limb girdle pattern. However, it may be markedly asymmetrical and occasionally distal musculature may be preferentially affected. The symptoms typically worsen at the end of the day and with extreme heat. They are also exacerbated by emotional stress, infection, pregnancy and menstruation.

The anti-MuSK phenotype often occurs in young women and is characterised by predominant facial, bulbar and respiratory muscle weakness. Myasthenic crisis is common, particularly at presentation, and many patients deteriorate rapidly early in the disease course and may require prolonged ventilatory support. Myasthenia can coexist with other autoimmune diseases such as diabetes rheumatoid arthritis, pernicious anaemia, SLE, vitiligo and thyroiditis. The differential diagnosis is summarised in Table 10.28.

### Diagnostic tests

The diagnosis of MG can be supported by clinical, laboratory and electrophysiological investigations.

An intravenous bolus of edrophonium may transiently improve the symptoms and signs of myasthenia and is the basis of the Tensilon test. However, false negatives are common, false positives occur with many other neuromuscular diseases, and it is contraindicated in the elderly or patients with cardiac disease because of the risk of cholinergic haemodynamic side effects including bradycardia and ventricular fibrillation. It should not be undertaken in

**Table 10.28** Differential diagnosis of myasthenia.

Ophthalmoplegia	Isolated cranial nerve palsies Thyroid eye disease Guillain–Barré syndrome Mitochondrial disease Oculopharyngeal muscular dystrophy Central causes (e.g. Internal carotid artery aneurysms, MS)
Bulbar and respiratory weakness	Botulism Acid maltase deficiency Motor neurone disease, Kennedy's disease Central causes (e.g. tumour, stroke and MS)
Proximal limb weakness	Myopathy including 'limb girdle', congenital myasthenia; inflammatory causes (e.g. polymyositis)
Myasthenic crisis	Guillain–Barré syndrome Botulism Myopathy (acid maltase deficiency) Motor neurone disease Brainstem stroke/inflammation LEMS Organophosphate poisoning Cholinergic crisis

LEMS, Lambert–Eaton myasthenic syndrome; MS, multiple sclerosis.

outpatients or without the availability of atropine to reverse the cholinergic side effects. Because neuroimmunological and electrical tests are now available the Tensilon test is often unnecessary.

Electrophysiological studies (Chapter 4) looking at repetitive stimulation and single fibre EMG (SFEMG) are abnormal in MG. Repetitive stimuli at a rate of 3 Hz lead to a decrement in the CMAP amplitude of >15% which should be reproducible. SFEMG is the most sensitive neurophysiological investigation of neuromuscular transmission. An increase in jitter (trial-to-trial variation in latency from stimulus to response) may be restricted to the ocular or facial muscles and blocking (intermittent failure of excitation of the muscle fibre) is also seen. However, SFEMG is not specific and jitter may be seen in other disorders of the NMJ, nerve or muscle.

The antibodies are measured mainly by immunoprecipitation of <sup>125</sup>I- $\alpha$  bungarotoxin labelled ACh receptors. AChRab are detected in approximately 75% of patients with generalised myasthenia and 50% with pure ocular myasthenia. AChRab are the most specific marker for MG but they may rarely be found in association with thymoma, SLE, autoimmune liver disease, inflammatory neuropathies and RA (especially when taking penicillamine) without any clinical evidence of myasthenia. Levels of AChRab fluctuate with disease severity in an individual patient.

Anti-titin muscle antibodies are present in approximately 25% of patients with MG but in up to 90% with concurrent thymoma. Anti-MuSK antibodies occur in >50% of seronegative myasthenia gravis (SNMG) cases and are not found in ACRAb positive MG cases. Other autoantibodies that may be present in myasthenia include LRP4, titin, ryanodine receptor, anti-smooth muscle, antinuclear, antithyroid antibodies as well as rheumatoid factor and antibodies to gastric parietal cells and red blood cells.

## Management

There are few randomised controlled trials in MG but treatment is based on clear principles which are determined by the age, sex, disease pattern and severity, the risk of side effects and the availability of close clinical and investigational monitoring. Treatment may be symptomatic (anticholinesterases), disease modifying (immunosuppression with steroids, immunosuppressant drugs, immunoglobulins or plasma exchange) and/or surgical (thymectomy).

Anticholinesterases are the first line of treatment. They are of value in the early symptomatic treatment of MG as a single therapy or later as an adjunct to immunotherapy. Pyridostigmine is the most widely used. Side effects of anticholinesterases include muscle fasciculation and weakness occurring as a result of excessive stimulation of the nicotinic acetylcholine receptors. The abdominal cramps, diarrhoea, increased bronchial and oral secretions can be mitigated by antimuscarinic medication. Persistence of myasthenic weakness despite increasing doses of pyridostigmine is an indication for immunosuppressant treatment. MuSKAb related myasthenia is less responsive to anticholinesterase medication than AChRab positive myasthenia.

Corticosteroids can be extremely effective in improving myasthenic weakness and establishing remission. There is considerable variability in dosage, duration of treatment and clinical response to steroids. They should be commenced in hospital because of the significant risk of deterioration in proximal strength during the first 2 weeks of treatment. The risk is reduced if an incremental dosage is used. Marked improvement will occur in more than 50% of patients and remission in 25% with the time to maximum benefit approximately 6 months. Only 5% will show no significant improvement. While steroids are effective and inexpensive, their use is limited by considerable toxicity and they should be weaned to the

lowest dosage possible to prevent glucocorticoid side effects. All patients likely to receive more than 7.5 mg/day steroid for more than 6 months should be treated to prevent iatrogenic osteoporosis, preferably with a bisphosphonate.

Azathioprine has been shown to reduce the dosage of prednisolone required to maintain remission and to reduce the number of treatment failures. The effects of azathioprine (<2.5 mg/kg) are extremely slow to develop and a therapeutic dosage may take up to 2 years for the full clinical effect to be seen. The risk of azathioprine toxicity is reduced by screening for the activity of the enzyme thiopurine methyltransferase (TPMT) which metabolises azathioprine. The risk of myelosuppression is increased in those with low activity.

Mycophenolate and methotrexate (MTX) have been used individually as alternative second line immunosuppressant agents if azathioprine has been ineffective or not been tolerated. They are both well tolerated with relatively few side effects although it is important to emphasise that MTX is administered weekly and carries a risk of hepatic toxicity.

Ciclosporin has also been shown to be effective in a randomised controlled trial. Ciclosporin has similar efficacy to azathioprine but works more rapidly. Its use is limited by significant side effects including nephrotoxicity and hypertension which contraindicate its use in pre-existing renal disease and necessitate the need for regular blood monitoring. Cyclophosphamide is now rarely used in MG because of its toxicity.

Rituximab is a monoclonal antibody to the B-cell marker CD20. It has been effective on an anecdotal basis in both ACRAb and MuSK Ab positive MG. Side effects include neutropenia and increased susceptibility to infection.

Plasma exchange reduces AChRab titres significantly but is often ineffective in SNMG. It is valuable in producing short-term improvement of severe myasthenic weakness but difficulties and complications of venous access, biochemical derangements and high overhead costs limit its use. IVIG is similar in efficacy to plasma exchange and is valuable in producing short-term improvement in myasthenic crisis and also occasionally as a long-term maintenance therapy. There remains considerable uncertainty about the role of immunomodulation in MuSK myasthenia but a similar regimen of management is generally used.

Thymectomy has been used in the treatment of MG for 50 years. In most young patients with thymic enlargement the gland will show histological changes of thymic hyperplasia affecting the cortico-medullary junction and the germinal centres. Approximately 15% of patients with MG have a thymoma (Figure 10.21) while up to 50% of patients with thymoma will develop myasthenia which may occur even after thymectomy. CT or MRI of the mediastinum should be undertaken in all patients with MG to exclude thymoma. Most are benign and encapsulated; however, 10% show malignant features with invasion of the capsule, local spread, seeding or even distant metastasis. Postoperative radiotherapy is recommended for invasive thymoma in which the tumour capsule has been penetrated. If metastatic spread has occurred, chemotherapy may be highly effective with varying regimes including cyclophosphamide, vincristine, cisplatin and doxorubicin proving effective, not just in reducing the thymoma, but also in controlling the myasthenia. However late recurrence can occur.

Objective evidence of the efficacy and role of thymectomy has been elusive. Evidence from open studies indicates thymectomy for non-thymomatous autoimmune MG increases the probability of remission or improvement and a recent randomised control trial indicates a benefit of thymectomy over steroids alone. Up to 46% of

**Figure 10.21** Large anterior mediastinal thymoma in an 80-year-old patient with mild generalised myasthenia gravis (black arrow).

patients with thymic hyperplasia may achieve full remission within 2–5 years of surgery and significant improvement and reduced treatment will be seen in up to 40%. Thymectomy is indicated for patients with seropositive MG from late childhood up to the age of 60 years. In those over 60 years, those with seronegative or ocular MG the role of thymectomy is less clear. The procedure is usually undertaken via the trans-sternal route but there is increasing use of video-assisted thoracoscopic surgery (VATS).

### Ocular myasthenia gravis

In about 15% of MG the disease remains localised to the orbicularis oculi and extraocular muscles although EMG may show generalised NMJ abnormalities. Remission occurs in approximately 20%. Response to anticholinesterases is often disappointing. Immunosuppression with steroids and azathioprine may be necessary if ptosis or diplopia are symptomatic.

### Pregnancy and myasthenia

The effects of pregnancy on the patient and fetus should be considered separately. Myasthenia may worsen, improve or remain stable during pregnancy but there is a significant risk of deterioration in the puerperium. Pregnancy should ideally be planned when the patient is strong, steroids should be maintained at the lowest therapeutic dosage and, if possible, other immunosuppressants should be avoided. If pre-eclampsia occurs, magnesium sulfate should not be used because of the risk of further impairment of NMJ transmission.

The newborn infant is at risk of transient neonatal myasthenia which occurs in about 10% of myasthenic pregnancies. This condition is caused by transmission of AChRAb across the placenta. The neonate may require transient ventilator support but the weakness resolves over a few days.

### Myasthenic crisis

Myasthenic crisis indicates the development of ventilatory failure. Approximately 20% of patients with MG will develop myasthenic crisis and in 10% there may be more than one episode. Respiratory failure in MG may be precipitated by bronchopneumonia, systemic sepsis, medication, surgery or inadequate treatment often related to a rapid tapering of the steroid dosage. Rarely, cholinergic crisis or the commencement of high-dose corticosteroids is to blame. In acute respiratory failure, urgent elective tracheal intubation and ventilation should be considered when the vital capacity falls below 15 mL/kg. The rate of progression, the presence of bulbar weakness and the state of the patient are also crucial to the decision (Chapter 20).

### Cholinergic crisis

Cholinergic crisis is rare but should be suspected in patients taking high doses of anticholinesterase medication who have extensive cholinergic side effects including sweating, hypersalivation, excessive bronchial secretion and miosis. Eventually, flaccid weakness and respiratory failure develop. It may be necessary to admit the patient to ITU, intubate and ventilate and withdraw all anticholinergic medication.

### Anaesthesia and peri-operative care

Elective surgery in patients with myasthenia should be undertaken with experienced anaesthetic support following pre-operative plasma exchange or IVIG if necessary. This is because myasthenic crisis may be precipitated by anaesthesia, the stress of surgery and non-depolarising neuromuscular blocking agents.

### Other causes of abnormal neuromuscular transmission

Botulism is the most important condition which may mimic MG (Chapter 9). Snake venoms, tick paralysis and toxic agents including organophosphates may affect neuromuscular transmission. Organophosphates are used as nerve agents (Chapter 19) but are also widely employed as pesticides. Exposure may be occupational, food-borne or as a consequence of suicide attempts. Acute exposure results in cholinergic crisis. Respiratory muscle weakness is resistant to atropine and intubation is required. Longer term organophosphate exposure may lead to a myasthenic syndrome or an axonal sensory motor neuropathy. Rarely, organophosphate toxicity may also cause late onset of neuropsychiatric and cognitive impairment or a parkinsonian syndrome.

### Lambert–Eaton myasthenic syndrome

Lambert–Eaton myasthenic syndrome (LEMS) is a rare disorder caused by impaired release of ACh by the presynaptic terminal of the NMJ. It is associated with underlying malignancy or autoimmune disease. The voltage-gated calcium channel (VGCC) at the NMJ is characterised by an  $\alpha 1A$  subunit and antibodies to this P/Q type VGCC can be measured by immunoprecipitation using  $^{125}I$ -conotoxin. VGCC antibodies cause aggregation and internalisation of the VGCC thereby reducing the number of functional P/Q type VGCCs on the presynaptic motor terminal of the NMJ. This, in turn, results in reduced action potential dependent ACh release from the motor nerve terminal.

### Clinical features

The onset is often insidious with the gradual development of progressive weakness and fatigue. The condition may occur at

any age but is more common after 40 years. Underlying malignancy may be present in about 50% of patients although this may not become apparent until more than 4 years after the onset of LEMS.

Fatigue is prominent at presentation. Weakness may affect the proximal muscles, particularly the legs, and is often associated with aching and stiffness. Autonomic features including dry mouth, constipation and impotence are also common. Ophthalmoplegia, ptosis, bulbar and respiratory muscle weakness can occur but are less common than in seropositive autoimmune MG. Examination findings are characterised by proximal weakness with a fatigable component. Reflexes are reduced or absent but after a short period of sustained effort they become brisker showing the phenomenon of post-tetanic potentiation.

The most common underlying tumour is small cell lung cancer (>80%) but LEMS also occurs with lymphoproliferative disorders, malignant thymoma and rarely with carcinoma of the breast, stomach, colon, prostate, kidney and bladder.

### Aetiology

LEMS is an autoimmune disorder driven by antibodies to the VGCC (anti-VGCC Ab) of the presynaptic terminal. Serum from up to 90% of patients with paraneoplastic and autoimmune LEMS contain anti-VGCC Ab. In patients with small cell lung cancer it is likely that cancer cells contain antigen which mimics VGCC and induces the production of antibodies while the mechanism of production in the autoimmune condition is unclear.

### Investigations

The diagnosis of LEMS is established by the presence of anti-VGCC Ab and by characteristic electrophysiological findings. A small CMAP, a decremental response to repetitive stimulation at low frequency (1–5 Hz) and an increment following sustained maximum voluntary contraction or 20–50 Hz repetitive stimulation are typical. SFEMG shows increased jitter and block.

A search for underlying malignancy and in particular small cell lung cancer must be conducted including FDG-PET if other tests are negative. Patients with malignancy negative LEMS should be closely followed up as an underlying tumour may become apparent after a long latent period.

### Treatment

Any underlying carcinoma must be appropriately treated. Successful treatment often leads to improvement in LEMS.

Specific treatment is directed towards facilitation of neuromuscular transmission, removal of the antibody or suppression of its production. Pyridostigmine has a mild effect in enhancing neuromuscular transmission but most patients require 3,4-diaminopyridine (3,4-DAP) which blocks presynaptic Ca<sup>2+</sup> channels, lengthens depolarisation of the nerve terminals and increases quantal ACh release. 3,4-DAP is associated with paraesthesiae, anxiety and insomnia and an increased risk of seizures. If severe weakness persists despite these treatments immunomodulation treatment is indicated. The response to plasma exchange and IVIG is less reliable than in MG. Prednisolone, azathioprine and ciclosporin are all effective in LEMS.

### Congenital myasthenia

Congenital myasthenic syndromes (CMS) are a heterogeneous group of genetic disorders caused by abnormalities of the NMJ that interfere with normal synaptic transmission. They are

generally autosomal recessive and are conventionally classified according to the site of defective neuromuscular transmission (presynaptic, synaptic and post-synaptic) although diagnosis increasingly depends on the identification of the specific gene defect. The conditions are rare but important to distinguish from SNMG because of the implications for management and genetic advice. In most patients there is a malformation in the structure or function of the pre- or post-synaptic NMJ. Presynaptic deficits are caused by reduced numbers of ACh molecules per synaptic vesicle, impaired quantal release mechanisms or reduced efficacy of individual quanta. The most common cause of post-synaptic CMS is a mutation in the genes encoding the AChR subunits that can either impair ion channel gating or reduce the number of end-plate receptors leading to slow channel, fast channel or AChR deficiency syndromes. Slow channel syndromes are dominantly inherited and are due to prolonged ion channel activation. Synaptic impairment is caused by end-plate acetylcholine esterase deficiency.

The classification of CMS is summarised in Table 10.29.

### Clinical features

CMS may present in infancy with hypotonia, failure to thrive, delayed motor milestones and unexplained apnoeic episodes. In children and adults the conditions are manifest as fatigable or fluctuating, ocular, facial and bulbar weakness although limb and truncal wasting and weakness may also be prominent. The weakness tends to progress during adolescence but then often stabilises. There may be episodic worsening of the weakness, possibly triggered by intercurrent events such as pyrexia. On examination there is fatigable muscle weakness on exertion but a prominent myopathy and scoliosis may be present. Distal weakness, ocular and pupillary abnormalities are also occasionally present. There may be a positive family history. In infancy CMS may mimic muscular dystrophy, congenital and metabolic myopathy, spinal muscular atrophy or structural brainstem anomalies. In children and adults it is necessary to distinguish CMS from SNMG, forms of MND, LGMD and neuropathies. The differential diagnosis of CMS is summarised in Table 10.30.

### Investigation

Standard MG investigations document an abnormality at the NMJ. Confirmatory diagnostic evidence comes from morphological and genetic NMJ studies. These include microelectrode recordings of miniature end-plate potentials to nerve stimulation, EM studies of intercostal muscle, AChR density studies using iodine-123 labelled bungarotoxin, patch clamp studies of individual channels at the NMJ and genetic studies of target genes in the AChR and post-synaptic structure.

### Management

The management of CMS is summarised in Table 10.29.

### Muscle diseases

The diagnosis of muscle disease has undergone groundbreaking transformation in the past 20 years, as a result of advances in immunohistochemistry, metabolic studies and genetics which enable accurate diagnosis of many inflammatory, genetic and metabolic muscle diseases. With the advent of new knowledge, many patients are now having their diagnoses revised and refined. This will inevitably lead to improved understanding of the natural history of muscle diseases and their treatment.

**Table 10.29** Causes of congenital myasthenia.

Diagnosis	Defect in NMJ	Gene	Clinical features	Treatment
<b>Pre-synaptic defect</b>				
Choline acetyltransferase (ChAT) deficiency	Failure of ACh resynthesis or packaging	ChAT	Recurrent apnoeic spells Impaired pupillary responses	AChE inhibitors (variable response), 3,4 DAP
<b>Synaptic</b>				
End-plate acetylcholinesterase deficiency	Failure to anchor AChE in synaptic cleft	ColQ	Recurrent apnoeic episodes from infancy Variable myasthenic symptoms between attacks. Axial weakness.	Reduced active signal transmission No response to AChE inhibitors Ephedrine Ephedrine
<b>Post-synaptic defect</b>				
AChR deficiency				
AChR mutation	Reduce number of end-plate receptors. Non-functioning $\epsilon$ subunit replaced by fetal $\gamma$	CHRNE CHRNA CHRNB CHRND	Neonatal onset. Severe ophthalmoplegia, ptosis and feeding difficulties. Mild bulbar or respiratory involvement Generalised weakness	Reduced active signal transmission Cholinesterase inhibitors (partial response)
AChR kinetic abnormality				
Slow channel	Prolonged ion channel activation in response to ACh	CHRNE CHRNA CHRNB CHRND	Variable age of onset. Autosomal dominant Cervical weakness with mild bulbar or respiratory involvement. Weakness and wasting in extensor, distal muscles due to endplate myopathy caused by prolonged channel activation (depolarising block)	Drugs which block AChR ion channel when in an 'open state' Fluoxetine, quinidine, Salbutamol, AChE inhibitors
Fast channel	Abnormally brief ion channel activation in response to ACh	CHRNE CHRNA CHRNE	Respiratory insufficiency at birth. Recurrent respiratory crises. Severe ophthalmoplegia	Reduced active signal transmission AChE inhibitors or 3-4DAP
AChR clustering pathway				
Rapsyn mutation	Deficiency and instability of AChR at motor end-plate	RAPSN	Arthrogrypsis multiplex congenital. Early onset associated with hypotonia, bulbar and respiratory impairment Facial malformations, contracture of hands and ankles Episodes of respiratory failure Tendency to improve with time	Reduced active signal transmission AChE inhibitors or 3-4DAP
DOK 7	Binds to MuSK which controls the aggregation of AChR. Incomplete synaptogenesis results	DOK7	Highly variable Proximal > distal limb girdle weakness Childhood – waddling gait, falls. Ptosis, stridor, bulbar and respiratory impairment Benign forms may develop in adults	AChE inhibitors (variable response) – may worsen some patients 3-4 DAP Ephedrine, salbutamol

AChE inhibitors, Anticholinesterase inhibitors ACh, acetylcholine; ACR, acetylcholine receptor; CMS, congenital myasthenia syndrome.

### Basic muscle biology

Muscle is a complex assembly of interacting proteins, outlined in Chapter 2. Its principal function is to respond to stimulus from a motor neurone by physically shortening its contractile apparatus with the conversion of electrical and chemical energy into mechanical energy.

The basic unit of a striated muscle is the myofibril. The myofibril is made up from many repeating functional multi-protein complexes of actin, myosin and titin called sarcomeres, the smallest functional unit of muscle. Thousands of sarcomeres are arranged end-to-end, giving muscle its striated microscopic appearance and

form the contractile apparatus. ‘Thin’ filaments of actin and ‘thick’ myosin filaments are arranged such that they may slide over each other, retaining their own length but shortening the sarcomere as the thin filaments are pulled towards the centre. The myofibrils are enveloped in the mesh-like structure of the sarcoplasmic reticulum, which is central to excitation–contraction coupling. The electrical stimulation of the muscle cell causes a release of calcium ions from the intracellular sarcoplasmic reticulum. This in turn activates the contractile apparatus (Figure 10.22a) and an energy-dependent interaction occurs between the actin and myosin filaments of the sarcomere. As calcium levels fall, the interaction between actin and myosin ends, the sarcomere extends again and the muscle relaxes.

Together with the sarcomere is an array of other structures. First, a series of structural proteins anchor the contractile apparatus within the sarcomere (Figure 10.22a). A number of further proteins then link the sarcomere to the cell membrane (the sarcolemma) and

extracellular matrix (Figure 10.22b). Dystrophin is attached at one end to actin and at the other to a complex of glycoproteins (including, amongst others, the dystroglycans, sarcoglycans and laminin) that are closely associated with the sarcolemma. In addition, various ion channels span the cell membrane, and their role in moderating the influx and efflux of potassium, sodium, calcium and chloride is crucial to proper muscle function.

Muscle is a complex structural and functional unit. Genetic or acquired abnormalities of any of the proteins or processes discussed earlier may result in disease. Muscle is also a highly metabolically active tissue and is therefore vulnerable to disturbances in energy including primary disorders of carbohydrate and lipid metabolism as well as mitochondrial oxidative phosphorylation.

### Clinical assessment of the patient with muscle disease

A confident clinical diagnosis can often be made in disorders of muscle such as Duchenne muscular dystrophy, myotonic dystrophy type 1, fascioscapulohumeral dystrophy (FSHD) and inclusion body myositis. In other muscle diseases, the clinical assessment remains important in guiding genetic and metabolic testing as well as interpretation of the muscle biopsy.

### History

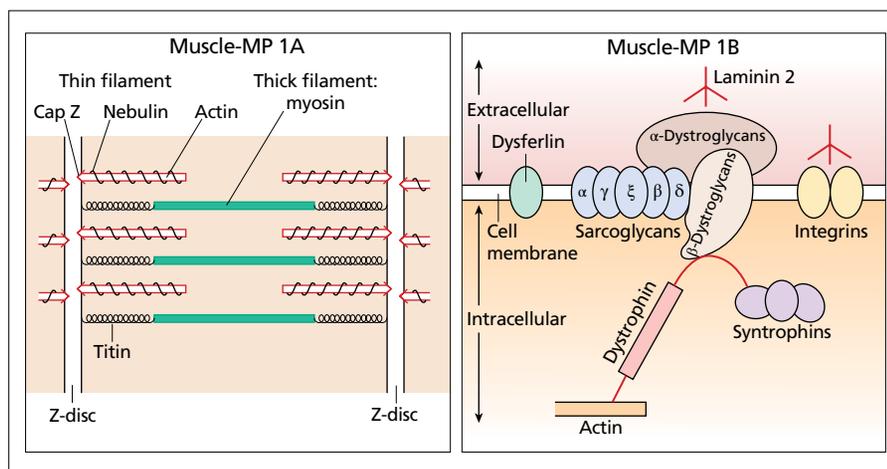

There are a limited number of symptoms of muscle disease which are listed in Table 10.31. However, the interpretation of these symptoms is critical in guiding differential diagnosis and management. When patients describe ‘weakness’ they may be referring to ‘stiffness’, ‘fatigue’ or ‘pain’ as well as loss of power.

The onset and course of patients’ symptoms is helpful in defining the aetiology of the muscle problem. Specific questions should be asked about the patient’s antenatal history, birth, developmental milestones, sporting ability as well as academic and physical achievements in youth. The onset of a muscle problem can often be traced back many decades before the apparent onset and this can be helpful in formulating the differential diagnosis.

The history should document the current neuromuscular functional status of the patient. This would include a history of double

**Table 10.30** Differential diagnosis of congenital myasthenic syndromes (CMS).

Neonatal	Spinal muscular atrophy
	Congenital myopathies – central core, nemaline, myotubular
	Congenital muscular dystrophy
	Mitochondrial myopathy
	Brainstem anomaly
	Mobius syndrome
	Infantile botulism
	Autoimmune myasthenia gravis
Older patients	Motor neurone disease
	Peripheral neuropathy
	Congenital muscular dystrophy – fascioscapulohumeral, limb girdle
	Mitochondrial myopathy
	Myasthenia gravis (AChRAB, MuSKAb, SNMG)

**Figure 10.22** (a) Simplified schematic representation of the muscle contractile apparatus. Thin filaments are comprised of actin molecules as the core, wrapped in the template protein, nebulin, plus troponin and tropomyosin (latter two not shown). They are capped at the Z-disc with CapZ and at the other end with tropomodulin (not shown). Thick filaments of myosin are bound by titin to the Z-disc. One element of titin is elastic. Contraction involves interaction of the thick and thin filaments so the latter move towards the centre. (b) Simplified schematic representation of the muscle cell membrane and associated non-neuromuscular junction proteins (NB some components are omitted for clarity).

**Table 10.31** Issues important in history-taking in muscle disease.

Symptom	Details
Weakness	Confirmation of reduced strength and function Onset, duration and progression Assessment of degree of weakness and subsequent disability (e.g. date of first use of walking aids) Pattern of muscle involvement – proximal limb (reaching objects from shelves, standing from sitting) versus distal limb (opening jars or bottles, tripping over) versus selective focal Variability and, if present, exacerbating or relieving factors (always consider the possibility of fatigability)
Pain	Confirmation of myalgia, rather than, for example, impaired sensation Localised versus generalised Severity Precipitating, exacerbating or relieving factors Association with any other symptom
Cramps	Localised versus generalised Precipitating, exacerbating or relieving factors Association with any other symptom
Stiffness	Identification of specific failure of relaxation (myotonia), e.g. difficulty releasing grip or opening eyes Localised versus generalised Exacerbating or relieving factors
Fatigue	Distinction from other symptoms Precipitating, exacerbating or relieving factors
Pigmenturia	Precipitating factors Association with any other symptom

vision, swallowing and speech difficulties, neck weakness, proximal and distal limb weakness and problems with mobility. It may be helpful to quantify this with clinical scales, such as the MRC grading system, to assess change over time. Clear documentation of functional abilities also aids completion of social care and driving assessment. Respiratory symptoms, especially those of neuromuscular respiratory failure, often first manifest as unrefreshing sleep, orthopnoea, morning headache or excessive daytime sleepiness. Recurrent chest infections and the use of non-invasive ventilation are also important in assessing the functional consequences of neuromuscular respiratory failure and dysphagia.

Pigmenturia ('coca-cola urine') should be specifically asked about, in conjunction with provocation factors such as exercise or fasting in patients who are felt to have had episodes of rhabdomyolysis. Some patients may have had solitary or only infrequent episodes.

Paroxysmal or variable symptoms (e.g. cramps, spasms, stiffness, weakness) require further questioning, seeking to identify provoking, exacerbating or relieving factors especially in defining the clinical features of a channelopathy.

Other organ systems are commonly involved in muscle diseases. Cardiac symptoms (palpitations, exertional dyspnoea, ankle swelling and paroxysmal nocturnal dyspnoea) may occur as cardiac disease often coexists with muscle disease. A suspected multi-system condition requires attention to other systems (e.g. the rash

**Table 10.32** Simple bedside functional motor tests.

Lifting head from lying down
Straight leg rising from lying down
Standing from lying down and/or squatting and/or sitting
Ability to walk on heels or on tiptoes
Ability to hop on one foot
Ability to run
Time to walk a specified distance
Time to climb a flight of stairs
Raising arms above head

of dermatomyositis, cataracts in myotonic dystrophy type 1 and deafness in mitochondrial disease).

Assessment of the past medical history is directed at identifying other conditions that may either cause muscle symptoms (e.g. rheumatological or endocrine disease), or make their management more difficult (e.g. orthopaedic conditions or a peripheral neuropathy). Specific questions should be asked about any difficulties with anaesthesia. Myotonic dystrophy may first be revealed by peri-operative cardiac arrhythmia or difficulty weaning from a ventilator, while certain myopathies, notably central core disease but also the dystrophinopathies, can lead to postoperative malignant hyperthermia. A thorough medication history is also required, particularly with regard to statin use, but also should include over-the-counter preparations, alternative remedies and recreational drugs. Any temporal association with symptoms should be explored.

### Examination

A complete basic neurological examination is recommended and where appropriate further clinical tests performed, for example testing for myotonia. Inspection should be focused on assessment of muscle bulk, involuntary movements (fasciculation, myokymia, myotonia), skeletal abnormalities (e.g. kyphoscoliosis, dysmorphism), contractures and scars from previous muscle/nerve biopsies and orthopaedic surgery.

Power assessment may require additional examination techniques to those routinely employed. Subtle facial weakness can be revealed by formally testing eyelid and lip closure. Specific requests for buccal, palatal and lingual consonant production in addition to a demonstration of a cough and a sustained note can indicate more specific impairments. Neck extension and flexion should be tested with the patient both lying and upright. Experienced clinicians learn that muscle strength testing needs appreciation of the confounding effects of suboptimal effort ('give-way' weakness) or when pain is a limiting factor. Accordingly, bedside tests of disability rather than impairment can give a more useful guide, particularly on serial examinations, to assess disease progression or treatment effect when impairment testing is not reliable (Table 10.32).

Myotonia should be tested by sustained grip or eyelid closure, and/or by percussion of appropriate muscles (e.g. thenar eminence, forearm or tongue).

Respiratory function can be assessed by looking for abdominal paradox on deep inspiration and expiration (the abdomen normally distends on inspiration because the diaphragm descends as it contracts), as well as specific assessment of sniff and cough strength. Spirometry allows quantification of respiratory function, with the

caveat that poor effort and air leak resulting from facial weakness must be taken into consideration.

## Investigation of muscle diseases

### Creatine kinase

This enzyme is continuously released at low level into the circulation. This process is increased by injury to the muscle including exercise. In addition, there is considerable variation in CK levels across a normal population. CK is proportional to the muscle bulk of an individual, and routine exercise and alcohol will increase levels. Furthermore, values in Afro-Caribbean are higher than in the Caucasian population. The CK result should be interpreted in light of an appropriate normal range and background exercise levels. Quantification of different isozymes (e.g. myocardial CK-MB) is usually unhelpful, and other enzymes may be released from skeletal muscle, such as ALT/AST. It is important to note that several muscle diseases may not be associated with a rise in CK in some patients.

### Neurophysiology

Needle EMG can be helpful in distinguishing myopathy from neurogenic weakness. The classic findings in myopathy are spontaneous activity with fibrillations, positive sharp waves and complex repetitive discharges plus polyphasic, low amplitude, short duration units on voluntary contraction (Chapter 4). This pattern is common to several underlying processes and neurophysiological examination is less useful in refining the diagnosis of muscle disease than when used to investigate neuropathy. Other electrophysiological phenomena may be seen, such as myotonia, while specialised serial examination before and after cooling a limb, or after short or long periods of standardised exercise or 'exercise EMG' form a crucial element in assessing patients with possible muscle channelopathies.

### Muscle biopsy

Muscle biopsy is often necessary to confirm a clinical diagnosis. It should be considered and, if possible, performed in all cases before any treatment is initiated. Close liaison with the pathologist and laboratory technician is essential because experience in both the preparation of biopsy material and its microscopic evaluation is critical. At a practical level, this will usually mean sending the patient to a specialist centre. The muscle selected for biopsy should ideally be moderately involved, and not fibrotic. Pathologists often have particular experience with interpreting changes in particular muscles and this information needs to be considered when planning a muscle biopsy.

Initial histological diagnosis is based on the presence or absence of inflammatory change, necrosis, fibrosis, fibre atrophy, fibre size and shape or other structural changes (vacuoles, inclusion bodies). Enzyme stains may identify certain conditions (e.g. absent acid phosphatase in McArdle's disease, or reduced cytochrome oxidase staining in mitochondrial disorders). Immunostaining (e.g. dysferlin, dystrophin and the sarcoglycans) have greatly improved the diagnosis of dystrophies. Immunocytochemistry for MHC Class I and immune cell markers has greatly improved the diagnosis of primary inflammatory muscle disease as well as inflammatory dystrophies. If required, EM may detect more subtle abnormalities (e.g. features of mitochondrial disease).

### Metabolic testing

Exercise testing (most safely performed non-ischaemically), with serial collection of blood samples for lactate and ammonia levels in normal subjects generates a three- to fivefold increase in both. In glycolytic or glycogenolytic disorders, the lactate rise is reduced (or absent) with excessive elevation of ammonia. Myoadenylate

deaminase deficiency, by contrast, causes a normal rise in lactate but no change in ammonia. Exercise testing is increasingly not performed as more specialised metabolic and genetic testing has become available. Specialised centres can perform assays of enzyme function in muscle for the mitochondrial respiratory chain, carnitine metabolism, fatty acid flux studies, as well as the enzymes involved in glycogen metabolism.

### Genetic testing

Specific DNA analysis has revolutionised diagnosis of muscle disease. Where a clinical diagnosis can often be accurately made, for example myotonic dystrophy type 1 or FSHD, genetic testing should be the first step in investigation. In other genetic disorders of muscle, such as the limb girdle dystrophies, genetic testing should be appropriately guided by other findings including the muscle biopsy although with the advent of improved genetic screening of several disorders at once as part of a 'panel', the need for a diagnostic muscle biopsy in these conditions will probably reduce.

### Genetic muscle diseases

The clinical management and understanding of genetic muscle disease is changing rapidly as a direct result of the wealth of recent molecular genetic discoveries. Approximately 1/6000 of the UK population has one of many diverse genetically determined muscle diseases and the spectrum of clinical phenotypes is broad. Duchenne muscular dystrophy, caused by mutations in the dystrophin gene, is a young onset, severe, progressive muscle wasting disease which can be lethal in late teens without appropriate respiratory and cardiac support. In contrast, myopathies caused by mutations in mitochondrial DNA can develop in late adult life manifesting as external ophthalmoplegia or mild proximal myopathy with a relatively indolent course. The mortality in genetic muscle diseases is often determined by the degree of cardiac and/or respiratory muscle involvement and therefore cardiorespiratory screening is essential in the assessment of patients presenting with suspected genetic muscle disease. Careful clinical evaluation and attention to the family history can reduce the differential diagnosis sufficiently to rely on direct genetic testing alone and a muscle biopsy may not be required. The distinction between inflammatory and genetic myopathies can be difficult and genetic testing may be helpful in making a clear diagnosis. For example, a specialist muscle service may review patients where prominent inflammatory infiltrates on biopsy have led to the erroneous diagnosis of polymyositis in patients subsequently shown genetically to have dysferlinopathy or FSHD.

Where a precise DNA-based diagnosis is possible patients and families can be provided with accurate prognostic and genetic counselling information and entered into a rational screening programme for recognised complications. As national networks for DNA-based diagnosis become available more patients will have access to this diagnostic precision.

Genetic testing is now often the first investigation in myotonic dystrophy and FSHD and a muscle biopsy is usually not required. In other more clinically heterogeneous genetic muscle diseases, such as limb girdle muscular dystrophy (LGMD), muscle biopsy with careful immunohistochemical analysis is usually required to direct gene testing. However, as gene sequencing technologies become increasingly available even LGMD gene analysis may be selected at an earlier stage in the diagnostic process.

In this section we mention the more common genetic muscle diseases (Table 10.33) encountered by adult neurologists. The aim is to describe clinical features and to suggest efficient diagnostic strategies (Table 10.34). DNA-based diagnosis may accelerate and

simplify the diagnostic process, thereby providing the most accurate information for patients with these diseases.

### Muscular dystrophies

The muscular dystrophies are a group of a genetic diseases that cause skeletal myodegeneration. Many genes causing muscular dystrophies have recently been described and the causative proteins have many cellular functions. Dystrophic muscle is possibly the non-specific end result of a number of different pathogenic pathways. The proteins identified include sarcolemmal structural proteins (e.g. dystrophin, sarcoglycans and dysferlin), nuclear envelope proteins (emerin, lamin A/C), enzymes (calpain, fukutin-related protein), sarcomeric proteins (e.g. myotilin, desmin) and extracellular matrix proteins (e.g. laminin, collagen type 6; Figure 10.22b). For some disorders, such as the myotonic dystrophies, two genes account for the majority of cases and their testing is readily available. In contrast, the LGMDs are genetically heterogeneous and require more complex assessment of clinical parameters with muscle biopsy testing to guide genetic analysis.

*Xp21 dystrophies: the dystrophinopathies* Dystrophin is a major muscle cell structural protein that lies just below the sarcolemma and helps to stabilise the sarcolemma during muscle contraction. It links intracellular actin to a complex set of transmembrane proteins which in turn link to elements of the extracellular matrix

**Table 10.34** Diagnostic strategies for inherited myopathies.

Condition	DNA based diagnosis available?	Muscle biopsy needed?
Xp21 dystrophies (dystrophinopathies)	Yes, but negative gene test does not exclude diagnosis	Yes, if genetic test negative
Emery–Dreifuss muscular dystrophy	Yes, but usually only after immunohistochemistry for lamin a/c and emerin	Yes, muscle biopsy remains important
Limb girdle muscular dystrophies	Yes, check FKRP/calpain-3 genes initially. If negative muscle immunohistochemistry will reduce number of candidate proteins	Yes, muscle biopsy required in most cases
Facioscapulohumeral dystrophy	Yes, indirect genetic test available through regional genetics laboratory	Not usually unless genetic test for FSHD negative. Inflammatory muscle biopsy may cause difficulty distinguishing from polymyositis
Oculopharyngeal muscular dystrophy	Yes	Not usually
Myotonic dystrophy type 1 and 2	Yes	Not usually, unless gene tests for MD/PROMM negative
Bethlem myopathy	Consider skin and muscle biopsy. Exclude lamin a/c, emerin and SEPN1	May be helpful for exclusion. May not be definitive
Mitochondrial respiratory chain diseases	Yes (?age associated decline in MtDNA mutation load in blood). POLG gene analysis in CPEO	Yes (a) If blood MtDNA analysis negative (b) Muscle needed for mitochondrial enzyme analysis (c) Muscle MtDNA better for MtDNA analysis
Metabolic muscle disorders (glycogenoses, lipidoses)	Yes, but not usually first line	Yes. Also consider specialist metabolic testing, often first line, e.g. non-ischaemic lactate test (glycogenoses) or blood acylcarnitine/urinary organic acids (lipid disorders)

CPEO, chronic progressive external ophthalmoplegia; FKRP, fukutin-related protein; FSHD, facioscapulohumeral dystrophy; MD, myotonic dystrophy; POLG, polymerase gamma; PROMM, proximal myotonic myopathy; SEPN1, selenoprotein 1.

(particularly to an extracellular protein called laminin). Genetic defects in the dystrophin protein are associated with two major phenotypes: Duchenne and Becker muscular dystrophy.

Duchenne is a progressive and lethal dystrophy affecting boys in which there is a severe reduction in the amount of the dystrophin protein in muscle. There is no curative treatment, but improved ventilatory support, spinal surgery for kyphoscoliosis and the use of corticosteroids increase quality of life and life expectancy. Adult men with Duchenne are increasingly common and adult clinical practice needs to meet this new challenge with an active multi-disciplinary approach.

Becker muscular dystrophy is commonly encountered in adult muscle practice. The severity of the phenotype correlates with the amount of dystrophin protein. Patients with Becker present with a limb girdle pattern of muscle weakness with pseudohypertrophy of calf muscles, which is often the clinical diagnostic clue. Cardiomyopathy is an important complication and occasionally severe dilated cardiomyopathy may be the presenting feature.

Diagnosis can be achieved by genetic testing through multiplex ligation-dependent probe amplification (MLPA) analysis, PCR and analysis of muscle dystrophin mRNA, although a 'negative' genetic test does not exclude the diagnosis of Becker's muscular dystrophy where reduced sarcolemmal dystrophin on muscle biopsy may be continue to support the diagnosis in spite of negative genetics.

Genetic counselling for families is important. One-third of cases of dystrophinopathy represent new mutations within a family. Female carrier status may be associated with a mild clinical phenotype but most female carriers are asymptomatic. The importance of the need for an effective treatment has provoked great interest in gene therapy approaches and clinical trials of genetic treatments, including exon skipping, are in progress.

**Congenital muscular dystrophy** The congenital muscular dystrophies are a genetically heterogeneous group of disorders which often present at birth with floppy infants and subsequently impaired motor and sometimes cognitive development. Skin, heart and bone can also be affected. Kyphoscoliosis is common. The degree of CNS involvement is often related to the overall severity of the condition. Patients at the mildest end of the spectrum may present later in life to the adult muscle clinic with an indolent myopathy and contractures.

Mutations in several genes may cause CMD and can be classified into five main subtypes, based on the underlying molecular defects. Several of these genes are allelic for other forms of muscular dystrophy such as lamin A (*LMNA*) (Emery–Dreifus muscular dystrophy (EDMD types 2/3) and limb girdle muscular dystrophy (*LGMD1B*)) and fukutin-related protein (FKRP) (*LGMD2I*).

- 1 Genes encoding for structural proteins of the basal membrane or extracellular matrix of the skeletal muscle fibres. This includes collagen 6 genes (Ulrich–Bethlem congenital muscular dystrophy); laminin  $\alpha 2$  (merosin) and integrin  $\alpha 7$ .
- 2 Genes encoding for putative or demonstrated glycosyltransferases, which affect the glycosylation of  $\alpha$  dystroglycan, an external membrane protein of the basal membrane. Genes belonging to this category include *POMT1/2*; *POMGnT1*; fukutin; fukutin-related protein (FKRP);
- 3 Selenoprotein 1, which encodes an ER protein.
- 4 *LMNA*-related CMD.
- 5 Several CMD phenotypes have been described and linked but genetic clarification awaits.

**Bethlem myopathy** Bethlem myopathy is usually an autosomal dominant myopathy caused by mutations in one of three different genes for collagen type 6: *COL6A1* and *COL6A2* on chromosome 21q22.3 and *COL6A3* on chromosome 2q37 and is allelic to the more severe form, Ulrich CMD. Onset of this so-called contractural phenotype is typically in the first or second decade. In childhood there are delayed motor milestones, waddling gait and tripping with falls. There is slow progression in the first decade although there may be stabilisation and even transient improvement of muscle strength in the second decade. There is subsequently slow progression. Life expectancy is usually normal and there is no evidence for cardiorespiratory involvement. Two-thirds of patients require a wheelchair by the age of 50 years. Physical examination shows generalised symmetrical muscle atrophy particularly in the shoulder girdle, upper arms and below the knees. Later there is forearm and neck flexor weakness. There is no ophthalmoplegia and facial weakness is rare. Prominent flexion contractures at the interphalangeal joints of the fingers, elbows and ankles are present in most patients and contractures at the metacarpophalangeal joints, shoulders (pectoralis major), tibialis anterior, hamstrings, quadriceps and erector spinae and jaw muscles frequently occur with no relationship between the severity of the weakness and the severity of the contractures. Treatment is supportive.

Muscle biopsy is non-specific. Immunofluorescence of patient fibroblast cultures sometimes shows a reduced expression of collagen type 6 but can be normal. Genetic testing is not widely available. The differential diagnosis includes other myopathies with prominent early contractures including EDMD, autosomal dominant LGMD and rigid spine syndrome with mutations in the selenoprotein N (*SEPN1*) gene.

**Limb girdle muscular dystrophies** The limb girdle muscular dystrophies (LGMD) share an association with progressive proximal limb girdle weakness but each form often has other particular clinical features, for example 'rippling muscles' in caveolin-3 and tongue hypertrophy in FKRP, although these features are not consistent. Several new genes have recently been described to cause LGMD and these code for proteins with many different functions (Table 10.35). Currently, patients often undergo a muscle biopsy with immunocytochemistry and immunoblotting being used to target genetic analysis. In the near future, a LGMD gene panel test will probably help in the diagnostic process and obviate the need for a muscle biopsy in some patients. The recessive LGMDs are far more common than the dominant forms. Three of the most common recessive forms for which gene testing is increasingly available are considered in detail.

**Calpainopathy – LGMD2A** LGMD caused by calpain mutations typically develops between 2 and 40 years with most patients presenting in their late teens to mid thirties. Early milestones are usually normal and pelvic girdle muscle weakness precedes later development of shoulder girdle weakness. Severe early onset forms with CNS involvement as well as more scapulohumeral upper limb variants have been described. On examination, there is typically a scapulohumeral/pelvic distribution of weakness. The involvement of periscapular muscles is reminiscent of FSHD but facial involvement is minimal or absent. Muscle atrophy is usually a prominent feature, as opposed to hypertrophy in many other dystrophies (e.g. Becker dystrophy and LGMD2I). Particular atrophy of the posterior compartment of the thigh may be a distinguishing clinical feature compared to other LGMDs. Loss of ambulation usually occurs

**Table 10.35** Genes/proteins causing limb girdle muscular dystrophies (LGMD).

Type	Chromosome	Protein	Clinical
<b>Autosomal dominant</b>			
LGMD 1A	5q22–q34	Myotilin	Rare, distal legs affected first; slow progression, late CMP in 50%; CK 2–10 × normal
LGMD 1B	1q	Lamin a/c	Rare; proximal legs affected first; slow progression; CMP in 60%; CK 1–2 × normal
LGMD 1C	3p25	Caveolin	Uncommon; variable phenotype: raised CK to progressive proximal weakness, no CMP, CK 3–40 × normal
LGMD 1D	7q	Unknown	Two families; proximal weakness, no CMP, CK 1–3 × normal
LGMD 1E	6q23	Unknown	Single family, proximal weakness, frequent sudden death from CMP; CK 2–4 × normal
LGMD 1F	7q32	Unknown	Single family, proximal weakness, no CMP CK often normal
<b>Autosomal recessive</b>			
LGMD 2A	15q15	Calpain	Uncommon but many different mutations found, very varied phenotype; no CMP, CK 3–80 × normal
LGMD 2B	2p13	Dysferlin	Uncommon with many different mutations and variable phenotype (including within family); typically distal weakness; no CMP, CK 10–80 × normal
LGMD 2C	13q	γ-sarcoglycan	Rare, often early onset and loss of walking; respiratory weakness in some, CMP unusual, CK 5–20 × normal
LGMD 2D	17q21	α-sarcoglycan	Rare, variable phenotype but can be early onset, CMP unusual; CK 5–20 × normal
LGMD 2E	4q12	β-sarcoglycan	Rare; typically early onset with severe disability; CMP occasionally; CK 5–20 × normal
LGMD 2F	5q33	δ-sarcoglycan	Rare; early onset with severe disability; proximal weakness; CMP unusual; CK 10–50 × normal
LGMD 2G	17q11	Telethonin	Rare; teenage onset with proximal and distal leg weakness; CMP in 50%; CK 10–30 × normal
LGMD 2H	9q31	TRIM32	Very rare, slow progression; no CMP; CK 2–20 × normal
LGMD 2I	19q13	FKRP	Most common in UK; variable phenotype but respiratory involvement not uncommon and CMP in 30%; CK 4–30 × normal
LGMD 2J	2q31	Titin	Very rare; allelic to Finnish distal myopathy: causes proximal weakness but often relatives with distal weakness
LGMD 2K	9q34	POMT1	Rare; progressive proximal weakness with learning disability and ankle contractures; CK 8–40 × normal
LGMD 2L	11p13	None known	Very rare; CK very raised, no CMP. French–Canadian families, quadriceps and biceps weakness
LGMD 2M	9q31	Fukutin	Very rare; CK very high, infantile onset, proximal and distal weakness legs > arms. May improve with steroids

CK, creatine kinase; CMP, cardiomyopathy; FKRP, fukutin-related protein; POMT, protein O-mannosyltransferase.

10–30 years after the onset. Cardiac involvement is not a feature and reduced vital capacity seems to occur only in severe very advanced cases. CK is elevated initially in the course of the disease but not as high as in LGMD2I, dystrophinopathies or LGMD2B.

**Dysferlinopathy – LGMD2B** There is a broad phenotypic range associated with mutations in the dysferlin gene and these include a

proximal LGMD type presentation and a distal presentation (also known as Miyoshi myopathy; see Distal myopathies). In the LGMD presentation, weakness usually begins between in the late teens to early twenties and is associated with a pelvifemoral distribution, often with marked quadriceps involvement. The onset may be relatively abrupt with a very high CK leading to polymyositis as a differential diagnosis. Later, weakness in the arms develops with

particular involvement of the biceps. Weakness usually spares the deltoids and also the periscapular muscles so scapula winging is not typical. The involvement of the posterior compartment of the leg is not uncommon and can be early. Imaging of gastrocnemius may show early changes and may be diagnostically helpful in an otherwise LGMD presentation. Facial and extraocular muscles are spared. Cardiac involvement is not reported, but may patients develop a reduced vital capacity with time.

In the lower limb posterior calf compartment presentation, weakness of ankle plantar flexors often prevents early walking on toes, and is called Miyoshi myopathy. The weakness often spreads to include the limb girdle muscles. A very high CK and sometimes marked inflammatory infiltrates in the muscle biopsy can cause confusion with myositis but immunohistochemistry using dysferlin antibodies in combination with genetic analysis of the dysferlin gene is usually diagnostic.

**Fukutin-related protein (FKRP) dystrophy (LGMD2I)** LGMD2I presents typically to adult clinics from late teens to early twenties with a mild phenotype but can present with a severe Duchenne-like pattern of weakness in infancy. The distribution of muscle involvement is similar, irrespective of the severity with a predilection for axial, neck flexor and the proximal pelvic and shoulder girdle muscles. Facial muscles are usually spared. Scapula winging is common. There may be striking hypertrophy of the tongue, brachioradialis, calves and sometimes the quadriceps. In contrast, there may be atrophy of pectoralis major and deltoid muscles. Prominent lumbar lordosis is common and exercise-induced cramping is a frequent symptom. Importantly, one-third of cases develop a dilated cardiomyopathy. Respiratory muscle involvement is also common, manifesting as nocturnal hypoventilation. In contrast to dystrophinopathies, respiratory failure may occur even while the patient remains ambulatory. LGMD2I is caused by mutations in the gene known as the fukutin-related protein (FKRP) which codes for a glycosylation enzyme.

**Facioscapulohumeral muscular dystrophy** FSHD is an important autosomal dominant disorder frequently encountered in adult specialist muscle practice. Patients commonly have facial muscle weakness as the initial symptom, which may be followed by periscapular and humeral muscle involvement. Later in the disease course lower limb weakness, particularly affecting the anterior tibial and abdominal wall, may occur. It is notable that the distribution of weakness is often asymmetric, with the right side often being more involved. Isolated periscapular weakness without facial involvement may occur. Prominent axial involvement often causes an exaggerated lumbar lordosis and clavicular pectoral atrophy causes striking and typical appearances in the anterior chest wall. The severity is variable ranging from isolated asymmetrical scapular winging through to pronounced early onset weakness rendering the patient wheelchair-bound. Scoliosis, deafness and retinal vasculopathy are uncommon additional features and a severe infantile form with CNS involvement can occur.

FSHD is almost fully penetrant by the age of 30 years. FSHD is linked to chromosome 4q35, but identification of the causal gene remained elusive for many years. Recently, a mechanism has been proposed in the majority of cases, to involve the released expression of the gene DUX4 caused by contraction of a non-coding repeated DNA sequence or 'D4Z4'. The genetic test for FSHD currently still consists of examination for the D4Z4 contraction but this is likely to develop in the near future.

**Oculopharyngeal muscular dystrophy** Oculopharyngeal muscular dystrophy (OPMD) is an uncommon disorder characterised by late onset pharyngeal muscle weakness and ophthalmoplegia. It is usually autosomal dominant and highly penetrant although recessive inheritance may occur. OPMD may enter into the differential diagnosis in patients with late onset ophthalmoplegia and for those with bulbar weakness. The most common genetic defect is an expansion of a short (GCG) 7–13 triplet repeat in the poly-A binding protein 2 (PAB2) gene on chromosome 14q. Genetic testing for the expanded repeat sequence is available and usually obviates the need for muscle biopsy. Patients can develop a mild late onset limb girdle pattern of weakness although this is uncommonly severely disabling.

**Myotonic dystrophies** Myotonic dystrophy type 1 (dystrophia myotonica or DM1) is an autosomal dominant multi-system disorder ranging in severity from a severe congenital myopathy, which may be fatal, to late onset isolated cataracts. It is the single most common form of adult-onset muscular dystrophy. Neuromuscular symptoms include facial weakness, ptosis, neck flexion, long finger flexor and ankle dorsiflexion weakness with myotonia. Variable additional symptoms include cataracts, endocrine disturbance such as hypogonadism and impaired glucose tolerance, cardiac arrhythmias, frontal balding, cognitive impairment, primary daytime somnolence, bowel symptoms similar to IBS and respiratory muscle weakness. A clinical diagnosis can often be made with one or more of these additional features in combination with the typical muscle phenotype.

DM1 is caused by an expansion in an unstable trinucleotide repeat (CTG) in the 3' untranslated region of a gene on chromosome 19 called myotonin protein kinase (DMPK). DM1 shows genetic anticipation and this correlates with expansion in the size of the repeat sequence. Recent evidence suggests that the expanded repeat may exert its toxic effect at the RNA level. The expanded untranslated repeat sequence in mRNA forms abnormal degradation resistant ribonuclear inclusions. The intranuclear inclusions impair the function of pre-mRNA splicing factors which in turn leads to misplicing of many pre-mRNA species. This may explain the diverse multi-system clinical involvement. For example, there is evidence that expression of the skeletal muscle voltage-gated chloride channel mRNA is altered in patients with myotonic dystrophy which would cause myotonia. Mutations in this chloride channel are also the basis of the pure myotonic disorder myotonia congenita.

The diagnosis of myotonic dystrophy is usually straightforward on clinical grounds but there is often a clinical delay of several years. DNA-based diagnosis is the initial investigation of choice. A detailed family history will usually reveal other affected members. Genetic counselling is a vital part of the consultation because of genetic anticipation. It is particularly important to identify females at risk of inheriting the gene in pedigrees because the severe, often lethal, congenital form is confined to the offspring of affected females. Women can be offered appropriate antenatal pre-implantation genetic diagnosis.

Patients with myotonic dystrophy should be followed up in a muscle clinic where they can be monitored for systemic complications. Premature mortality is high with an average life expectancy of 54 years which is mostly caused by cardiorespiratory complications. In most patients, myotonia is not symptomatic and does not require treatment. In those patients with symptomatic myotonia mexilitene can be effective. Excessive daytime sleepiness is a major problem and may respond to psychostimulants such as modafinil. Prominent

imbalance causes falls, is a major cause of morbidity and is often multi-factorial in aetiology. Patients may require ankle foot orthoses which can improve imbalance.

In an appropriate clinical context, if the genetic test for DM1 is negative, then DM2 should be tested. This less common disorder is characterised by proximal rather than distal weakness, but in other respects may exhibit similar features to DM1. CNS involvement may occur. Muscle pain may be a prominent symptom. The genetic defect underlying DM2 is a CCTG repeat sequence expansion in intron 1 of a zinc finger protein gene on chromosome 3 (*ZNF9*). Similarly to DM1, there is evidence that this untranslated defect operates at the RNA level, causing ribonuclear inclusions. Both anticipation and a severe congenital form have not been described in DM2 (Figure 10.23).

**Emery–Dreifuss muscular dystrophies** The Emery–Dreifuss muscular dystrophies (EDMD) are often clinically characteristic and should be considered if contractures are a prominent early clinical feature. Patients present with a scapulo-humero-peroneal pattern of muscular weakness and often have strikingly thin muscles. Contractures of the cervical extensor muscles as well as the biceps and long finger flexor tendons are common. Cardiac conduction defects are also frequent and cardiac screening is important.

**Figure 10.23** Typical clinical appearance of a patient with myotonic dystrophy. Note ptosis, frontal balding, typical facies and distal wasting.

EDMD is caused by mutations in several genes including those coding for nuclear envelope proteins emerin and lamin A/C whose function remains uncertain. Emerin mutations are associated with causing the X-linked form of EDMD and lamin A/C causes the less common dominant and recessive forms. Mutations in the lamin A/C gene have also been described other diseases including a form of LGMD (LGMD1B; Table 10.35), an autosomal recessive axonal neuropathy and partial lipodystrophy.

**Myofibrillar myopathies** The myofibrillar myopathies (MFM) are characterised by slowly progressive weakness with distal muscle involvement in 80% of patients and more prominent proximal than distal weakness in 25% cases. Facial involvement is uncommon. Some patients experience sensory symptoms, muscle stiffness, aching, or cramps. Peripheral neuropathy is present in about 20% of affected individuals. Clinically significant cardiomyopathy is present in 15–30% of patients and desminopathy may present with a pure cardiomyopathy. Respiratory muscle involvement may also occur.

Muscle histology often defines these conditions and consists of a combination of inclusions and vacuoles. The inclusions often stain immunocytochemically for myotilin and desmin. The CK is normal to modestly raised. Definitive diagnosis is made by genetic testing.

At the time of publication, the genetic basis of myofibrillar myopathies has been elucidated in approximately 50% of cases. Mutations have been identified in *DES*, the gene encoding desmin; *CRYAB*, encoding alpha-crystallin B chain; *MYOT*, encoding myotilin; *LDB3* (*ZASP*), encoding LIM domain-binding protein 3; *FLNC*, encoding filamin-C, and *BAG3*, encoding BAG family molecular chaperone regulator 3. More recently, mutations in *FHL1*, encoding four and a half LIM domains protein 1, and *DNAJB6*, encoding DnaJ homolog subfamily B member 6 have been described. These are all inherited in an autosomal dominant manner except for the X-linked *FHL-1* and the uncommon recessive form of *CRYAB*.

The differential diagnosis includes sporadic inclusion body myopathy (IBM) and IBM2 resulting from mutations in *GNE*. With the advent of genetic testing, some patients who were previously defined as having IBM have been found to have a form of MFM. Other differentials have been suggested to include DM1 and DM2 although these are often phenotypically very different from MFM. Other distal myopathies including dysferlinopathy are also included.

#### Distal myopathies

The distal myopathies are a heterogeneous group of genetic and acquired muscle disorders characterised by progressive muscle weakness and wasting predominantly affecting the feet and hands. Most genetic and acquired muscle diseases have a proximal presentation and distal myopathies may be confused with a primary neurogenic disorder. There are at least 17 genetically defined distal myopathies described in the literature and most of these are very rare (Table 10.36).

When a patient presents with a predominant distal myopathy, in addition to the disorders outlined in Table 10.36, other diagnostic possibilities to consider include IBM) myofibrillar myopathy, myotonic dystrophy and distal hereditary motor neuropathy. Usually, in each of these conditions there are associated clinical features which aid the diagnostic process. Exclusion of other conditions by careful clinical evaluation, genetic testing and often muscle biopsy. Often, biopsy of a distal lower limb muscle is more likely to reveal diagnostic pathology. Increasingly, MRI may be used to identify muscle involvement which may lead to the development of typical patterns associated with specific diseases and aid muscle selection for biopsy.

**Table 10.36** Summary of the six well-characterised distal myopathies.

Disease	Onset	Weakness	Biopsy	Genes
Welander	>40	Hands	Dystrophic, rimmed vacuoles	AD, 2p13
Miyoshi	>15	Posterior calf	Dystrophic	AR, dysferlin
Nonaka	>15	Anterior calf	Myopathic, rimmed vacuoles	AR, GNE
Tibial MD	>35	Anterior calf	Dystrophic, rimmed vacuoles	AD, titin
LODM	>40	Anterior calf	Vacuoles	AD, 2q31
EODM	3–25	Anterior calf	Myopathic	AD, 14q

AD, autosomal dominant; AR, autosomal recessive; EODM, early onset distal myopathy; GNE, glucosamine (UDP-N-acetyl)-2-epimerase/N-acetylmannosamine kinase; LODM, late onset distal myopathy; MD, muscular dystrophy.

### Congenital myopathies

The congenital myopathies are a group of uncommon muscle disorders that were defined on the basis of distinctive morphological muscle biopsy features and presentation at birth. They are a heterogeneous group of disorders but, generally, patients present as floppy infants, with feeding and breathing difficulties, sometimes with congenitally dislocated hips, and then usually develop delayed motor milestones. The muscle weakness generally follows a fairly indolent course with a benign prognosis, at least when patients are younger. Some patients sometimes first come to attention in the adult muscle clinic. Central core myopathy, nemaline myopathy and centronuclear myopathy are of particular note and are described here.

**Central core disease** Central core disease (CCD) is an autosomal dominant disorder with onset often at birth or in early childhood with non-progressive limb and sometimes facial weakness with hypotonia. Patients usually live into adulthood. There may be a breech presentation, sometimes with dislocated hips, foot deformities or arthrogryposis. Motor milestones are delayed. There is mild proximal symmetrical muscle weakness and ambulation is usually achieved. Disability is usually mild. Significant cardiorespiratory problems are rare. CCD is associated with an increased risk of malignant hyperthermia (MH). However, the relationship between CCD and MH is complex and only around 30% of CCD patients have MH susceptibility. Most patients with pure MH have histologically normal muscle. Muscle biopsy in CCD typically shows central cores that are devoid of oxidative enzyme and phosphorylase activity. Both MH and CCD are often caused by mutations in the ryanodine receptor gene *RYR1*. MH susceptibility testing should be offered to patients with CCD. A more uncommon recessive form of central core disease is associated with CPEO and is often in the differential diagnosis of mitochondrial disease and congenital myasthenia gravis.

**Nemaline myopathy** Nemaline myopathy (NM) is characterised by the presence of rod-shaped structures (nemaline rods) in the muscle fibres. Inheritance can be autosomal dominant or recessive and to date mutations in seven genes have been described. Three clinical severities are seen: a severe congenital form, the typical congenital form and an adult onset form.

The severe congenital form presents with severe neonatal hypotonia and respiratory insufficiency. Reduced fetal movements are

reported *in utero*. Occasionally there may be severe arthrogryposis and dilated cardiomyopathy. Early mortality because of respiratory complications is common. Occasional long-term survival with respiratory support has been described accompanied by major motor weakness and inability to ambulate. The typical congenital form presents with neonatal hypotonia with less respiratory difficulty. Weakness is milder and although motor milestones are delayed, independent ambulation is achieved and most patients have an independent life.

The adult onset form presents between the ages of 20 and 50 years. Myalgia may be predominant with moderate proximal weakness which is usually slowly progressive. Facial muscle weakness and neck flexion weakness are common in all forms. The face is often elongated with a tent-shaped mouth and a high arch palate. The degree of the facial abnormality correlates with the overall severity of the condition. Some adult cases have been described with more rapidly progressive weakness. Respiratory involvement, associated with diaphragm weakness, is rare but can occur; nemaline myopathy should always be considered in the adult presenting with unexplained respiratory muscle weakness. All the known NM genes identified encode components of the sarcomeric thin filaments. In AD NM mutations in  $\alpha$  and  $\beta$  tropomyosin are described. In recessive NM, nebulin and troponin-1 mutations are described. Mutations in *ACTA1* may cause either dominant or recessive disease.

**Centronuclear myopathy** Three forms have been described. The severe X-linked form is associated with mutations in myotubularin. Bilateral ptosis, facial weakness, and ophthalmoplegia are common. Skeletal features include pectus carinatum, micrognathia, knee and hip contractures, elongated birth length, narrow face, slender/long digits, and macrocephaly. Patients often present *in utero* with reduced fetal movements and polyhydramnios. The prognosis is poor but those who survive the first year life, in spite of needing ventilatory support, will often survive in adulthood. The autosomal dominant form is often caused mutations in dynamin-2. Most patients have a mild phenotype with onset in adolescence or adulthood with axial/neck flexor as well as distal more than proximal limb weakness and slow progression. Other features include facial weakness, ptosis, ophthalmoplegia and contractures, especially of the ankles. The recessive form is often caused by mutations in amphiphysin-2 or *RYR1*. Presentation is often at birth but can be in childhood; approximately half of patients survive into adulthood.

### Skeletal muscle channelopathies (Chapter 3)

**Periodic paralyses and myotonias** Periodic paralysis and inherited myotonia were the first human disorders in which genetic dysfunction of ion channel genes was identified. They are conditions in which there is a disturbance in skeletal muscle fibre membrane excitability. The periodic paralyses are autosomal dominant disorders in which patients experience focal or generalised episodes of muscle weakness of variable duration. They have been characterised on the basis of the change in serum potassium early in an attack. In hyperkalaemic periodic paralysis potassium triggers an attack which will be ameliorated by glucose ingestion. In contrast, patients with hypokalaemic paralysis will notice improvement with potassium ingestion but worsening with glucose. The classification based upon potassium is useful clinically although a genetic classification has now possible (Table 10.37). Mutations in one of four skeletal muscle ion channels genes associate with human periodic paralysis. These are the voltage-gated sodium and calcium channel genes *SCN4A* and *CACNA1S* and the voltage-independent potassium channel genes *KCNJ2* and *KCNJ18*. All forms of periodic paralysis share the common feature that during an attack the muscle fibre membrane becomes electrically inexcitable but the mechanisms leading to this state vary.

Myotonia is a clinical disorder in which patients experience muscle stiffness because of a failure of normal electrical inactivation of activated muscle. Myotonia may result from genetic mutations in either the muscle voltage-gated chloride channel *CLCN1* gene (dominant or recessive myotonia congenita) or the voltage-gated sodium channel *SCN4A* gene (dominant paramyotonia congenita).

**Hyperkalaemic periodic paralysis and myotonias caused by skeletal muscle sodium channel dysfunction** In hyperkalaemic periodic paralysis (hyperPP) patients typically experience recurrent attacks

of muscle weakness starting in the first decade of life. Precipitants include rest following exercise, cold, potassium ingestion or stress. Attacks may vary in severity from mild weakness to total paralysis. The duration of attacks is usually less than 2 hours. Typically, the attack frequency declines with age but patients often develop a fixed myopathy of variable severity. Muscle biopsy in such cases often reveals tubular aggregates and or a vacuolar change. In humans, unlike equine forms, death is extremely rare in hyperPP or hypoPP. Cardiac arrhythmias are also uncommon except in Andersen's syndrome (see Periodic paralysis and cardiac arrhythmias).

HyperPP is caused by gain-of-function point mutations in the muscle sodium channel *SCN4A*. Sodium channel  $\alpha$ -subunit mutations (*SCN4A*) lead to defective fast inactivation of the skeletal muscle  $\text{Na}^+$  channel. The resulting persisting inward sodium current (a gain-of-function) impairs repolarisation and increases membrane excitability. Depending on the degree of increased membrane excitability, a patient may experience myotonia or paralysis. It is notable that similar gain-of-function mutations in a neuronal sodium channel gene *SCN1A* result in increased neuronal excitability and associate with a form of epilepsy, thus representing a direct pathophysiological parallel between muscle and brain sodium channel diseases.

Many attacks are brief and do not require treatment. If necessary, acute attacks can be terminated by ingestion of carbohydrate or inhaled salbutamol. Preventative treatment with acetazolamide or a thiazide diuretic may be required. It remains unproven if reducing attack frequency with such agents reduces the likelihood of the subsequent development of myopathy.

Paramyotonia congenita (PMC) is a form of myotonia that appears during exercise and worsens with continued activity. EMG at rest often shows some myotonia. Low temperature often precipitates symptoms in these patients and cooling produces repetitive

**Table 10.37** Skeletal muscle channelopathies: a genetic classification.

Gene	Channel	Disease	Inheritance
CACNA1S*	Calcium channel	HypoPP1	AD
	L-type calcium $\alpha$ -subunit	MH	AD
SCN4A*	Sodium channel Nav1.4 $\alpha$ -subunit	HyperPP	AD
		PMC	AD
		PAM	AD
		HypoPP2	AD
KCNJ2*	Potassium channel, $\text{K}_i$ 2.1	Andersen's syndrome	AD
KCNJ18	Potassium channel K Kir 2.6	Thyrotoxic Hypokalaemic Periodic paralysis	AD
CLCN1*	Chloride channel, CIC1	Myotonia congenita	AD/AR
		MD1, MD2 <sup>†</sup>	AD
RYR1	Ryanodine receptor	MH	AD
	Calcium release channel	Central core disease	AD <sup>‡</sup> AR

AD, autosomal dominant; AR, autosomal recessive; CIC1, chloride channel 1 gene/channel; HyperPP, hyperkalaemic periodic paralysis; HypoPP, hypokalaemic periodic paralysis;  $\text{K}_i$  2.1, potassium inward rectifier; MH, malignant hyperthermia; PAM, potassium aggravated myotonia; PMC, paramyotonia congenita.

\* DNA-based diagnosis available in UK.

<sup>†</sup> Altered splicing of *CLCN1* has been shown in both forms of myotonic dystrophy (MD) as the basis of the myotonia.

<sup>‡</sup> Gain-of-function.

spontaneous motor unit discharges with a decrement in the muscle action potential amplitude. PMC is also caused by mutations in the voltage-gated skeletal muscle sodium channel  $\alpha$ -subunit (*SCN4A*) and PMC is therefore allelic with hyperPP. PMC is inherited as a highly penetrant autosomal dominant trait. Mutations have been found throughout the gene, although exon 24 appears to be a hotspot for mutations. PMC associated point mutations confer a gain-of-function. However, the resulting impairment of fast inactivation is less than that associated with mutations associated with hyperPP. Mexiletene is an effective symptomatic treatment for PMC. Milder forms of myotonia without cold sensitivity are also described in association with different sodium channel point mutations, known as potassium aggravated myotonia.

**Hypokalaemic periodic paralysis – a muscle calcium or sodium channel disorder** Hypokalaemic periodic paralysis (hypoPP) is autosomal dominant with *de novo* dominant mutations accounting for one-third of cases. Attacks are precipitated by a period of exercise followed by rest or by carbohydrate loading. Attacks typically develop in the early hours of the morning and may last hours to days. Serum potassium is typically low at the onset but may normalise quickly. Attack frequency tends to decline with age but a fixed myopathy may develop. Myotonia does not occur in hypoPP.

Point mutations in two separate muscle channel genes may cause hypoPP. The majority of cases harbour one of three point mutations in the L-type calcium channel, *CACNA1S* (also known as hypoPP type 1). Far less frequent mutations have been described in the muscle sodium channel *SCN4A* (known as hypoPP-type 2).

Mutations in the L-type calcium channel  $\alpha_1$ -subunit (dihydropyridine receptor; *CACNA1S*) account for about 70% of cases of hypoPP. All mutations are arginine substitutions in the voltage sensor (S4) of the channel protein. It remains unclear how mutations in *CACNA1S*, which does not have a major role in determining muscle membrane excitability, causes the symptoms; however, recent studies suggest that the S4 causative mutations result in a gating pore current that is important in causing episodic muscle membrane depolarisation.

HypoPP associated with *CACNA1S* mutations exhibits reduced penetrance in females (50%) compared to complete penetrance in males. Specific mutations appear to have discrete clinical features, for example R528H is common, with later onset and associated myalgias.

HypoPP can also be caused by missense loss-of-function mutations in the voltage sensor of domain 2 of *SCN4A* but these are uncommon in the United Kingdom. There is some evidence that such hypoPP cases may experience worsening of attacks with prominent myalgia when exposed to acetazolamide. In this setting an alternative carbonic anhydrase inhibitor dichlorphenamide seems to be effective.

In summary, current evidence indicates that hyperPP is a gain-of-function disorder caused by *SCN4A* point mutations. In contrast, hypoPP associates with S4 mutations that predict a gating pore current in either *CACNA1S* or *SCN4A*.

**Thyrotoxic periodic paralysis** This is a rare condition causing attacks indistinguishable from hypoPP but in the presence of thyrotoxicosis. The disorder is most common in young Asian and Latin American men in whom 10% of thyrotoxic males develop episodic weakness. Candidate gene sequencing has revealed mutations in *KCNJ18* which encodes Kir 2.6, an inwardly rectifying potassium

channel that is expressed in skeletal muscle and transcriptionally regulated by thyroid hormones in one-third of patients.

**Periodic paralysis and cardiac arrhythmias – a skeletal muscle potassium channel disorder** Most cases of periodic paralysis do not associate with cardiac arrhythmias because the responsible channel (*CACNA1S*, *SCN4A*) is not expressed in cardiac muscle. Andersen-Tawil syndrome is a form of dyskalaemic periodic paralysis in which cardiac involvement is frequent (the resting ECG commonly shows bigeminy). In addition to periodic paralysis, patients may have atrial and/or ventricular arrhythmias and may also have characteristic facial and skeletal features (Figure 10.24). From a practical point of view, this disorder should be considered in any case of periodic paralysis with arrhythmia.

Andersen's syndrome is caused by mutations in a potassium channel termed Kir2.1. This inward rectifying potassium channel Kir2.1 is encoded by *KCNJ2* on chromosome 17q23. The functional channel is a homotetramer important for cardiac and skeletal muscle membrane hyperpolarisation and also has a role in skeletal bone precursor cell migration and fusion during development. There is intrafamilial variability and partial manifestation of the phenotype is common. During an attack, serum potassium is most commonly low but may be normal or high. In patients with hypokalaemia, oral potassium supplements may improve the weakness. In some families, increasing plasma potassium concentration with acetazolamide improves arrhythmias at the expense of exacerbating weakness. Once the diagnosis is made detailed cardiac assessment is needed. However, the optimum management to prevent malignant arrhythmias is not certain.

**Myotonia congenita – a skeletal muscle chloride channel disorder** Dominant (Thomsen's disease) and recessive (Becker's disease) forms of myotonia congenita are recognised. Patients experience differing degrees of muscle stiffness and muscle hypertrophy. The dominant form is less common and generally milder. Patients present with muscle stiffness because of impaired voluntary muscle relaxation. Patients describe marked muscle stiffness at the onset of activity, but the more they continue the less stiff the muscles become – the 'warm-up phenomenon.' While 90% show myotonia on EMG, only 50% have percussion myotonia on examination. There is usually normal power at rest, although a minority have proximal weakness. Muscle hypertrophy and myalgia may occur in both forms but are more prominent in the more common recessive form of the disease. Electrophysiologically, *in vivo* myotonia (and paramyotonia) is characterised by uncontrolled repetitive action potentials at the sarcolemma initiated by a voluntary activation. This persistent involuntary activation prevents the patient from relaxing the muscle, hence the complaint of muscle stiffness and limitation of free flowing movements.

Both forms of myotonia congenita are caused by mutations in a muscle voltage gated chloride channel (*CLCN1*) located on chromosome 7q35.10. There is evidence that, unlike all other voltage-gated ion channels, this channel has two separate ion pores through which chloride ion passage may occur. The resting membrane potential in skeletal muscle is mainly dependent upon the chloride channel conductance; *CLCN1* mutations result in impaired chloride conductance and so produce partial depolarisation of the membrane. This creates the electrophysiological condition of increased excitability and repetitive firing after muscle activation, necessary for myotonia to occur. In patients who require treatment there is randomised controlled trial evidence that mexiletine is effective.

**Figure 10.24** Typical facial and hand/foot appearances in Anderson–Tawil syndrome. Note hypertelorism, micrognathism, low set ears, down-turned mouth, short digits, clinodactyly of the fifth digits and syndactyly of the toes.

## Metabolic muscle disease

### Mitochondrial respiratory chain diseases

**Mitochondrial function and dysfunction** Mitochondria are highly dynamic intracellular organelles with critical roles in numerous cell functions, including energy (ATP) generation via the respiratory chain and oxidative phosphorylation (OXPHOS) system (a series of enzyme complexes embedded in the inner mitochondrial membrane; Figure 10.25), calcium homeostasis, and cell-specific functions such as neurotransmitter biosynthesis. Mitochondria are unique among cellular organelles in possessing their own genetic material, a circular double-stranded 16.5 kb DNA molecule encoding 13 polypeptide components of OXPHOS enzymes and 24 RNA molecules needed for the intramitochondrial synthesis of these 13 polypeptides. Diseases related to mitochondrial dysfunction were first recognised more than 50 years ago, with the clinical description of Luft's disease (euthyroid hypermetabolism). However, the genetic basis of these disorders did not begin to be unravelled until 1988, when the first mitochondrial DNA (mtDNA) mutations were reported. Since then more than 150 pathogenic mtDNA mutations have been described ([www.mitomap.org](http://www.mitomap.org)). Furthermore, it is now recognised that more than 1000 proteins make up the mitochondrial 'proteome' and that mutations in any of the nuclear genes encoding the vast majority of these proteins may, theoretically at

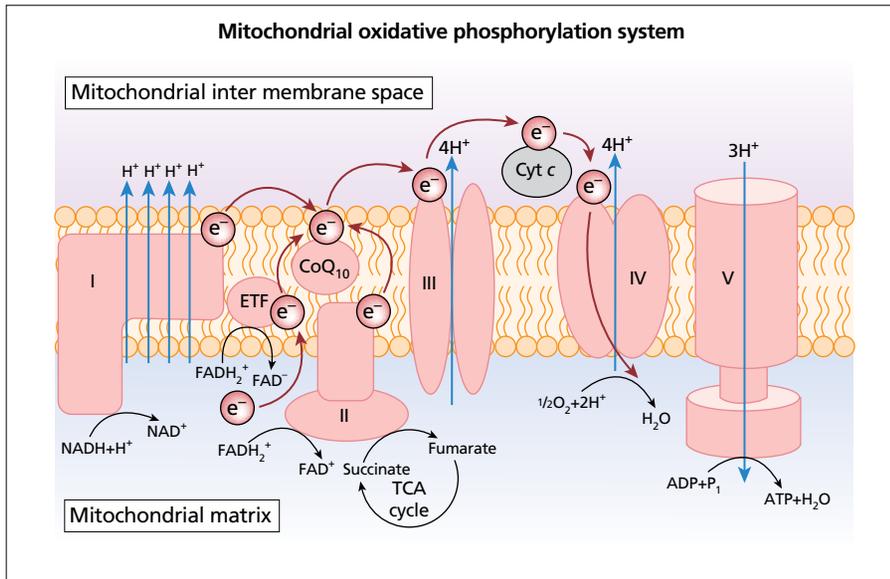

least, cause mitochondrial disease. So far mutations in approximately 200 of these genes have been linked to human disease.

**Clinical features of mitochondrial disorders** Mitochondrial disorders are defined as inherited disorders affecting OXPHOS (directly or indirectly), and are estimated to have a birth prevalence of 1 in 5000. Presenting clinical features are extremely heterogeneous, particularly in childhood, but most affected adults have predominantly neuromuscular symptoms. Myopathic features include progressive external ophthalmoplegia (PEO), isolated proximal myopathy (or occasionally distal myopathy; Figure 10.26), exercise intolerance and rhabdomyolysis, which is an infrequent but recognised complication.

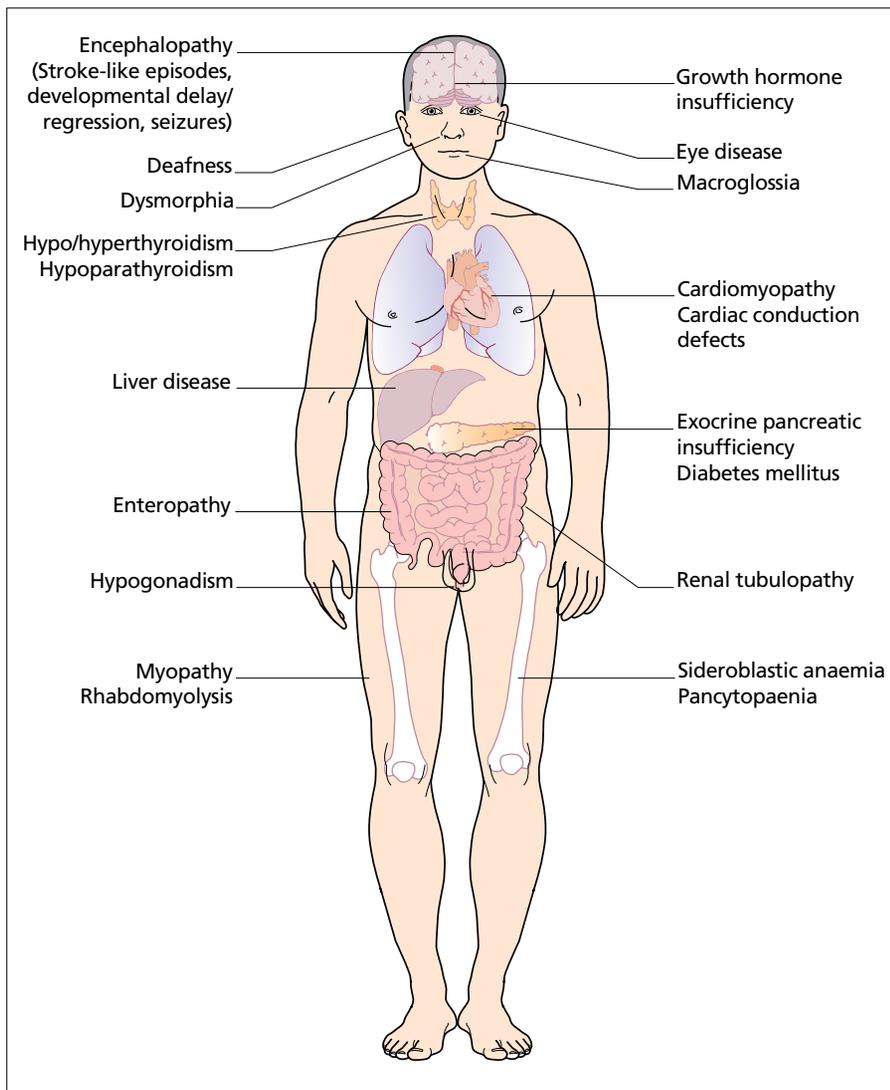

Although many adults have an isolated myopathic phenotype, complex multi-system disorders are increasingly recognised, including discrete constellations of symptoms forming specific clinical syndromes, as described later and summarised in Table 10.38.

### Mitochondrial myopathies

**Progressive external ophthalmoplegia** The muscles most frequently involved by mitochondrial disease are the extraocular muscles, leading to PEO and bilateral symmetrical ptosis, usually without diplopia. Proximal limb musculature may also be involved by the

**Figure 10.26** Clinical features of mitochondrial disease.

**Table 10.38** Clinical mitochondrial syndromes presenting in adult life.

Acronym or eponym	Syndrome	Clinical features
MELAS	Mitochondrial encephalomyopathy, lactic acidosis, stroke-like episodes	Stroke-like episodes, migraines, dementia, ataxia, cardiomyopathy, deafness, gastrointestinal dysmotility
MIDD	Maternally inherited diabetes and deafness	Diabetes, deafness, maculopathy, cardiomyopathy, renal disease
MERRF	Myoclonus, epilepsy, ragged red fibres	Myoclonus, seizures, ataxia, deafness, dementia, lipomas
LHON	Leber's hereditary optic neuropathy	Subacute bilateral loss of vision
NARP	Neurogenic muscle weakness, ataxia, retinitis pigmentosa	Peripheral neuropathy, ataxia, pigmentary retinopathy
PEO	Progressive external ophthalmoplegia	Ptosis, limitation of eye movements
KSS	Kearns–Sayre syndrome	PEO (<20 years), pigmentary retinopathy, cerebellar ataxia, heart block
ADPEO	Autosomal dominant PEO	PEO, dysphagia
ARPEO	Autosomal recessive PEO	PEO, optic atrophy, cardiomyopathy
SANDO	Sensory ataxic neuropathy, dysarthria and ophthalmoparesis	Ataxia, neuropathy, dysarthria, PEO
MEMSA	Myoclonic epilepsy, myopathy, sensory ataxia	Epilepsy, ataxia, myopathy
MNGIE	Mitochondrial neurogastrointestinal encephalomyopathy	Gastrointestinal dysmotility, PEO, myopathy, demyelinating neuropathy
ADOA	Autosomal dominant optic atrophy	Optic atrophy, SNHL, SANDO-like disorder
CMT2A	Charcot–Marie–Tooth disease type 2A	Axonal sensorimotor neuropathy, optic atrophy
Alpers*	Progressive sclerosingpoliodystrophy	Intractable epilepsy, liver disease
Leigh's*	Subacute necrotising encephalomyelopathy	Progressive loss of neurological function, dystonia, ataxia, seizures, optic atrophy, respiratory failure

\*Presentation in adult life is extremely rare.

disease process, manifesting as fatigue and exercise intolerance. Pain is an unusual feature. The most common cause of PEO is a sporadic single large-scale mtDNA deletion (SLMD). Several Mendelian PEO syndromes are now recognised, which may be inherited as autosomal dominant (ADPEO) or autosomal recessive (ARPEO) traits. These disorders are caused by mutations in nuclear-encoded genes needed for maintenance of the mitochondrial genome (Table 10.39) and may be suspected if multiple deletions are detected on long-range PCR of the mtDNA. ADPEO may also be suggested by the family history. Patients with ADPEO and ARPEO may present additional clinical problems, including ataxia, peripheral neuropathy, dysphagia and other bulbar symptoms, cataracts, depression, cardiac involvement and endocrine disturbance.

**Kearns–Sayre syndrome** Some patients with SLMDs have a more severe presentation, known as the Kearns–Sayre syndrome (KSS), which is defined as onset before 20 years of PEO with pigmentary

retinopathy and one of: cardiac conduction defect, raised CSF protein (>1 g/L) or cerebellar ataxia. Eighty per cent of patients with KSS have a SLMD, but recently autosomal recessive KSS caused by *RRM2B* mutations has been reported.

**Exercise intolerance and rhabdomyolysis** Isolated myopathy with exercise intolerance and myoglobinuria may be associated with mtDNA point mutations affecting complex III and IV subunits, and are usually sporadic. Rhabdomyolysis is more usually a feature of mitochondrial fatty acid beta oxidation defects, but may also be seen in co-enzyme Q<sub>10</sub> deficiency. Although proximal myopathy is typical in mitochondrial disease, recently distal myopathy caused by *POLG* mutations has been reported.

**Mitochondrial neuropathies** Peripheral neuropathy is an increasingly recognised feature of mitochondrial disease. In some cases it is mild or even subclinical, but in other individuals neuropathy may

**Table 10.39** Classification of mitochondrial respiratory chain diseases.

Genetic defect	Inheritance	Phenotype
<b>Defects of mitochondrial DNA</b>		
Mutations affecting protein synthesis:		
SLMDs	Sporadic	PEO, myopathy, KSS
tRNA point mutations	Maternal	MELAS, MIDD, MERRF
rRNA point mutations	Maternal	Aminoglycoside-induced SNHL
Mutations of protein coding genes:		
Complex I subunits ( <i>MTND1-6</i> )	Maternal	LHON, MELAS, LS
Complex III subunit ( <i>MTCYTB</i> )	Maternal	Exercise intolerance
Complex IV subunits ( <i>MTCO1-3</i> )	Maternal	Myopathy
Complex V subunits ( <i>MTATP6/8</i> )	Maternal	LS, NARP, isolated neuropathy
<b>Nuclear gene defects</b>		
OXPHOS subunits, e.g.		
Complex I subunits	Recessive	LS
Complex II subunits( <i>SDHA-B</i> )	Recessive	LS
Complex II subunits ( <i>SDHB-D</i> )	Dominant	Paraganglionoma, pheochromocytoma
OXPHOS assembly factors, e.g.		
Complex I assembly factors ( <i>NDUFAF...</i> )	Recessive	LS, cardiomyopathy, exercise intolerance
Complex IV assembly factors ( <i>SURF1</i> )	Recessive	LS
mtDNA replication factors, e.g.		
<i>POLG, PEO1</i>	Dominant	ADPEO
<i>POLG</i>	Recessive	ARPEO, SANDO, MEMSA, Alpers' disease
Nucleoside metabolism, e.g.		
<i>RRM2B, ANT1</i>	Dominant	ADPEO
<i>TK2, DGUOK, RRM2B</i>	Recessive	ARPEO
<i>TYMP</i>	Recessive	MNGIE
Aminoacyl tRNA synthetases, e.g.		
<i>AARS2</i>	Recessive	Leukodystrophy and ovarian failure
<i>DARS2</i>	Recessive	LBSL
<i>HARS2, LARS2</i>	Recessive	Perrault's syndrome (POF and SNHL)
<i>MARS2</i>	Recessive	ARSAL
<i>YARS2</i>	Recessive	MLASA
FeS cluster biogenesis, e.g.		
<i>ISCU</i>	Recessive	Myopathy with exercise intolerance
<i>FXN</i>	Recessive	Friedreich's ataxia
Co-enzyme Q <sub>10</sub> biosynthesis, e.g.		
<i>ADCK3</i>	Recessive	Cerebellar ataxia ± seizures
Mitochondrial protein import, e.g.		
<i>TIMM8A</i>	X-linked	Deafness–dystonia syndrome
Mitochondrial dynamics, e.g.		
<i>MFN2, GDAP1</i>	Dominant	CMT2A, CMT4A
<i>OPA1</i>	Dominant	ADOA
Mitochondrial membrane lipid biosynthesis/remodelling, e.g.		
<i>TAZ</i>	X-linked	Barth's syndrome
<i>SERAC1</i>	Recessive	MEGDEL

This table has largely focussed on mitochondrial disorders presenting in or surviving into adult life.

ADOA, autosomal dominant optic atrophy; ADPEO, autosomal dominant PEO; ARPEO, autosomal recessive PEO; ARSAL, autosomal recessive spastic ataxia with leukoencephalopathy; CMT, Charcot–Marie–Tooth; KSS, Kearns–Sayre syndrome; LBSL, leukoencephalopathy with brainstem and spinal cord involvement and lactate elevation; LHON, Leber's hereditary optic neuropathy; LS, Leigh's syndrome; MEGDEL, methylglutaconaciduria, deafness, encephalopathy, Leigh-like; MELAS, mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes; MEMSA, myoclonic epilepsy, myopathy, sensory ataxia; MERRF, myoclonic epilepsy with ragged red fibres; MIDD, maternally inherited diabetes and deafness; MLASA, myopathy, lactic acidosis, sideroblastic anaemia; MNGIE, mitochondrial neurogastrointestinal encephalopathy; NARP, neurogenic muscle weakness, ataxia and retinitis pigmentosa; PEO, progressive external ophthalmoplegia; POF, premature ovarian failure; SANDO, sensory ataxia, neuropathy, dysphagia and ophthalmoplegia; SLMDs, single large-scale mtDNA deletions; SNHL, sensorineural hearing loss.

be the predominant or only clinical manifestation of mitochondrial disease. Several multi-system disorders with a major neuropathy have been reported, most commonly a sensorimotor axonal neuropathy. Patients with moderate levels of maternally inherited point mutations (m.8993T>G/C) in the mitochondrial *MT-ATP6* gene, encoding a subunit of the ATP synthase, may have neurogenic muscle weakness, ataxia and retinitis pigmentosa (NARP) syndrome. The same mutations at very high mutant loads (>90%) are associated with Leigh's syndrome. However, other patients with point mutations in this gene have a much milder phenotype clinically indistinguishable from CMT disease. Patients with recessive *POLG* mutations may have a neuropathy syndrome known as sensory ataxia, neuropathy, dysphagia and ophthalmoplegia (SANDO) or ataxic neuropathy syndrome (ANS). These patients typically have multiple mtDNA deletions in skeletal muscle biopsies. In other patients neuropathy may be associated with DNA depletion (i.e. quantitative mutation of mtDNA), for example in patients with *MPV17* mutations. *MPV17* disease includes Navajo neurohepatopathy (a founder disease in the Navajo population in south-western United States) in which a severe sensorimotor neuropathy is associated with corneal ulceration, acral mutilation, liver disease, leukoencephalopathy and metabolic acidosis. Patients with mutations in the outer mitochondrial membrane GTPase mitofusin 2, which is critical for mitochondrial fusion, present with dominant CMT type 2A, and may additionally have optic atrophy, whereas mutations in another outer mitochondrial membrane protein *GDAP1* are associated with recessive CMT4A. Finally, demyelinating peripheral neuropathy is a feature of mitochondrial neuro-gastrointestinal encephalopathy (MNGIE) syndrome (see Multi-system mitochondrial disorders), and rarely may be seen in MELAS, MERRF and Leigh's syndromes.

#### Mitochondrial optic neuropathies

**LHON** Leber's hereditary optic neuropathy (LHON) is a maternally inherited subacute optic neuropathy characterised by painless sequential loss of vision in both eyes. More than 90% of cases have one of three common mtDNA point mutations (m.11778G>A, m.3460G>A and m.14484T>C) in genes encoding subunits of complex I of the respiratory chain. These mutations are homoplasmic (i.e. present in 100% mutation load) but penetrance is extremely variable and differs between the sexes. Males have an approximately five times greater risk of loss of vision, possibly because of a protective effect of oestrogen in females. In most patients loss of vision is the only symptom, but occasional patients have additional problems, including cardiac arrhythmias, peripheral neuropathy and multiple sclerosis-like symptoms.

**ADOA** Autosomal dominant optic atrophy (ADOA, also known as Kjer's optic neuropathy) is the most common inherited optic neuropathy in Caucasian populations and is caused by mutations in *OPA1*, encoding an inner mitochondrial membrane GTPase with roles in mitochondrial morphology and dynamics and mtDNA maintenance. Optic atrophy begins in childhood (typically by 6 years) and is slowly progressive, with vision loss varying from mild to severe. Intrafamilial variability is recognised. Individuals with the *R445H* mutation frequently have associated sensorineural hearing loss (SNHL) while up to 20% of patients may have a multi-system neurological disorder resembling SANDO (see Mitochondrial neuropathies).

#### Mitochondrial encephalomyopathies

**MELAS** Mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS) syndrome is a multi-system

disorder characterised by the occurrence of stroke-like episodes before the age of 40 years, frequently associated with seizures, migrainous headache, anorexia, vomiting and lactic acidosis. Transient hemiparesis, altered consciousness and cognitive blindness may occur during the stroke-like episodes, which are thought to be caused by microangiopathy and endothelial dysfunction, although the precise mechanisms are still debated. The disease course is usually relentlessly progressive, with recurrent stroke-like episodes leading to visual disturbance and motor and cognitive decline. Eighty per cent of cases have a common mtDNA point mutation, m.3243A>G. Nearly 30 different mtDNA point mutations have been implicated in the remaining 20% of cases, although similar symptoms may occasionally result from nuclear gene mutations such as *POLG* mutations. Other clinical features of MELAS syndrome include sensorineural hearing loss (SNHL), ataxia, diabetes mellitus, and cardiac, renal and gastrointestinal disturbance. Many of these features may occur in isolation in patients with the m.3243A>G mutation, with the full MELAS syndrome occurring in a minority (<10%) of individuals with this mutation.

**MERRF** In MERRF (myoclonic epilepsy with ragged red fibres) syndrome, onset is usually in late childhood with myoclonus, typically associated with ataxia. Other clinical features of this syndrome include generalised epilepsy, SNHL, optic atrophy, pigmentary retinopathy and lactic acidosis. Some individuals also have multiple symmetrical lipomatosis. Most patients with this syndrome have a mtDNA point mutation, m.8344A>G, although other mtDNA point mutations have also been associated with this phenotype, and patients with recessive *POLG* mutations (see Chapter 7) may have similar presentations. In practice, there is often considerable overlap between MERRF and MELAS, with stroke-like episodes sometimes occurring in the former. Moreover, recently it has become clear that the m.8344A>G mutation is associated with marked phenotypic heterogeneity.

**Alpers' and other mitochondrial epilepsy syndromes** Several epilepsy syndromes have been associated with recessive *POLG* mutations. Alpers–Huttenlocher syndrome (also known as progressive sclerosing poliodystrophy or progressive neuronal degeneration of childhood with liver disease) is one of the most severe presentations of recessive *POLG* mutations. Intractable seizures usually begin in infancy but may occur at any time during childhood. In some cases there is preceding developmental delay and hypotonia. Initial seizures are focal, often involving the right arm, evolving through epilepsy partialis continua to status epilepticus. Seizures are resistant to multiple antiepileptic drugs and death may follow status epilepticus or acute liver failure, which may be precipitated by sodium valproate. For this reason valproate therapy is generally avoided in the treatment of mitochondrial epilepsy, at least until *POLG* mutations have been excluded. Later onset *POLG* epilepsies are now considered under the umbrella term myoclonic epilepsy, myopathy, sensory ataxia (MEMSA) syndrome, which includes patients previously described as having spino-cerebellar ataxia with epilepsy (SCAE). The first symptom in MEMSA is often ataxia, together with recurrent seizures (usually myoclonic) and myopathy.

**Leigh's syndrome** Leigh's syndrome, or subacute necrotising encephalopathy, has a birth prevalence of at least 1/40 000. It usually presents in infancy with stepwise neurodevelopmental regression related to intercurrent illnesses and other metabolic stresses, and usually has a relentlessly progressive course leading to death in early

childhood. However, occasional cases present in adult life and increasingly childhood-onset cases are surviving into adulthood (possibly related to improved supportive care), and so the adult neurologist should be familiar with this cause of severe neurodisability. Blood and/or CSF lactate levels are usually elevated, and characteristic neuro-imaging appearances are of bilateral symmetrical lesions in the basal ganglia and/or brainstem, which appear hyperintense in T2-weighted sequences. Leigh's syndrome is associated with remarkable genetic heterogeneity, with more than 50 genes (including both mitochondrial and nuclear genes) linked to this condition so far.

#### Multi-system mitochondrial disorders

**MIDD** Maternally inherited diabetes and deafness (MIDD) is one of the most common presentations of the m.3243A>G mutation which has been traditionally linked to MELAS (see Mitochondrial encephalomyopathies). Deafness usually precedes the onset of diabetes by several years. The diabetes is comparatively easy to manage although insulin may be needed. Other clinical features related to m.3243A>G may be observed in patients with MIDD, including hypertrophic cardiomyopathy, renal impairment (caused by focal segmental glomerulosclerosis), ataxia, myopathy and stroke-like episodes.

**MNGIE** Mitochondrial neurogastrointestinal encephalopathy (MNGIE) is caused by thymidine phosphorylase deficiency, leading to impaired mtDNA replication because of intramitochondrial nucleoside imbalance. This in turn leads to progressive mtDNA depletion and accumulation of mtDNA rearrangements and point mutations. Affected individuals may be healthy in childhood and typically present late in the second decade with intestinal pseudo-obstruction, which may be associated with demyelinating peripheral neuropathy, PEO and optic atrophy. MRI reveals a leukoencephalopathy, which is usually relatively asymptomatic.

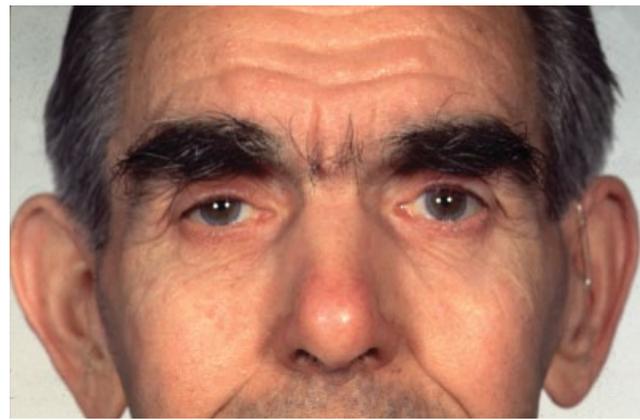

**Other multi-system disorders** As mitochondria are present in all human cells with the exception of mature erythrocytes, mitochondrial dysfunction can potentially involve any organ system, as indicated by Figure 10.27, and these clinical features may present in any combination at any age.

**Disorders associated with secondary mitochondrial dysfunction** Space precludes the detailed discussion of these disorders, but secondary mitochondrial dysfunction has been reported in several neuro-degenerative disorders, including Parkinson's, Huntington's and Alzheimer's diseases, as well as in normal healthy ageing.

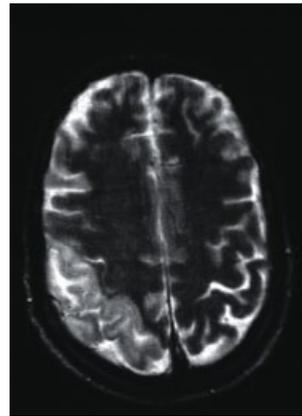

**Diagnosis** Investigation of mitochondrial disease needs to take a multi-modality approach, including some or all of the following investigations, depending on the clinical presentation.

**Blood investigations** Blood lactate may be elevated in mitochondrial disease, but is frequently normal in adult patients. CK may be mildly elevated but is not usually informative. In MNGIE syndrome, plasma and urine thymidine and deoxyuridine levels are elevated; the diagnosis is confirmed by demonstrating reduced activity of thymidine phosphorylase in platelets.

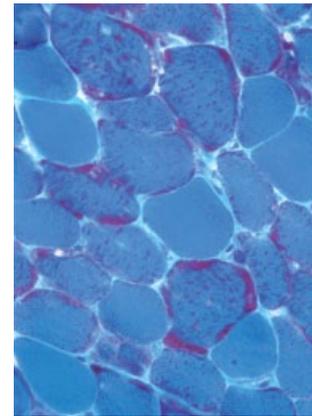

**Neuro-imaging** MRI of the brain is typically normal in patients with mitochondrial myopathies, neuropathies and optic neuropathies. However, acute stroke-like episodes, MRI of the brain in

(a)

(b)

(c)

**Figure 10.27** (a) Mitochondrial myopathy. Note not only the ptosis but hearing aid indicating deafness. (b) Typical stroke of a patient with mitochondrial disease, occipitoparietal and not respecting usual anatomical vascular territories. (c) Ragged red fibres stained with Gomori trichrome stain represent muscle fibres with peripheral accumulations of abnormal mitochondria.

patients with MELAS usually reveals unilateral T2 hyperintensities in a parieto-occipital distribution (not confined to specific vascular territories), which subsequently resolve. Leigh's syndrome is characterised by bilateral symmetrical T2 hyperintensities involving the basal ganglia and/or brainstem. Leukoencephalopathy may be seen in MNGIE and other mitochondrial encephalopathies, such as the syndrome of leukoencephalopathy with brainstem and spinal cord involvement and lactate elevation (LBSL) caused by *DARS2* mutations.

**Neurophysiology** Approximately 50% of adult patients with mitochondrial disorders have electromyographic evidence of myopathy, while axonal sensorimotor polyneuropathy is observed in about 35% of cases. Demyelinating neuropathy is seen in MNGIE. The electroencephalogram has a characteristic appearance in the early stages of Alpers' syndrome (unilateral occipital rhythmic high-amplitude delta with superimposed [poly] spikes; RHADS), although later becomes non-specifically abnormal.

**Muscle histology** The histological hallmark of mitochondrial disease, the ragged-red fibre (RRF), is best visualised by the modified

Gomori trichrome stain, in which mitochondria appear red. The 'ragged' appearance results from subsarcolemmal accumulation of mitochondria. RRF frequently stain negatively for cytochrome oxidase (COX) and positively in the succinate dehydrogenase (SDH) stain, leading to 'ragged-blue' fibres in the sequential COX–SDH combined stain. Although a small number of RRF may be a normal feature of ageing muscle, the presence of any RRF below the age of 40 years is considered abnormal, as is the observation of greater than five RRF above the age of 60. Other non-specific histological features that may be observed in patients with mitochondrial disease include accumulation of lipid droplets within muscle fibres and type 2 fibre predominance.

**Muscle biochemistry** OXPHOS enzyme activities can be measured using spectrophotometric assays in skeletal muscle biopsies and may reveal isolated deficiency of a single enzyme or combined deficiencies of multiple enzymes, particularly in childhood-onset disease. However, OXPHOS enzyme activities are typically normal in most adults with mitochondrial disease, even those with confirmed genetic defects, reflecting the relatively milder disorders presenting in adults.

**Mitochondrial genetics** Point mutations of mtDNA were initially linked to LHON and later to a multitude of clinical presentations. To date >150 different mtDNA point mutations have been reported, and these have been catalogued in the Mitomap online database ([www.mitomap.org](http://www.mitomap.org)). Many of these mutations have only been described in single families and so are considered provisionally pathogenic, until reported to cause a similar phenotype in a second unrelated family, at which time a confirmed pathogenicity status is assigned. The first genetic defects reported in mitochondrial disorders were large-scale rearrangements of the mtDNA in patients with PEO. Single mtDNA deletions arise sporadically, but some patients have multiple mtDNA deletions because they have a Mendelian disorder of mtDNA maintenance. Mutations in 11 different nuclear-encoded genes have so far been linked to defective mtDNA replication. With the recent widespread adoption of whole exome sequencing, a rapidly increasing number of nuclear genes have been associated with mitochondrial disease (Table 10.39).

A stepwise approach to the genetic diagnosis of mitochondrial disease in adults is illustrated by the flowchart (Figure 10.28).

**Treatment** Currently, very few curative therapies exist for mitochondrial disorders, with the following notable exceptions:

**Disorders of coenzyme Q<sub>10</sub> biosynthesis** Primary CoQ<sub>10</sub> deficiencies (i.e. disorders of CoQ<sub>10</sub> biosynthesis) are usually diagnosed in childhood but may present in adult life, for example with ataxia, seizures or myopathy. Early CoQ<sub>10</sub> supplementation has been associated with a good prognosis, but extremely high doses may be needed, up to 2.4 g/day.

**MNGIE** Allogeneic haematopoietic stem cell transplantation has been suggested as a potentially curative therapy for MNGIE, but mortality has been ~50% in reported cases to date, related to transplant-related complications or disease progression.

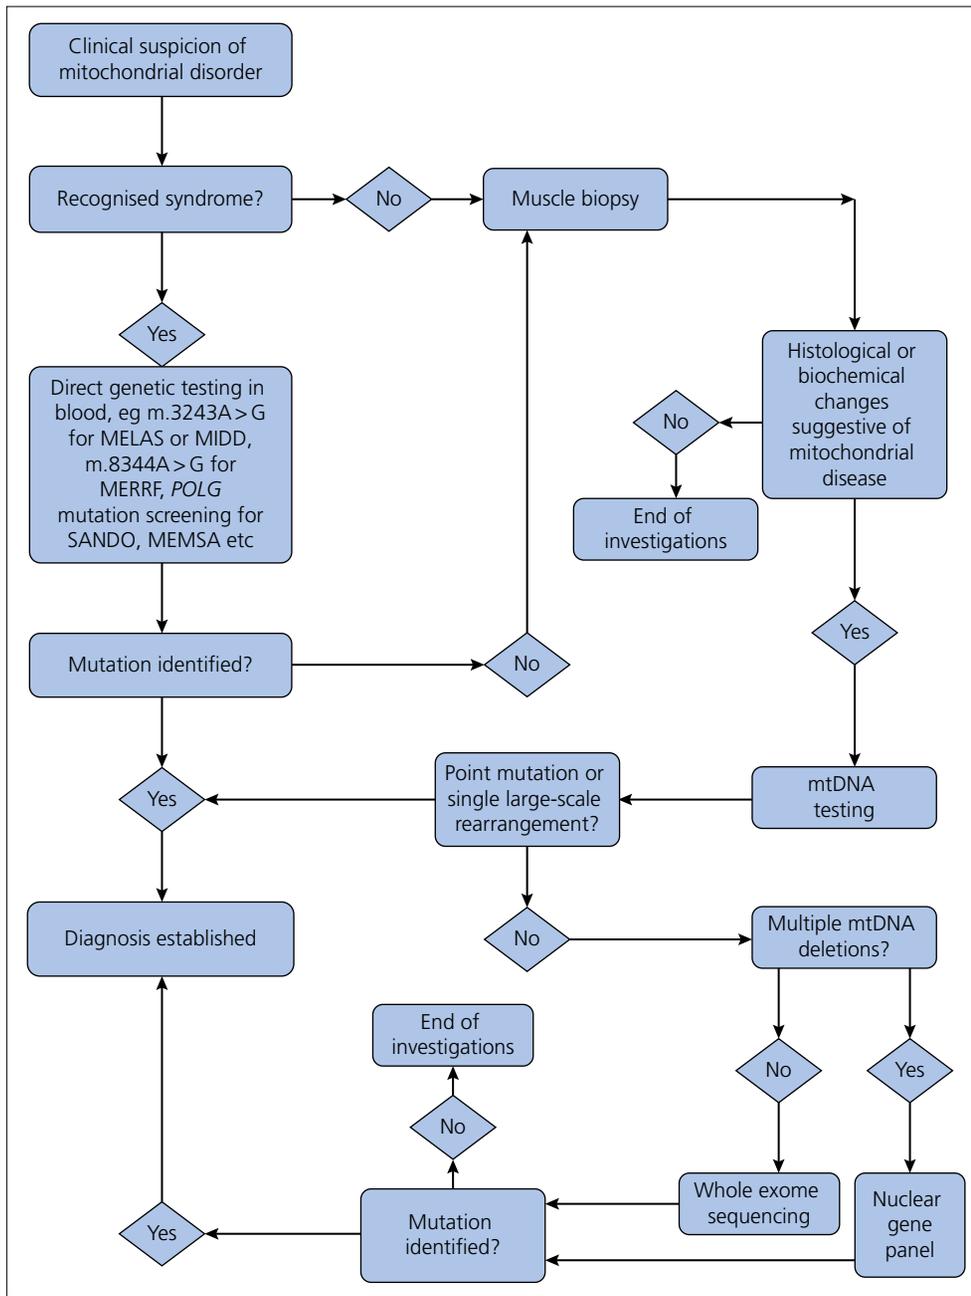

**Symptomatic therapy** For all other mitochondrial diseases, supportive treatment in a multi-disciplinary setting is the mainstay of management, as follows:

- **Seizures:** antiepileptic drugs, according to seizure type; valproic acid is contraindicated in patients with POLG mutations.

- **Dystonia:** baclofen, trihexphenidyl, botulinum toxin injections, consider deep brain stimulation.
- **Ptosis:** surgery (e.g. brow suspension) to improve the cosmetic appearance; problem frequently recurs, necessitating further surgery.
- **Hearing loss:** hearing aids and/or cochlear implants, according to severity.
- **Endocrine disturbance:** oral hypoglycaemics (avoid metformin as may precipitate lactic acidosis) or insulin, as clinically indicated, for diabetes mellitus; thyroxine for hypothyroidism; hydrocortisone for adrenal insufficiency.
- **Cardiac disease:** pacemaker or implantable cardiac defibrillator for conduction defects; medical therapy for cardiomyopathy; consider heart transplantation if isolated severe heart disease.
- **Renal disease:** electrolyte replacement in tubulopathy; consider renal transplantation in end-stage renal disease, depending on severity of neurological disease and other multi-system involvement.
- **Gastrointestinal disturbance:** formal dietetic evaluation and adequate nutritional support, including enteral feeding if unsafe swallow or unable to take sufficient calories orally; prokinetics and laxatives for constipation; antiemetics if persistent nausea/vomiting; pancreatic enzyme replacement if exocrine pancreatic insufficiency.
- **Psychological support:** this is extremely important for affected patients and their families, particularly as depression and psychiatric disturbance are increasingly recognised manifestations of mitochondrial disease.

**Experimental approaches** Many different agents have been proposed for the treatment of mitochondrial disorders, but it has proved extremely difficult to design and execute effective clinical trials for this group of clinically and genetically heterogeneous disorders, with unpredictable disease progression. Particular problems have been the selection of validated, objective and clinically relevant outcome measures. A recently updated Cochrane systematic review identified very few well-designed clinical trials for mitochondrial disease, and results were conflicting. Many treatments are still at the stage of preclinical evaluation and include novel antioxidants and agents designed to stimulate mitochondrial biogenesis (e.g. bezafibrate), manipulate mitochondrial dynamics and rescue defects of mitochondrial nucleoside metabolism. Gene therapy has been performed in mouse models of MNGIE using AAV vectors, while other gene therapy strategies (e.g. MitoTALENs) are at very early preclinical stages of development. Finally, techniques have been developed that have allowed exchange of nuclear genetic material between embryos in primates, and these are now being explored as potential methods to avoid transmission of mtDNA defects in humans.

**Conclusions** Mitochondrial disorders are clinically, biochemically and genetically heterogeneous conditions sharing the common feature of abnormal oxidative phosphorylation. Traditionally, syndromic neuromuscular (PEO) and CNS (MELAS, MERRF) diseases, characterised by RRF myopathy and underlying mtDNA mutations, were the most frequently recognised mitochondrial disorders in adults presenting to neurologists. However, multi-system disorders, often of childhood onset and caused by nuclear gene mutations, are increasingly being transitioned to the adult neurology clinic, leading to changing perceptions of these complex diseases. As the genetics of these disorders are resolved by next generation sequencing strategies, new therapeutic targets and modalities are likely to emerge.

**Figure 10.28** Flowchart for diagnosis of mitochondrial disorders in adults.

### Glycogenoses and lipid storage disorders (Chapter 19)

In addition to mitochondrial respiratory chain disorders, the other metabolic disorders in muscle include defects in glucose metabolism (glycogen storage disorders) and defects in fat metabolism (lipid storage disorders). Patients with these autosomal recessive disorders generally develop muscle pain on exertion. Myoglobinuria and sometimes fulminant rhabdomyolysis may occur. Patients with McArdle's disease (the most common glycogenosis caused by myophosphorylase deficiency) present with muscle pain soon after commencing exercise. The pain can be severe and cramping, often causing the patient to stop. A second wind phenomenon is common. The forearm non-ischæmic lactate test will show a blunting of the expected rise in muscle lactate induced by repeated isometric

exercise because of a failure to breakdown glycogen. Muscle biopsy will allow histoenzymatic staining for myophosphorylase, absent in McArdle's disease. Genetic testing is available but is usually performed after the metabolic defect has been confirmed.

Of the many disorders of lipid metabolism, the most common lipid storage disorder is carnitine palmitoyl transferase II (CPT-II) deficiency. Adults with CPT-II deficiency usually present with muscle pain induced by prolonged exercise, and often the pain may not develop until some time after exercise. Post-exercise myoglobinuria is frequent. Rhabdomyolysis is more likely to occur after fasting or if there is intercurrent infection or dehydration. Hypoketotic hypoglycaemia may occur. Occasionally, patients with CPT-II deficiency present with a painless proximal myopathy. Muscle biopsy

light microscopy may reveal abnormal accumulations of lipid. Muscle tissue can be used for specific enzyme assays. The pattern of acyl-carnitines in blood is particularly useful whenever a lipid storage disorder is being considered. Molecular genetic diagnosis is available.

**Conclusions** The diagnosis of patients with genetic muscle disorders has truly entered the molecular genetic era. DNA-based diagnosis is now available for many of these disorders and often removes the need for invasive tests such as muscle or nerve biopsy. Efficient selection of genetic tests is important and neurophysiology has a particularly important role in this regard for genetic muscle channelopathies. Muscle biopsy remains essential in certain situations, for example in the comprehensive investigation of patients with LGMD and in some metabolic myopathies. It is worth noting that while a blood sample is all that is required for testing in nuclear gene disorders, muscle tissue remains most useful for mitochondrial DNA analysis. In our view, all clinical neurologists need to be aware that a wealth of genetic diagnostic possibilities exists for these patients, and that achieving such diagnostic precision on a routine basis is important. Often, this will involve referral to a specialist muscle service.

## Acquired muscle diseases

### Inflammatory myopathies

The inflammatory myopathies are diseases whose primary pathology is inflammation within muscle. This definition thus excludes those genetic muscle disorders discussed earlier in which inflammatory change may occur (e.g. dystrophinopathy, FSHD or dysferlinopathy), and also diseases in which inflammation affects associated structures rather than muscle itself, as in polymyalgia rheumatica. The inflammatory myopathies can be divided into four principal classes on the basis of their aetiology (Table 10.40). Their diagnosis can be further refined by distinctive clinical and pathological features that reflect differing fundamental causes and processes, although at present the latter are incompletely understood.

### Idiopathic inflammatory myopathies

These are the most commonly encountered acquired muscle diseases and discussion of them forms the framework for the remaining conditions. The three subtypes are:

- 1 **Dermatomyositis (DM)** in which the inflammatory process may also involve the skin.

- 2 **Polymyositis (PM)**: isolated inflammation of the muscles (but similar findings may occur in association with several rheumatological diseases; see Polymyositis).

- 3 **Inclusion body myositis (IBM)** has a distinctive clinical pattern with less, if any, inflammatory change on biopsy.

All three share the key features of proximal lower limb wasting and weakness as the main clinical findings. However, they may be distinguished by specific features of both their clinical presentation and the findings of investigations. All are caused by separate pathological mechanisms. However, distinguishing one from another, or indeed from other conditions, can be difficult. There remains both incomplete understanding of their aetiology and a dearth of evidence on which to base decisions about their treatment.

### Dermatomyositis

DM causes inflammation of muscle and typically, the skin. Epidemiological data are imprecise, but DM is uncommon, with an incidence of approximately 1/100 000. Unlike the other idiopathic inflammatory myopathies, cases in children are well recognised and it is by far the most common such condition in that age group. DM is more common in non-Caucasians and in women.

DM is a humorally mediated autoimmune disorder, in which the pathology is that of a microvasculopathy (Figure 10.29). Activated complement is found deposited in muscle capillaries and other tissues, which directs subsequent cellular inflammation. The trigger to this is unknown but postulated mechanisms include deposition of circulating immune complexes, or a response to an as yet unknown endothelial antigen.

Clinically, DM typically produces a subacute, progressive, proximal and symmetrical weakness, affecting the lower limbs more than the arms. Rarely does the condition lead to pronounced distal weakness. CK is usually raised. There is often some myalgia, but not severe pain. The extraocular and facial muscles are typically spared, but dysphagia may be a problem in severe or advanced cases, while neuromuscular respiratory compromise may also develop. Rarely, a more explosive presentation can occur, even leading to overt myoglobinuria.

The skin manifestations of DM usually precede the myopathy, but they may be difficult to detect if they are not specifically looked for, particularly in people with dark skin. The classic dermatological presentations are the 'heliotrope' erythematous rash of the face (especially the eyelids) and upper trunk. This rash is photosensitive, and often occurs with some oedema and telangiectasia. The hands can typically demonstrate Gottron papules, thickening over the surfaces of the knuckles, but may also show either a more subtle general coarseness of the skin ('mechanic's hands') or nail bed capillary change.

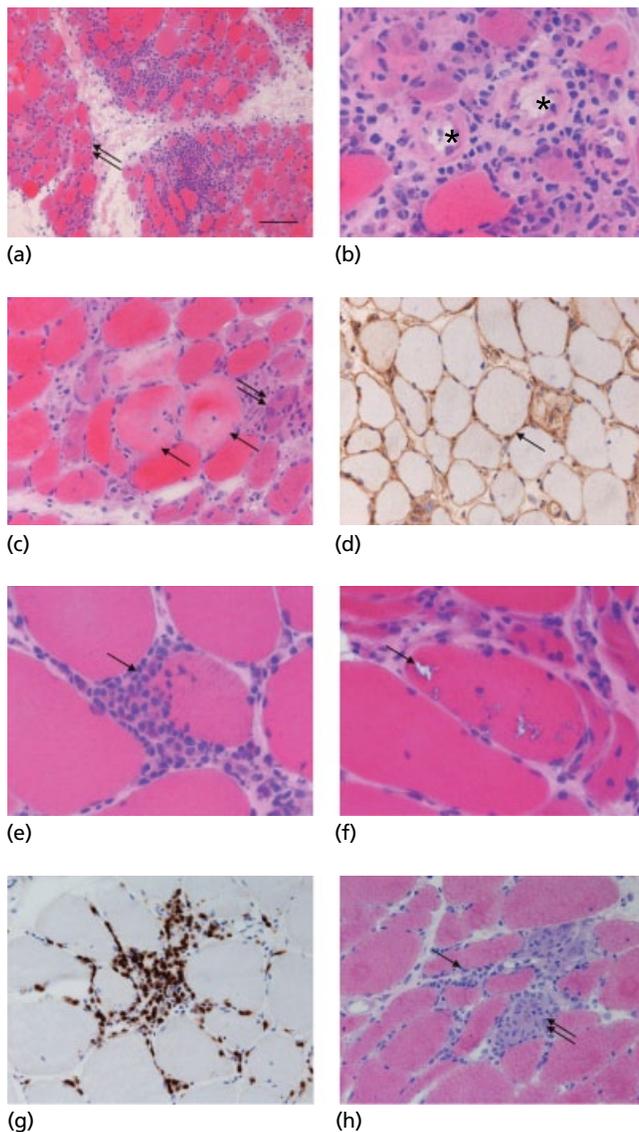

Occasionally, patients have only the skin changes, without clinical weakness or any elevation of CK, leading to the diagnostic term dermatomyositis sine myositis. However, muscle biopsy in these cases can demonstrate, even if only subtly, the abnormalities seen in DM. In such amyopathic patients, the condition may even resolve without need for immunosuppressive treatment, although recent work identified a high incidence of interstitial lung complications. Finally, typical DM over time may lead to calcinosis within affected tissues. This can be quite marked and produces striking changes on imaging. Early treatment is thought beneficial to minimise this last complication.

Other systems may also be involved in DM, notably the lungs and the heart. Approximately 20% of patients demonstrate evidence of an interstitial lung disease which can rarely be the first symptom.

**Table 10.40** The inflammatory myopathies.

<b>Idiopathic</b>
Dermatomyositis, polymyositis, inclusion body myositis
<b>Associated with connective tissue disease</b>
SLE, rheumatoid arthritis, mixed connective tissue disease, Sjögren's disease
<b>Infective/post-infective</b>
Viral (HIV, EBV, CMV, HTLV-1), bacterial (staphylococcal, Lyme, tuberculosis), parasitic (nematodes, cestodes, protozoa)
<b>Miscellaneous</b>
Vasculitic, non-infective granulomatous (e.g. sarcoid), eosinophilic syndromes

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HTLV, human T-lymphocyte virus; SLE, systemic lupus erythematosus.

**Figure 10.29** In dermatomyositis atrophic fibres often display a perifascicular arrangement (a, double arrow). Lymphocytic infiltrates are frequently perivascular (b, \*indicate small arterioles) and perimysial but may extend into the endomysium. There is fibre necrosis (c, arrows) and regeneration (c, double arrow). MHC Class I is expressed at the sarcolemma (d, arrow). The features of inclusion body myositis include endomysial lymphocytic infiltration with infiltration into intact muscle fibres (e, arrow) and rimmed vacuoles that occur in fibres without lymphocytic infiltration (f, arrow). The inflammatory infiltrate is composed predominantly of CD8-positive T lymphocytes (g). In polymyositis the inflammation is largely endomysial in location (h, arrow). In this example necrotic fibres infiltrated by macrophages are prominent (h, double arrow). a–c, e, f, h: haematoxylin and eosin; d: immunohistochemical staining for MHC Class I; g: immunohistochemical staining for CD8. Bar in (a) represents 100  $\mu\text{m}$  in (a); 50  $\mu\text{m}$  in (c), (d), (g) and H and 25  $\mu\text{m}$  in (b), (e) and (f).

The most common symptoms are of cough and dyspnoea, typically with bibasal crepitations on auscultation of the chest. Lung complications are most commonly slowly progressive but symptoms can develop acutely. Twenty five per cent of those patients with

abnormal pulmonary investigations remain asymptomatic. Pulmonary complications are associated with Jo-1 (anti-tRNA synthetase) IgG antibodies. These are present in 20% of patients with DM and of whom 70% have evidence of interstitial lung disease. The lung pathology is variable, but only bronchiolitis obliterans is likely to respond to immunosuppression. Early treatment, aiming to prevent permanent pathological muscle change, also prevents severe long-term pulmonary disease.

The exact incidence of cardiac involvement in idiopathic myositis is uncertain but several studies found congestive heart failure and ischaemia to be more common than in controls. Up to 50% of cases in some series have ECG evidence of dysrhythmias, conduction block or ischaemic change pointing to a high incidence of subclinical cardiac involvement. Case reports have identified similar inflammatory changes in both the myocardium and conducting system to that found in skeletal muscle.

Large series of cases of DM find an approximate 20% association with malignancy, most commonly with adenocarcinoma and gynaecological tumours. Those most at risk are older, female and non-Caucasian patients. A thorough clinically directed approach to detecting an underlying malignancy is therefore indicated, with careful history-taking and examination for undisclosed symptoms or signs (e.g. weight loss, post-menopausal bleeding, breast lump or rectal mass). Appropriate further examination with imaging and/or specialist review is indicated to identify any occult cancer. Guidelines exist (see References) but these recognise the absence of clear evidence for how to investigate some conditions and which techniques to utilise. Our practice is to perform whole body FDG-PET-CT in all cases, together with mammography and pelvic imaging (ultrasound/MRI) in women, and testicular ultrasound in men, plus to consider older patients for colonoscopy.

The prognosis of DM is worse in those with pulmonary or cardiac complications, underlying malignancy, arthritis, hypergammaglobulinaemia or in acute or febrile presentations.

### Polymyositis

Polymyositis is characterised by a progressive, proximal and symmetrical weakness without the skin lesions seen in DM. It is probably of similar or slightly lower incidence and prevalence to DM. It is very rare in those under 20 years, and is typically a disease of middle or later life. The course of PM is variable but is somewhat slower to evolve than DM. Although it can be rapidly progressive, the most frequent presentation is a slowly worsening proximal weakness over several months, in which the exact onset is difficult to pinpoint. Myalgia is typical but rarely severe. As with DM, the legs are typically more affected than the arms, distal and facial weakness is rare but respiratory muscle involvement can occur and can be life-threatening; the latter is most often seen when the disease is rapidly worsening.

Polymyositis differs fundamentally from DM in being a cell-mediated disease. CD8-positive T lymphocytes respond to an unknown muscle antigen by invading and destroying non-necrotic muscle fibres that express major histocompatibility complex protein (MHC-I; Figure 10.29). Unlike DM, blood vessels are spared. Respiratory and cardiac complications can develop at similar rates as occur in DM. Polymyositis also shares with DM the particular association of interstitial lung disease with antisynthetase antibodies.

Because PM presents with an absence of helpful associated clinical signs such as the skin involvement of DM or the particular pattern of weakness of typical IBM, 'pure' PM can be diagnosed in error. At the clinically milder end of the spectrum, care must be

taken not to over-interpret pain or submaximal effort on examination. At the other, PM must be distinguished from other conditions that can provoke a raised CK and inflammatory changes on biopsy. All the clinical and investigation findings must be considered together and an open mind kept to the need to review or revise a diagnosis over time. In particular, 'failure' to respond to immunosuppressants should raise the possibility that a dystrophic process is, in fact, the cause.

There is a less established association of PM with neoplasia than with DM and guidelines for assessment of the latter do not extend to include PM. We recommend considering the possibility of an occult cancer and undertaking clinical review and investigation as per DM.

### Inclusion body myositis

Sporadic inclusion body myositis occurs somewhat more frequently than DM or PM and is probably the most prevalent acquired myopathy. Unlike either PM or DM it appears to be most commonly a disease of Caucasian men. Other racial groups seem less frequently affected and the male to female ratio is 3 : 2. Typically, IBM occurs late in life and onset before age 30 years is highly unusual. Very rare familial forms of 'IBM' (either autosomal recessive or dominant) are increasingly recognised as instead being cases of myofibrillar myopathies, or caused by extremely rarely identified mutations in the gene encoding either valosin-containing protein (VCP): an overlapping but variable syndrome of a myopathy with inclusions on biopsy, Paget's disease of bone and frontotemporal dementia, or UDP-N-acetylglucosamine 2-epimerase (GNE), which causes a distal myopathy with rimmed vacuoles but which spares the quadriceps.

The onset of IBM is insidious and usually slower than seen with PM or DM. Classically, IBM causes a distinctive pattern of wasting and weakness most involving the quadriceps and deep finger flexors (Figure 10.30). This compromises the most crucial functions of the upper and lower limbs, hand grip and maintaining upright posture. Consequently, falls may occur relatively early, because of buckling of the knees. Dysphagia occurs in 10–30% but respiratory muscle weakness is unusual. Ankle dorsiflexion weakness can also occur, and taken together these distal signs, plus occasional mild facial involvement and a usually asymmetrical pattern of weakness, allow clinical distinction to be made from other conditions, including the other idiopathic inflammatory myopathies.

The aetiology of IBM is uncertain. Whether it is a degenerative process and whether any endomysial inflammatory component (which may be substantial) is merely a secondary process is still debated. Support for it being degenerative rests principally on both the finding of amyloid material in the almost pathognomic cellular inclusions and rimmed vacuoles seen on biopsy (Figure 10.30), and the failure of IBM to respond to all immunosuppressant medications in controlled trials. However, against this comes recent identification of antibodies to cytosolic 5'-nucleotidase 1A (CN1A) with reported high specificity (up to 98%) and sensitivity (up to 79%) for IBM, though with both false positives and false negatives. CN1A is of uncertain function, but may have a role in DNA repair. It is expressed in muscle and antibodies to it label the rimmed vacuoles of IBM patients' muscle biopsies. Antibody testing is not available as a diagnostic tool, but may prove useful as part of overall assessment and, if securely established, would point to immune system dysfunction underlying IBM.

There appears to be no link to malignancy and pulmonary or cardiac complications are not to be expected.

**Figure 10.30** Inclusion body myositis may present with focal weakness of the quadriceps muscles, in this case easily identified by the focal wasting seen in comparison to the lower leg compartments.

### Investigation of inflammatory myopathy

**Serum creatine kinase levels** The level of serum CK is raised in all three conditions and offers some guide to the degree of inflammation. It may be raised up to 50 times normal in severe PM and DM; the typical rise in IBM is, however, typically less than 10-fold. It is very important to note that definite deterioration can occur without an accompanying rise in CK, especially of DM. It is crucial to bear in mind that quoted 'normal' values of CK can be misleadingly low, as there is considerable variation in CK levels across a normal population. CK values are in rough proportion to muscle mass and also correlate with ethnic origin: people of African heritage show higher CK. Furthermore, exercise, muscle injury and alcohol intake will all raise measured CK. As such, diagnosis of 'pure PM' should never be made solely on a borderline elevation in CK levels.

**Neurophysiology** Typical myopathic features are common in myositis, while frequent fibrillation and spontaneous repetitive discharges can be indicative of active inflammation. A useful rule of thumb from highly experienced practitioners is that when EMG is performed to confirm myopathy, seemingly normal findings frequently turn out to be IBM.

**Muscle biopsy** Muscle biopsy is the keystone of diagnosis. It should be considered and if at all possible performed in every case before treatment is initiated. The idiopathic inflammatory myopathies share some pathological features but aspects of the pathology of each may be diagnostic (Table 10.41; Figure 10.29). Typical changes are not always present, however, and thus interpretation can be difficult. The clinical and pathological findings need to be interpreted in conjunction to make the correct diagnosis.

**Table 10.41** Characteristic pathological findings of the idiopathic inflammatory myopathies.

Condition	Muscle fibres	Blood vessels
DM	Focal infarctions; perifascicular atrophy	Capillary necrosis and undulating tubules or other endothelial abnormalities; deposition of immunoglobulin and activated complement membrane attack complex
PM	Partial invasion of non-necrotic fibres by activated CD8 lymphocytes and macrophages (seen less in IBM and not in DM). Uniform expression of class I MHC products on surface of all fibres	Rarely involved: possible secondary capillary necrosis
IBM	Rimmed vacuoles; inclusions staining for ubiquitin and amyloid; 15–18 nm tubular filaments in nucleus or cytoplasm (may require extensive EM)	Can be normal; possible increased capillarity

DM, dermatomyositis; EM: electron microscopy; IBM, inclusion body myositis; MHC: major histocompatibility complex; PM, polymyositis.

**Muscle MRI** Imaging of muscle disease is increasingly undertaken but not yet established as a standard part of the diagnostic process for inflammatory myopathy. Serial imaging of cases undergoing treatment can be used as an indicator of response, but this should be undertaken only as part of a wider assessment, most crucially that of clinical change.

#### Extended investigation of inflammatory myopathies

- **Lung:** a chest radiograph may identify bibasal shadowing. Chest radiography is insensitive, being normal in 10% of those with proven lung involvement. High-resolution CT scanning is more sensitive, characteristically revealing linear opacities and a 'ground glass' appearance of the lung bases. Pulmonary function tests are also indicated; a restrictive pattern with reduced lung volumes and decreased diffusing capacity for carbon monoxide is typical.
- **Heart:** an ECG is indicated in all patients. Clinical evidence of cardiac involvement necessitates further assessment with 24-hour Holter recording, echocardiography and review by a cardiologist.

#### Treatment of idiopathic inflammatory myopathies

The treatment of idiopathic inflammatory myopathies is based largely on expert opinion rather than evidence. Indeed, the Cochrane collaboration's systematic review on the treatment of DM and PM concluded that, 'the small number of randomised controlled trials of immunosuppressants and immunomodulatory therapies are inadequate to decide whether these agents are beneficial'. Guidelines for management remain open to the influences of personal practice, but one suggested approach is given in Table 10.42.

For IBM no beneficial effect has been demonstrated for any agent tested. Despite this, individual cases may show a response to medication, essentially when a significant degree of inflammatory change is shown on biopsy. Under such circumstances, a trial of steroid (30–40 mg/day oral prednisolone for 3–4 months) should be considered, and if successful, the dose slowly reduced, introducing steroid-sparing drugs if appropriate.

In all cases, non-pharmacological measures to support the patient are also crucial. Multi-disciplinary assessment from physiotherapists, occupational therapists and, if indicated, speech therapists, dietitians and colleagues from other medical disciplines, is recommended. Regular follow-up to assess progress and identify and treat potential complications is essential.

**Table 10.42** Treatment of the idiopathic inflammatory myopathies, in the absence of evidence.

<b>Steroids, aiming for rapid stabilisation</b>
Prednisolone 1 mg/kg/day by mouth until CK normal, then reduce (e.g. 5–10 mg monthly, with slower reduction for the last 20–30 mg)
If very acute resolution required: IV methylprednisolone 500mg / day for 5 days to initiate steroid course
Osteoporosis and gastric ulcer prophylaxis
<b>Steroid-sparing agents</b> (aiming to reduce side effects and maintain disease control)
<b>First line</b>
1 Azathioprine, starting at 1 mg/kg or below, and increasing by 25 mg every 1–2 months to a maximum of 2.5 mg/kg, as tolerated and guided by the degree of lymphocyte suppression and clinical response Thiopurine methyltransferase checked beforehand Blood monitoring of FBC and LFT necessary.
2 Methotrexate, increasing to 20–25 mg/day maximum once weekly with folic acid on other days, blood monitoring required; watch for pulmonary fibrosis and cirrhosis. NPSA guidelines available in UK
<b>Second line</b>
1 Ciclosporin: of use if first line drugs ineffective; blood monitoring required
2 IVIG: for refractory cases, particularly if deteriorating and rapid response sought
3 Cyclophosphamide, consider if poor response to other drugs (may be given as cycles of IV preparation in combination with other drugs; see peripheral nerve vasculitis)

CK, creatine kinase; FBC, full blood count; IV, intravenous; IVIG, intravenous immunoglobulin; LFT, liver function test; NPSA, National Patient Safety Agency.

#### Inflammatory myopathies associated with connective tissue disease

Although rheumatological diseases can lead to weakness through either musculoskeletal deformity, neuropathy, muscle ischaemia or medication side effects, certain patterns of inflammatory myopathy are recognised, albeit infrequently. Systemic sclerosis occurs in conjunction with a DM-like picture in approximately 5–10% of cases,

and a similar proportion of people with SLE have a condition that resembles PM. Sjögren's syndrome can rarely be seen with features similar to either DM or IBM. Myositis is very rare with either rheumatoid arthritis or polyarteritis nodosa. Muscle biopsy should be considered in any patient with a confirmed rheumatological illness who develops otherwise unexplained weakness, in particular if the CK is raised and EMG identifies myopathic features.

**Inflammatory and other myopathies associated with infection** A number of viruses cause myositis. Common infections (Coxsackie, EBV, CMV, influenza) have all been associated with acute and chronic muscle inflammation, although such complications are rare and the underlying mechanism is unclear. A definite causative link has been established for the retroviruses HIV and human T-lymphocyte virus (HTLV-1) and myositis.

At seroconversion, HIV can lead to a polymyositis that can be explosive enough to provoke myoglobinuria, and which is steroid-responsive. A nemaline rod myopathy may also develop at this stage of infection, with a raised CK and specific findings on biopsy. With the onset of AIDS, a necrotising myopathy with proximal weakness, typically a normal CK and necrotic fibres on biopsy occurs. HIV wasting disease or 'slim' is frequently encountered in sub-Saharan Africa, but rarely in industrialised populations. 'Slim' is defined as more than 10% weight loss, weakness and fever or diarrhoea for at least 1 month, without any other causative condition. It appears to be caused by a combination of increased metabolic demand, anorexia, possible endocrine derangement and altered lipid metabolism. It leads to muscle wasting without myalgia, and when biopsied most typically shows type II fibre atrophy. Treatment is with improved nutrition and antiretrovirals. People with HIV are also at greater risk of infectious pyomyositis, which is typically multi-focal and slower to evolve than the non-HIV-associated form. The range of causative organisms also differs with cryptococcus, toxoplasma, CMV and atypical mycobacteria implicated.

HTLV-1 is endemic in the Caribbean and Japan and most commonly leads to a slowly evolving myelopathy. However, it can alternatively provoke a polymyositis, which seems to follow expression of HTLV-1's tax-1 protein in muscle cells, rather than any sustained viral replication. HTLV-1 induced PM may respond to immunosuppression.

Non-viral infective myopathies occur with bacteria or parasites. Suppurative pyomyositis is typically a tropically acquired illness in which a staphylococcal abscess forms at the site of injury. In industrialised populations, immunosuppression from medication or conditions such as diabetes, liver disease or malignancy are more commonly associated than HIV. Staphylococci account for the great majority of infections but others including TB and fungi also occur. The diagnosis is largely clinical and treatment includes aspiration (which aids identification of the infective organism) and drainage if required and appropriate antibiotics.

Lyme disease, in addition to its more frequent CNS and nerve involvement, can unusually lead to myositis; this may be either a localised painful swelling or a rarer generalised dermatomyositis-like picture. Treatment is of the underlying spirochaete with appropriate antibiotics.

Some parasites cause focal or multi-focal muscle inflammation. Cestodes (cysticerci), nematodes (trichinella) and protozoa (toxoplasma, trypanosomes), all typically ingested in undercooked meat, can infect muscle. Muscle symptoms are often mild and self-limiting and it is involvement of the CNS that prompts identification and medication.

## Other rare inflammatory myopathies

**Granulomatous myopathies** Granulomatous myopathies present as a slowly evolving proximal weakness, which is often painful and possibly develops to include dysphagia. Over time, flexion contractures may develop in the forearms and muscle hypertrophy may become evident. The serum CK is typically elevated and muscle biopsy demonstrates focal non-caseating granulomas. The differential is wide, including sarcoidosis (which can rarely present in such a manner, and in which the CK may not rise), autoimmune conditions (rheumatoid arthritis, mixed connective tissue disease, granulomatosis with polyangiitis (Wegener's granulomatosis) or in association with myasthenia gravis and thymoma) plus some infections (fungal, mycobacterial, protozoal). Many, but not all, respond to treatment with steroids.

**Eosinophilic myopathic syndromes** Three forms of inflammatory myopathy are associated with eosinophilic infiltration of muscle, a systemic eosinophilia, or both. Eosinophilic polymyositis is similar to the classic PM described above, but occurs in conjunction with eosinophils, which are elevated in the circulation and prominently present on muscle biopsy. In eosinophilic fasciitis, pathological inflammation is limited to the fascia, and the fascia lata is the best site for confirmatory biopsy. Finally, dietary L-tryptophan, apparently contaminated by an acetaldehyde ditryptophan derivative, led to the eosinophilia myalgia syndrome. A marked eosinophilia developed with muscle pain and weakness with a scleroderma-like skin reaction and a peripheral neuropathy. Symptoms resolved after the medication was ended, although steroids were required to speed improvement in some cases.

**Macrophagic myofasciitis** This is a very rarely identified but pathologically distinctive focal reaction at the site of vaccination, possibly directed against the aluminium hydroxide adjuvant of the vaccines. Originally described in France, after the adoption of hepatitis B vaccination, cases have now been reported from other countries. Many patients report systemic systems of fatigue, and CK can be significantly raised. Several years may elapse between the vaccination and the onset of the syndrome. Periodic acid-Schiff (PAS) positive macrophage infiltration of connective tissue is seen on biopsy. Steroid treatment has been reported as beneficial.

**Myopathies associated with malignancy** Weakness may simply accompany tumour-induced cachexia, but cancers can cause a number of other muscle disorders. Dermatomyositis and (less so) polymyositis can be associated with a range of malignancies (ovary, lung, gastrointestinal, non-Hodgkin's lymphoma) and, if so, have a worse prognosis.

An aggressive necrotising myopathy is rarely seen in older patients with cancer (lung, gastrointestinal adenocarcinoma and breast). A rapidly progressive proximal weakness is typically accompanied by an elevated CK, while muscle biopsy demonstrates foci of necrosis. Steroids and treatment of the underlying tumour may help arrest symptoms.

Rare paraneoplastic antibody-driven myopathies have also been reported. Waldenström's macroglobulinaemia can generate IgM against the muscle proteoglycan decorin. Myasthenia gravis, with or without underlying thymoma, can generate antibodies against skeletal muscle that cause rippling muscle disease: painful cramps with visible ripples of the muscle that often worsen with pyridostigmine but improve with immunosuppression.

### Endocrine myopathies

**Thyroid** Hypothyroidism frequently causes non-specific fatigue, myalgia and cramps and may also raise the CK level. Untreated and over time a proximal symmetrical weakness can develop. The CK is not related to the level of weakness. Typically, the EMG shows myopathic changes and the histopathological findings are non-specific. Less commonly, myokymia may be seen and rarely severe muscle oedema may develop with subsequent rhabdomyolysis. The myopathy responds to thyroid replacement but is slow to do so.

Hyperthyroidism when severe is often associated with muscle weakness. Unlike hypothyroidism, distal muscles can be affected, sometimes in isolation. CK is not elevated. Symptoms are worse with severe and acute hyperthyroidism ('thyroid storm'). There is a rare inflammatory myopathy associated with hyperthyroidism, clinically similar to the idiopathic condition, and also causing a raised CK.

**Adrenal** Cushing's syndrome leads to steroid myopathy as described later, while Addison's disease (whether primary or iatrogenic) typically causes myalgia, cramps and fatigue. Inadequate circulating levels of corticosteroids may lead to proximal weakness, which can lead to respiratory difficulty. Adequate steroid replacement is curative.

**Parathyroid** Both inadequate and excessive levels of parathyroid hormone may lead to a mild progressive proximal myopathy. CK is more frequently raised in the former case, but normal in the latter.

**Acromegaly** Untreated, excess growth hormone will cause a proximal weakness, sometimes with muscle hypertrophy and with an elevated CK. Some 50% of acromegalics show myopathic changes on EMG. Correction of the underlying condition leads to resolution of the myopathy.

### Necrotising autoimmune myopathy

Necrotising autoimmune myopathy (NAM) is a form of acquired myopathy characterised by subacute onset of symmetrical, proximal, predominantly lower limb weakness associated with dysphagia, respiratory muscle weakness, abnormal echocardiogram, markedly elevated CK level and EMG showing fibrillation potentials and myotonic discharges. It is idiopathic in 50% but other cases are related to statin treatment, connective tissue disorders (e.g. scleroderma, mixed connective tissue disease) and malignancy. NAM is associated with autoantibodies specific for signal recognition particle (SRP) or 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR). Muscle biopsy shows necrotic muscle fibres with regeneration but little or no inflammatory change. It is usually treated with IVIG and prednisolone but is refractory and often requires long-term immunosuppression with multiple agents.

### Drugs and myopathy

A variety of drugs have been identified as causing a myopathy (Table 10.43). Some, such as steroids, will eventually cause a deleterious effect on all those who receive them. Others, such as statins, will do so to only some. The spectrum of drug-induced myopathy varies from an asymptomatic raised CK to profound weakness with rhabdomyolysis. Drugs may also worsen an existing muscle disease or, alternatively, unmask one that was previously hidden.

**Statin myopathy** Statins inhibit the enzyme HMG CoA reductase, reducing the formation of cholesterol and also ubiquinone (co-enzyme Q10). Series identify an eightfold risk of myopathy in those taking statins, raised to 42-fold if a fibrate is taken concurrently. This equates to about 1–6/10 000 treated. Large-scale studies

of those who take statins find the most common problem is of an asymptomatic elevation of CK, and the most frequent symptoms are of myalgia and cramps. Together such mild to trivial findings affect up to 10% of patients. By contrast, side effects requiring hospitalisation (incapacitating pain, overt weakness or rhabdomyolysis) occur at less than 1/10 000 patient years. The increasing prescription of statins to prevent vascular disease (over 4 million people in the United Kingdom were taking a statin in 2014), has not been mirrored in specialist practice dealing with more cases of severe muscle side effects. Minor problems appear anticipated and managed in primary care, and the wider publicity and awareness of statin-associated myopathy appears effectively 'protective', with patients abandoning medication as soon as any mild symptom develops (perversely so, in terms of wider public health). Overall, it appears that the risk of statin-induced myopathy is dose-dependent and varies between individual drugs (one form, cerivastatin, was withdrawn from the market because of its higher risk of myopathy). Problems are also more likely in the elderly or those with diabetes, hypothyroidism or concurrent renal or liver disease. Also at greater risk are those taking fibrates, or inhibitors of the hepatic enzyme CYP3A4 (including ciclosporin, proton pump inhibitors, various antifungals, calcium-channel blockers, SSRIs, grapefruit juice).

The classic pathological finding of severe statin-induced myopathy is of muscle necrosis. Alternatively, statins can induce inflammatory or mitochondrial change (the latter with normal CK), or unmask an underlying metabolic condition.

A suggested management strategy for statin myopathy is given in Table 10.44. Stopping the statin usually leads to improvement within a few weeks, so allowing trial re-administration of either a lower dose or an alternative statin, but myalgia and raised CK may persist and severe myopathy can leave permanent sequelae.

**Table 10.43** Drugs associated with myopathy.

Lipid-lowering: statins, fibrates, nicotinic acid, ezetimibe
Steroids
Abuse: alcohol, heroin, cocaine
Cardiac: amiodarone, perhexiline
Rheumatological treatments: colchicines, chloroquine, hydroxychloroquine
Other: ipecac (anorexics), streptokinase, zidovudine, $\alpha$ -interferon, d-penicillamine

**Table 10.44** Management of statin myopathy.

Prevention	Start those at higher risk on lowest dose statin (e.g. simvastatin, pravastatin 10 mg/day)
CK raised without symptoms	Check CK again after 2 weeks; discontinue statin if CK rises further or symptoms develop
CK raised with symptoms	Stop statin. Consider co-enzyme Q10. Then: If symptoms resolve and the CK falls to normal, reinstitute statin at lowest dose If symptoms or elevated CK persist for 6 months off treatment, then perform muscle biopsy (to look for exposed inflammatory/mitochondrial myopathy) If the symptoms worsen or CK rises further, then proceed to urgent muscle biopsy

CK, creatine kinase.

**Zidovudine and other antiretrovirals** A toxic mitochondrial myopathy may follow the use of zidovudine (AZT), because of its inhibition of mitochondrial DNA replication. Those affected develop myalgia, exercise intolerance, proximal or generalised weakness and raised CK, usually after some time on the drug. A muscle biopsy is indicated, looking for cytochrome oxidase-negative fibres, not least to differentiate the diagnosis from that of HIV myositis. The myopathy usually resolves when zidovudine is stopped, although 3–4 months may be required. Zidovudine is also well recognised for its potential to expose a pre-existing carnitine deficiency.

Recently, the syndrome of nucleoside-associated lactic acidosis was been reported. Multiple symptoms including abdominal pain, vomiting, cough, shortness of breath, weight loss, together with myopathy and a painful axonal neuropathy develop subacutely in the first months of treatment. Cases have been reported up to 3 years after treatment began. Serum lactate is raised and muscle biopsy reveals necrosis plus mitochondrial abnormalities. Treatment is supportive, with fluids and bicarbonate to neutralise the acidosis, and the retroviral drug should be stopped. However, mortality is high at up to 50% and recovery is slow.

**Steroid myopathy** Chronic administration of steroids reduces muscle protein synthesis, leading to insidious proximal weakness, especially of the quadriceps muscles. CK is not elevated and so any

such rise necessitates separate investigation. Myopathy can occur at any dose but the incidence is highest with dexamethasone, beta-methasone and triamcinolone, while for prednisolone daily doses in excess of 40 mg appear to confer the highest risk.

The pathological change is of selective type II (particularly IIB) fibre atrophy. The condition is usually reversible and so if possible steroids should be withdrawn. If withdrawal is not possible, the dosage should be reduced to the minimum and/or switched to an alternate-day regimen.

### Rhabdomyolysis

Rhabdomyolysis is the breakdown of striated muscle fibres that leads to the release of muscle enzymes into the circulation. It is the final common pathway for varying aetiologies. Myoglobinuria occurs when the haem-binding protein, myoglobin, appears in the urine leading to a brownish discoloration with concentrations >250 µg/mL. The severity of rhabdomyolysis can vary from an asymptomatic elevation of muscle enzymes to severe electrolyte imbalance with acute renal failure. Rhabdomyolysis usually results from muscle injury because of trauma or other external causes (e.g. medication or intoxication) but may also develop if there is an underlying muscle disorder (Table 10.45). Therapeutic medication, substance abuse and toxins can cause rhabdomyolysis through a

**Table 10.45** Causes of rhabdomyolysis.

Acquired muscle disease	
Exertion	Extreme exertion, status epilepticus, status asthmaticus, prolonged involuntary movement
Crush	Multiple trauma, prolonged immobility (e.g. pre-operative, coma, torture)
Temperature	Pyrexia, exposure to extreme heat, burns
Ischaemia	Arterial occlusion, compartment syndrome, DIC, sickle cell disease
Metabolic	Hyper-/hyponatraemia, hypophosphataemia, hyperosmolar state
Endocrine	Hypothyroidism, diabetic ketoacidosis, non-ketotic hyperosmolar coma
Alcohol	
Inflammatory	Polymyositis, dermatomyositis, vasculitis, paraneoplastic necrotising myopathy
Drugs (Chapter 19)	Coma induced by alcohol, opioids or CNS depressants Agitation (e.g. following amphetamines). Possibly associated with serotonin syndrome or neuroleptic malignant syndrome Prolonged involuntary movements (e.g. drug-induced dystonic states) Metabolic effects – statins, antidepressants, carbon monoxide, colchicines
Toxins	Snake bites
Infections	Viral – HSV, enterovirus, influenza A + B, CMV, EBV, adenovirus, HIV Bacterial – acute pyomyositis, staphylococcal/streptococcal Others – plasmodium, trichinella, toxoplasma
Inherited muscle disease	
Metabolic	Disorders of glycolytic – glycogenolytic pathway Disorders of fatty acid oxidation Disorders of purine cycle Mitochondrial respiratory chain Malignant hypothermia
Other hereditary muscle disease	e.g. congenital myopathy, dystrophinopathy, myotonic dystrophy

CMV, cytomegalovirus; DIC, disseminated intravascular coagulopathy; EBV, Epstein–Barr virus; HSV, herpes simplex virus.

wide variety of mechanisms including prolonged coma, seizures, agitation, hypothermia, metabolic effects or direct myotoxicity.

Presentation depends on the cause of rhabdomyolysis. Onset may be subclinical or with mild muscle pain, cramps and swelling. However, there is usually severe myalgia, muscle swelling and pigmenturia in association with greatly elevated CK (often >100 000). Compartment syndrome is characterised by severe muscle swelling in a limited anatomical space which may cause extreme pain and secondary vascular and neural compromise. The onset of renal failure may be manifest as oliguria and hypotension with haem pigmented casts. Electrolyte derangement arises from muscle lysis and renal failure and may include severe hyperkalaemia and hyperphosphataemia with hypocalcaemia resulting from deposition of calcium salts within injured muscles. A secondary hypoalbuminaemia with hypotension, shock and cardiac arrhythmias may develop.

Management is treatment of the underlying disorder, correction of fluid and electrolyte abnormalities and prevention of renal failure. This usually involves plasma volume expansion with forced diuresis. The development of compartment syndrome may require fasciotomy.

# Multiple Sclerosis and Demyelinating Diseases

Siobhan Leary<sup>1</sup>, Gavin Giovannoni<sup>2</sup>, Robin Howard<sup>1</sup>, David Miller<sup>2</sup> and Alan Thompson<sup>1,2</sup>

<sup>1</sup>National Hospital for Neurology & Neurosurgery

<sup>2</sup>UCL Institute of Neurology

Multiple sclerosis is an inflammatory demyelinating disorder of the central nervous system (CNS). Although the characteristic pathological lesions were first described over 150 years ago, its aetiology and pathophysiology remain to be fully elucidated. However, advances in pathological, immunological and genetic techniques have provided a greater understanding of the disease mechanisms involved. The application of magnetic resonance imaging (MRI) over the last three decades has also provided important insights into the dynamics of the disease which have subsequently been used in diagnosis and monitoring. Multiple sclerosis is a complex disease with an unpredictable prognosis which can cause numerous and diverse symptoms and accumulating disability. Major advances in disease modification have been made in the last two decades and multiple sclerosis is no longer an 'untreatable' condition. However, the efficacy of current therapeutic agents is limited to the earlier relapsing remitting phase of the disease. Management requires a responsive and comprehensive approach involving multiple health disciplines. This chapter outlines the features of multiple sclerosis as we understand them today and reviews current practice in diagnosis and management. Other demyelinating diseases are also reviewed.

## Epidemiology

It is estimated that there may be 100 000 people living with multiple sclerosis in the United Kingdom (population ~63 million). The prevalence probably lies between 125 and 175/100 000 population, with an annual incidence of new cases between 3.1 and 7.2/100 000. The estimated lifetime risk from birth of receiving a multiple sclerosis diagnosis is 5.3/1000 in women and 2.3/1000 in men. The incidence of multiple sclerosis worldwide tends to increase with increasing latitude, although there are clear, and important, exceptions. It is more common in temperate regions, such as northern Europe, northern America and southern Australasia, but much rarer in the tropics. Geographical variations are seen over relatively small distances and, for example, it is more common in Scotland than in south-east England.

Multiple sclerosis typically presents between 20 and 40 years of age. Females are more susceptible than males by a factor of approximately 2.3 : 1. The incidence of multiple sclerosis in females has been disproportionately increasing, with a steady increase in the sex ratio of over 3 : 1 in several countries.

## Migration studies

Migration studies have demonstrated that people who migrate from one geographical area to another before adolescence are essentially subject to the same level of risk of the area to which they migrate. Subjects who migrate after adolescence carry with them the risk, and hence incidence, of multiple sclerosis from the area from which they migrated. However, although the risk of multiple sclerosis consistently declines in migrants from high-risk to low-risk areas, the converse is not seen consistently in migrants from low-risk to high-risk areas. For example, an increase is not initially seen in Caribbean and Asian immigrants to the United Kingdom, although the risk can increase over time and the benefit is not passed on to the next generation. Migration may explain the higher incidence of multiple sclerosis than expected for latitude in countries like Israel and South Africa.

## Health economics

Multiple sclerosis is the most common cause of neurological disability in young adults and health care costs result in considerable financial burden to society. Many people are in education or employment at the time of diagnosis but, over time, reduced capacity to work and unemployment is common, which results in further indirect costs to society. In 2010, the cost of multiple sclerosis in Europe was estimated at €27 000 per person with multiple sclerosis per year. The total annual cost across Europe was estimated at €14.6 billion, with just over one-third arising from direct health care costs and the remainder from non-medical and indirect costs.

## Aetiology

The aetiology of multiple sclerosis is complex and cannot be ascribed to a single genetic or environmental factor. There is wide acceptance that interactions between genes and environmental factors lead to tissue injury by autoimmune mechanisms, implicated by immunological and pathological observations in people with multiple sclerosis and by extensive studies in the animal model experimental allergic encephalomyelitis (EAE). Multiple sclerosis is associated with other putative autoimmune disorders, including Hashimoto thyroiditis, psoriasis, inflammatory bowel disease and possibly type 1 diabetes mellitus, but not rheumatoid arthritis or systemic lupus erythematosus (SLE). This suggests that people with multiple sclerosis can be predisposed to autoimmunity in general.

### Genetic susceptibility

It is well recognised that genetic factors contribute to the occurrence of multiple sclerosis. Twin studies have demonstrated much higher concordance rates in monozygotic twins (~30%) than dizygotic twins (~5%), which also varies with latitude, but nowhere near the 100% rate which would be expected if it was solely a genetic disease. Family studies have demonstrated that relatives of people with multiple sclerosis have a greater risk for the disease than the general population, ~3–5% in first degree relatives. No increased risk is seen in adopted relatives, indicating that the risk is related to genetic rather than microenvironmental factors.

Numerous genes that contribute to multiple sclerosis susceptibility have been identified, but they exert a relatively modest effect on disease risk. The strongest genetic linkage identified is with alleles of the human lymphocyte antigen (HLA) region, part of the major histocompatibility complex (MHC). In the most recent international genome-wide association study, five alleles at three different loci in the HLA region influence multiple sclerosis susceptibility: the HLA-DRB1\*1501, \*0301 and \*1303 alleles, the HLA-A\*0201 allele and the HLADPB1\*0301 allele. There are likely to be multiple epistatic interactions at the HLA class I and II loci with susceptibility and resistance alleles interacting to determine overall multiple sclerosis risk. Multiple sclerosis has been associated with over 100 single nucleotide polymorphisms in the human genome; the vast majority of these polymorphisms are linked to genes involved in the immune system. This strongly supports multiple sclerosis being an autoimmune disease.

### Environmental factors

Geographical gradients, migration studies and high discordant rates in monozygotic twins indicate that the environment has a significant influence on the development of multiple sclerosis. Migration studies suggest that exposure to environmental factor(s) in early adolescence is associated with the development of multiple sclerosis. As multiple sclerosis may be uncommon in areas where sanitation is poor and the prevalence of parasitic infections is high, and as there is an increased incidence of autoimmune diseases in developed countries, the 'hygiene hypothesis' has been evoked. This suggests that exposure to infections in early childhood can protect against multiple sclerosis. However, the hygiene hypothesis has been largely discredited by conjugal pair, adopted children and sibship studies, which show no attributable risk to the familial micro-environment. Family-based genetic epidemiological approaches have found no evidence of non-genetic transmissibility within the familial micro-environment, which implies that the environment appears to influence the risk of multiple sclerosis at a population level. Several environmental factors have been proposed as aetiologically significant in multiple sclerosis, including transmissible agents and non-infectious factors.

### Transmissible agents

Numerous transmissible agents have been implicated as the possible cause of multiple sclerosis. Suggested candidates include Epstein–Barr virus (EBV), human herpes virus type 6 (HHV-6) and human endogenous retroviruses (HERV). The epidemiological data associating EBV infection with multiple sclerosis is the strongest. A consistent finding is that almost all subjects with multiple sclerosis, >99%, are infected with EBV compared with only ~94% of control subjects. People who have had infectious mononucleosis or who have high titres of anti-EBV antibodies have a higher risk of developing multiple sclerosis than subjects who have not had infectious mononucleosis or who have low titres of anti-EBV antibodies.

The association of EBV infection with multiple sclerosis can simply be a ubiquitous epiphenomenon that is required at the onset of the disease. There are several theories to explain how infection causes multiple sclerosis but definitive evidence to suggest causation has been lacking. Pathological studies have found evidence of EBV infection in B cells and plasma cells in the brain, with viral reactivation in acute lesions and ectopic B-cell follicles, in multiple sclerosis and to a lesser extent in other neuro-inflammatory diseases. This still does not establish causation, but it suggests that EBV persistence and reactivation can have an important role in pathogenesis.

### Vitamin D and sunlight exposure

Two associated factors that have been recognised as a potential explanation for the link between geography, in particular latitude, and the incidence of multiple sclerosis is sunlight exposure and vitamin D status. Experimental and epidemiological data suggest that high levels of vitamin D decrease the risk of multiple sclerosis. Taking vitamin supplementation, which includes vitamin D, has been associated with a reduction in the risk of developing multiple sclerosis. Small uncontrolled studies suggest vitamin D supplementation can decrease the incidence of relapses, but the results are inconsistent. A lower risk of multiple sclerosis is associated with high serum 25-hydroxy vitamin D levels in subjects of European extraction. In the Northern hemisphere it has been reported that significantly fewer people with multiple sclerosis are born in November and significantly more are born in May, with a reversal of this ratio in the Southern hemisphere, although these observations may be susceptible to confounding factors. For month of birth and risk of multiple sclerosis to be associated, there could be an interaction with the environment that acts during gestation or shortly after birth. This month of birth effect may be linked to the vitamin D status of the mother but this has not been confirmed. It has been proposed that immune system maturation *in utero* can be affected by vitamin D levels, with low levels predisposing to the development of autoimmunity later in life.

### Smoking

Smoking prior to the onset of multiple sclerosis has emerged as a significant, albeit moderate, risk factor for the subsequent development of multiple sclerosis. Smoking can increase the risk of developing progressive disease. It has been suggested that smoking can explain the increase in incidence of multiple sclerosis in females, but this is unlikely as this increase predates the increase in incidence of female smokers.

Other environmental factors such as diet, alcohol consumption, recreational drug use, oral contraceptive pill exposure and vaccination have not been shown to increase the risk of multiple sclerosis.

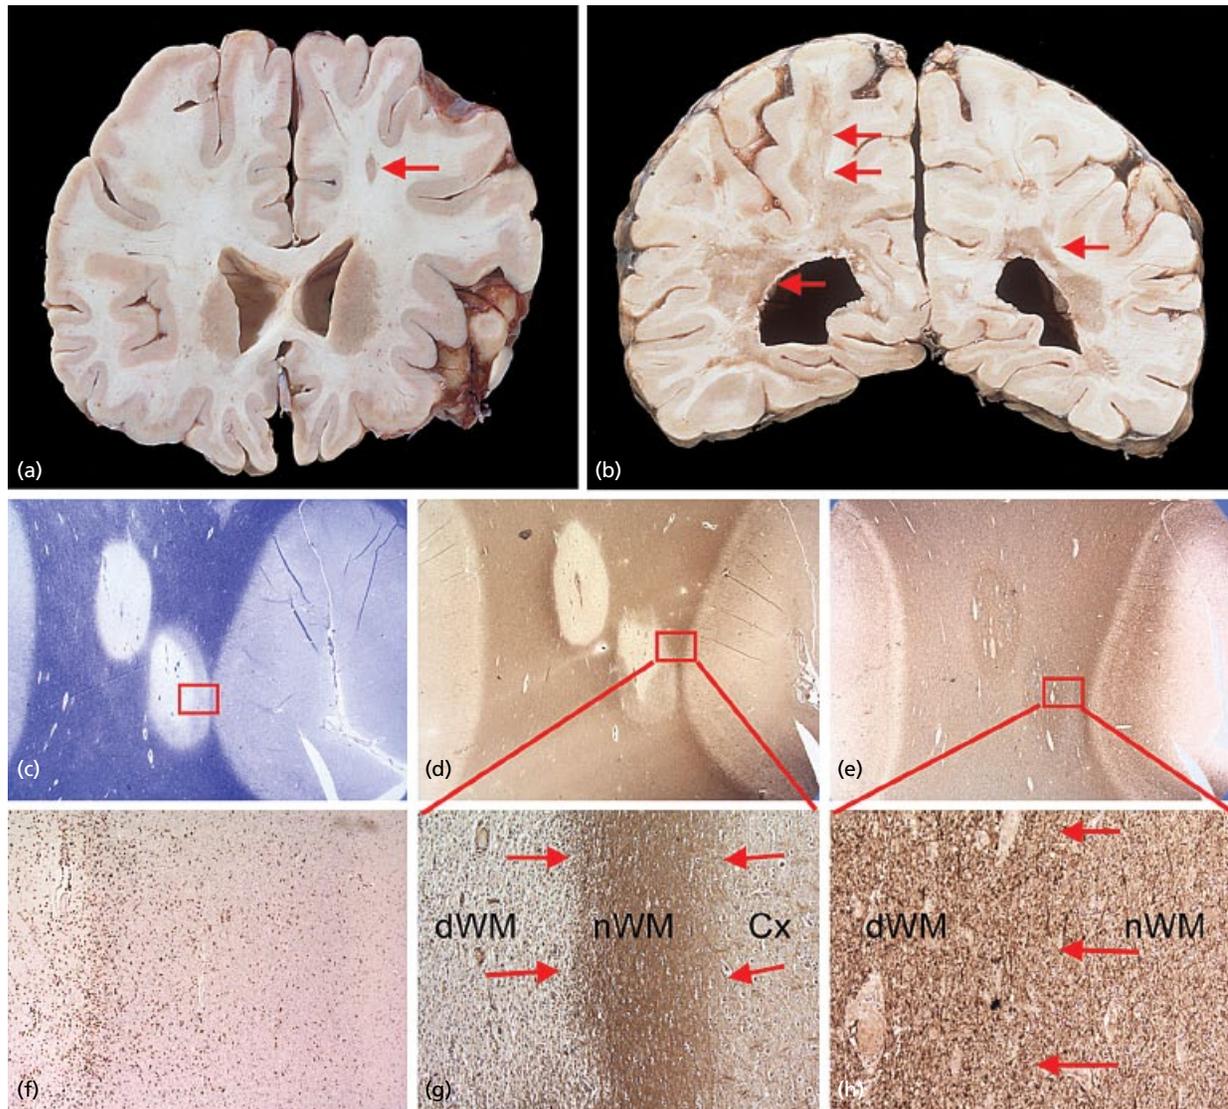

### Pathophysiology

The characteristic pathological feature of multiple sclerosis is the focal plaque or lesion. The lesions of multiple sclerosis were first depicted by Carswell in 1838 and the principal elements were described by Charcot in 1868 – demyelination, relative preservation of axons, gliosis and a variable amount of inflammation. This histological overview remains just as accurate today but the precise roles and inter-relationships of these elements in the pathogenesis of multiple sclerosis are still not fully elucidated. Furthermore, it is evident that the pathology of multiple sclerosis is not just confined to white matter lesions but involves the grey matter and macroscopically normal-appearing white matter (NAWM) and axonal loss can be marked in white matter lesions.

## Pathology

Lesions occur throughout the CNS but particularly in the optic nerves, peri-ventricular white matter and corpus callosum, brainstem and cerebellar white matter, and cervical cord. Macroscopically, lesions are generally round or oval and, in broad terms, can be pink and soft, representing acute or active lesions, or grey and firm, representing chronic lesions (Figure 11.1). Brain atrophy and

ventricular enlargement and atrophy of the spinal cord and optic nerves may be evident. Microscopically, acute lesions are characterised by active demyelination with marked inflammatory infiltrates, predominantly T lymphocytes and macrophages, associated with a variable degree of axonal damage and loss (Figure 11.1). In chronic lesions there is extensive loss of myelin, abundant astrocytic gliosis and axonal loss.

**Figure 11.1** Macroscopic and microscopic findings in multiple sclerosis. (a,b) Macroscopic pathology of demyelination (coronal sections of formalin fixed brains). (a) Arrow pointing to a small circumscribed demyelination in the frontal white matter. Loss of myelin appears grey, similar to cerebral cortex. (b) Coronal section of the occipital lobe with extensive multifocal and confluent demyelinations (arrowhead). (c-e) Two foci of demyelination, one with partial remyelination (red box) stained for myelin or axons. (c) Luxol fast blue stains myelinated structures dark blue and the punched-out well-demarcated defects indicates loss of myelin. (d) Myelin basic product (MBP) immunohistochemistry labels myelinated fibres, and shows the same punched-out demyelination with a smaller rim of remyelination fibres in the lowest lesion. (e) Immunohistochemical staining of phosphorylated neurofilament demonstrates the presence of axons within the demyelinating lesions, which appear of slightly increased density than the surrounding intact white matter. (f) CD68 immunohistochemistry labels microglia and macrophage activity. The area corresponds to the red rectangle in (c-e), it clearly shows a demarcation between demyelinated and remyelinated regions. (g) High power magnification of the boxed area in (d) (MBP) on the left with loss of the myelin (demyelinated white matter [dWM]), a myelinated area in the centre (WM) and normal cortex (Cx) with myelinated on the right, all indicated by arrows. (h) High magnification of the labelled area in (e) shows the axons in the lesion on the left (dWM) and outside the lesion (nWM), the border is indicated by arrows. **Table 11.1** Pathological classification of active multiple sclerosis lesions.

I	T-cell/macrophage associated
II	Antibody/complement associated
III	Distal oligodendroglialopathy
IV	Oligodendrocyte degeneration in the peri-plaque white matter

Source: Adapted from Lucchinetti *et al.* 2000.

Different patterns of demyelination in active lesions have been described. Lucchinetti *et al.* (2000) studied actively demyelinating lesions in a large sample of multiple sclerosis biopsy and post-mortem samples and proposed four different patterns (Table 11.1). Inflammatory infiltrates, dominated by T lymphocytes and macrophages, were seen in all lesions. Patterns I and II were similar and lesions were typically sharply demarcated and centred on small veins and venules. High numbers of oligodendrocytes were seen. Pattern II was distinguished from Pattern I by prominent deposition of immunoglobulins and complement. Patterns III and IV were associated with signs of oligodendrocyte dystrophy. Pattern III lesions were diffuse with ill-defined borders. They were not centred on vessels and there was a preserved rim of myelin around vessels in some lesions. Unlike other patterns, where loss of myelin proteins was evenly distributed, there was a preferential loss of myelin-associated glycoprotein. There was pronounced loss of oligodendrocytes and oligodendrocyte apoptosis was seen. Pattern IV lesions were sharply demarcated. There was loss of oligodendrocytes and oligodendrocyte death was seen in a small rim of peri-lesional white matter. All active lesions within an individual patient exhibited the same pattern and there was no intra-individual heterogeneity. Patterns I and II were found in all clinical subtypes of multiple sclerosis. Pattern III was mainly found in people with disease duration of less than 2 months. Pattern IV lesions were least common and only found in a variant of primary progressive disease. Therefore it was suggested that mechanisms of demyelination can be different in different subtypes and stages of the disease. However, this concept has not been universally accepted and there is a potential bias associated with the inevitable limitations in access to tissue containing acute lesions. Since the original observation was made, other studies have reported different types of active lesions within the same individual, and it has been suggested that the Pattern III lesions represent a very early stage in the development of acute lesions.

The role of inflammation in the pathogenesis of lesions also remains unclear. Axonal damage, which is sometimes abundant, is seen in the presence of active inflammation, but is also evident in chronic demyelinated lesions. Lesions in people who have died shortly after a relapse have been shown to have zones of extensive oligodendrocyte apoptosis and microglial activation in myelinated tissue (Pattern III) containing few or no lymphocytes or myelin phagocytes suggesting that lesion formation can be related to a process other than inflammation.

Active lesions are predominantly seen in acute relapsing disease and are rare in secondary and primary progressive disease, in which chronic lesions predominate. However, slow expansion of chronic lesions can occur in progressive disease. These lesions are characterised by a rim of activated microglia, at the edge of the lesion, which are associated with active demyelination.

Remyelination is seen in a large proportion of lesions, often at the edges of lesions, although it can be present throughout the lesion. Remyelination can be extensive and result in remyelination of the

complete lesion, described pathologically as a shadow plaque. Although historically remyelination has been felt to occur predominantly in early relapsing disease, it is now apparent that extensive remyelination can also occur in progressive disease. It is not known why remyelination occurs in some lesions and not others.

Pathological abnormalities are also seen in NAWM. In contrast to the extensive inflammation seen in focal lesions, there can be a mild but diffuse inflammatory reaction in NAWM. Peri-vascular cuffing and diffuse inflammatory infiltrates and microglia activation are seen. Diffuse axonal injury is also evident. This does not correlate with the extent of lesions and so is not explained by Wallerian degeneration arising from focal lesions alone. Therefore, there appears to be a mechanism of axonal injury that is independent of focal lesions. Pathological changes are also not just confined to the white matter, and striking cortical demyelination can be seen. Subcortical lesions can extend into the cortex or small focal lesions can be present within the cortex, but extensive subpial demyelination can also occur. Both cortical demyelination and the diffuse changes seen in the NAWM are present far more extensively in progressive than in relapsing disease. Subpial demyelination is especially marked in secondary progressive multiple sclerosis.

It has been previously suggested that relapses and disease progression can occur through distinct mechanisms, with relapses resulting from inflammatory demyelination and progression resulting from neurodegeneration. The recent advances in the elucidation of the immunopathology of multiple sclerosis provide support for a more unifying hypothesis. Multiple sclerosis typically starts with acute inflammation, arising from specific immune mechanisms, which are discussed later, resulting in focal inflammatory demyelinating lesions. Over time, inflammation becomes sequestered within the CNS. This inflammation can be non-specific and low grade but it drives the slow expansion of chronic lesions and the diffuse injury in the NAWM and cortex.

### Autoimmune pathogenesis

The first step in the autoimmune pathogenesis of multiple sclerosis is believed to be that an environmental agent(s) combined with a genetic predisposition results in the production of pathological auto-reactive T cells. After a latent period of 10–20 years a breakdown in immunological tolerance, possibly by a systemic trigger such as a non-specific viral infection or exposure to a superantigen, activates these autoreactive T cells.

During the normal process of immunosurveillance, memory CD4<sup>+</sup> T-helper (Th) cells or a T-helper subset producing IL-17 (Th-17) cells, selectively cross the blood–brain barrier, through a process involving the interaction of their cell surface adhesion molecules with those expressed on CNS endothelium. Once within the peri-vascular space, these cells are presumably activated by professional antigen-presenting cells (probably macrophages or microglia) to proliferate and produce pro-inflammatory cytokines. Antigen recognition occurs via the trimolecular complex, consisting of HLA, T-cell receptor and CD3 molecules. This requires additional co-stimulatory signals, for example interactions between HLA MHC I and II molecules and their respective CD8 and CD4 molecules, and CD28/B7-2/1 pairs.

Humoral immunity appears to have an important role in multiple sclerosis, and intrathecal antibody synthesis is characteristic of the disease. The presence of B-cell clonal expansion in cerebrospinal fluid (CSF) and in lesions indicates an antigen-driven response within the CNS. Ectopic B-cell follicles have also been found in the meninges and are anatomically associated with sub-pial cortical demyelinating lesions, providing further evidence that B cells are

involved in immunopathogenesis. Meningeal inflammation occurs in the brain and spinal cord and in both regions has been associated with neuroaxonal loss in the adjacent parenchyma, suggesting that it can be a significant mechanism contributing to the neurodegeneration and cortical grey matter demyelination that is prominent in progressive multiple sclerosis.

Potential autoantigens implicated in the pathogenesis of multiple sclerosis have included myelin basic protein (MBP), proteolipid protein (PLP), myelin-associated glycoprotein (MAG), myelin oligodendrocyte glycoprotein (MOG) and alpha-B crystallin. The presence of specific cytokines, like transforming growth factor  $\beta$  (TGF- $\beta$ ), IL-6, IL-12, IL-17, IL-21 and IL-23, govern the type of T-helper response. Th1-like cytokines (IL-2, IFN $\gamma$  and TNF- $\alpha$ ) or Th23-like cytokines (IL-17) initiate a cell-mediated inflammatory cascade which activates macrophages, microglia, astrocytes and endothelial cells. This results in further cytokine production and recruitment of inflammatory cells by the up-regulation of adhesion molecule expression on endothelial cells and by the production of chemo-attractants, such as chemokines. Astrocytes and macrophages produce mutually stimulating cytokines (IL-1 and TNF- $\alpha$ ). These and other pro-inflammatory T-cell cytokines up-regulate the production of numerous mediators of inflammation, which are toxic to oligodendrocytes, axons and neurons. These substances include tumour necrosis factor  $\alpha$  (TNF- $\alpha$ ), free oxygen and nitrogen radicals, complement, proteases and eicosanoids.

Autoantibodies, particularly to surface myelin antigens, can be crucial to the development of demyelination. Autoantibodies to axonal elements (e.g. gangliosides and neurofilaments) can have functional consequences and can contribute to conduction abnormalities and axonal loss. In addition to myelin damage, programmed cell death or apoptosis of the oligodendrocyte can occur as a result of oxidative stress and death signalling induced by TNF- $\alpha$ . Antibodies and complement assist Fc-receptor mediated phagocytosis by opsonisation. Phagocytosis also occurs via the macrophage scavenger and low-density lipoprotein receptors. T-regulatory cells and immunomodulatory cytokines produced by these cells are important in down-regulating and controlling the focal inflammation. Elimination of autoreactive T cells by apoptosis can be important in controlling inflammation.

The combination of both cell and humorally mediated inflammatory cascades causes oligodendrocyte, axonal and neuronal toxicity, which in turn is believed to release sequestered CNS antigens which are hypothesised to initiate further cycles of autoimmune-induced inflammation via intra- or intermolecular antigen determinant spreading.

Inflammatory demyelination results in a reduction in the safety factor of conduction, with complete or intermittent conduction block, which produces clinical symptoms and signs, some of which can be intermittent. Resolution of inflammation and oedema initially can result in clinical improvement. Over a longer time, remyelination and/or axonal plasticity (synthesis of new sodium channels along demyelinated axonal segments) restores axonal conduction, albeit with a reduced safety factor of conduction, which results in remission. There is evidence that growth factors produced as part of the inflammatory response stimulate the process of remyelination. Synaptic plasticity can also compensate for defective conduction. Transient neurological symptoms can occur secondary to the residual reversible conduction block, typically in relation to fatigue, changes in body temperature and systemic inflammation. Ephaptic transmission can cause paroxysmal positive neurological symptoms. Axonal loss, as a consequence of acute or diffuse injury, causes permanent neurological impairment and disability.

In summary, the hypothetical autoimmune pathogenesis for multiple sclerosis has an initial phase of multi-focal inflammatory demyelination in white matter that is mediated through a systemic adaptive immune response (activated T cells) and accounts for a relapsing remitting clinical course. There is a subsequent phase characterised by a more widespread low grade inflammatory process – involving white and grey matter lesions and NAWM – which is mediated through an innate immune response within the CNS (activated microglia, meningeal and peri-vascular inflammation), leading to widespread neuroaxonal loss and a progressive clinical course. This sequential process would explain the evolution from a relapsing remitting to secondary progressive course and a primary progressive course could be because of a milder initial adaptive immune response phase that is not expressed clinically.

## Clinical course

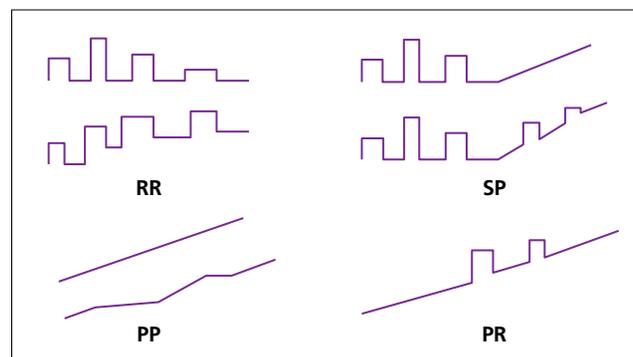

Multiple sclerosis is characterised by lesions disseminated throughout the CNS, which can appear, disappear or gradually worsen over time, and this is reflected in its clinical presentation and course. Its presentation is variable and its course and prognosis are unpredictable, although broad clinical categories of the disease are well recognised.

### Types of multiple sclerosis

Clinical disease activity in multiple sclerosis can manifest as relapses or insidious progression. According to the occurrence and timing of these features, four main categories of multiple sclerosis were outlined in 1996 in the widely accepted classification of Lublin and Reingold (Figure 11.2).

### Relapsing remitting multiple sclerosis

Approximately 85% of individuals present with relapses and remissions. A relapse is defined as an episode of acute or subacute neurological dysfunction lasting a minimum of 24 hours. A relapse usually evolves over days or weeks, plateaus and then remits to a variable degree, from minimal resolution to complete recovery. Further relapses can then occur at irregular intervals. The average relapse frequency in the relapsing remitting phase of the disease (without disease modifying treatment) is approximately one relapse per year.

**Figure 11.2** Clinical course of multiple sclerosis: illustration of the relationship between increasing disability and time in the different types of multiple sclerosis (PP, primary progressive; PR, progressive relapsing; RR, relapsing remitting; SP, secondary progressive). (After Lublin and Reingold 1996.)

### Secondary progressive multiple sclerosis

Relapsing remitting multiple sclerosis can evolve into a gradually progressive course with accumulating irreversible neurological deficit and disability, classified as secondary progressive multiple sclerosis. The proportion of people developing secondary progressive disease increases with length of follow-up. In a large Canadian natural history study, 41% of people with relapsing remitting multiple sclerosis entered the secondary progressive phase within 6–10 years of disease onset increasing to 58% between 11 and 15 years after onset. After 20 years, approximately 80% had developed secondary progressive multiple sclerosis. Superimposed relapses can continue to occur in the secondary progressive phase, although less frequently as the disease progresses.

### Primary progressive multiple sclerosis

In primary progressive multiple sclerosis there is insidious disease progression from onset, resulting in gradual accumulation of neurological deficit or disability, without relapse or remission. It accounts for approximately 10–15% of multiple sclerosis. Males and females are affected with equal frequency. The average age of onset is older in primary progressive multiple sclerosis, approximately 40 years compared to 30 years in relapsing remitting multiple sclerosis.

### Progressive relapsing multiple sclerosis

Progressive relapsing multiple sclerosis refers to the small number of people who have progressive disease from onset with superimposed relapses, but the term is now rarely used. Insidious progression is the predominant feature and relapses are usually mild. Progressive relapsing multiple sclerosis is considered to be largely similar to primary progressive multiple sclerosis. Approximately one-quarter of people initially diagnosed with primary progressive multiple sclerosis will later have relapses, and a relapse can occur decades after disease onset.

The classification of clinical course was revised in 2013. Clinically isolated syndrome was added and progressive relapsing multiple sclerosis eliminated. It was recommended that all forms of multiple sclerosis should be subcategorised as either active or non-active. Active multiple sclerosis is defined as the occurrence of clinical relapse or new T2 or gadolinium-enhancing lesions over a specified period of time. Progressive multiple sclerosis should be subcategorised into those who have shown signs of disability progression over a given time period and those who have remained stable. It was also recommended that the patients whose disease is advancing through relapses should be described as 'worsening', and that the term 'disease progression' should be reserved for those with truly progressive disease.

### Natural history and prognosis

The natural history of multiple sclerosis is extremely variable. The spectrum of disease activity ranges from clinically asymptomatic demyelinating lesions, detected incidentally on imaging (radiologically isolated syndrome) or at postmortem, to an aggressive course with rapidly accumulating disability. It is not possible to predict prognosis in an individual, but natural history studies have provided data on disease progression in different multiple sclerosis populations.

### Clinically isolated syndrome

A clinically isolated syndrome refers to a first acute episode suggestive of CNS demyelination, and it can be the first presentation of multiple sclerosis. The average risk of developing multiple sclerosis

following a clinically isolated syndrome has been reported as between 30% and 70%, although the risk increases with the length of follow-up. People presenting with unilateral optic neuritis may have a lower risk of converting to multiple sclerosis than other clinical presentations, although high conversion rates have been seen in the United Kingdom, where the prevalence of multiple sclerosis is also high. Abnormal MRI at first presentation has been consistently shown to confer a higher risk of conversion to multiple sclerosis than if MRI is normal. Long-term follow-up studies, ranging from 7 to 20 years, have reported the development of multiple sclerosis to occur in 56–88% of people with lesions on MRI and in 8–22% of those with a normal scan. The lesion number and load at first presentation can also have prognostic relevance, with higher lesion loads modestly predictive of the likelihood of developing disability in the long term.

### Established multiple sclerosis

Natural history studies have conventionally assessed disease progression in multiple sclerosis by measuring the time taken to reach disability milestones. Such studies have shown that the median time to reach a level of disability requiring assistance for walking is between 15 and 30 years.

There has been debate as to the effect of the disease type on long-term prognosis. Relapsing remitting multiple sclerosis has been felt to carry a better prognosis, but a French natural history study from a single large centre reported that disease progression in the long term is largely independent of disease type once a person has acquired a moderate level of disability (level 4 on the Kurtzke expanded disability status scale). However, this requires replication in other studies. Although accumulation of irreversible disability is slower in the relapsing and remitting phase, once the secondary progressive phase is entered the initial course does not seem to significantly influence long-term prognosis.

The influence of residual disability from relapses on long-term accumulation of disability has been similarly debated. Residual neurological deficit following a relapse is common. For example, an increase in disability was demonstrated in one study in up to 42% of people at 2 months following a relapse. However, further recovery can take place over a longer time. Analysis of the placebo arms of treatment trials in relapsing remitting multiple sclerosis has suggested that relapses, although resulting in confirmed disability over 6 months, do not seem to have a consistent effect on the development of sustained disability over the course of a typical study (mean 2.66 years). Further study is required to understand the effect of relapses on long-term disability.

The age of onset does not seem to significantly influence long-term prognosis. Younger age of onset has previously been considered a good prognostic marker but this is not really the case as, although the time to develop permanent disability can take longer, disability still occurs at a younger age. The older age of onset associated with primary progressive multiple sclerosis has also previously been felt to be a poorer prognostic marker. However, the average age of onset in primary progressive multiple sclerosis is similar to that of the progressive phase in secondary progressive multiple sclerosis. The rate of progression is also similar in the primary and secondary progressive groups, with disability milestones being reached at similar ages.

Male sex has been suggested to be associated with a poorer prognosis, but recent studies suggest that this may not be clear-cut. Factors reported to be associated with a more favourable prognosis include monosymptomatic onset, afferent symptoms (sensory, optic neuritis) at onset, complete recovery from first attack, a long

interval between first and second relapses, a low relapse frequency in early disease and minimal disability after 5 years from the onset of first symptoms. However, such associations are weak and it is not possible to reliably predict individual prognosis.

### Benign multiple sclerosis

Benign multiple sclerosis refers to a disease course with accumulation of minimal or no disability. There is no consensus definition, but it is often taken as an Expanded Disability Status Scale (EDSS) score  $\leq 3$  (Table 11.2) at 10–15 years after disease onset. A systematic review of published studies has reported the frequency of benign multiple sclerosis as 26.7%, but the proportion of people with benign disease decreases with length of follow-up. In a large British Columbian cohort only half of those with benign disease at 10 years still fulfilled the criteria at 20 years, with the remainder having developed secondary progression. There are no reliable indicators of a benign course, although follow-up over 20 years in a US cohort found that the longer the disease duration and the lesser the disability, the more likely an individual was to remain stable. It is well recognised that even long-standing benign disease can progress with the development of severe disability.

### Aggressive multiple sclerosis

An aggressive or malignant disease course can result from severe or frequent relapses with little or no neurological recovery or from rapid disease progression. However, aggressive disease is uncommon and early death in multiple sclerosis is rare.

The Marburg variant of multiple sclerosis refers to an acute fulminant disease course, usually monophasic, which can result in death within a few months. Its clinical presentation relates to its site, which can be cerebral, brainstem or spinal cord. In cerebral presentations, confusion and seizures can occur. MRI shows large tumefactive lesions, correlating with destructive hypercellular demyelinating lesions on neuropathological examination, which typically enhance and can have associated oedema and mass effect. The condition must also be distinguished from acute disseminated encephalomyelitis, acute haemorrhagic leukoencephalitis and vasculitis.

Baló concentric sclerosis refers to a particular neuropathological lesion variant, which can also be evident on MRI, characterised by alternating concentric layers of myelin loss and relative preservation of myelin. It can be seen in association with a fulminant course, although it can also occur in more benign disease.

### Early onset multiple sclerosis

Although rare, the onset of multiple sclerosis can be in childhood. Early onset, before the age of 16 years, occurs in approximately 2–5% of individuals. A relapsing remitting disease onset is typical, and a primary progressive course is much rarer than in adult onset disease. Prognosis can be considered better in that the time to develop disability is longer than in adult onset multiple sclerosis, but overall individuals develop disability at a younger age. Over half are likely to develop secondary progressive multiple sclerosis by the age of 30 years. The paediatric multiple sclerosis population can be an ideal group in which to study aetiological factors, and there has been a recent upsurge of interest in this group. A large international collaboration has reported that paediatric multiple sclerosis can be associated with exposure to EBV, but not with other common childhood viral infections. A Canadian nationwide study has followed children who presented with a clinically isolated syndrome and found that the risk for developing multiple sclerosis was increased in the next 3 years by

**Table 11.2** Expanded Disability Status Scale (EDSS). Functional systems (FS) are: pyramidal, cerebellar, brainstem, sensory, bowel and bladder, visual and cerebral.

0.0	Normal neurological examination
1.0	No disability, minimal signs in one FS
1.5	No disability, minimal signs in more than one FS
2.0	Minimal disability in one FS
2.5	Minimal disability in two FS
3.0	Moderate disability in one FS or mild disability in three or four FS, although fully ambulatory
3.5	Fully ambulatory but with moderate disability in one FS and mild disability in one or two FS; or moderate disability in two FS; or mild disability in five FS
4.0	Fully ambulatory without aid, self-sufficient up and about some 12 hours a day despite relatively severe disability in one FS or combinations exceeding limits of previous steps; able to walk without aid or rest some 500 m
4.5	Fully ambulatory without aid, up and about much of the day, able to work a full day, may otherwise have some limitation of full activity or require minimal assistance; able to walk without aid or rest some 300 m
5.0	Ambulatory without aid or rest for about 200 m; disability severe enough to impair full daily activities (e.g. to work a full day without special provisions)
5.5	Ambulatory without aid or rest for about 100 m, disability severe enough to preclude full daily activities
6.0	Intermittent or unilateral constant assistance (cane, crutch, brace) required to walk about 100 m with or without resting
6.5	Constant bilateral assistance (canes, crutches, braces) required to walk about 20 m with or without resting
7.0	Unable to walk beyond approximately 5 m even with aid, essentially restricted to wheelchair; wheels self in standard wheelchair and transfers alone, up and about in wheelchair some 12 hours a day
7.5	Unable to take more than a few steps; restricted to wheelchair; may need aid in transfer, wheels self but cannot carry on in standard wheelchair a full day; may require motorized wheelchair
8.0	Essentially restricted to bed or chair or perambulated in wheelchair, but may be out of bed itself much of the day; retains many self-care functions; generally has effective use of arms
8.5	Essentially restricted to bed much of day; has some effective use of arm(s); retains some self-care functions
9.0	Helpless bed patient; can communicate and eat
9.5	Totally helpless bed patient; unable to communicate effectively or eat/swallow
10.0	Death due to multiple sclerosis

the presence of MRI brain lesions, CSF oligoclonal bands, the HLA DRB1\*15 allele, previous EBV infection and low vitamin D levels.

### Mortality

Mortality rates are increased compared to the general population. The average life expectancy in multiple sclerosis has been reported to be reduced by between 7 and 14 years. The proportion of deaths attributed to complications of multiple sclerosis is at least half. The risk of suicide in the multiple sclerosis population is increased and can be more than twice the rate of the general population. Although the long-term effects of disease-modifying therapy on the course of multiple sclerosis are not yet clear, their potential to increase survival is supported by a 21-year follow-up report from the pivotal interferon  $\beta$ -1b trial.

### Factors affecting relapse activity

Various health and lifestyle factors have been proposed to affect relapse activity in multiple sclerosis. It is important that people with multiple sclerosis are aware of these factors to facilitate informed decisions regarding their lifestyle.

### Infections

Systemic infections can trigger a relapse or exacerbate existing symptoms of multiple sclerosis. An association between common viral and bacterial infections and risk of relapse has been documented, but such infections are difficult to avoid. Infections can occur as a complication of multiple sclerosis (e.g. urinary tract infections resulting from retention and chest infections resulting from aspiration). Therefore, addressing the underlying cause of infections can be preventative and, where possible, infections should be anticipated and treated early. Cigarette smoking, aside from its well-known health risks, can increase the occurrence of respiratory tract infections and should be discouraged.

### Pregnancy

The effect of pregnancy on disease activity is an important concern among women of childbearing age. A large prospective study of pregnancy in multiple sclerosis confirmed that relapse rate declines during pregnancy, especially in the third trimester, increases during the first 3 months postpartum and then returns to pre-pregnancy rate. The incidence of postpartum relapse was 28%. An increased relapse rate in the pre-pregnancy year and during pregnancy, and higher disability at pregnancy onset, were associated with a higher risk of postpartum relapse. Epidural analgesia and breastfeeding were not found to increase the risk of relapse. There is no evidence for an adverse effect of pregnancy on the long-term course of multiple sclerosis and some studies have identified a better long-term course in multiparous than nulliparous women.

### Stress

Prospective studies have reported stressful life events to be associated with an increased risk of relapse. A meta-analysis also supported an association between stressful life events and subsequent relapses although did not link relapse to specific stressors. Physical trauma has been proposed to trigger relapses but a systematic review of the evidence has not supported this link.

**Diet** Despite popular interest in the effect of diet on multiple sclerosis there is currently little evidence to support an association between dietary factors and disease activity. A systematic review concluded that no dietary intervention has been shown to

significantly affect disease progression. Linoleic acid, an omega-6 fatty acid, was associated with slight decreases in relapse rate and severity, but the studies were small and of limited design. Vitamin D supplementation has been reported to reduce relapse rates, but the available data are not conclusive; larger studies are ongoing.

### Vaccines

The question of whether vaccination can immunologically trigger a relapse has been investigated and there is no clear evidence to support this hypothesis. Most vaccines have not been investigated prospectively, but a double-blind, placebo controlled study of influenza vaccine showed no effect on relapse rate or disease progression. There has been particular concern regarding hepatitis B vaccination but a large case cross-over study found no increased risk of relapse following either hepatitis B or indeed any vaccination. Current expert opinion is that vaccinations are not contraindicated in multiple sclerosis, and national guidelines recommend that people with multiple sclerosis can be offered vaccination against influenza according to the individual's needs. However, it must not be forgotten that live vaccines can be contraindicated in individuals on immunosuppressant therapy (i.e. BCG, oral polio vaccine, MMR [measles–mumps–rubella], rotavirus, yellow fever, varicella zoster).

### Clinical features

Multiple sclerosis can cause a wide variety of symptoms mirroring involvement of any part of the CNS. The spinal cord, optic nerves and brainstem are commonly involved sites. In a European database of clinically isolated syndromes, 46% of individuals presented with a spinal cord syndrome, 21% with optic neuritis and 10% with a brainstem syndrome. The presentation was polysymptomatic in 23% of cases. Differences in presenting symptoms are seen between disease types. In relapsing remitting multiple sclerosis, the most common symptoms are sensory and visual, whereas in primary progressive disease the most usual presentation is locomotor. During the course of the disease a multitude of symptoms can occur: weakness, spasticity, numbness, paraesthesia, pain, visual loss, diplopia, ataxia, tremor, vertigo, sphincter and sexual dysfunction, dysphagia, dysarthria, respiratory dysfunction, temperature sensitivity, fatigue, cognitive and psychiatric disturbance.

There are no symptoms or signs that are pathognomonic for multiple sclerosis, although characteristic clinical features are seen. Optic neuritis is a common manifestation. It presents with eye pain, which is exacerbated by eye movement, and blurring of vision. The visual impairment can progress over a few days, but not usually longer than 1–2 weeks. Continued progressive visual failure or loss of perception to light should alert to the possibility of alternative diagnoses. On examination, colour vision and visual acuity are impaired and a scotoma, classically central, can be detected. The optic disc can be normal but swelling can be present, and pallor of the optic disc can develop later. A relative afferent pupillary defect is usually present.

Diplopia can be a presenting symptom and usually is symptomatic of a VIth nerve palsy or an internuclear ophthalmoplegia. As the disease advances, unilateral or bilateral internuclear ophthalmoplegia, identified on conjugate lateral gaze as impaired adduction on the side of the lesion and nystagmus of the abducting eye, is commonly seen but can often be asymptomatic.

A partial spinal cord syndrome is a frequent presentation. Typically, altered sensation starts in one foot and spreads to involve both legs and, to a varying extent, ascends to the trunk and arms. Variable degrees of numbness and tingling can occur but complete

loss of sensation is unusual. On examination, all sensory modalities can be impaired and a sensory level can be discerned although, as the relapse recovers, a persistent bilateral sensory level is uncommon. Oppenheim hand, a functionally impaired hand caused by loss of position sense, can be a characteristic presentation of a lesion in the posterior columns of the cervical cord.

Motor involvement becomes more common as the disease advances and weakness is a prominent symptom. Weakness is usually greater in the legs than the arms, and paraparesis is frequently asymmetrical. Spasticity can manifest as stiffness, clonus or spasms. On examination, signs usually reflect upper motor neurone involvement with hypertonia, hyper-reflexia and positive Babinski responses. However, focal wasting, flaccidity and loss of tendon reflexes can be seen, and can result from denervation in the spinal cord.

Spinal cord involvement also commonly results in bladder and bowel disturbance. Bladder disturbance can result from a combination of detrusor hyper-reflexia, manifesting as urgency, frequency and incontinence, and incomplete emptying because of sphincter dyssynergia and poorly sustained detrusor contractions, resulting in hesitancy and incomplete emptying. Constipation is the most common bowel symptom, although urgency and incontinence are not infrequent. Sexual function in males and females is frequently affected, because of central neurological dysfunction, although psychological and other factors can also contribute.

An initial cerebellar presentation is uncommon but cerebellar involvement is frequent during the course of the disease, evidenced by nystagmus, dysarthria, limb ataxia, intention tremor and truncal ataxia. Gait ataxia can contribute to the classic spastic ataxic gait, but it can also cause disabling gait disturbance in the absence of significant weakness and spasticity.

Fatigue can be one of the most disabling symptoms in multiple sclerosis, and can impact on all activities. An exercise-induced motor fatigue, with increasing leg weakness on walking, and an unprovoked but severe generalised exhaustion may be reported. Fatigue appears to be related to electrophysiological and immunological effects of multiple sclerosis, and is often worse during relapses, but disturbed sleep, medication and depression can also be contributory factors. Heat sensitivity is a common symptom, caused by the increased temperature inducing slowing of nerve conduction. Uhthoff's phenomenon refers to the transient blurring of vision on exercise or in hot environments brought about by underlying optic nerve disease.

Cognitive impairment is well documented to occur in multiple sclerosis and mild deficits can be apparent in early disease. Attention, information processing, memory and executive functions are predominantly affected. Severe dementia can occur but, particularly in early disease, can suggest an alternate diagnosis. Depression occurs more frequently than in the general population but is usually mild and is often reactive to the diagnosis and ensuing neurological deficits. Emotional lability, with involuntary crying or laughing in the absence of subjective mood disorder, can occur. Psychosis is an uncommon manifestation of multiple sclerosis, but may rarely be the presenting episode.

Pain is common in multiple sclerosis and is usually chronic. It is often myelopathic in origin, typically resulting in a burning pain in the legs and hands. Paroxysmal pain can occur, most notably trigeminal neuralgia. Pain can also result indirectly from other related problems such as spasms and musculoskeletal complications.

A characteristic feature of multiple sclerosis is the occurrence of paroxysmal symptoms, resulting from electrical instability within

lesions. A typical episode is of acute onset with symptoms of short duration, less than 2 minutes, occurring up to 30 or more times a day. The whole episode usually resolves spontaneously within a few weeks to months. The nature of the symptoms reflects the underlying site of the lesion. Infratentorial lesions can result in trigeminal neuralgia and paroxysmal dysarthria and ataxia. Tonic spasms, painful tonic contractions usually involving one or two limbs unilaterally, can arise from sites in the cortico-spinal tract. Other paroxysmal sensory disturbances can occur and paroxysmal itching is described.

Other positive symptoms include Lhermitte's symptom, a brief electrical sensation radiating down the back into the legs or arms precipitated by neck flexion, caused by a lesion in the cervical cord, and phosphenes resulting from optic nerve demyelination. Lesions involving the facial nucleus or nerve can cause hemifacial spasm or facial myokymia. Epilepsy, originating from juxtacortical or cortical lesions, is seen 2–3 times more commonly than in the general population, and rarely may be the presenting symptom.

## Diagnosis

Multiple sclerosis is a clinical diagnosis that requires appropriate expertise to confirm evidence of CNS lesions disseminated in time and space and to exclude other diseases. Investigations can be used to:

- Exclude other diseases
- Provide evidence of dissemination in time and space, and
- Provide evidence of immunological disturbance.

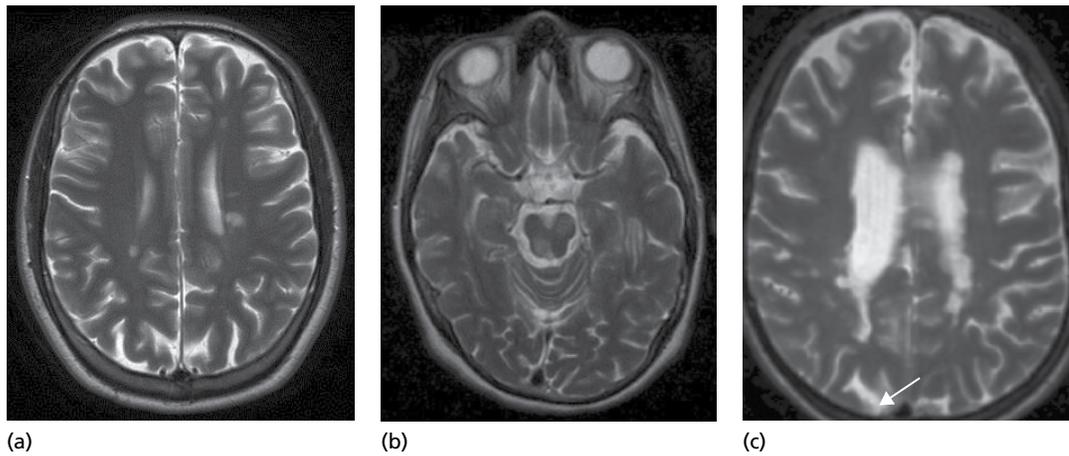

### Diagnostic investigations

#### Magnetic resonance imaging

The plaques of white matter demyelination in multiple sclerosis are readily visualised on MRI by virtue of an increase in the amount and mobility of water protons in the lesions. The standard imaging sequence is a T2-weighted spin echo or fast spin echo, with an additional fast FLAIR (fluid attenuated inversion recovery) sequence that suppresses signal from CSF and increases the conspicuity of cerebral hemisphere lesions.

The value of MRI in diagnosis comes through its high sensitivity for detecting clinically silent lesions, and showing them in characteristic locations; the detection of blood–brain barrier breakdown in acute lesions using gadolinium-enhanced T1-weighted MRI is also a useful finding. MRI can be normal in clinically definite multiple sclerosis, but this is unusual: lesions are seen in the brain in approximately 95% and spinal cord lesions in approximately 70% with a clinically definite diagnosis. The characteristic locations for foci of demyelination are peri-ventricular, corpus callosum, juxtacortical, brainstem, cerebellar white matter and spinal cord (Figure 11.3). Lesions are usually small (3–10 mm diameter), can have an oval or rounded shape, and usually extend to the parenchymal surface in the brainstem and spinal cord. Cord lesions are most often seen in a posterior or lateral location, involve white and grey matter, and affect only part of the cord in cross-section (Figure 11.4). Gadolinium enhancement is invariable in new lesions in relapsing multiple sclerosis, can be homogeneous or ring-shaped, and lasts an average of 2–6 weeks (Figure 11.5).

In people with a clinically isolated syndrome (CIS), clinically silent cerebral white matter lesions are seen in 50–70%. The presence of MRI lesions confers a relatively high risk for future development of clinically definite multiple sclerosis as already discussed. Development of new T2 or gadolinium-enhancing lesions on

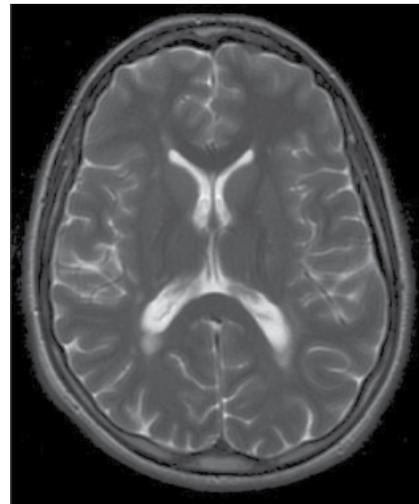

**Figure 11.3** Typical lesions in multiple sclerosis: (a) periventricular; (b) infra-tentorial, (c) juxtacortical lesion (arrow) (MRI T2W axial).

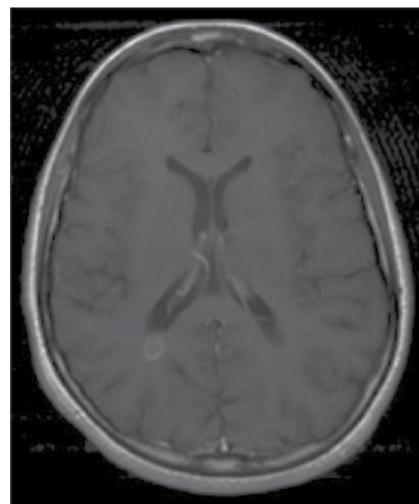

**Figure 11.4** Typical lesions in the cervical cord in multiple sclerosis (MRI T2W sagittal).

follow-up MRI increases the likelihood of early clinical relapses and, accordingly, the development of clinically definite multiple sclerosis.

The major limitation of MRI is specificity: there are many other causes of cerebral white matter lesions (Table 11.3). Small vessel disease is an especially common cause of areas of T2 hyperintensity on white matter and over one-third of the general population aged over 50 years will exhibit areas of high signal. These are small, and mainly subcortical rather than peri-ventricular. Basal ganglia involvement is not uncommon and central pontine abnormalities are also seen (unlike multiple sclerosis, not extending to the surface). Cord lesions do not occur with ageing per se and their detection in older patients is a particularly useful pointer to demyelination.

CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; SLE, systemic lupus erythematosus.

Other multi-focal and inflammatory disorders can at times be difficult to distinguish from multiple sclerosis on clinical and imaging grounds: sarcoidosis, SLE, Sjögren's syndrome, Behçet's disease, CNS vasculitis, acute disseminated encephalomyelitis (ADEM) and

**Figure 11.6** Atypical lesion in multiple sclerosis mimicking a cerebral tumour (MRI T2W axial).

neuromyelitis optica (NMO). There are some distinctive imaging findings, for example meningeal enhancement in sarcoidosis; multifocal, punctate and peri-vascular enhancement in CNS vasculitis; extensive brainstem and diencephalic lesions in Behçet's disease; monophasic disease activity in ADEM, with partial and sometimes marked resolution at follow-up; extensive longitudinal cord lesions in ADEM and NMO. Numerous other non-inflammatory white matter disorders can also enter the differential diagnosis, for example progressive multifocal leukoencephalopathy, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL). In leukodystrophies (e.g. Krabbe's disease, adrenomyeloneuropathy) or metabolic disorders such as phenylketonuria, the white matter abnormalities are typically symmetrical. Rarely, demyelinating lesions can manifest as a single, large, atypical-appearing or tumefactive lesion within a cerebral hemisphere mimicking a cerebral tumour (Figure 11.6). Sometimes such lesions are accompanied by other smaller lesions that are typical for demyelination and thereby assist diagnosis. The tumefactive lesions tend to be extensive but circumscribed with little mass effect or vasogenic oedema and there may be pathological ring enhancement, although more atypical features can occur; ultimately, the lesions will become smaller, and sometimes appear to resolve rapidly with corticosteroid therapy.

Conventional T2-weighted MRI sequences are very insensitive to cortical grey matter lesions and abnormalities in NAWM that are nevertheless abundant in multiple sclerosis. Some cortical lesions are detected using more sophisticated imaging techniques, including double inversion recovery and phase sensitive inversion recovery sequences and higher resolution imaging on high field scanners, although an added diagnostic value of such approaches has not been shown. Quantitative MRI abnormalities have been demonstrated in NAWM and include decreased magnetisation transfer ratio, increased T1 relaxation time, increased mean diffusivity and decreased *N*-acetylaspartate on spectroscopy. While the development of techniques to better detect and quantify these more extensive abnormalities may have some diagnostic role in future, the greater importance seems likely to be in understanding pathogenic mechanisms and assigning prognosis.

### Cerebrospinal fluid

When both clinical and imaging features are characteristic of multiple sclerosis, many neurologists will not feel that a lumbar puncture is required, although there are some geographical variations in practice. In those regions where Lyme disease is common (Chapter 9), exclusion of this treatable condition warrants a lumbar puncture in almost all suspected multiple sclerosis cases (however, it should be noted that the usual clinical features of neuroborreliosis – facial palsy and meningoradiculitis – are not a common presentation for multiple sclerosis). In clinically definite multiple sclerosis, intrathecally synthesised oligoclonal immunoglobulin G (IgG) bands are found in approximately 90% of patients. A parallel blood sample is required to demonstrate the intrathecal origin of bands as the passive transfer of bands from the systemic circulation has no diagnostic value. Isoelectric focusing and immunodetection of oligoclonal bands is the gold standard technique to provide evidence of intrathecal antibody synthesis (Figure 11.7). A raised IgG index can be informative but is not as sensitive or specific. About two-fifths of patients have a mildly raised CSF white cell count (5–50 mononuclear cells/mm<sup>3</sup>) and protein.

Oligoclonal bands occur in other CNS inflammatory disorders including infections (e.g. neurosyphilis, subacute sclerosing panencephalitis [SSPE], neuroborreliosis, human T-lymphocyte virus type 1 [HTLV-1] associated myelopathy and CNS varicella zoster), vasculitis, collagen-vascular disorders and paraneoplastic disease but they are less common in neurosarcoidosis, Behçet's disease and NMO. Whereas in multiple sclerosis the antigenic specificity of the bands is largely unknown, in SSPE and varicella zoster they are largely directed against measles and herpes zoster antigens, respectively.

Laboratory procedures for optimal CSF examination in suspected multiple sclerosis have been defined recently by an expert international panel. Some new laboratory methods for detecting

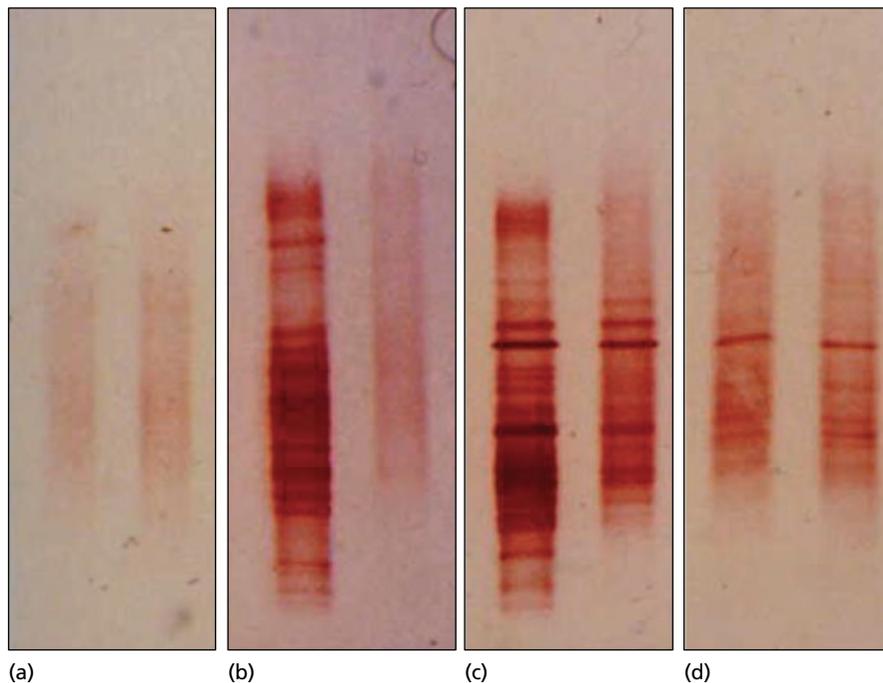

oligoclonal bands, including IgM bands, have been investigated and suggested as being more sensitive and specific in diagnosing and predicting the course of multiple sclerosis. More extensive studies are required to determine their clinical utility.

### Evoked potentials

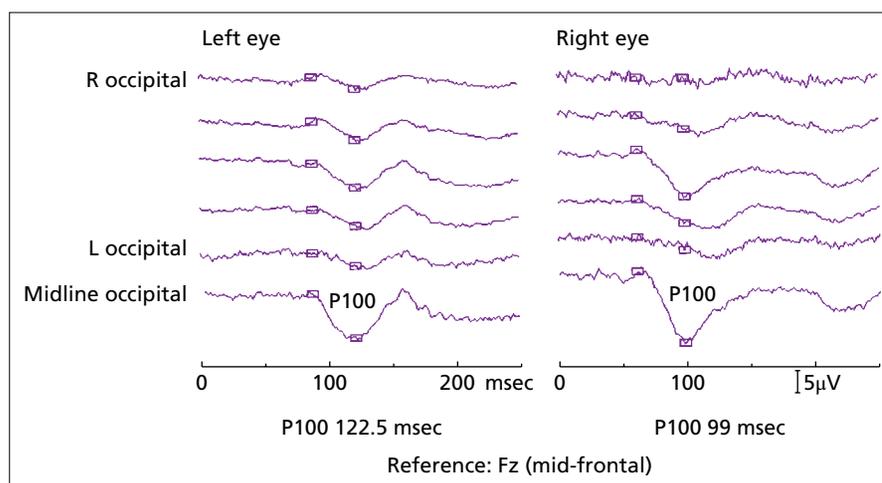

For 10–20 years prior to the widespread introduction of MRI, evoked potentials were important and frequently used diagnostic investigations. Their role was similar to MRI: detection of clinically silent CNS white matter lesions. Because they are less sensitive in this respect than MRI, they are not often requested as part of contemporary diagnostic work-up. The most useful of these investigations is the visual evoked potential; the demonstration of a markedly delayed P100 wave of normal amplitude provides strong evidence for optic nerve demyelination (Figure 11.8). It can still be useful in supporting the diagnosis, especially when the clinical syndrome is in the spinal cord or brainstem and MRI is normal or shows only minor non-specific abnormalities or is obtained in an older age group where the specificity of white matter abnormalities is less. Brainstem auditory evoked potentials and somato-sensory evoked potentials are generally less useful, although can sometimes have a role in establishing the nature of a lesion.

### Autoantibodies

No autoantibody has been confirmed to be diagnostic for multiple sclerosis to date. A study of patients with CIS – who also had MRI abnormalities and CSF oligoclonal bands indicating a high likelihood for multiple sclerosis – reported that the presence of antimyelin antibodies in serum substantially increased the risk for developing clinically definite multiple sclerosis. However, several subsequent studies were consistently negative, reporting as high a frequency of such antibodies in healthy controls or in those with

**Figure 11.7** Isoelectric focusing of paired cerebrospinal fluid (CSF) and serum. (a) CSF negative/serum negative; (b) CSF positive/serum negative; (c) CSF positive/serum positive but with fewer bands; (d) CSF positive/serum positive with the same bands. The oligoclonal band patterns in (b) and (c) indicate intrathecal antibody synthesis.

**Figure 11.8** Visual evoked potential in left optic neuritis: delayed P100 waveform from left eye; normal response from right eye.

non-converting CIS as in those who develop multiple sclerosis. Anti KIR4.1 antibody (a potassium channel antibody) has been reported to be present in almost 50% of people with multiple sclerosis, but in only 1% with other neurological diseases and not at all in healthy controls, but this finding has not been reproduced in other studies.

### Diagnostic criteria

Diagnostic criteria for multiple sclerosis have evolved over recent decades with the emergence and widespread availability of newer laboratory investigations that improve the accuracy of diagnosis, and allow it to be made earlier. However, an incontestable core requirement of all the criteria is objective clinical evidence for a disease affecting CNS white matter. Multiple sclerosis cannot be diagnosed in an asymptomatic individual based on MRI findings alone. The criteria also require evidence that the CNS white matter disorder is disseminated in space and time; where they vary is that the early criteria required clinical evidence for dissemination, whereas more recent criteria allow MRI evidence of dissemination. The evolution of diagnostic criteria over the last 50 years shows how experience of the use of new technology has changed the diagnostic process in patients with clinically suspected CNS demyelination.

### Schumacher criteria

The diagnostic criteria of Schumacher *et al.* (1965) were an attempt to logically integrate dissemination in space and time based solely on clinical manifestations. Definite cases of multiple sclerosis were classed as having objective clinical evidence for disease affecting two or more regions of CNS white matter (dissemination in space), and occurring in episodes lasting at least 24 hours and separated by at least 1 month or with progression over 6 months (dissemination in time), in a person aged 10–50 years at onset and in whom no better explanation could be found by an experienced clinician. This clinically based description remains useful today, and while more detailed aspects of clinical, imaging and CSF findings should be appropriately focused on, one should always keep in mind the caveat 'there is no better explanation'.

### Poser criteria

The Poser criteria (1983) retained the concept of at least two relapses with signs of a corresponding CNS white matter lesion in two or more locations as the basis for diagnosing clinically definite

multiple sclerosis. They introduced laboratory features to strengthen the diagnostic classification in patients in whom clinical evidence suggested probable or possible multiple sclerosis but was insufficient to be certain, for example a patient with two relapses and clinical signs of one lesion could, with additional clinically silent evoked potential abnormalities (and silent MRI lesions when MRI became widely available subsequent to the criteria being published in 1983), be considered as definite multiple sclerosis. The Poser criteria gave particular weight to the evidence provided by CSF oligoclonal bands indicating an immunological disorder of the CNS. Thus, a patient with two relapses and signs of single CNS lesion plus unmatched CSF oligoclonal bands was classified as laboratory supported definite multiple sclerosis.

### McDonald 2001 criteria

The major change in practice leading to further revisions of the Poser criteria was the widespread use of MRI and the emerging evidence that certain imaging features were suggestive of multiple sclerosis. In particular, Barkhof and Tintore had shown that in patients with CIS, three or four of the following brain MRI features had a high specificity for developing clinically definite multiple sclerosis:

- >9 T2 or  $\geq 1$  gadolinium-enhancing lesions
- >3 periventricular lesions
- >1 juxtacortical lesions, and
- >1 infratentorial lesions.

The International Panel that developed the McDonald 2001 diagnostic guidelines adopted the Barkhof–Tintore criteria as evidence for dissemination in space with the modification that one cord lesion could substitute for one brain lesion. The Panel also proposed an alternative, non-evidence based criterion for dissemination in space: two T2 lesions and the presence of CSF oligoclonal bands. They also had a complex MRI requirement for dissemination in time, erring on the side of caution, defined as either a gadolinium-enhancing lesion occurring at least 3 months after the clinical onset or a new T2 lesion shown to have developed more than 3 months after clinical onset. It was thus possible, for the first time, to use imaging evidence for dissemination in space and time to diagnose multiple sclerosis in patients with a single clinically manifest CNS lesion (CIS), but the MRI occurrence of new disease activity had to be at least 3 months following the CIS.

### McDonald 2005 criteria

The 2001 criteria were criticised by some as being too liberal – the argument being that anything other than clinically definite multiple sclerosis would run the risk of false positive diagnoses – and by others as being too conservative – the argument being that because patients with CIS with multiple MRI lesions have a high likelihood of developing clinically definite multiple sclerosis, they may as well be diagnosed as multiple sclerosis at presentation.

When the 2001 criteria were applied to two natural history cohorts that had been recruited with a CIS, from specialist centres, and were being followed up with serial clinical and MRI evaluation, they were found to have a high specificity and positive predictive value for development of clinically definite multiple sclerosis over the next 3 years. However, sensitivity of the early dissemination in time criterion – a gadolinium-enhancing lesion after 3 months – was low. One study reported that allowing a new T2 lesion at 3 months of follow-up (many of which must have occurred within 3 months of clinical onset) increased sensitivity without compromising specificity. The substitution of a single spinal cord lesion for a brain lesion had a negligible effect on performance of the criteria in patients with isolated optic neuritis, although substituting all visible cord lesions for an equivalent number of brain lesions considerably increased sensitivity of the Barkhof–Tintore criteria for dissemination in space in patients at the time of multiple sclerosis diagnosis.

A reconvened International Panel in 2005 made revisions to the MRI criteria for dissemination in space and time. These allowed any number of cord lesions to substitute for a brain lesion, and a gadolinium-enhancing cord lesion to substitute for an enhancing brain lesion. They also allowed for any new T2 lesion occurring more than 30 days after clinical onset to constitute evidence for dissemination in time. The criteria affirmed that there must be objective clinical evidence for a CNS lesion (i.e. an abnormality on neurological examination). A suggestive symptom alone (e.g. Lhermitte's symptom) was considered insufficient.

### McDonald 2010 criteria

Application of the 2005 criteria to a multicentre European CIS cohort indicated that they retain a high overall specificity, and that dissemination in time is more specific than dissemination in space per se. However, the criteria were criticised for several reasons. First, the inclusion of a gadolinium-enhancing lesion as evidence for dissemination in space was illogical as it is actually a feature of lesion activity. Secondly, the counting of lesions (a total of nine brain lesions, or three in a periventricular location) was cumbersome in clinical practice. Thirdly, the dissemination in time criteria still imposed a delay to diagnosis, and there would often need to be three scans before a new T2 lesion qualified as evidence (i.e. the first at presentation with a CIS, a second 30 days or more later and a third scan at a still later time to show the qualifying new lesions). Through the work on the European (MAGNIMS) collaboration, simplified criteria for dissemination in space and time were developed and when implemented in a multi-center CIS cohort were found to have a high sensitivity and specificity for development of clinically definite multiple sclerosis. These criteria were adopted in the 2010 McDonald criteria and are as follows:

- *Dissemination in space*: one or more clinically silent T2 lesions involving at least two of four locations that are characteristic for multiple sclerosis: juxtacortical, periventricular, infratentorial and spinal cord.
- *Dissemination in time*: either a new T2 lesion seen on any follow-up scan regardless of the timing of the baseline scan in relation to

CIS onset *or* both gadolinium-enhancing and non-enhancing lesions on a single scan.

The 2010 criteria continue to require clinical evidence of a process that involves CNS white matter. This will normally be confirmed by objective neurological examination although an historical episode that is highly suggestive of demyelination, but for which examination findings are not available, may qualify. The alternative dissemination on space criteria of two T2 lesions and oligoclonal bands are no longer included.

### Diagnostic criteria for primary progressive multiple sclerosis

The diagnosis of primary progressive multiple sclerosis can be problematic. The differential diagnosis is different from relapse onset presentation: it is, most often, the differential diagnosis of a progressive spastic paraplegia or a progressive brainstem/cerebellar syndrome, in order the two most common presentations of primary progressive multiple sclerosis. Experience with the performance of MRI and/or CSF findings in two large cohorts with a diagnosis of primary progressive multiple sclerosis has helped to inform diagnostic guidelines. The McDonald 2010 criteria for primary progressive require that there has been a progressive CNS syndrome for at least 1 year, and two of three of the following.

- Evidence for dissemination in space in the brain based on one or more T2 lesions in at least one area characteristic for multiple sclerosis: juxtacortical, periventricular, infratentorial.
- Evidence for dissemination in space in the spinal cord based on two or more T2 lesions in the spinal cord.
- Positive CSF (isoelectric evidence of oligoclonal bands and/or elevated IgG index).

The MRI lesions should be asymptomatic in the case of a progressive brain stem or spinal cord syndrome, there should be no better explanation and in patients with a progressive myelopathy, an alternative structural disorder of the cord should always have been excluded by spinal MRI (Table 11.4).

### Radiologically isolated syndrome

From time to time, patients with non-specific symptoms such as headache are found on MRI to have lesions that are typical for demyelination and that fulfill the MRI component of the McDonald criteria for multiple sclerosis. The term radiologically isolated syndrome has been used to describe such individuals. Radiologically isolated syndrome is not included in the McDonald diagnostic criteria as the requirement for having clinical evidence for demyelination is not satisfied. However, it is known from sequential autopsy series that clinically silent multiple sclerosis occurs: in series reported in Canada and Denmark in the 1980s, the frequency was about 1 in 500–1000, which approximates to the frequency of clinically manifest disease in these countries. Recent follow-up of cohorts with a radiologically isolated syndrome has reported the development of clinical manifestations of demyelination in about one-third after 5 years. It is prudent that such individuals are counselled about the association of such MRI findings with multiple sclerosis and offered follow-up.

### Differential diagnosis

The differential diagnosis of multiple sclerosis is wide and a myriad of neurological disorders can mimic the varying manifestations of the condition. The differential diagnosis can be considered in terms of diseases that cause:

- A single episode of neurological disturbance which can be focal involving a single site (e.g. optic nerve or spinal cord), or multi-focal

**Table 11.4** Differential diagnosis of a progressive spinal cord syndrome.

<b>Tumour</b>
Intramedullary – glioma, ependymoma
Intradural – meningioma, neurofibroma

Spinal cord haemorrhage

### The diagnostic process

It is important that the diagnostic process is centred on the needs of the individual with multiple sclerosis. The diagnostic phase is an anxious time, and delay in diagnosis and poor communication is a common cause for complaint. People want a clear and accurate diagnosis and access to appropriate support and information. National guidelines make recommendations for best practice during the diagnostic process. However, there is still wide variation in the services provided throughout the United Kingdom and diagnosis often occurs in a random and unsupported manner. This can be partly explained by the over-stretched medical services, but forward planning and reorganisation of

services could address this problem. There is some evidence that a coordinated diagnostic clinic facilitates an efficient, supportive and cost-effective setting to manage the diagnostic phase. However, the diagnostic model will depend on the locally

available expertise and resources. The clinical nurse specialist has been a key development in recent years and is well placed to facilitate the diagnostic process.

## Management

In recent years, clinical guidelines have been published that aim to improve the standards of care provided to people with multiple sclerosis. Notably in the United Kingdom, the National Institute for Health and Care Excellence (NICE) published guidelines on the management of multiple sclerosis in 2003 and these were updated in 2014. Health and social care professionals involved in the care of people with multiple sclerosis should be aware of current evidence-based practice in order to optimise the standard of management. People with multiple sclerosis should be encouraged to participate fully in decisions on their management. Management requires a comprehensive and multi-disciplinary approach addressing medical, functional, psychological and social aspects of the disease and interventions should be responsive and timely (Table 11.8). Management strategies are required to:

- Provide education and support
- Manage acute relapses
- Modify the course of the disease, and
- Treat symptoms and provide rehabilitation.

## Education and support

Education and support are an integral part of management from the time of diagnosis and throughout the disease course (Table 11.9). Individuals should be provided with information regarding multiple sclerosis, and specific information relating to their disease type and its management. This will facilitate their active participation in their own management. Multiple sclerosis specialist nurses have an essential role in this in the United Kingdom, and can provide individualised educational and supportive sessions. Health care professionals work closely with voluntary organisations to provide educational materials such as information booklets, teaching manuals to explain the biology of multiple sclerosis and online decision-making aids for choosing disease-modifying therapies. The Multiple Sclerosis Society in the United Kingdom also coordinates educational programmes, such as Getting to Grips courses for newly diagnosed individuals.

## Management of acute relapses

Management of acute relapses should be comprehensive, addressing all aspects of the relapse. Multi-disciplinary input may be required, particularly if recovery is less than complete. The first step is to assess whether new or increased symptoms are caused by a relapse of multiple sclerosis.

## Assessment

In the event of new or increased symptoms, people with multiple sclerosis should be able to identify and contact a health care professional who can advise or direct them to the most appropriate local service. A formal assessment should be made to diagnose a relapse as early as possible. The possibility of another medical cause for the increase in symptoms must be considered. It is important that an infective cause such as a urinary tract infection, which can be otherwise clinically silent, is excluded. The possibility of dual neurological pathology (e.g. a compressive lesion mimicking a spinal cord relapse) should also be considered. If the new symptoms are thought to be unrelated to multiple sclerosis, access to the appropriate service and treatment should be facilitated.

It is essential that the service provided is flexible and responsive to the unpredictable and acute needs of people experiencing a

**Table 11.8** Recommendations for comprehensive review (NICE 2014).

---

Ensure all people with MS have a comprehensive review of all aspects of their care at least once a year

Ensure the comprehensive review is carried out by healthcare professionals with expertise in MS and its complications. Involve different healthcare professionals with expertise in specific areas of the review if needed

Tailor the comprehensive review to the needs of the person with MS assessing:

- MS symptoms
  - mobility and balance including falls
  - need for mobility aids including wheelchair assessment
  - use of arms and hands
  - muscle spasms and stiffness
  - tremor
  - bladder, bowel and sexual function
  - sensory symptoms and pain
  - speech and swallowing
  - vision
  - cognitive symptoms
  - fatigue
  - depression and anxiety
  - sleep
  - respiratory function
- MS disease course
  - relapses in last year.
- General health
  - weight
  - smoking, alcohol and recreational drugs
  - exercise
  - access to routine health screening and contraception
  - care of other chronic conditions
- Social activity and participation
  - family and social circumstances
  - driving and access to transport
  - employment
  - access to daily activities and leisure.
- Care and carers
  - personal care needs
  - social care needs
  - access to adaptations and equipment at home

Refer any issues identified during the comprehensive review of the person with MS to members of the MS multidisciplinary team and other appropriate teams so that they can be managed

Ensure people with MS are offered a medication review

Ensure people with MS have their bone health regularly assessed and reviewed

Ensure people with MS and severely reduced mobility are regularly assessed and reviewed for risk of contractures

Check people with MS and severely reduced mobility at every contact for areas at risk of pressure ulcers

Discuss the care provided by carers and care workers as part of the person's care plan. Ensure carers know about their right to a local authority carer's assessment and how to apply for one

Refer people with MS to palliative care services for symptom control and for end of life care when appropriate

---

**Table 11.9** Providing information and support for multiple sclerosis (MS) (NICE 2014).**Information at the time of diagnosis**

The consultant neurologist should ensure that people with MS and, with their agreement their family members or carers, are offered oral and written information at the time of diagnosis. This should include, but not be limited to, information about:

- What MS is
- Treatments, including disease-modifying therapies
- Symptom management
- How support groups, local services, social services and national charities are organised and how to get in touch with them
- Legal requirements such as notifying the Driver and Vehicle Licensing Agency and legal rights including social care, employment rights and benefits

Discuss with the person with MS and their family members or carers whether they have social care needs and if so refer them to social services for assessment. Ensure the needs of people with MS are addressed

Offer the person with MS a face-to-face follow-up appointment with a healthcare professional with expertise in MS to take place within 6 weeks of diagnosis

**Ongoing information and support**

Review information, support and social care needs regularly. Continue to offer information and support to people with MS or their family members or carers even if this has been declined previously

Ensure people with MS and their family members or carers have a management plan that includes who to contact if their symptoms change significantly

Explain to people with MS that the possible causes of symptom changes include:

- Another illness such as an infection
- Further relapse
- Change of disease status (e.g. progression)

Talk to people with MS and their family members or carers about the possibility that the condition might lead to cognitive problems

When appropriate, explain to the person with MS (and their family members or carers if the person wishes) about advance care planning and power of attorney

---

relapse. The demands on general neurology and medical services often make this difficult. One model to address this issue is to set up a specialist relapse clinic to assess and manage acute episodes. A dedicated telephone line to the specialist service can also facilitate direct access.

**Treatment**

If a relapse has been diagnosed, treatment to hasten the recovery from the relapse should be considered. Steroid therapy is the only recommended drug treatment. NICE guidelines recommend that steroid therapy should be offered if the relapse affects ability to perform routine tasks.

**Steroid therapy** It has been established that steroid therapy can accelerate the recovery from a relapse, although a long-term benefit has not been proven. Its precise mode of action is uncertain but there are

several potential mechanisms, including reduction of oedema, stabilisation of the blood–brain barrier, reduction of pro-inflammatory cytokines and induction of T-cell apoptosis. Efficacy was suggested in early studies with intramuscular adrenocorticotrophic hormone (ACTH), but this practice has been discontinued. Intravenous methylprednisolone, which is now widely used, has been proven to hasten recovery, and to be as effective as ACTH. The comparative efficacy of intravenous and oral steroid therapy has been more contentious. The largest study to address this issue, the Optic Neuritis Treatment Trial, was a randomised placebo controlled study in acute optic neuritis that compared intravenous methylprednisolone, followed by oral prednisone, with oral prednisone alone. Visual recovery was accelerated in the intravenous group, but not in the lower dose oral group. No benefit in long-term visual outcome was seen in either group. An increased rate of new attacks of optic neuritis was seen in the oral prednisone group, and a reduction in the rate of development of multiple sclerosis was reported in the intravenous group at 2 years. However, the beneficial effect of treatment on the development of multiple sclerosis was not sustained at follow-up of 3 years and longer. More recently, a large randomised controlled non-inferiority study showed that oral high dose methylprednisolone was not inferior in improving disability scores than intravenous methylprednisolone for acute relapses of multiple sclerosis and had a similar safety profile.

NICE guidelines recommend oral methylprednisolone 0.5 g/day for 5 days for the treatment of relapse of multiple sclerosis. Intravenous methylprednisolone 1 g/day for 3–5 days should be considered as an alternative for people in whom oral steroids have failed or not been tolerated, or who need hospital admission for a severe relapse or monitoring of conditions such as diabetes or depression.

Steroid therapy can have side effects and, although their incidence is low, the potential risks as well as benefits should be discussed with the individual. Adverse events from intravenous methylprednisolone in the short-term include taste disturbance, facial flushing, insomnia, psychiatric disturbance, exacerbation of acne and transient hypertension and hyperglycaemia. Steroid therapy can exacerbate infection, which should be excluded before treatment, and urinalysis to rule out urinary tract infection should be performed routinely. Urinary dipstick testing is a rapid screening technique with strong negative predictive value; if infection is suggested, co-treatment with antibiotics may be considered to avoid delay in steroid therapy while the result of urine culture is awaited. Gastrointestinal disturbance, such as peptic ulceration, can be exacerbated. Therefore it is prudent to screen for a history of any other risk factors and cover with a gastric acid inhibitor may be required. Long-term complications are rare with intermittent intravenous steroid therapy, but prolonged courses of oral steroids are more likely to assume the risks of long-term therapy. The relationship between pulsed steroids and osteoporosis has not been established, although osteoporosis can be seen as a result of impaired mobility. Serious complications, such as avascular necrosis, rarely occur.

**Other therapies** No other immunomodulating therapies are routinely recommended for the treatment of acute relapses. Placebo controlled trials of intravenous immunoglobulin (IVIG) in addition to intravenous methylprednisolone have demonstrated no significant benefit over methylprednisolone alone. A small randomised controlled trial of plasma exchange in patients with acute severe neurological deficits caused by demyelinating diseases, which had failed to respond to steroid therapy, showed improvement in some patients. Plasma exchange can be considered

in the event of a catastrophic acute relapse that has not responded to steroid therapy.

**Supportive measures** Management of acute relapses should be comprehensive, addressing all consequences of the relapse and not just limited to steroid therapy. Practical supportive measures, such as the provision of care or equipment, may be required. Specific treatment for new symptoms is sometimes necessary, but if the relapse is responding to steroids or improving spontaneously the duration of symptoms may be too short to warrant treatment. Symptomatic treatment can be required for symptoms that persist, or that are distressing even for a short period such as trigeminal neuralgia.

Multi-disciplinary input from neurological rehabilitation services may facilitate the functional recovery from a relapse, and such input should run in parallel with any medical treatment. A randomised controlled trial showed that a multi-disciplinary rehabilitation approach was superior to a standard ward routine in people with multiple sclerosis receiving pulsed intravenous steroid therapy. Inpatient rehabilitation can also be beneficial, particularly in people with incomplete recovery from relapses with moderate to severe disability.

### Disease-modifying therapy

Developing strategies to modify the course of multiple sclerosis requires an understanding of the underlying pathogenic mechanisms. Although these mechanisms are not fully understood, it is evident that inflammatory demyelination predominates in early disease and that neuroaxonal loss advances over time. Possible therapeutic strategies include:

- Immunomodulation to prevent or reduce inflammatory relapses
- Neuroprotection to prevent or slow disease progression
- Remyelination and repair to reverse neurological deficit and prevent disease progression.

Immunomodulation can be most useful in early disease. Neuroprotection and remyelination are plausible strategies for later disease, but can also be useful in early disease. The currently available therapies all seem to work through immunomodulation and the reduction of relapse activity. No therapies have been proven to be effective for relapse independent progression or to have a primary neuroprotective or reparative mechanism.

### Currently available therapies

In the last two decades, a number of therapies have been shown to reduce relapse activity in multiple sclerosis. This is a major step forward in the management of multiple sclerosis but it is not without controversy as, although beneficial effects on relapses and disease progression can be seen in the short-term, the long-term effects on progression of disease and disability remain unproven. Furthermore, the treatments are expensive and their cost-effectiveness continues to be a cause for debate.

Interferon  $\beta$  and glatiramer acetate have been conventional first line disease-modifying therapy in relapsing remitting multiple sclerosis for more than a decade. There has also been a role for mitoxantrone as induction or rescue therapy in patients with rapidly progressive relapsing remitting or secondary progressive multiple sclerosis. However, alternative management strategies are now evolving as therapies with superior efficacy have become available. The licensing of the monoclonal antibody natalizumab marked a new development in disease modification of relapsing remitting multiple sclerosis. Natalizumab and the more recently licensed

alemtuzumab are significantly more effective than conventional disease-modifying therapy, but this is tempered by life-threatening adverse events. Although this shift to more aggressive management of multiple sclerosis may be daunting, it is bringing the management approach in line with that of other immune-mediated diseases such as rheumatoid arthritis. The licensing of fingolimod has been another landmark development, being the first oral disease-modifying therapy, soon followed by teriflunomide and dimethyl fumarate.

### Interferon $\beta$ and glatiramer acetate

Natural interferon  $\beta$  is a glycosylated protein, synthesised by fibroblasts, that has antiviral, immunomodulatory and antineoplastic effects. The original rationale for its use in multiple sclerosis was based on the hypothesis that the condition is triggered by an underlying viral infection. Although this has not been established as the mechanism of benefit, interferon  $\beta$  was shown to be effective in reducing relapses in multiple sclerosis. The precise mechanism of action of interferon  $\beta$  in multiple sclerosis is unclear and it is likely to involve several different effects that modify the immune response. Relevant immunological effects include improvement of suppressor T-cell function, increased production of anti-inflammatory cytokines and neurotrophic and gliotrophic factors, and antagonism of the effects of interferon  $\gamma$ . Interferon  $\beta$  reduces T-cell migration by inhibition of matrix metalloproteinases and down-regulation of adhesion molecules, which can inhibit T-cell migration across the blood–brain barrier. Interferon  $\beta$  also has a direct effect on plasma cells, modulating IgG synthesis, which can stimulate natural interferon production by lymphocytes and inhibit T-cell proliferation.

There are three recombinant preparations of interferon  $\beta$  available: interferon  $\beta$ -1b, which is non-glycosylated and differs slightly in amino acid sequence from natural interferon  $\beta$ , and two preparations of interferon  $\beta$ -1a, which are glycosylated and identical in sequence to interferon  $\beta$ . They have all been investigated in randomised placebo controlled Phase III trials in relapsing remitting and secondary progressive disease and in clinically isolated syndromes.

### Interferon $\beta$ -1b

A randomised controlled trial of subcutaneous interferon  $\beta$ -1b (250  $\mu$ g on alternate days) in relapsing remitting multiple sclerosis was the first Phase III trial of interferon  $\beta$  to be completed. There was a 34% reduction in annual relapse rate over 2 years, a reduction in relapse severity and an increased proportion of subjects remaining relapse free on treatment. On MRI, there was an 80% reduction in disease activity, as measured by number of active scans and new lesions, and a reduction in lesion load. Interferon  $\beta$ -1b has also been shown to delay conversion to multiple sclerosis and development of disability in subjects with clinically isolated syndromes.

The effect of interferon  $\beta$ -1b in secondary progressive multiple sclerosis has been less clear. A European Phase III trial reported a delay in the progression of disability of 9–12 months over 2–3 years in treated subjects both with and without superimposed relapses. MRI showed a reduction in lesion load and new lesion activity. The clinical results were not reproduced in a North American trial which showed no effect on disease progression, although positive effects were seen on relapse rate and MRI activity. A post hoc analysis attributed this discrepancy to the North American cohort being less clinically active and having fewer relapses.

### Intramuscular interferon $\beta$ -1a

A Phase III trial of intramuscular interferon  $\beta$ -1a (30  $\mu$ g once weekly) in relapsing remitting multiple sclerosis demonstrated a reduction of relapse rate by one-third in the treated group. The trial was terminated early and in the smaller group of patients who had completed the 2 years of follow-up the reduction in relapse rate was 18%. Time to sustained disability progression was significantly greater in treated subjects. A reduction in enhancing lesions was seen on MRI. Intramuscular interferon  $\beta$ -1a has also been shown to delay conversion to multiple sclerosis in clinically isolated syndromes.

Intramuscular interferon  $\beta$ -1a (60  $\mu$ g once weekly) had limited clinical effect in secondary progressive multiple sclerosis in a Phase III trial. A favourable effect was seen on one measure of disability progression, the Multiple Sclerosis Functional Composite, but this was largely because of effects on upper limb rather than locomotor function, and no effect was seen on the EDSS. There was a reduction in relapse rate and MRI lesion activity in the treated group.

### Subcutaneous interferon $\beta$ -1a

A Phase III trial of subcutaneous interferon  $\beta$ -1a (22  $\mu$ g or 44  $\mu$ g three times weekly) in relapsing remitting multiple sclerosis demonstrated a reduction in relapse rate by 27% in the low-dose and 33% in the high-dose groups over 2 years. Progression of disability was delayed in both treatment arms, with greater delay in the higher dose group. A reduction in active lesions and in lesion load was seen on MRI. Subcutaneous interferon  $\beta$ -1a (22  $\mu$ g once weekly) has also been shown to delay conversion to multiple sclerosis in subjects with clinically isolated syndromes.

In secondary progressive multiple sclerosis, a Phase III trial showed no effect of subcutaneous interferon  $\beta$ -1a on progression of disability, although positive effects were seen on relapses and MRI activity.

**Side effects** The most common systemic side effect of interferon  $\beta$  is a transient post-dose flu-like reaction with symptoms such as fever, myalgia and headache. These symptoms tend to improve over time and are ameliorated by symptomatic treatment. Injection site reactions are common with the subcutaneous preparations. Abnormalities of liver enzymes and the blood count sometimes occur; although not commonly clinically significant, and blood parameters should be monitored. Rarely, an autoimmune hepatitis or thyroid disease can develop and nephrotic syndrome has been reported. An association with depression has been reported, and interferon  $\beta$  can be contraindicated if there is a history of severe depression. Monoclonal gammopathy should be excluded prior to treatment as systemic capillary leak syndrome has been associated with the administration of interferon  $\beta$ .

**Neutralising antibodies** Treatment with interferon  $\beta$  is associated with the production of neutralising antibodies (NAbs), which can reduce or abolish the bioavailability and efficacy of interferon  $\beta$ . The incidence of NAbs in the pivotal relapsing remitting studies at 2 years was 42% with interferon  $\beta$ -1b, 24% (22  $\mu$ g) and 13% (44  $\mu$ g) with subcutaneous interferon  $\beta$ -1a and 22% with intramuscular interferon  $\beta$ -1a. Subsequent studies suggest a lower incidence of NAbs for intramuscular interferon  $\beta$ -1a. The presence of NAbs has been shown to correlate with reduced clinical, MRI and biological markers of therapeutic efficacy. NAbs cross-react with all preparations of interferon  $\beta$  and so the effects cannot be avoided by

switching preparation. Guidelines for NAb testing have been suggested but they are not universally accepted and the role of NAb testing in routine clinical practice remains unclear. NABs sometimes disappear with follow-up, but a persistent and high titre is more likely to be associated with loss of efficacy.

### PEGylated interferon $\beta$

Conjugation of polyethylene glycol (PEG) to interferon  $\beta$  is a possible approach to reduce the frequency of dosing and side effects and to optimise the efficacy of interferon  $\beta$ . Several PEGylated preparations of interferon  $\beta$  are in development. A Phase III trial of PEGylated interferon  $\beta$ -1a reported a 35% reduction in relapse rate with a 2-weekly dosing regimen, and this preparation has been licensed.

### Glatiramer acetate

Glatiramer acetate is a synthetic mixture of polypeptides containing four amino acids. Its exact mechanism of action is not clear but can involve induction of regulatory T cells, MHC blocking and T-cell receptor antagonism. It has also been suggested that its effects can be mediated by brain-derived neurotrophic factor. A randomised placebo controlled Phase III trial of subcutaneous glatiramer acetate (20 mg/day) in relapsing remitting multiple sclerosis demonstrated a 29% reduction in relapse rate in the treated group. Subsequently, a randomised controlled MRI study reported a reduction in enhancing lesions and accumulation of lesion load as well as a reduction in relapse rate.

Glatiramer acetate has been shown to delay conversion to multiple sclerosis in subjects with CIS. No placebo controlled trials of glatiramer acetate in secondary progressive multiple sclerosis have been reported; a Phase III trial in primary progressive multiple sclerosis was negative. A randomised controlled study of oral glatiramer acetate in relapsing remitting multiple sclerosis was negative.

Glatiramer acetate has a favourable side effect profile. A transient acute post-dose reaction with shortness of breath and palpitations can occur. Erythema and lipoatrophy can occur at the injection site, and lymphadenopathy has been reported.

A placebo-controlled trial of glatiramer acetate 40 mg three times a week showed a 34% reduction in relapses. In an open label comparative study with the standard dose, glatiramer acetate 40 mg three times a week had a significantly lower rate of injection-related adverse events and was perceived to be more convenient.

**Comparative studies** Comparative studies of different interferon  $\beta$  preparations have been carried out. A prospective study of subcutaneous interferon  $\beta$ -1b and intramuscular interferon  $\beta$ -1a found interferon  $\beta$ -1b to have a superior effect on relapses, disease progression and the development of new lesions on MRI. Subcutaneous interferon  $\beta$ -1a (44  $\mu$ g three times a week) has also been reported to have greater efficacy, as evidenced on relapses and MRI lesion activity, than intramuscular interferon  $\beta$ 1a (30  $\mu$ g once weekly). This seems to indicate that the effects of interferon  $\beta$  are dose-related. This is supported by a study of low-dose subcutaneous interferon  $\beta$ -1a (22 or 44  $\mu$ g once weekly) in relapsing remitting multiple sclerosis which showed no significant clinical effect.

Prospective studies comparing high dose subcutaneous interferons  $\beta$ -1a and  $\beta$ -1b with glatiramer acetate showed no significant difference in relapse activity.

In summary, interferon  $\beta$  and glatiramer acetate have been proven to reduce relapse rate in relapsing remitting multiple

sclerosis by approximately one-third over 2–3 years, and to delay conversion to clinically definite multiple sclerosis in clinically isolated syndromes. Interferon  $\beta$  can reduce accumulation of disability through prevention of relapses but the effect appears modest. Conflicting results have been found in secondary progressive multiple sclerosis, but interferon  $\beta$  does not seem to have a significant impact on progression unrelated to relapses. Open-label follow-up studies have suggested that the benefit from treatment may be sustained, but no controlled studies are available to answer the question of whether interferon  $\beta$  and glatiramer acetate improve prognosis in the long term. Axonal loss, the pathological correlate of disability, can occur from first presentation and so it is suggested that early treatment can have a long-term protective effect but this remains unproven. Currently, there is insufficient evidence to draw conclusions as to the long-term efficacy of interferon  $\beta$  and glatiramer acetate therapy.

**Prescribing guidelines** All the interferon  $\beta$  formulations and glatiramer acetate are licensed in the United Kingdom for ambulatory individuals with relapsing remitting multiple sclerosis. Interferon  $\beta$ -1b is also licensed for secondary progressive multiple sclerosis with superimposed relapses. Prescribing in the UK National Health Service (NHS) is subject to strict clinical guidelines, produced by the Association of British Neurologists (ABN), and funding of treatment is governed by the Department of Health's Risk Sharing Scheme. Treatment with interferon  $\beta$  and glatiramer acetate is recommended in subjects with active multiple sclerosis, which is normally indicated by two relapses in 2 years. Updated guidelines also allow for treatment of clinically isolated syndrome when MRI evidence predicts a high likelihood of recurrent episodes.

### Natalizumab

Natalizumab is the first monoclonal antibody to be licensed for use in multiple sclerosis. Monoclonal antibodies are a new class of biological agent designed to interact with specific target antigens and thus have highly selective effects on the immune system. Natalizumab is a recombinant humanised monoclonal antibody directed against  $\alpha$ 4-integrin, an adhesion molecule that is primarily expressed on T cells. Natalizumab blocks the adhesion of activated T cells with the vascular cell adhesion molecule, expressed on the luminal surface of vascular epithelium, and so prevents activated cells crossing the blood–brain barrier.

In a randomised placebo controlled Phase III trial over 2 years, intravenous natalizumab (300 mg monthly) reduced relapse frequency by 68%, delayed disease progression by 42% and reduced enhancing lesions by 92%. Natalizumab was generally well tolerated, although 4% of subjects developed a hypersensitivity reaction. Other side effects included fatigue and headache. Persistent anti-natalizumab antibodies developed in 6% of subjects and were associated with a decrease in efficacy. A randomised controlled Phase III trial of combination therapy of natalizumab and intramuscular interferon  $\beta$ -1a found superior efficacy compared with interferon  $\beta$ -1a monotherapy. However, two subjects on combination therapy developed progressive multifocal leukoencephalopathy (PML) and one subject died, and another fatal case of PML occurred during natalizumab treatment for Crohn's disease.

A recent randomised placebo-controlled study has shown no benefit from natalizumab in secondary progressive multiple sclerosis.

**Natalizumab-related PML** Post-marketing surveillance has revealed further cases of PML occurring on natalizumab monotherapy. As of September 2015, over 140 000 subjects have received natalizumab with 585 confirmed cases of treatment-related PML and an estimated overall risk of 4.03/1000 patients. The following risk factors have been identified to be associated with an increased risk of PML:

- **Presence of anti-JCV antibodies:** JC virus must be present in an individual for PML to develop. A reliable and validated assay to detect anti-JCV antibodies is now available and can be used to identify individuals carrying the JC virus. The risk of developing PML is significantly increased in patients who are anti-JCV antibody positive compared to antibody-negative patients, although the absolute risk is small. The risk in patients who are antibody negative is not zero as the assay has a false negative rate of approximately 2.5%, and seroconversion can occur. The rate of seroconversion appears to be higher in patients on natalizumab and has been reported as 16% over 18 months.
- **Duration of treatment:** the risk of PML is increased in patients treated for more than 2 years. There is limited experience in patients who have received more than 4 years of treatment and so the risk with longer duration of treatment is not yet clear.
- **Prior immunosuppressant use:** the risk of PML is increased in patients with a history of prior treatment with an immunosuppressant (excluding corticosteroids, interferon  $\beta$  and glatiramer acetate).

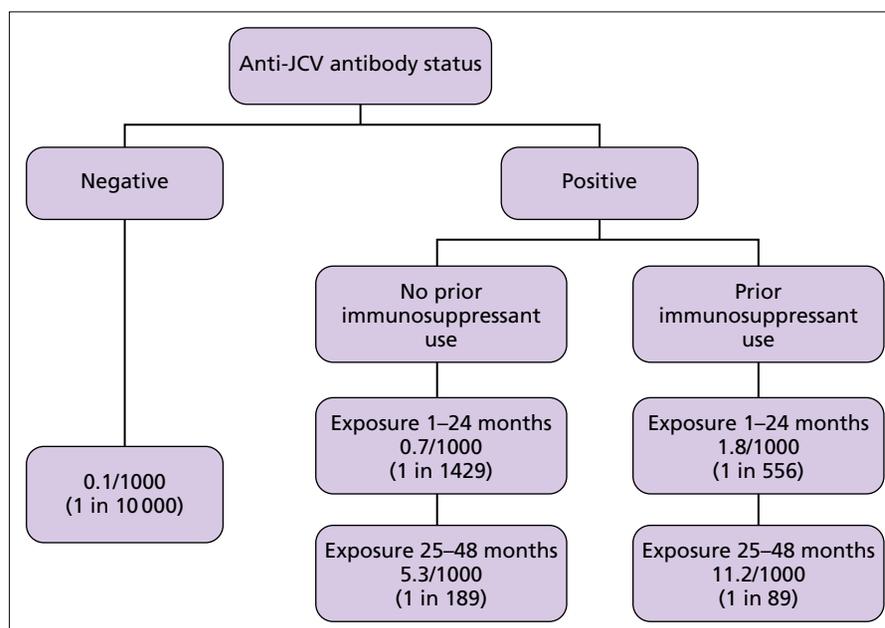

Analysis of these risk factors has led to the development of an algorithm to stratify risk (Figure 11.9). The risk of PML is lowest in patients who are anti-JCV antibody negative, with a currently estimated risk of 0.1/1000 patients. The risk is highest in patients who are anti-JCV antibody positive, have a history of prior immunosuppressant therapy and a treatment duration of >24 months,

with an estimated risk of 11.2/1000 patients. The anti-JCV antibody index is a quantitative measure which can allow further stratification of an individual's risk of PML.

PML can be fatal (in ~23% of cases) or cause severe disability. Early diagnosis of PML appears to improve outcome, and so vigilance to the symptoms and signs of PML is vital. Management consists of discontinuation of natalizumab. Plasma exchange to accelerate the removal of natalizumab has been used in the majority of cases. Immune reconstitution inflammatory syndrome (IRIS) occurs frequently following the removal of natalizumab, within days to several weeks, and can also cause disability or be fatal. IRIS is usually treated empirically with high dose corticosteroids.

**Other side effects** Hypersensitivity reactions, including serious systemic reactions, can occur, usually during or up to 1 hour after the infusion and patients should be observed over this time. Reactions can occur with any infusion, but are greatest with early infusions and with re-exposure after an extended period without treatment. Hypersensitivity reaction is a permanent contraindication to further treatment. Cases of liver injury have been reported and liver function should be monitored. No increased incidence in malignancy has been seen to date, and reports of skin cancer appear to be in keeping with background incidence.

**Prescribing guidelines** In view of the risk of PML, the licence for natalizumab has been restricted. It is licensed in Europe for individuals who have failed to respond to interferon  $\beta$  or those with rapidly evolving severe relapsing remitting disease, defined as at least two disabling relapses in 1 year and evidence of active disease on MRI (Table 11.10). Prescribing in the United Kingdom is subject to NICE guidelines and natalizumab is only recommended for individuals with rapidly evolving severe relapsing remitting multiple sclerosis. Patients should be informed of the risk of PML (and IRIS)

**Figure 11.9** Risk stratification tool: risk of PML in patients exposed to natalizumab stratified according to presence of anti-JCV antibodies, prior immunosuppressant use and treatment duration. Source: Biogen Idec Medical Information Service 2014.

**Table 11.10** Definition of rapidly evolving and severe relapsing remitting multiple sclerosis (NICE 2007).

Two or more disabling relapses in 1 year
and
One or more gadolinium-enhancing lesions on brain MRI
or
A significant increase in T2 lesion load compared with a previous recent MRI

with natalizumab, and that this risk increases after 2 years of treatment, and to be aware of the symptoms of PML and the need to report symptoms urgently. Informed consent to treatment should be obtained at initiation and if treatment is to be continued after 2 years. It is recommended that patients should be monitored with MRI within 3 months prior to starting natalizumab, annually during treatment, and if there any symptoms possibly indicative of PML. A wash-out period following previous immunosuppression is recommended.

Although there are currently no national guidelines incorporating risk stratification, this can be used to facilitate treatment decision-making in clinical practice. Testing for anti-JCV antibody should be offered prior to starting therapy, and re-testing of antibody negative patients every 6 months is suggested. It is also suggested that the frequency of MRI monitoring should be increased if anti-JCV antibody positive to a minimum of 6-monthly, and more frequently if the antibody index is high.

### Fingolimod

Fingolimod is an oral immunomodulatory agent derived from the fungal metabolite myriocin. It is phosphorylated *in vivo* and acts as an agonist of the sphingosine 1-phosphate receptor-1 on lymphocytes. This results in internalisation of the receptor, failure of lymphocyte egress and sequestration of lymphocytes in secondary lymphoid tissues, and so causes a reversible redistribution of lymphocytes. This reduces the infiltration of pathogenic lymphocytes into the CNS. Fingolimod crosses the blood–brain barrier and it has been suggested that it also can act via interaction with sphingosine 1-phosphate receptors on neural cells.

In a randomised placebo controlled Phase III trial of two doses of fingolimod (0.5 and 1.25 mg once daily) over 2 years, annualised relapse rate was significantly reduced by 54% with fingolimod 0.5 mg and 60% with 1.25 mg. Disability progression was reduced by 30% and 32% with fingolimod 0.5 and 1.25 mg, respectively. Significant effects were also seen on MRI activity with an approximately 75% reduction in new lesions and a 35% reduction in rate of brain volume loss. A randomised controlled Phase III trial over 1 year comparing fingolimod 0.5 and 1.25 mg with intramuscular interferon  $\beta$ -1a demonstrated a significantly reduced relapse rate on fingolimod, with the greatest reduction of 52% in the 0.5 mg group. Two fatal viral infections (disseminated primary varicella zoster and herpes simplex encephalitis) occurred in the 1.25 mg group. Other adverse events in the Phase III studies included transient bradyarrhythmias on initiation of treatment, non-fatal herpes virus infections, macula oedema, mild hypertension, elevated liver enzyme levels and lymphopenia. Skin cancers did occur, but the incidence of malignancies was not significantly raised. Post licensing, a few cases of serious viral infections, including PML, have been reported.

**Prescribing guidelines** Fingolimod (0.5 mg/day) is licensed in Europe for individuals with high disease activity despite treatment with interferon  $\beta$  or with rapidly evolving severe relapsing remitting multiple sclerosis. In the United Kingdom, NICE has recommended its use only for patients who have an unchanged or increased relapse rate or ongoing severe relapses compared with the previous year despite treatment with interferon  $\beta$ . The manufacturer also has to provide fingolimod with a discount as part of the UK NHS patient access scheme.

Since initial authorisation, an unexplained death in a patient within 24 hours of taking fingolimod has led to further regulatory advice on cardiovascular safety. Fingolimod is not recommended for patients with a history of cardiovascular or cerebrovascular disease or who take heart-rate lowering medication. On initiation of treatment, the electrocardiogram should be monitored before receiving the first dose and for at least 6 hours after. Vaccination against varicella zoster virus is recommended in antibody-negative patients prior to treatment. Monitoring of full blood count and liver function on treatment, and ophthalmological review for macula oedema are also recommended.

### Teriflunomide

Teriflunomide is an oral agent that reversibly inhibits dihydroorotate dehydrogenase, an essential enzyme involved in pyrimidine synthesis, and decreases T and B-cell proliferation and function. Teriflunomide is the active metabolite of leflunomide which has been used in rheumatoid arthritis.

In a randomised placebo controlled Phase III trial of two doses of teriflunomide in relapsing multiple sclerosis with or without progression, annualised relapse rates were reduced by 31.2% in the 7 mg group and 31.5% in the 14 mg group. The risk of disability progression was reduced by 23.7% in the 7 mg group and 29.8% in the 14 mg group. An 80% reduction in enhancing lesions was seen on the higher dose, and a 25% reduction in brain atrophy was seen with both doses. The most common adverse events included diarrhoea, nausea, hair thinning and elevated liver enzyme levels. No serious opportunistic infections or increased incidence of malignancy were seen. In another placebo controlled Phase III trial, teriflunomide 14 mg reduced relapse rate by 36.3% and reduced disability progression by 31.5%, whereas teriflunomide 7 mg reduced relapse rate by 22.3% and showed no significant effect on disability. A randomised controlled Phase III trial of teriflunomide versus high-dose subcutaneous interferon  $\beta$ -1a showed no statistical superiority of either drug, but teriflunomide was better tolerated. The most common adverse events associated with teriflunomide in these studies included diarrhoea, nausea, hair thinning, headache, elevated liver enzyme levels and neutropenia. No serious opportunistic infections or increased incidence of malignancy were seen. Teriflunomide has also been shown to delay conversion to multiple sclerosis in clinically isolated syndrome.

**Prescribing guidelines** Teriflunomide is recommended for treating adults with active relapsing remitting multiple sclerosis, only if they do not have highly active or rapidly evolving severe relapsing remitting multiple sclerosis. The recommended dose is 14 mg once daily. Liver enzymes should be assessed before initiation of therapy, every 2 weeks during the first 6 months of treatment, and every 8 weeks thereafter or as clinically indicated. There is a serious risk of teratogenicity and a long washout period (2 years) or an accelerated elimination procedure is needed for women who wish to conceive having stopped treatment.

### Alemtuzumab

Alemtuzumab is a humanised monoclonal antibody directed against CD52, a cell surface antigen expressed on >95% of T and B lymphocytes, as well as monocytes and macrophages, but not stem cells. Alemtuzumab causes prolonged lymphocyte depletion, including the autoreactive T cells that have a role in the pathogenesis of multiple sclerosis, while there is a reconstitution of B-cell numbers over several months. A small study in secondary progressive multiple sclerosis demonstrated a dramatic reduction in relapse rate and enhancing lesions but about half of the subjects still experienced progressive disability and increasing brain atrophy. Initial studies in relapsing remitting multiple sclerosis similarly showed a dramatic reduction in frequency of relapses and MRI activity, but there was also a favourable effect on disease progression. Therefore, it has been suggested that therapy may be most effective in early disease.

In a randomised controlled Phase III trial in subjects with previously untreated relapsing remitting multiple sclerosis over 2 years, intravenous alemtuzumab (12 mg/day for 5 days at baseline and 3 days at 12 months) was compared with high dose subcutaneous interferon  $\beta$ -1a. Alemtuzumab reduced relapse rate by 54.9% but, unlike the preliminary studies, no significant effect on disability progression was seen. A reduction in the proportion of subjects with enhancing and new lesions was seen, and alemtuzumab slowed brain volume loss by approximately 40%. In a Phase III trial over 2 years of alemtuzumab versus high dose subcutaneous interferon  $\beta$ -1a in subjects who had relapsed on interferon  $\beta$  or glatiramer acetate, alemtuzumab reduced relapse rate by 49.4% and reduced disease progression by 42%.

Infusion of alemtuzumab can cause an acute inflammatory response with pyrexia, malaise and rash, and can transiently exacerbate pre-existing neurological symptoms. Therefore, pretreatment with corticosteroids is recommended. Other adverse effects include infections and autoimmune complications. Infections have been predominantly of mild to moderate severity and include cutaneous herpes infections. Autoimmune thyroid disorders have been reported in one-third of subjects. There is an increased incidence of immune-mediated thrombocytopenia purpura, which can be life-threatening, and nephropathies, including antglomerular basement membrane disease. An association with thyroid papillary carcinoma has been reported.

**Prescribing guidelines** Alemtuzumab is licensed in Europe for the treatment of adults with relapsing remitting multiple sclerosis with active disease defined by clinical or imaging features. The recommended dosage of alemtuzumab is 12 mg/day administered by intravenous infusion for two treatment courses. The initial treatment course lasts 5 consecutive days followed 12 months later by the second treatment course of 3 consecutive days. Patients should be pre-treated with corticosteroids immediately prior to administration, and given oral prophylaxis for herpes infection. Regular monitoring for early signs of autoimmune disease should be continued for 48 months following the last treatment course.

### Dimethyl fumarate

Dimethyl fumarate is an oral fumaric acid ester. Fumaric acid esters have been used to treat psoriasis for several years and there has been evidence to suggest immunomodulatory effects. The mechanism of action of dimethyl fumarate has been proposed to be mediated through activation of the transcription factor Nrf2 antioxidant response pathway and experimental data have suggested anti-inflammatory and neuroprotective effects.

In a randomised placebo controlled Phase III trial of two doses of dimethyl fumarate (240 mg twice daily and 240 mg three times daily) in relapsing remitting multiple sclerosis over 2 years, a significant treatment effect was seen on the primary end-point of proportion of patients who had a relapse by 2 years. Annualised relapse rates were reduced by 53% in the twice daily dimethyl fumarate group and by 48% in the three times daily group, and the risk of disability progression was reduced by 38% and 34%, respectively. The number of new or enlarging lesions on MRI was reduced by 85% in the twice daily group and by 74% in the three times daily group. A randomised placebo controlled Phase III trial with an additional reference comparator group randomised to glatiramer acetate showed a similar treatment effect on relapses, with a 44% reduction in annualised relapse rate in the twice daily dimethyl fumarate group and 51% reduction in the three times daily group. However, no significant effect on disability progression was seen.

Previous experience of fumaric acid esters in the treatment of psoriasis has indicated a good safety profile with the main side effects being flushing and gastrointestinal symptoms, but PML has occurred rarely. In the Phase III trials, adverse events associated with dimethyl fumarate included flushing, gastrointestinal events and decreased lymphocyte counts. There were no opportunistic infections and no increased incidence of malignancy. Post licensing, a few cases of PML have been reported.

**Prescribing guidelines** Dimethyl fumarate is recommended for treating adults with active relapsing remitting multiple sclerosis, only if they do not have highly active or rapidly evolving severe relapsing remitting multiple sclerosis. The recommended dose is 120 mg twice daily in the first week of treatment and 240 mg twice daily thereafter. The frequency of flushing and gastrointestinal adverse reactions can be managed by temporarily (up to a month) reducing the dose to 120 mg twice daily.

To summarise the guidance for prescribing of the currently available disease modifying therapies for active relapsing remitting multiple sclerosis in the UK NHS:

- Interferon  $\beta$ , glatiramer acetate, teriflunomide, alemtuzumab and dimethyl fumarate are first line therapies.
- Natalizumab can be used first or second line in rapidly evolving severe disease.
- Fingolimod can be used second line following interferon  $\beta$  failure.

### Initiation of treatment

It is widely accepted that treatment should be started as early as possible in eligible patients. Treatment should be initiated and supervised by a multiple sclerosis specialist neurologist, after careful and informed discussion with the individual and, where available, with nurse specialist support. The optimal strategy to approach treatment is not yet clear. One approach is to start with a less effective but less toxic therapy and, if there is continued disease activity, escalating to a more potent therapy. Alternatively, it may be decided to start the most effective therapy as early as possible. Treatment can now be aimed at not only suppressing clinical disease activity but also MRI activity, with a treatment goal of 'no evidence of disease activity'. The ABN has updated its guidelines for prescribing disease-modifying treatments in 2015 and its recommendations for starting treatment are summarised in Table 11.11. However, there remain considerable uncertainties concerning the appropriate indications for these new agents.

**Table 11.11** ABN recommendations for starting disease-modifying treatment (after Scolding *et al.* 2015).

---

Eligible patients will normally be ambulant (maximum EDSS 6.5). There are no treatments licensed for use during pregnancy

---

The currently licensed disease-modifying treatments divide broadly into two classes:

- 1 Drugs of moderate efficacy (Category 1)
  - Interferon  $\beta$
  - Glatiramer acetate
  - Teriflunomide
  - Dimethyl fumarate
  - Fingolimod
- 2 Drugs of high efficacy (Category 2)
  - Alemtuzumab
  - Natalizumab

**Relapsing–remitting MS**

Patients who have had two or more clinical relapses in the previous 2 years are considered to have ‘active’ disease that warrants consideration of disease-modifying treatments

Most are likely to start treatment with a Category 1 drug

Dimethyl fumarate and fingolimod are likely the more effective drugs in Category 1, with the advantage of being oral agents

**More active relapsing–remitting MS**

Patients can be classified as having more active MS by frequent clinical relapses and/or MRI activity either when untreated or while on a Category 1 drug

Recommend use a Category 2 drug

In individuals who are risk-averse or have infrequent minor relapses, it may be appropriate to change to another Category 1 drug

**Clinically isolated syndrome**

Consider treatment for individuals within 12 months of a significant clinically isolated syndrome, if MRI evidence establishes a diagnosis of MS or predicts a high likelihood of recurrent episodes, and perhaps particularly if CSF examination shows CNS-restricted oligoclonal immunoglobulin bands

**Primary or secondary progressive MS**

None of the current disease-modifying treatments is recommended in non-relapsing secondary progressive MS or in primary progressive MS

Some people with relapsing secondary progressive MS, whose relapses are their main cause of increasing disability, may benefit from disease-modifying treatment

---

### Discontinuation of treatment

Deciding when to discontinue treatment is a difficult area in which evidence is lacking. The ABN recognises the importance of patient choice and that it is not feasible to have mandatory criteria which apply to all. It is recommended to consider stopping disease modifying therapy in the event of significant side effects (but to consider alternative treatment), the development of non-relapsing secondary progressive multiple sclerosis, and pregnancy.

### Emerging therapies

The following therapies have demonstrated efficacy in Phase III trials but are not currently licensed.

**Daclizumab** Daclizumab is a monoclonal antibody targeted against the CD25 antigen, the IL-2 receptor alpha chain, and its effects can be mediated through blocking the expansion of autoreactive T cells or the expansion of regulatory natural killer cells. It is licensed for renal transplantation. In a randomised controlled Phase III trial, subcutaneous daclizumab 150 mg every 4 weeks reduced annualised relapse rate by 45%. The number of new or enlarging lesions was reduced by 54% and gadolinium-enhancing lesions by 65%. There was an increased risk of infection, rash, dermatitis and hepatic enzyme abnormalities.

**Ocrelizumab** Ocrelizumab is a humanised monoclonal antibody targeting CD20. It has previously been investigated in rheumatoid arthritis but study was discontinued because of opportunistic infections. In a placebo controlled Phase II trial of two doses of ocrelizumab (600 and 2000 mg), an 89% and 96% reduction in enhancing lesions and an 80% and 73% reduction in relapse rates were seen in the low and high dose groups, respectively. There was one death on high dose ocrelizumab as a result of systemic inflammatory response syndrome. Two Phase III studies of intravenous ocrelizumab (600 mg every 6 months) versus subcutaneous interferon  $\beta$ -1a in relapsing remitting multiple sclerosis have preliminarily been reported to reduce annualised relapse rates by up to 47%. A Phase III study of ocrelizumab in primary progressive multiple sclerosis has been preliminarily reported to reduce the risk of disability progression by 24%.

### Other therapies

**Mitoxantrone** Mitoxantrone is a synthetic antineoplastic agent of the anthracendione family, with broad cytotoxic and immunomodulatory activity. It intercalates with DNA and inhibits DNA repair, and has immunosuppressive effects on proliferating cells, including T cells, B cells and macrophages. It also reduces pro-inflammatory cytokines and induces apoptosis and necrosis of B lymphocytes and monocytes. Two small trials initially suggested efficacy in relapsing remitting and secondary progressive subjects with very active disease, with a reduction in relapse rate and in enhancing lesions on MRI. A pivotal randomised placebo controlled trial of intravenous mitoxantrone (5 or 12 mg/m<sup>2</sup> 3-monthly) for 2 years in worsening relapsing remitting and secondary progressive multiple sclerosis showed a significant effect of the higher dosage on a multivariate clinical measure, including a reduction in progression of disability and relapses.

Mitoxantrone is a potentially toxic agent. High cumulative doses impair ventricular function and can cause symptomatic cardiac failure. Treatment should not exceed a maximum cumulative dose of 140 mg/m<sup>2</sup> and monitoring of cardiac function is required throughout and following treatment. Mitoxantrone causes bone marrow suppression and leukopenia and the full blood count should be monitored. Treatment-related acute leukaemia occurs rarely; an incidence of 0.8% has been reported, but this may be higher with longer follow-up. Other side effects include nausea and vomiting, and alopecia, although usually mild. Amenorrhoea occurs in approximately one-quarter of women. It is usually transitory, but it is more likely to be permanent in older women, and women should be counselled regarding the possibility of infertility.

In view of the toxicity of mitoxantrone, its use should be restricted to subjects with aggressive and rapidly progressing disease. It is not licensed for multiple sclerosis in the United Kingdom, and there are no national prescribing guidelines. It is usually reserved for people who have failed or are not eligible for existing licensed disease-modifying therapies. In such

circumstances it can be considered if there have been two relapses resulting in residual disability during the previous year, or documented substantial progression in disability over 1 year, and if there are new and enhancing lesions on MRI. However, its use in relapsing remitting multiple sclerosis is now largely superseded by natalizumab and other new agents.

The following non-licensed therapies have been investigated in multiple sclerosis, but are not routinely recommended because of insufficient evidence or side effects.

**Azathioprine** Azathioprine is a derivative of 6-mercaptopurine and acts as an antimetabolite to decrease DNA and RNA synthesis and therefore lymphocyte proliferation. Several randomised controlled trials of azathioprine have been carried out in multiple sclerosis. A meta-analysis confirmed a slight clinical benefit but debated whether this may be outweighed by side effects, which include hepatic and bone marrow toxicity.

**Cladribine** Cladribine (2-chlorodeoxyadenosine) is a purine nucleoside analogue. It acts as a prodrug and is activated through phosphorylation and its accumulation leads to apoptosis. It has a preferential effect on T and B lymphocytes and causes lymphocyte depletion. Initial exploratory study of subcutaneous cladribine had a favourable effect in relapsing remitting multiple sclerosis, but a randomised controlled trial of intravenous cladribine in progressive multiple sclerosis was negative. A placebo controlled Phase III trial of oral cladribine in relapsing remitting multiple sclerosis showed a significant reduction in annualised relapse rate and MRI activity. However, because of concerns about a small number of cancers and effects on the immune system, it has not been licensed in Europe or the United States and the manufacturer has withdrawn cladribine worldwide.

**Cyclophosphamide** Cyclophosphamide is a cytotoxic alkylating agent with immunosuppressant and immunomodulatory properties. It has been suggested that cyclophosphamide can suppress disease activity in patients with progressive disease, particularly with an active inflammatory component. Most studies have been uncontrolled and no benefit has been demonstrated on disability progression in small placebo controlled trials. The use of cyclophosphamide is also limited by side effects including leukopenia, bladder toxicity and increased risk of malignancy. A systematic review did not support its use in clinical practice.

**Haematopoietic stem cell transplantation** Autologous haematopoietic stem cell transplantation (HSCT) has been performed in people with progressive types of multiple sclerosis. No randomised controlled trials have been reported. In uncontrolled retrospective studies it is reported that about 60–70% of patients are progression-free, although study design precludes meaningful interpretation. Mortality was about 5–6% in early studies but in more recent years, as there has been a move away from high-intensity regimens, mortality rates have been about 1–2%.

HSCT is essentially a profoundly potent immunomodulatory therapy and so its use in progressive disease may be too late. A small uncontrolled study using a reduced-intensity regimen in patients with relapsing remitting disease reported at least stabilisation of progression in all patients. A larger multi-centre study is underway.

**Intravenous immunoglobulin** IVIG has been shown to have a beneficial effect on relapse rate and a significant reduction in

enhancing lesions has been reported. IVIG is a blood product that is in scarce supply and so, with other agents of similar efficacy available, it is not widely used. A randomised controlled trial of IVIG in secondary progressive multiple sclerosis was negative.

**Laquinimod** Laquinimod is an oral formulation of quinoline-3-carboxamide. It appears to have immunomodulatory effects, reducing leukocyte infiltration into the CNS, and a neuroprotective effect has also been suggested. Two placebo controlled Phase III trials of laquinimod (0.6 mg once daily) in relapsing remitting multiple sclerosis showed only modest or non-significant reductions in annualised relapse rate. A positive effect on disability progression and significant reductions in brain atrophy were reported. Laquinimod has not been approved for use in relapsing remitting multiple sclerosis. Further studies of two doses of laquinimod (0.6 and 1.2 mg) in relapsing remitting multiple sclerosis and primary progressive multiple sclerosis are underway.

**Methotrexate** A small randomised controlled trial of low-dose oral methotrexate in progressive multiple sclerosis reported a favourable effect on progression on tests of upper limb function, but there is insufficient evidence to recommend its use.

**Percutaneous venoplasty** A small uncontrolled study suggested that chronic cerebrospinal venous insufficiency (CCSVI), caused by abnormalities in the internal jugular and azygous veins, is associated with multiple sclerosis, and proposed percutaneous venoplasty as a treatment for CCSVI. Findings from subsequent studies have been contradictory, and procedure-related deaths have occurred. NICE guidance has stated that the current evidence on efficacy is inadequate and the procedure should only be used in clinical trials. Multiple recent imaging studies that have included non-multiple sclerosis control subjects have found no significant association of CCSVI with multiple sclerosis.

**Rituximab** Rituximab is a chimeric monoclonal antibody directed against the CD20 antigen, which is expressed on B cells, and it causes depletion of B lymphocytes. It is already used in the treatment of B-cell lymphoma and rheumatoid arthritis. In a placebo controlled Phase II trial in relapsing remitting multiple sclerosis, rituximab halved relapse activity and significantly reduced gadolinium-enhancing lesions. The main adverse effects were infusion-associated events and about one-quarter of patients developed antibodies. Further investigation of rituximab in multiple sclerosis is not planned, but similar agents with less immunogenicity are being studied.

**Negative studies** Many other therapeutic trials have been carried out in multiple sclerosis and failed to show significant benefit. These include trials of hyperbaric oxygen, total lymphoid irradiation, sulfasalazine, oral myelin, anti-CD4 antibody, ustekinumab (a monoclonal antibody targeting interleukin-12/23) and dirucotide (a synthetic peptide analogue). There have also been therapies that have increased disease activity, including lenercept (a TNF neutralising agent) and atacicept (a B-cell targeted therapy), or caused unforeseen serious adverse events, such as cardiopulmonary toxicities with roquinimex.

### Future immunomodulatory therapies

Monoclonal antibody therapies, directed at specific immune targets, remain among the most promising therapies for the future. Ofatumumab is a fully human monoclonal antibody which, like

rituximab and ocrelizumab, targets CD20. Intravenous ofatumumab reduced MRI brain lesion activity by >99% in a Phase II study. A Phase II study of subcutaneous ofatumumab has been preliminarily reported to also significantly reduce MRI activity. Although monoclonal antibody therapies can be effective, in view of the associated immunological side effects, developing much smaller or more targeted agents is desirable. Fingertegrast is a small oral anti- $\alpha 4\beta$ -integrin molecule and it has been shown to reduce gadolinium-enhancing lesions and to be well tolerated in a Phase II study.

### Neuroprotection and remyelination

Most of the therapies investigated to date have primarily targeted the inflammatory response in multiple sclerosis. However, the role of acute inflammation mediated by a systemic adaptive immune response in the development of long-term axonal loss and permanent disability is not established and other potential mechanisms for chronic neuroaxonal loss exist. Therefore, it is also important to explore agents that can protect axons independently of acute inflammation and so prevent disease progression. Various neuroprotective agents have been suggested, including glutamate antagonists, sodium channel blockers, cannabinoids and statins. A protective effect of sodium channel blockers has been demonstrated in animal models, but a Phase II trial of lamotrigine in secondary progressive multiple sclerosis was negative. A Phase III trial investigating the neuroprotective effects of tetrahydrocannabinol in primary and secondary progressive multiple sclerosis has recently been reported to be negative. A significant beneficial effect of high dose simvastatin on brain atrophy, and small effects on measures of disability progression, has been preliminarily reported in a Phase II study.

Although it is hoped that the newer therapies, given in early disease, can have a beneficial effect on long-term outcome, therapeutic approaches are still required to address neuronal damage that has already occurred. Strategies to facilitate remyelination and axonal repair are being explored. Such therapeutic approaches include promotion of endogenous remyelination and stem cell replacement therapies. Various growth factors have been explored in animal models, but have not translated into clinical practice. Anti-LINGO-1 (leucine-rich repeat and Ig domain containing NOGO receptor interacting protein 1) antibody is a small domain-specific antibody which blocks inhibition of myelination and promotes remyelination in animal studies, and this is being evaluated further in clinical trials. Stem cell replacement therapies may be more promising, although there are a number of obstacles to overcome, not least how to replace cells in a disease that is disseminated throughout the CNS. Therapies can utilise embryonic stem cells or adult stem cells harvested from various sites. Clinical studies of autologous HSCT have been carried out, as discussed earlier, but have involved intensive immunosuppression which carries serious risks. Exploratory studies of autologous bone marrow derived mesenchymal stem cell therapy have been reported with no serious adverse events and evidence of neuroprotection has been suggested.

### Disease-modifying therapy in primary progressive multiple sclerosis

Until recently, no treatment has been proven to modify the course of disease in primary progressive multiple sclerosis. Phase III trials of glatiramer acetate and rituximab found no significant clinical effect. Smaller trials of interferon  $\beta$ , mitoxantrone and riluzole have

been negative or inconclusive. Ocrelizumab has preliminarily been reported to be the first drug to be beneficial in primary progressive multiple sclerosis, but peer-reviewed publication is still awaited.

### Symptomatic treatment

Symptomatic treatment and rehabilitation remain essential elements of management and complement current disease-modifying therapies which have little impact on existing neurological impairment and disability. The evidence base for most symptomatic treatments is at best modest, although national management guidelines provide some limited direction. Symptomatic management can be challenging as people usually have multiple symptoms or functional deficits. Symptoms should not be considered in isolation, particularly as treatment of one problem can exacerbate or cause another, and management should take a holistic approach. This requires input from a wide range of health disciplines and draws on a variety of clinical resources, often best exemplified by specialised multi-disciplinary clinics and inpatient or community-based rehabilitation. Education remains a fundamental component of management, and essential if successful self-management is the goal. The management of specific key symptoms is now discussed.

### Fatigue

Fatigue is one of the most disabling symptoms of multiple sclerosis from the patients' perspective. Treatment is difficult and often unsatisfactory. Any treatable contributory factors such as disturbed sleep patterns because of nocturia, nocturnal spasms or pain and depression should be addressed. Fatigue can be worse as the day progresses. A fatigue management programme, addressing daily routine and conserving energy, is the mainstay of treatment. Graded aerobic exercise programmes can also be helpful. Symptoms may be worse in heat and humidity, which may need to be avoided, and some people can benefit from pre-cooling before undertaking activity.

Drug therapy can be considered, although the evidence for efficacy is limited. Amantadine, which has cholinergic, monoaminergic and glutaminergic effects on the CNS, has been reported to improve fatigue when compared with placebo, although the benefit is limited. Side effects include insomnia, hallucinations, gastrointestinal disturbance, dry mouth, livedo reticularis and peripheral oedema. Studies of modafinil, a central stimulating agent, have provided conflicting results and it is not recommended for use in Europe to treat conditions other than narcolepsy because of concerns about the risk of neuropsychiatric disorders, skin and hypersensitivity reactions, and cardiovascular side effects.

The potassium channel blocker 4-aminopyridine has been proposed to improve fatigue by potentiating synaptic transmission and improving nerve conduction. A beneficial effect on fatigue was initially suggested in small studies, but results were inconsistent. Other drug therapies, including pemoline and carnitine, have been suggested but there is little evidence to support their use.

### Spasticity

Spasticity (Chapter 18) can cause stiffness, spasms, pain and contractures and as a result adversely affect mobility, seating, comfort, activities of daily living and care. Management should not primarily aim to abolish spasticity, but rather optimise function, alleviate pain and facilitate care. Management incorporates education, physical therapy, drug therapy and, very occasionally, surgery. A multi-disciplinary approach is essential. Exacerbating factors such as infection, constipation, pain and pressure ulcers must be identified and addressed, and it is important to educate the

individual and carer to avoid such triggers. First line treatment is usually physiotherapy which can reduce tone without exacerbating weakness. Review of seating and bed positioning is often helpful. A home exercise or standing programme can be very valuable. Management should aim to prevent contractures but if they do occur, serial plaster casts, removable splints and standing programmes can all have a role in treatment.

Broadly speaking, spasticity is caused by disinhibition of spinal reflexes because of an upper motor neurone lesion and so drug therapies often target spinal pathways. Treatment should start with a small dose and be titrated up slowly until the desired effect is achieved or unacceptable side effects occur. Monotherapy is desirable. The most commonly used agent is baclofen, a chlorophenyl derivative of gamma aminobutyric acid (GABA) and a GABA  $\beta$ -agonist. It acts on pre- and post-synaptic receptors to potentiate spinal inhibition. The most common side effects are drowsiness and muscle weakness, which are particularly unwelcome in multiple sclerosis. Large doses can result in CNS and cardiorespiratory depression. Abrupt withdrawal should be avoided as it can cause rebound spasticity, hallucinations and epileptic seizures.

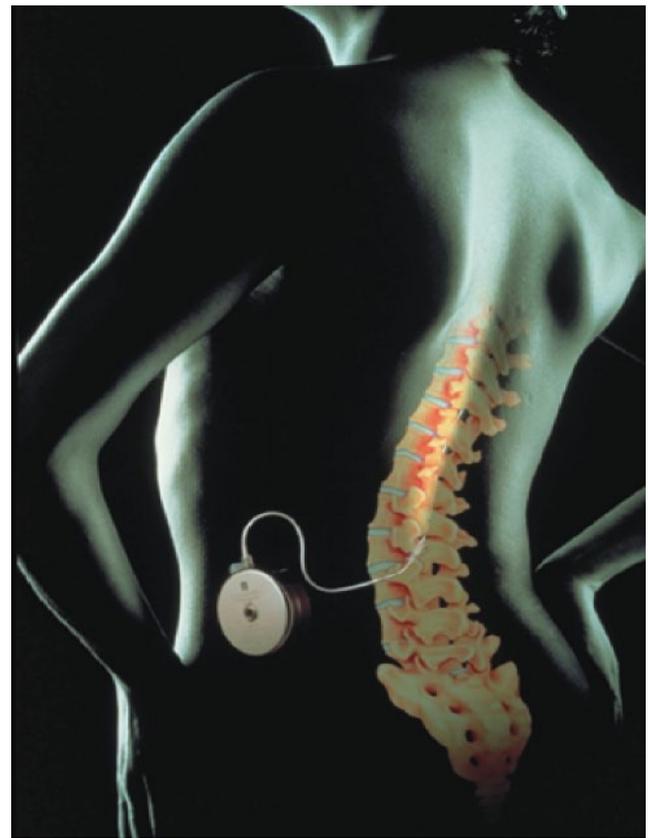

Gabapentin enhances GABA function and has been suggested to have a beneficial effect on spasticity in small placebo controlled studies. It is generally well tolerated, although side effects include sedation and dizziness. NICE guidelines recommend baclofen and gabapentin as first line drug agents for spasticity in multiple sclerosis.

Tizanidine acts through its  $\alpha_2$ -adrenergic properties resulting in spinal inhibition. Placebo controlled trials have shown it to be effective in reducing spasticity. It has been reported that this is not associated with an increase in weakness, but there is little evidence for this in clinical practice. Side effects include dizziness, drowsiness, dry mouth, fatigue and hypotension. Hepatotoxicity can occur and liver function tests should be monitored during the first few months of treatment.

Dantrolene reduces muscle contraction via the inhibition of calcium release in muscle fibres. It acts peripherally and it can be used as an adjunct to a centrally acting drug. Side effects are common and include nausea, diarrhoea, weakness and fatigue. Irreversible hepatotoxicity can occasionally occur and liver function should be monitored closely. As less toxic drugs have become available, dantrolene is now rarely used.

Benzodiazepines, such as diazepam and clonazepam, reduce muscle tone through augmentation of the inhibitory effects of GABA. The use of benzodiazepines may be limited by their sedative effects but they can be useful as a short-term intervention or for treatment of nocturnal spasms.

Cannabinoids have generated much public interest and a beneficial effect on spasticity was initially reported in small studies. Their effect is mediated through cannabinoid receptors in the CNS. A large randomised placebo controlled trial of oral cannabis extract and the synthetic cannabinoid, delta-9-tetrahydrocannabinol, found no benefit on physician-based spasticity measures. There was an improvement in patient-reported spasticity measures, although they may have been affected by unmasking. Further randomised controlled trials of cannabis extract oromucosal spray have also reported a benefit on patient-reported measures of spasticity. Side effects include dizziness, disorientation and, rarely, psychiatric disturbance, gastrointestinal disturbance, increased appetite, dry mouth and oral ulceration. Cannabis extract oromucosal spray is licensed in the United Kingdom for people with multiple sclerosis with moderate to severe spasticity who have not responded

**Figure 11.10** Abdominally placed baclofen pump and intrathecal catheter. Courtesy of Medtronic.

adequately to other antispasticity medication. An initial trial of therapy to demonstrate a significant response and a titration period to reach the optimal dose is required. It has proved useful in postponing more invasive management.

Oral spasticity agents can be limited by systemic side effects, particularly when high doses are required in severe spasticity. Locally administered agents, including intrathecal and intramuscular therapies, can therefore be helpful although they are more invasive. Such treatments should not be performed in isolation, and require a comprehensive approach with specialist multi-disciplinary input and monitoring.

For severe generalised spasticity, intrathecal therapies can be considered. Intrathecal baclofen directly targets the spinal receptors that mediate spasticity. Much smaller doses are required than orally and there is a reduction in systemic side effects. Baclofen is administered into the subarachnoid space via a catheter from an abdominally placed subcutaneous pump (Figure 11.10). The pump is externally programmable so that the regime of baclofen can be changed in response to clinical need; this flexibility is vital in a progressive disease such as multiple sclerosis. Long-term studies have indicated that intrathecal baclofen is an effective and well-tolerated treatment of spasticity. However, adverse effects, related to both the implanted device and the dosing, can occur and can rarely be life-threatening. Patients must be selected carefully and generally have severe spasticity resulting in severe functional disability or pain that has not responded to oral medication.

Intrathecal phenol can also be an effective treatment for spasticity in a small group of carefully selected patients. It causes indiscriminate nerve destruction, and damage to the sacral nerves can cause bladder, bowel and sexual dysfunction. However, it is a relatively simple procedure and is a useful option in severely disabled patients with existing loss of sphincter function and in whom the more complex treatment of intrathecal baclofen is not feasible.

For focal spasticity, intramuscular botulinum toxin can be useful. It reduces muscle activity through presynaptic neuromuscular blockade. Benefit has been reported in the treatment of distal limb spasticity. It is less helpful with spasticity in large muscles, although it can reduce leg adductor spasticity. It is maximally effective when used in combination with physiotherapy and a stretching exercise programme. Intraneural phenol injection is an alternative focal therapy but is now rarely used.

Surgery has a limited role in the current management of spasticity and techniques such as surgical rhizotomy are now little used. Surgical release of contractures can occasionally be required to improve comfort or function.

### Weakness

Treatment for weakness should aim to optimise strength, endurance and function. Therapy-directed exercise programmes, including aerobic training, are the mainstay of treatment. Supportive measures, such as orthoses for focal weakness or specialist seating for postural weakness, should be provided as appropriate. Functional electrical stimulation can be of benefit for foot drop in selected individuals.

A recent large randomised controlled Phase III study of sustained-release 4-aminopyridine assessed its effect on walking ability. An improvement in walking speed was seen in 35% of subjects on active treatment, with an average improvement of 25%. Side effects include paraesthesiae, dizziness, insomnia, anxiety, fatigue, nausea and seizures. Prescribing of 4-aminopyridine is not routinely funded in the United Kingdom, but can be considered for selected patients with severe walking disability who demonstrate a significant symptomatic improvement with a trial of therapy. It should not be used if there is a history of seizures or moderate to severe kidney problems.

### Ataxia

Cerebellar ataxia is an extremely disabling symptom and is exceedingly difficult to treat. Truncal ataxia can adversely impact on walking, standing and even sitting, and limb tremor and dysmetria can restrict any limb function. Therapeutic options include physical therapy, drug therapy and surgery, although all have limited efficacy. Physiotherapy and occupational therapy are first line interventions and should address posture, seating and aids to improve function and safety. Drug therapy is usually unrewarding. Small studies or anecdotal reports of isoniazid, ondansetron, gabapentin, carbamazepine, propranolol, primidone, clonazepam and levetiracetam provide insufficient evidence to support their routine use in clinical practice. A small randomised controlled trial of targeted injection of botulinum toxin type A has reported a significant improvement in upper limb tremor.

Stereotactic thalamotomy and thalamic electrostimulation have been reported to be of benefit for tremor, particularly if proximal, although the evidence is limited and the interventions carry significant risks. Neurosurgery can be considered if tremor is severe and intractable. Gamma knife thalamotomy can be a less invasive alternative, and has been reported to induce functional improvement in tremor, but further study is required.

### Bladder and bowel dysfunction

Bladder dysfunction in multiple sclerosis can result from detrusor hyper-reflexia and incomplete emptying. It is important to assess whether incomplete emptying is occurring before initiating treatment as this can be exacerbated by drugs for detrusor instability. This is carried out by measuring the post-micturition residual which can be measured simply by ultrasound. If the residual is >100 mL, clean intermittent self-catheterisation should be considered. An external bladder stimulator can be tried in ambulatory individuals reluctant to self-catheterise.

If the residual is <100 mL, treatment should be directed at detrusor hyper-reflexia which can be treated successfully with antimuscarinic drugs. The most commonly used include oxybutynin, tolterodine and solifenacin. Side effects include dry mouth, which may be dose-limiting, constipation, blurred vision and fatigue. Desmopressin, usually administered intranasally, is an effective and well-tolerated treatment for nocturia and nocturnal enuresis; administered at bedtime it reduces diuresis overnight. It can also be used to reduce daytime urinary frequency (e.g. when travelling), but it must never be used more than once in 24 hours.

Detrusor injections of botulinum toxin type A have been shown to be highly effective for severe urgency and incontinence; its effect on bladder emptying usually requires clean intermittent self-catheterisation afterwards. Percutaneous and transcatheter posterior tibial nerve stimulation have been reported to be beneficial for bladder overactivity, without compromising bladder emptying. Other nerve stimulation procedures, including sacral nerve root stimulation, can occasionally be considered.

If bladder symptoms are not controlled, despite the above measures, further assessment and advice from a specialist continence service should be sought. Supportive measures for urinary incontinence, such as reviewing toileting arrangements and considering a penile sheath or pads, should be offered. Pelvic floor exercises and encouraging regular bowel emptying can be beneficial. Education regarding the symptoms of urinary tract infections should be given, and infections should be treated with an appropriate antibiotic. If bladder dysfunction persists after other non-invasive measures have been tried, long-term indwelling catheterisation can be considered. Supra-pubic catheterisation is the preferred option, particularly if sexual function is active, and urethral catheterisation can cause long-term bladder neck and urethral damage. Surgical procedures such as urinary diversion or bladder augmentation may rarely have a role in refractory cases.

Bowel dysfunction may be less frequent than bladder dysfunction but is still common and can be difficult to treat. The most common symptoms are constipation, urgency and incontinence. Individuals with faecal incontinence should be assessed for constipation with overflow. It is important to establish a regular bowel regime. Maintaining an adequate fluid intake is advised, and increasing dietary fibre may be recommended although there is no specific evidence for this. Oral laxatives can be required. Bulking agents, such as ispaghula husk, and osmotic laxatives, such as lactulose or polyethylene glycol, can be tried. Stimulant laxatives, such as senna and bisacodyl, can be used in more severe constipation. If constipation persists, the use of suppositories or enemas should be considered. Behavioural biofeedback therapy has been reported to be of benefit for constipation and faecal incontinence in small studies in multiple sclerosis. Transanal irrigation may be a potentially promising therapy. Surgical intervention such as stoma formation can be considered rarely in severe cases where other measures have failed.

### Sexual dysfunction

Sexual dysfunction is a frequent but often neglected symptom. In males, the most common complaint is erectile dysfunction. Management has improved with the advent of phosphodiesterase inhibitors, such as sildenafil and tadalafil, which should be offered as a first line therapy. If ineffective, intracorporeal therapy with alprostadil (prostaglandin E1), administered as a urethral pellet, or papaverine can be used. In females, common symptoms include anorgasmia and decreased vaginal lubrication. Lubricants can be helpful, but drug therapy currently has little role. In both sexes any coexistent contributory factors such as depression, anxiety, diabetes, vascular disease and medications should be addressed. Counselling for individuals or couples should also be offered as appropriate.

### Pain and paroxysmal symptoms

Pain occurs in the majority of people with multiple sclerosis. It can be neurogenic, as a consequence of direct involvement of central pain pathways, or it can be nociceptive, often musculoskeletal, caused by secondary complications of neurological impairment.

Chronic pain is common and includes dysaesthetic extremity pain, painful leg spasms and musculoskeletal back pain. Amitriptyline, gabapentin and pregabalin are often used for dysaesthetic extremity pain. Other anticonvulsants, including carbamazepine, lamotrigine and levetiracetam, opioid analgesics, mexilitene and intravenous ketamine and lidocaine can also be used. Painful leg spasms are best managed by treating the underlying spasticity. Musculoskeletal pain can result from abnormal posture and gait; physical therapy input is the first line of treatment, although anti-inflammatory drugs and other analgesics, electrical stimulation and tricyclic antidepressants all have a role in treatment. Cannabinoids have been reported to improve pain in multiple sclerosis. Although cannabis extract is not licensed for treatment of pain in the United Kingdom, it can be prescribed on a named patient basis. For intractable chronic pain, more invasive therapies such as intrathecal drug therapy, transcutaneous electrical nerve stimulation, spinal cord stimulation and deep brain stimulation can possibly be considered. Cognitive behavioural therapy can be helpful in selected individuals. Patients for whom pain is a major issue should be referred to a multidisciplinary pain clinic and not simply told they have to live with it.

A minority of people with multiple sclerosis experience acute and paroxysmal neurogenic pain. Lhermitte's symptom, tonic spasms and trigeminal neuralgia are the most common paroxysmal pains. Carbamazepine and gabapentin can be effective for trigeminal neuralgia and other anticonvulsants, baclofen and misoprostol have been used. Surgery can be considered for intractable trigeminal neuralgia but may be less successful than in idiopathic trigeminal neuralgia; percutaneous procedures may be preferred. Other painful, and non-painful, paroxysmal symptoms can also respond to carbamazepine, gabapentin and other anticonvulsants.

### Cognitive and psychiatric dysfunction

Cognitive deficits are common in multiple sclerosis and can have a significant impact on all activities of daily living and quality of life. If symptomatic, a formal assessment of cognition should be offered and advice given regarding any implications of the results. In particular, cognitive dysfunction can affect employment and recognition of cognitive deficits allow adaptations to be made to enable the individual to maintain employment. Cognitive rehabilitation programmes can be of benefit, and techniques to assist memory, attention and executive function have been suggested, but are not

widely available. Any other contributory factors such as medication or mood disturbance should also be addressed. Drug therapies are being investigated but are currently not recommended. Initial small studies of the anticholinesterase inhibitor donepezil in multiple sclerosis reported improvement in memory, but no significant benefit was seen in a larger randomised controlled trial. A recent small randomised controlled trial of the neurostimulant lisdexamfetamine dimesylate showed improvements in processing speed and memory in multiple sclerosis.

Psychiatric morbidity is increased in multiple sclerosis with depression and anxiety predominating. A lifetime prevalence of depression in multiple sclerosis of approximately 50% has been reported. People with low mood should be screened as to the severity of depression, and referred for specialist psychiatric input if depression is severe. There is a significant increased risk of suicide in multiple sclerosis, and it is important to be vigilant about suicidal ideation. Simple screening tools, such as the Beck Depression Inventory, can easily be incorporated into clinical practice. Contributory factors, such as pain or social isolation, should be reviewed. In mild to moderate depression and in anxiety disorders, counselling and cognitive behavioural therapy can be helpful. Antidepressant therapy can be effective in many patients but agents with anticholinergic effects can exacerbate bladder and bowel symptoms. Selective serotonin and noradrenaline re-uptake inhibitors appear to be effective for depression and anxiety and are well tolerated in patients with multiple sclerosis. There is an increased prevalence of bipolar affective disorder and psychotic disorders in multiple sclerosis; management is based on the treatment of these disorders in the general population. Emotional lability may be helped by tricyclic antidepressants and selective serotonin re-uptake inhibitors.

### Visual dysfunction

Reduced visual function (Chapter 14) can occur as a result of optic neuritis, diplopia caused by ophthalmoplegia or oscillopsia from nystagmus. Drug therapy is of no help for permanent deficit from optic neuritis. Gabapentin and memantine have been reported to be of benefit in acquired nystagmus resulting from multiple sclerosis, but studies have been small. Prisms can be of some help in compensating for eye movement disorders. Visual function can also be improved by assessment in a low vision clinic and provision of adaptive equipment.

### Vertigo

Vertigo can occur acutely as part of a brainstem relapse but may persist. In acute vertigo, which can be complicated by nausea and vomiting, vestibular sedatives such as prochlorperazine and cinnarizine are useful as well as supportive measures such as bed rest and rehydration. Vestibular sedatives should not be used in the long term as they may obstruct vestibular compensatory mechanisms. Vestibular rehabilitation physiotherapy, and supportive mobility aids as appropriate, have a role in the management of persistent symptoms.

### Bulbar and respiratory dysfunction

Dysphagia is a common symptom and patients may most frequently describe coughing or choking on swallowing. Assessment by a speech therapist is at the core of management and advice on posture, eating patterns and diet is often helpful. In more severe cases, aspiration with the risk of chest infection can occur and individuals and carers should be alerted to this. Investigation with videofluoroscopy may be required. Further supportive measures such as the

use of fluid thickening agents, provision of appropriate seating and chest physiotherapy are valuable. Percutaneous gastrostomy may be required if swallowing is unsafe or oral intake is insufficient.

Speech disturbance is usually caused by dysarthria. It may be helped by speech therapy. In severe disease, speech can become unintelligible or anarthric and communication aids are required.

Respiratory dysfunction resulting from respiratory muscle weakness is common, although often not symptomatic, in multiple sclerosis. More severe involvement can result from acute lesions in the medulla or high cervical cord, and respiratory insufficiency occurs in advanced disease. Respiratory muscle training can improve muscle strength and pulmonary function. Early recognition of respiratory complications is important and ventilatory support, including continuous positive airway pressure or non-invasive ventilation, is occasionally necessary.

### Temperature sensitivity

Many people report a significant deterioration in function associated with an increase in temperature. Simple advice on heat avoidance, planning of activities around diurnal temperature variation and cooling should be given. Cooling garments can be of benefit for selected people. 4-Aminopyridine may improve function in patients with temperature sensitivity, but the evidence is very limited.

### Neurological rehabilitation

Outpatient and inpatient neurological rehabilitation programmes can be an effective approach to the comprehensive management of many of the problems described above (Chapter 18). Although rehabilitation methods have not been evaluated as stringently as pharmacological therapies, there is now evidence to support their use. Randomised controlled studies have shown inpatient rehabilitation reduces disability and improves quality of life in multiple sclerosis. Benefits gained from inpatient rehabilitation may be maintained for several months, but carry-over of benefits declines over time, reinforcing the need for continuity of care into the community. However, in the only double-blind controlled trial of inpatient rehabilitation in multiple sclerosis no significant benefit was reported, although this perhaps reflects methodological issues and highlights the difficulties in evaluating rehabilitation methods. Outpatient multi-disciplinary rehabilitation has also been reported to reduce disability. Physiotherapy alone improves mobility and well-being in multiple sclerosis, with similar effects seen for outpatient and home physiotherapy, although the benefit may only last a few weeks. Exercise therapies have also been reported to have beneficial effects in multiple sclerosis including improvements in muscle strength and mobility.

In evaluating the efficacy of rehabilitation it is essential that the outcome measures used are valid, sensitive and reliable. Historically, outcome measures have been developed without the application of rigorous psychometric methods and have been disease-based. More recently, using standard psychometric methods, patient-based measures such as the Multiple Sclerosis Impact Scale (MSIS-29) and the 12-Item Multiple Sclerosis Walking Scale (MSWS-12) have been developed. Preliminary study has shown them to be reliable and responsive, and such measures should facilitate the assessment of rehabilitation in multiple sclerosis.

Symptomatic treatment and rehabilitation in multiple sclerosis is not just limited to addressing physical and cognitive impairments but should encompass the social and psychological needs. The different requirements of people with long-term neurological conditions, including multiple sclerosis, have been set out in the National Service

**Table 11.12** Quality requirements for the management of long-term neurological conditions (Department of Health 2005).

1	A person-centred service
2	Early recognition, prompt diagnosis and treatment
3	Emergency and acute management
4	Early and specialist rehabilitation
5	Community rehabilitation and support
6	Vocational rehabilitation
7	Providing equipment and accommodation
8	Providing personal care and support
9	Palliative care
10	Supporting family and carers
11	Caring for people with neurological conditions in hospital or other health and social care settings

Framework (NSF) for long-term conditions (Table 11.12). Among these requirements, vocational rehabilitation and palliative care are specifically highlighted.

### Vocational rehabilitation

Work is a central activity for most adults and contributes to financial and social status. People with multiple sclerosis face restrictions in their ability to work leading to loss of employment. Factors relating to the disease and relating to the job and work environment affect the ability to work. Disease-related factors are not just confined to physical impairments but also include cognitive impairments and fatigue. The need for access to vocational rehabilitation has been highlighted, but specialist vocational rehabilitation services remain scarce. A focus group based study found that people with multiple sclerosis identified two key needs in the workplace: managing performance and managing expectations. It was suggested that people with multiple sclerosis required support to address the interaction of their impairments, workplace environment and demands of the work, and to provide expert knowledge about employment issues and legislation, and counselling and support to manage complex issues.

### Palliative care

Palliative care (Chapter 26) services have traditionally addressed the needs of people with cancer and terminal illness. In recent years, there has been a shift within these services to also provide support for people with non-terminal long-term conditions. The NSF highlights the need for access to palliative care services for people in the later stages of long-term neurological conditions. Palliative care services have particular expertise in symptom control, provision of social, psychological and spiritual support, and end of life care. There should be multi-disciplinary working across neurology, rehabilitation and palliative care services and staff involved in the care of people with advanced disease should be trained in palliative care skills. A survey of consultants in neurology, rehabilitation and palliative care has found that there is a shortfall in provision of palliative care services, and a lack of coordination between services. A randomised controlled trial of delivering specialist palliative care to people severely affected by multiple sclerosis found positive effects on key symptoms and improvement in caregiver burden in the short term. Further work is required to develop palliative care services specific to the needs of people with multiple sclerosis.

### Complementary and alternative medicine

Use of complementary and alternative medicine in multiple sclerosis is common, with at least one-third of people having tried at least one therapy. Although some therapies have been subject to controlled trials, the evidence base for most therapies is at best limited and insufficient to make definite recommendations. Cannabis has been one of the most extensively investigated therapies, as discussed, and there is limited evidence for dietary supplements such as linoleic acid. As many people will decide to use complementary and alternative medicine, access to accurate information should be available to assist decision making. It is particularly important that people are encouraged to evaluate any risks, both financial and health-related. Information is provided by voluntary organisations such as the MS Society and the MS International Federation.

### Neuromyelitis optica

Neuromyelitis optica (NMO), also known as Devic's disease, is an inflammatory demyelinating disease of the CNS. Although historically there has been debate as to whether NMO is a variant of multiple sclerosis, recent advances have shown that NMO is immunologically and pathologically distinct from multiple sclerosis and requires different treatment.

#### Epidemiology

The median age of onset of NMO is in the late thirties, but there is a wide age range from childhood to late adulthood. Females are more commonly affected than males in a ratio of >3 : 1. The prevalence of NMO has been reported as 0.3–4.4/100 000, with an incidence of 0.05–0.4/100 000, in different populations worldwide. NMO is much rarer than multiple sclerosis in Europe and North America. It can affect all ethnic groups but it makes up a greater proportion of demyelinating diseases in non-Caucasian populations. The optico-spinal variant of multiple sclerosis, which is common in Japan, has been found to be associated with the NMO specific aquaporin-4 antibody suggesting that it is the same disease as NMO.

Familial occurrence of NMO occurs in about 3% of cases. Familial cases are clinically indistinct from sporadic cases. HLA associations with increased risk of NMO have been reported, including DRB1\*0301 in Caucasian and DPB1\*0501 in East Asian populations. NMO susceptibility is not significantly related to variations in the aquaporin-4 gene.

#### Pathophysiology

An autoimmune basis to NMO has long been suspected because of the association with autoimmune diseases such as SLE, Sjögren's syndrome and thyroid disease. In 2004, a new autoantibody, NMO-IgG, was reported to be highly specific for NMO and to distinguish it from multiple sclerosis. The target antigen of NMO-IgG is aquaporin-4 (AQP4), a cell membrane water channel which is important in maintaining water homeostasis and widely distributed in the CNS. AQP4 is highly expressed in astrocytic foot processes, particularly in direct contact with pia and capillaries. AQP4 antibody is approximately 75% sensitive for NMO and >90% specific.

The specificity of AQP4 antibody suggests a direct pathological role for the antibody. Experimental data indicate that AQP4 antibody binds to AQP4 in astrocytic foot processes and causes complement-dependent cytotoxicity. Astrocyte destruction appears to

be the primary pathology and leads to secondary oligodendrocyte loss and demyelination and ultimately to axonal loss. Pathological data also provide support for this distinct pathophysiology. NMO lesions show peri-vascular inflammation with prominent complement and immunoglobulin deposition in keeping with a role for humoral immunity. Myelin may be preserved in early NMO lesions, whereas acute fragmentation and loss of glial fibrillary acid protein-positive astrocytes has been reported to be pathognomonic for NMO. *In vivo* magnetic resonance spectroscopy of the NMO lesions in the cervical cord has shown a reduction in the concentration of the glial cell marker myo-inositol, consistent with loss of astrocytes.

#### Clinical features

The hallmark features of NMO are episodes of optic neuritis and transverse myelitis. Concurrent optic neuritis and transverse myelitis occurs in a minority of patients. Optic neuritis is often rapidly evolving with severe visual loss, with recovery far less complete than in multiple sclerosis. Bilateral optic neuritis can occur, either simultaneously or sequentially over a few days. Transverse myelitis also develops rapidly and is often symmetrical and bilateral, with motor and sensory involvement. It often progresses to a severe paraparesis or quadriparesis with loss of bladder and bowel function. High cervical cord involvement can cause respiratory failure. Severe optic neuritis or transverse myelitis should alert to the possibility of NMO rather than multiple sclerosis. However, it is increasingly recognised that mild episodes of optic neuritis and transverse myelitis are also a presentation of NMO.

Other neurological features have previously been considered rare in NMO. However, with the availability of testing for AQP4 antibody as a biomarker of NMO, the spectrum of clinical phenotypes has expanded. Other characteristic clinical presentations include hiccups and vomiting caused by medullary involvement, and somnolence and endocrinopathies as a result of hypothalamic involvement. Presentations because of large cerebral hemisphere lesions and posterior reversible encephalopathy syndrome can also be seen.

Clinical differences have been reported between AQP4 seropositive and seronegative patients. The female predominance is not seen in seronegative disease. Seronegative patients are more likely to present with bilateral optic neuritis or simultaneous optic neuritis and transverse myelitis than seropositive patients, can have less severe attacks and are more likely to have a monophasic course.

#### Investigations

MRI has an important role in the investigation and diagnosis of NMO. In transverse myelitis, MRI of the spinal cord characteristically shows an intrinsic spinal cord lesion extending contiguously over three or more vertebral segments (Figure 11.11). Lesions typically occur in the cervical and thoracic cord, and there can be extension into the caudal medulla. Lesions are located centrally, and acute lesions can occupy most of the cross-sectional area and are often associated with cord swelling, T1 hypointensity and gadolinium enhancement. This appearance contrasts with multiple sclerosis where partial myelitis is usually associated with small, focal, asymmetrical and often superficial cord lesions that are T2 hyperintense but not T1 hypointense and that rarely extend over more than one segment. Following the acute phase, spinal cord atrophy may develop.

**Figure 11.11** Longitudinally extensive spinal cord lesion in neuromyelitis optica (MRI T2W sagittal).

MRI of the brain can be normal, particularly at initial presentation, but brain lesions are seen in the majority of patients during the course of the disease. Lesions in the hypothalamus and peri-aqueductal brainstem region are considered typical for NMO. Non-specific white matter lesions can often be seen, but the brain lesions may fulfill radiological criteria for multiple sclerosis in a significant proportion of cases. However, thorough inspection of the morphology and distribution of brain lesions can distinguish multiple sclerosis from NMO and periventricular and juxtacortical lesions are more characteristic for multiple sclerosis. Large and extensive cerebral lesions can occasionally also occur in NMO.

MRI in optic neuritis shows an intrinsic lesion in the affected nerve and acute lesions are often associated with swelling and gadolinium enhancement. Optic nerve lesions can be more extensive than typically seen in multiple sclerosis, and posterior nerve and chiasmal involvement may be more common.

CSF examination is often abnormal particularly in the acute presentation. There can be a CSF pleocytosis, which is usually mononuclear, but neutrophils can be present and may predominate. A cell count of  $>50/\text{mm}^3$  is not uncommon, and should alert that the diagnosis may not be multiple sclerosis. CSF protein is usually mildly elevated. Unmatched oligoclonal bands are present in less than one-third of cases and, unlike multiple sclerosis, their presence can be transient.

Testing for AQP4 antibody is now widely available and is an essential investigation in patients with suspected NMO. Second generation recombinant AQP4 antigen-based assays have been reported to yield the highest sensitivities (up to 87%). The role of testing for other putative biomarkers in seronegative NMO is not yet established, but myelin-oligodendrocyte glycoprotein antibodies have been reported in a few cases.

**Table 11.13** Neuromyelitis Optica Spectrum Disorders (NMOSD) diagnostic criteria for adult patients.

Diagnostic criteria for NMOSD with AQP4-IgG:

- At least one core clinical characteristic
- Positive test for AQP4-IgG using best available detection method (cell-based assay strongly recommended)
- Exclusion of alternative diagnoses

Diagnostic criteria for NMOSD without AQP4-IgG or with unknown AQP4-IgG status

- At least two core clinical characteristics occurring as a result of one or more clinical attacks and meeting all of the following requirements:
  - at least one core clinical characteristic must be optic neuritis, acute myelitis with LETM, or area postrema syndrome
  - dissemination in space (two or more different core clinical characteristics)
  - fulfillment of additional MRI requirements, as applicable
- Negative tests for AQP4-IgG using best available detection method, or testing unavailable
- Exclusion of alternative diagnoses

Core clinical characteristics

- Optic neuritis
- Acute myelitis
- Area postrema syndrome: episode of otherwise unexplained hiccups or nausea and vomiting
- Acute brainstem syndrome
- Symptomatic narcolepsy or acute diencephalic clinical syndrome with NMOSD-typical diencephalic MRI lesions
- Symptomatic cerebral syndrome with NMOSD-typical brain lesions

Additional MRI requirements for NMOSD without AQP4-IgG or with unknown AQP4-IgG status

- Acute optic neuritis requires brain MRI showing
  - normal findings or only non-specific white matter lesions, or
  - optic nerve MRI with T2-hyperintense lesion or T1-weighted gadolinium-enhancing lesion extending over  $>1/2$  optic nerve length or involving optic chiasm
- Acute myelitis requires associated intramedullary MRI lesion extending over
  - $\geq 3$  contiguous segments (LETM), or
  - $\geq 3$  contiguous segments of focal spinal cord atrophy in patients with history compatible with acute myelitis
- Area postrema syndrome requires associated dorsal medulla/area postrema lesions
- Acute brainstem syndrome requires associated periependymal brainstem lesions

LETM, longitudinally extensive transverse myelitis

### Diagnostic criteria

With the discovery of AQP4 antibody, diagnostic criteria have been revised to include seropositivity and have been widely adopted. The criteria have been updated in 2015 and no longer refer to NMO but use the unifying term NMO spectrum disorders (NMOSD; Table 11.13). NMOSD is stratified further by the presence or absence of AQP4 antibody. Core clinical characteristics are required for diagnosis, but the occurrence of both optic neuritis and transverse myelitis is not necessary for a diagnosis of NMOSD.

## Course and natural history

Although initially described as a monophasic disorder, the clinical course of NMO is relapsing in about 80–90% of cases. AQP4 seropositivity predicts a high risk of relapse, and the majority of seropositive patients may relapse within the first year. Many patients acquire severe and permanent disability with the initial attack, and recurrent attacks result in accumulating disability. Before the current era of early diagnosis and treatment, over half of patients were functionally blind in at least one eye or were unable to walk without assistance within 5 years. Mortality rates of approximately 30% within 5 years were also reported, but recent data suggest that mortality rates with longer follow-up are now <10%. The development of a secondary progressive phase is, unlike multiple sclerosis, very uncommon.

## Management

Acute attacks of NMO necessitate early and aggressive treatment. First line treatment is high-dose intravenous methylprednisolone followed by maintenance oral prednisolone. In patients with acute severe attacks unresponsive to high-dose steroids, the next step is plasma exchange. Efficacy of plasma exchange in acute attacks of demyelinating disease including NMO has been demonstrated in a small randomised controlled trial.

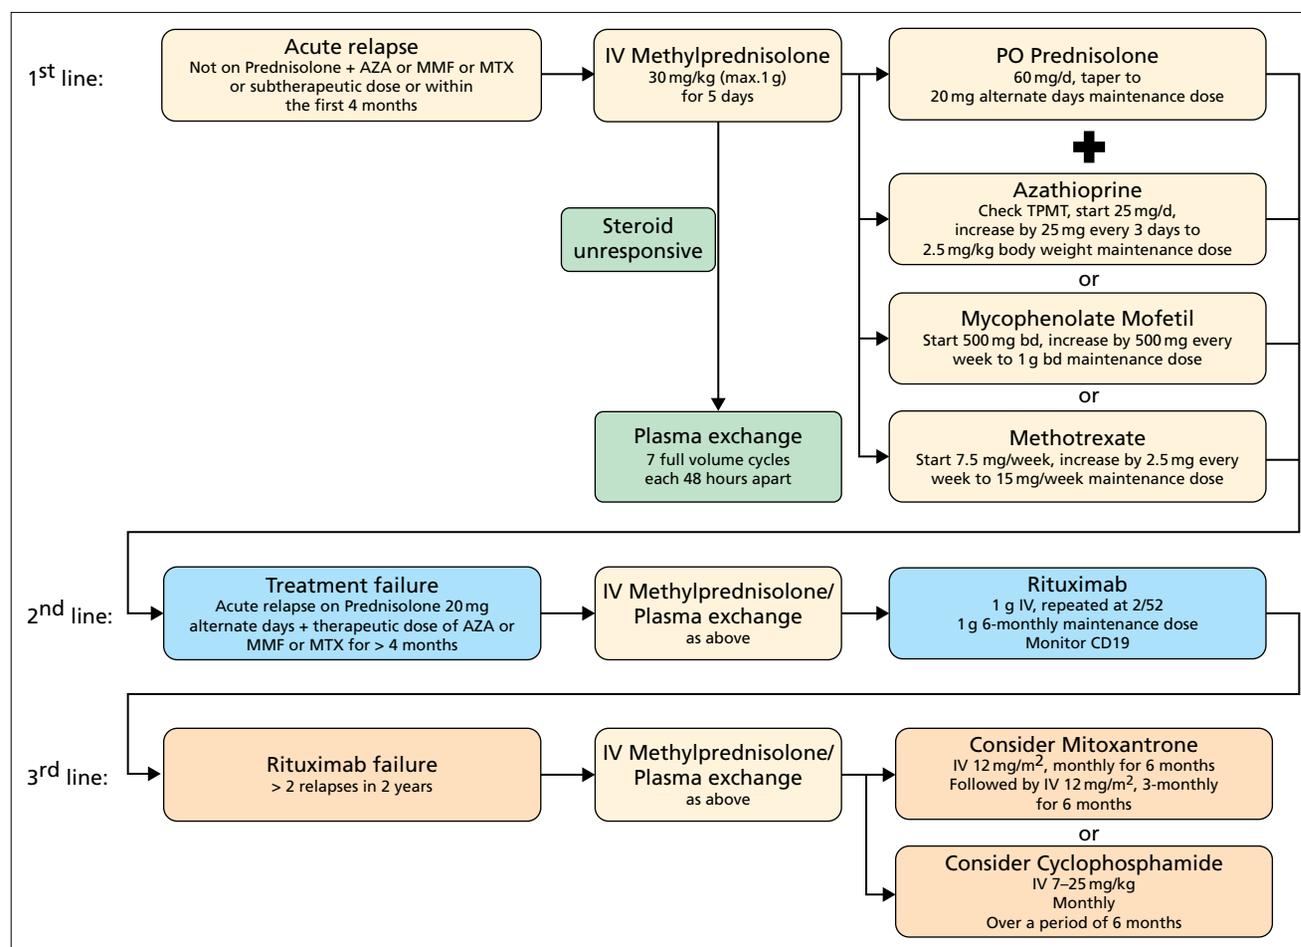

In patients with relapsing NMO and in those with a first attack who are AQP4 seropositive, long-term immunosuppression for relapse prevention is indicated. The evidence for immunosuppressive

therapies for relapse prevention in NMO is limited to retrospective and open-label studies, but their use is widely accepted in clinical practice. First line therapies include azathioprine, mycophenolate and methotrexate, in combination with oral prednisolone. If patients relapse on a therapeutic dose of first line therapy, rituximab is often used, which causes depletion of B cells and so may be expected to be useful in an antibody-mediated disease. Other second and third line therapies include mitoxantrone (although this cannot be used in the long-term because of the risk of cumulative cardiotoxicity), cyclophosphamide, cyclosporin and maintenance pulsed plasma exchange or IVIG. The importance of correct diagnosis is emphasised by reports that the multiple sclerosis disease modifying therapies of interferon  $\beta$ , natalizumab and fingolimod can make NMO worse.

The nationally commissioned NMO UK service has proposed a treatment algorithm for management of NMO (Figure 11.12). For patients with a single episode of longitudinally extensive transverse myelitis and negative AQP4 antibody, long-term immunosuppression is not recommended unless there is a relapse, although it has been suggested to continue maintenance oral prednisolone for a few months.

Potentially more disease-specific therapies such as the monoclonal antibodies eculizumab, which neutralises complement C5, tocilizumab, which targets the IL-6 receptor, and aquaporin, a protective AQP4 binding antibody, are being explored.

In view of the significant symptoms and disability that can develop in NMO, symptomatic treatment and rehabilitation are

**Figure 11.12** Neuromyelitis optica treatment algorithm. Source: Neuromyelitis Optica UK Service. (Courtesy of Dr J. Palace)

essential aspects of management. Management principles are the same as for multiple sclerosis, but it is important to be aware of and to treat symptoms that occur commonly such as hiccups, vomiting, tonic spasms and pain.

## Acute para-infectious inflammatory encephalopathies

Acute para-infectious encephalopathies are typically monophasic encephalitides characterised by multifocal inflammatory lesions, principally affecting the white matter of the CNS. There are two consistently distinguishable pathological subdivisions: acute disseminated encephalomyelitis (ADEM) and acute haemorrhagic leukoencephalitis (AHL).

### Acute disseminated encephalomyelitis

ADEM classically occurs in children and young adults. The mean age of onset in paediatric studies is reported as 5–8 years. It typically follows a febrile illness or vaccination by 1–4 weeks, often after the exanthem clears and the initial fever abates. ADEM is most frequently associated with childhood exanthemas particularly measles, rubella and varicella but other infections including mumps, enterovirus, EBV, herpes simplex virus, cytomegalovirus, HHV-6, HTLV-1, adenovirus, influenza A and B, *Mycoplasma*, *Chlamydia*, *Borrelia*, *Listeria*, *Leptospira* and beta-haemolytic streptococcus have all been implicated. Post-vaccination ADEM occurs less frequently. It has been particularly associated with rabies vaccine, notably the Semple neural vaccine, but has rarely been reported with the measles, pertussis, diphtheria, tetanus, rubella, Japanese B encephalitis, typhoid and hepatitis B vaccines.

### Clinical features

The onset is usually with a low-grade fever, headache and meningism preceding the development of drowsiness and encephalopathy which can progress to stupor and coma. Neurological deficits are typically multi-focal and include seizures, hemiparesis, paraparesis, ataxia, visual loss, sensory disturbance, dysphasia, cranial nerve palsies, choreoathetosis, myoclonus and sphincter disturbance. ADEM evolves rapidly over hours to days. It is rarely fulminant, with acutely raised intracranial pressure leading to tentorial herniation and death within 72 hours. Respiratory failure resulting from brainstem involvement can also occur. In some patients there is an associated acute psychosis, depression and hypersomnolence. A number of characteristic patterns are seen. Following measles infection, myelitis with hemiparesis or paraparesis is common. Post-rubella ADEM can be associated with seizures, coma and moderate pyramidal signs. Varicella can lead to cerebellar ataxia with a mild pyramidal defect. Rabies vaccination is associated with radicular and peripheral nerve involvement.

### Pathophysiology

It is generally accepted that the pathogenesis of ADEM is immune-mediated, rather than caused directly by infection. The exact mechanism of this is not clear. It has been proposed that the preceding infection or vaccine cross-activates an immune reaction to myelin through molecular mimicry. Alternatively, it has been suggested that the inflammatory response to the initial agent results in the activation of pre-existing encephalitogenic T cells.

Pathological examination of the brain in ADEM classically shows multiple peri-venous zones of demyelination in the cerebral white

matter. The changes found in patients dying early in the disease affect the small blood vessels of both grey and white matter with hyperaemia, endothelial swelling, vessel wall invasion by inflammatory cells, peri-vascular oedema and haemorrhage all preceding the demyelination. Patients dying later in the disease process show zones of lymphocytic infiltration and demyelination, often with relative axonal-sparing lesions; these are discrete and surround small and medium sized vessels which have peri-vascular pallor. Advanced lesions can show astrocytic proliferation with gliosis and mild meningeal inflammation. The lesions are generally homogeneous in appearance and appear to be of the same age.

### Differential diagnosis

ADEM can be difficult to distinguish from the first presentation of multiple sclerosis. A fulminant presentation may also be indistinguishable from AHL. In comparison with multiple sclerosis, ADEM tends to occur in younger patients (mainly children) and is more common in males. Encephalopathy, headache, fever and a multifocal presentation are more common, as is a history of a preceding infection or vaccination. Recently proposed diagnostic criteria for ADEM actually require there to be an encephalopathy and this is a particularly valuable point of distinction from clinically isolated syndromes associated with multiple sclerosis, which will not have clinical features of encephalopathy although there are sometimes extensive cerebral white matter lesions on MRI. Other CNS infections and inflammatory diseases must be excluded, and tumours are in the differential diagnosis of mass lesions (Table 11.14).

Distinguishing ADEM from multiple sclerosis can also be difficult if there are further episodes. In an attempt to distinguish ADEM and related disorders from multiple sclerosis, two international expert groups have proposed definitions for the major CNS

**Table 11.14** Differential diagnosis of acute disseminated encephalomyelitis (ADEM).

<b>Encephalitis</b>
Herpes simplex encephalitis
Varicella zoster virus
HIV
<i>Listeria monocytogenes</i>
<i>Mycobacterium tuberculosis</i>
<b>Inflammatory</b>

<b>Leukoencephalopathy</b>
Toxic
Vascular
Metabolic
Genetic
<b>Malignancy</b>
Diffuse infiltration
Paraneoplastic

**Table 11.15** Criteria for diagnosis of acute disseminated encephalomyelitis (ADEM).

Subacute encephalopathy (altered level of consciousness, behaviour or cognitive function)

Evolution over 1 week to 3 months; new symptoms, including focal/multifocal demyelinating syndromes, within the first 3 months from onset are allowed, as long as they are not separated by a period of complete remission from the initial symptoms (in which case the diagnosis is multiple sclerosis)

Accompanied by improvement or recovery although residual neurological deficits may be present

MRI shows predominantly symptomatic white matter lesions that

- Are acute
- Are multiple but rarely a single large lesion
- Are supra- or infra-tentorial or both
- Generally include at least one large (1–2 cm diameter) lesion
- Variably enhance with gadolinium (gadolinium enhancement is not required)
- May be accompanied by basal ganglia lesions, but their presence is not required

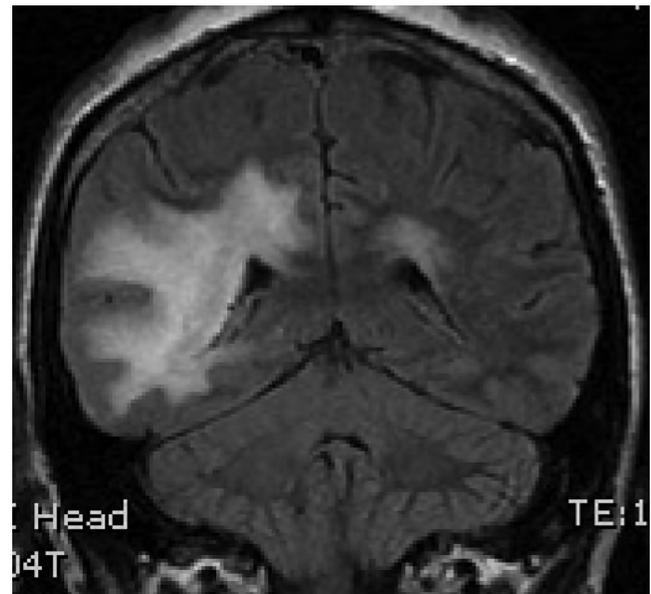

Source: Adapted from Miller *et al.* 2008. Reproduced with permission of Sage.

inflammatory demyelinating diseases including ADEM, although these are not yet validated. One group focused on the definitions for monophasic, recurrent and multiphasic ADEM in children. The other focused on adult presentation, when ADEM is uncommon, and rejected the category of multiphasic ADEM as it was felt to be indistinguishable from multiple sclerosis with an encephalopathic presentation (Table 11.15). This is an important distinction because there are specific disease-modifying treatments for such forms of relapsing multiple sclerosis.

### Investigations

CSF can be normal in up to 50% of patients but can reveal an elevation in the opening pressure and a mild lymphocytosis ( $>50/\text{mm}^3$ ), although occasionally there may be a polymorphonuclear leukocytosis. The protein is elevated in approximately 50%. Oligoclonal bands can be present acutely in up to 30% of patients but often disappear on repeat testing. CSF polymerase chain reaction (PCR) for viral infection can show the underlying precipitating agent. MRI is most useful in the diagnosis of ADEM, with abnormalities frequently evident on T2-weighted and FLAIR (Figure 11.13) imaging, although MRI can be normal early in the disease. The lesion load is often extensive with large and multi-focal lesions, which can be confluent and ill-defined. Lesions are not confined to the white matter but involve the cortical and deep grey matter. Mass lesions, mimicking tumours occur. 'Black holes', hypointense lesions on T1-weighted imaging, are typically absent. Lesions may enhance with gadolinium, reflecting their acute and synchronous development, but enhancement of the meninges is unusual. Spinal cord lesions are often large, extending over several levels, with swelling and mass effect, and have a predilection for the thoracic cord.

Although MRI appearances can be suggestive of ADEM, no features are specific to ADEM. It is not possible to distinguish ADEM from multiple sclerosis on the basis of MRI, although follow-up imaging can be helpful in the differential diagnosis. Brain MRI appearances can normalise in approximately 40% of patients with typical ADEM. The development of new lesions,

**Figure 11.13** Extensive confluent demyelination in acute disseminated encephalomyelitis (MRI FLAIR coronal).

after an interval of at least 3 months, is inconsistent with a diagnosis of monophasic ADEM.

### Clinical course and prognosis

ADEM is usually a monophasic illness which is self-limiting. Recovery takes place over weeks to months, and full recovery can occur in about 50–75% of cases. However, major neurological sequelae can occur in up to one-third of patients and mortality is approximately 5%. There appears to be a worse prognosis if seizures and coma accompany the acute illness. Common residual deficits include hemiparesis, ataxia, blindness, cognitive dysfunction and epilepsy. Recurrent or multi-phasic ADEM has been reported in up to 20% of patients (mainly children) but in adults it would seem more likely to indicate the existence of multiple sclerosis.

### Management

Management involves meticulous support and care, often in an intensive care unit, with adequate hydration and treatment of pyrexia, seizures and raised intracranial pressure. Patients can be given antibacterial and antiviral medication to treat the underlying infection. Empirically, first line treatment for ADEM is usually high dose intravenous methylprednisolone, for 3–5 days, followed by a tapering course of oral steroid over a few weeks. If unresponsive to steroids, plasmapheresis or IVIG can be considered, although the evidence for these is limited. Rarely, acute cerebral oedema, refractory to conventional management, may require decompressive hemicraniectomy.

### Acute haemorrhagic leukoencephalitis

Acute haemorrhagic leukoencephalitis (Hurst's disease) is a rare, severe acute fulminant encephalopathy. There is generally an abrupt onset following an infection, usually respiratory tract, and the precipitating symptoms can be masked. Onset is usually between 20 and 40 years, and it is more common in males. It can occur in children, and has been reported to occur in 2% of a large cohort of children with ADEM. Pathologically it is characterised by

peri-vascular inflammation with destruction of small vessels in association with haemorrhage and demyelination.

### Clinical features

The course is generally brief and rapid, commonly leading to death. Patients present with acute pyrexia, headache, photophobia, meningism leading to progressive encephalopathy with confusion, lethargy and deepening coma over a few days. Focal neurological signs develop and seizures may occur. Cerebral oedema usually develops, frequently causing tentorial herniation resulting in death.

### Investigations

There is marked elevation of the peripheral white cell count and erythrocyte sedimentation rate. The CSF pressure is raised with a moderately elevated protein level and a polymorphonuclear leukocytosis accompanied by an elevated red cell count and xanthochromia. Glucose levels are normal. Oligoclonal bands are rarely present. Computed tomography shows diffuse oedema and may show early haemorrhagic change, MRI shows numerous and large hyper-intense lesions on T2-weighted imaging. Haemorrhagic change can be seen with subsequent development of necrosis. Diffusion-weighted imaging can show restricted diffusion within lesions. Electroencephalography is abnormal in up to 90% of patients with diffuse slowing, although there may be lateralising features.

### Prognosis

The prognosis of AHL is grave and most patients (up to 70%) die within 1 week of onset. Survivors may have severe residual deficits including seizures, cognitive and psychiatric disturbances. Complete recovery is exceptional.

### Management

There is little evidence to guide management but, because of the acute inflammatory nature of the condition, high dose intravenous steroids are used. Surgical decompression can be necessary if severe cerebral oedema develops. Plasma exchange, IVIG and cyclophosphamide have also been tried, with a few reports of more favourable outcomes with early and aggressive treatment.

## CHAPTER 12

# Headache

Manjit Matharu<sup>1</sup>, Paul Shanahan<sup>2</sup> and Tim Young<sup>2</sup>

<sup>1</sup>UCL Institute of Neurology

<sup>2</sup>National Hospital for Neurology & Neurosurgery

Headache is the most common neurological reason for new presentations to general practitioners and to neurologists, and has a lifetime prevalence of 93% in men and 99% in women. As such, it represents a significant part of many clinicians' workload. Despite this, headaches and migraine in particular are a commonly overlooked cause of disability. The World Health Organization ranks a day spent with severe migraine as being equivalent in disability to a day spent with dementia, quadriplegia or psychosis.

While it should go without saying that accurate diagnosis improves management, the Landmark study showed that 76% of patients who had been diagnosed with non-migraine primary headache in primary care had met the criteria for migraine and a further 18% met the criteria for probable migraine. This suggests that there is considerable scope to improve our diagnostic skills in headache, and this represents a significant opportunity for clinicians, given how treatable many of these conditions are.

Although primary headaches constitute the vast majority of what is seen in clinical practice, there is no doubt that the possibility of an underlying secondary aetiology can cause concern in both the patient and the treating clinician. An important part of the initial assessment, therefore, involves determining the likelihood of a secondary cause of headache and investigating as appropriate.

The clinical approach to headache should start with an appropriate assessment and diagnosis, assisted by investigations where necessary, before proceeding to treatment.

## Evaluation of the headache patient

### Headache history taking

Assessment of headache, as with much of neurology, relies primarily on an accurate and detailed history supplemented by clinical examination. As many patients find pain a difficult experience to describe, it is the job of the clinician to bring out the salient features through comprehensive and careful history taking. We recommend particular attention to the following points.

*Onset and time course* The abrupt (or 'thunderclap') onset of severe headache may indicate subarachnoid haemorrhage or other vascular events such as venous sinus thrombosis or arterial dissection and should always be taken seriously, whereas migraine generally evolves more slowly. Migraine also tends to resolve gradually, often

with residual symptoms of lethargy and fatigue, whereas a trigeminal autonomic cephalalgia (TAC), such as cluster headache, may begin and end quite abruptly.

*Frequency and pattern of pain* As well as indicating the total burden of pain experienced, the frequency of attacks may provide a useful clue to diagnosis. For example, a patient experiencing several discrete attacks of pain per day (rather than a day-long headache with brief respites due to analgesia) is less likely to be describing migraine; other disorders such as a TAC or cranial neuralgia may need to be considered. Timing of the individual headaches may be informative: many patients with cluster headache experience attacks at fairly consistent times of day; patients with low cerebrospinal fluid (CSF) pressure may experience pain only on standing up.

*Duration of pain* Provided that the duration of the headache is not being influenced by analgesia, the duration of pain is one of the most helpful characteristics. Long-lasting headaches such as migraine, which typically lasts at least 4 hours without treatment, can be differentiated from shorter attacks such as cluster headache (typical duration 15–180 minutes), paroxysmal hemicrania (typical duration 5–30 minutes) or neuralgic pain (typically lasting seconds).

*Severity and quality of pain* While severity is clearly a subjective quality, it is an important component of overall headache disability and when combined with other attributes may suggest a diagnosis. The pain of tension-type headache, for example, is usually described as mild to moderate whereas that of cluster headache is generally severe or excruciating. The pain of migraine is often described as throbbing or pounding and trigeminal neuralgia is usually described as electric shock-like or stabbing, whereas tension-type headache may be described as pressing or tightening.

*Variability and pattern of pain* Predictable worsening or improvements in pain under certain conditions can be helpful. A consistent diurnal pattern of pain may raise the possibility of a secondary, pressure-related headache: pain caused by raised intracranial pressure may be worse in the morning after a night's recumbency, whereas that of low pressure headache (intracranial hypotension) is

typically minimal on waking and worsens after getting up and as the day goes on. Other causes of a headache maximal on waking include analgesia rebound headache and obstructive sleep apnoea. Cluster headache in some individuals can occur with striking predictability at the same times of day.

**Triggers** A wide range of triggers for migraine attacks have been reported, with the most common including hunger, thirst, lack of sleep, or occasionally oversleeping, stress or occasionally the reverse – winding down following a stressful period, hormonal changes particularly premenstrually and alcohol. Dietary factors seem to be less consistent, and while the popular perception is that migraine has frequent dietary triggers, this can be confounded by food cravings which may occur as a premonitory symptom of migraine and create confusion as to cause and effect. In cluster headache, alcohol is a reliable trigger for the majority of patients when they are experiencing a bout of attacks but not while in remission. Triggering of pain by the Valsalva manoeuvre may occur in cases of raised intracranial pressure, though it may also be seen in cases of low intracranial pressure where there is significant cerebellar tonsillar descent, as well as in cases of Chiari malformation. The neuralgic pain of trigeminal neuralgia, and sometimes that of SUNCT (short-lasting, unilateral neuralgiform pain with conjunctival injection and tearing) may be triggered by having the affected site stimulated by touch, movement, such as speaking or chewing or by a cold breeze on the face.

**Location of pain** The pain of tension-type headache is generally bilateral or holocranial. Although migraine derives its name from the Greek *hemicrania*, its location is often inconstant and, while 60% of migraineurs will experience unilateral attacks, these may swap sides, and 40% will experience bilateral attacks. The TACs, on the other hand, are very rarely bilateral. The pain of trigeminal neuralgia affects the second (maxillary) and third (mandibular) divisions of the trigeminal nerve in approximately 95% of cases, whereas SUNCT more usually affects the first (ophthalmic) division.

**Associated symptoms** Whereas tension-type headache has a paucity of associated symptoms, migraine is a frequently ‘feature-rich’ headache. The most common associated symptoms of migraine are nausea, sensory hypersensitivities (photophobia, phonophobia, osmophobia and sensitivity to motion), fatigue, which may precede the pain and frequently outlasts it, and cognitive effects from impaired concentration to irritability and mood change. It should be noted that these so-called migrainous features, while common in migraine, can also be seen, albeit less frequently, in other headache disorders.

Cranial autonomic symptoms are seen in many primary headache types but are most obviously associated with the TACs. Symptoms such as ptosis, lacrimation, conjunctival injection, rhinorrhoea, nasal congestion, facial flushing or sweating and a sensation of aural fullness may occur singly or in combination. They are ipsilateral to the pain in cluster headache, SUNCT, SUNA (short-lasting unilateral neuralgiform headache with cranial autonomic symptoms), paroxysmal hemicrania and hemicrania continua. These symptoms can also be seen in migraine, but more commonly bilaterally.

Pulsatile tinnitus may be reported by patients with abnormal CSF pressure (either high or low) and is often described as a pulsating, ‘whooshing’ noise.

**Aura** While most commonly associated with migraine, and occurring in 30% of patients, aura has been reported in many of the primary headache syndromes. The time course of the evolution of

symptoms often helps to distinguish it from other causes of transient neurological dysfunction such as transient ischaemic attacks. Typical migraine aura will develop gradually over minutes and may exhibit a somatotopic spread before settling. The most common form of aura is visual; indeed, as visual aura occurs in 99% of patients with aura, one should be wary of diagnosing aura in those who have never experienced visual symptoms. Typically, aura consists of a mixture of positive (e.g. scintillations, fortification spectra) and negative (e.g. scotomata) symptoms which evolves over several minutes and typically lasts from 5 minutes to an hour. Sensory aura (with spreading numbness and paraesthesiae) is the second most common form of aura, occurring in about 30% of patients with aura, with speech disturbance, motor aura and basilar-type aura (bilateral cortical or brainstem symptoms) occurring with decreasing frequency.

**Evolution of symptoms** While it is not unusual for primary headache syndromes to cause varying degrees of disability over time, a history of progressive worsening or evolving symptoms (e.g. the emergence of new aura in a patient with no prior history of aura), or abnormal findings on clinical examination may require further scrutiny or investigation to exclude the possibility of an emerging secondary headache.

**Past medical history** Any history of recent head or neck injury should be carefully sought. As well as being a significant cause of pain in its own right, trauma (occasionally minor trauma in those predisposed) may result in haemorrhage, arterial dissection, nerve injury, CSF leakage or infection, so it is helpful to note any relevant prior history such as anticoagulation or collagenopathy (Marfan’s syndrome, Ehlers–Danlos syndrome) which may increase the risks of secondary headache. Patients with a new diagnosis of migraine may give a history of cyclical vomiting or possibly travel sickness in childhood or adolescence.

Co-morbidities that may exacerbate or contribute to migraine becoming chronic include obesity, sleep apnoea, head injury, stressful life events and overuse of acute relief medication or caffeine, and these factors should be explored in those with increasing headache frequency.

A patient’s headache diary, recording carefully the frequency, severity and pattern of pain as well as any acute medication use, can be invaluable both in clarifying the diagnostic points above and in monitoring response to treatment.

### Examination of the patient with headache

Examination should be directed at excluding any underlying cause and identifying signs that warrant further investigation. At first presentation, all patients should have a thorough examination with particular attention directed to the following points.

In the acute setting, temperature, pulse rate and blood pressure should be measured and the level of consciousness/orientation assessed. Neck stiffness and signs of meningeal irritation should be looked for, as should any evidence of purpuric rash to suggest meningococcal septicaemia.

Fundoscopy should be performed to look for any evidence of papilloedema, while bearing in mind that its absence does not exclude raised intracranial pressure. Subhyaloid haemorrhages may sometimes be seen in subarachnoid haemorrhage.

Examination of the head and neck should include auscultation for cervical or cranial bruits, and assessment of range of neck movement. Palpation of the temporal arteries in patients over 50 years of age may reveal the thickened, often tender arteries of giant cell arteritis (GCA).

Full neurological examination may reveal focal abnormalities including visual field defects (in cerebral or chiasmal lesions) or enlargement of the blind spot, oculomotor disturbance, particularly VIth nerve palsies in raised intracranial pressure or Horner's syndrome, for example in carotid dissection or any evidence of focal neurological dysfunction which requires further investigation.

### Red flags for secondary headaches

In carrying out a full history and examination, the clinician should be alert to any symptoms or signs that raise the possibility of a secondary headache. In particular, the need for further investigations should be considered in the circumstances shown in Table 12.1.

### Investigation of the patient with headache

In those patients where a secondary cause of headache is suspected, further investigation is essential. This includes consideration of the following.

**Blood tests** Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) in cases of suspected GCA. Other investigation is directed at specific systemic diseases.

**Neuroimaging** Computed tomography (CT) imaging is capable of identifying subarachnoid haemorrhage with near 100% sensitivity when performed within 6 hours. Non-contrast magnetic resonance (MRI) enables high-quality structural imaging, including the posterior fossa, as well as highlighting arterial, venous and CSF circulation. Spinal imaging with heavily T2-weighted sequences may aid the detection of spinal CSF leaks in spontaneous intracranial

**Table 12.1** Features that should prompt consideration of secondary headaches.

Worsening headache with fever
Sudden-onset headache reaching maximum intensity within five minutes ('thunderclap headache')
New-onset neurological deficit
New-onset cognitive dysfunction
Change in personality
Impaired level of consciousness
Recent (typically within the past 3 months) head trauma
Headache triggered by Valsalva manoeuvre, coughing or sneezing
Headache triggered by exercise
Orthostatic headache (headache that changes with posture)
Symptoms suggestive of giant cell arteritis
Symptoms and signs of acute narrow-angle glaucoma
A substantial change in the characteristics of their headache
New-onset headache in the presence of any of the following:
• Compromised immunity, caused, for example, by HIV or immunosuppressive drugs
• Age under 20 years and a history of malignancy
• History of malignancy known to metastasise to the brain
• Vomiting without other obvious cause

Source: National Institute for Health and Care Excellence Clinical Guideline 150: Diagnosis and management of headaches in young people and adults, September 2012.

hypotension. Imaging is of no diagnostic value in primary headache, and in patients with a history suggestive of migraine and normal clinical examination findings, the rate of any significant abnormality on imaging is low. Diagnostic imaging should therefore only be a consideration where a secondary headache is suspected. Any decision to perform imaging in headache patients must weigh the potential diagnostic yield, and the reassurance provided against cost, and a definite potential for identification of incidental abnormalities, unrelated to the presenting complaint but capable of causing diagnostic confusion and anxiety.

**Lumbar puncture** In addition to its role in identifying inflammatory and infectious disorders, lumbar puncture, when not contraindicated, enables measurement of CSF pressure as well as its reduction by withdrawal of CSF, for example in cases of idiopathic intracranial hypertension.

## Secondary headaches

The third edition of the International Classification of Headache Disorders (ICHD-III) classifies secondary headaches according to the underlying cause. It is a prerequisite for diagnosis of secondary headache that the underlying condition is recognised as being capable of producing the headache phenotype experienced, and that where possible that the headache can be demonstrated to resolve with successful treatment of the underlying condition.

### Medication overuse headache

While for many clinicians the term secondary headache conjures images of intracranial catastrophes, it is important to remember that the most common cause of secondary headache is medication overuse. It has been estimated that 1.5% of the general population suffer from medication overuse headache (MOH). This entity develops most commonly in those patients with a pre-existing primary headache disorder, typically migraine or tension-type headache, and it is easy to see how a spiral of escalating headache frequency and escalating analgesia use can occur.

ICHD-III defines medication overuse as the use of simple analgesia (paracetamol, aspirin or non-steroidal anti-inflammatory drugs) on 15 or more days per month for at least 3 months. In contrast, triptan or opiate (including codeine) overuse is defined as use of these agents on 10 or more days per month for at least 3 months. It is important to note that frequency, not dosage, is the determinant of overuse; a small daily dosage is more likely to result in MOH than infrequent use of larger doses.

When occurring in the setting of a coexisting primary headache such as migraine, it may be very difficult to establish where migraine ends and MOH begins. Under such conditions, rationalisation of analgesia use is an important therapeutic as well as diagnostic step. Approximately half of patients with MOH who withdraw from analgesia for a 2-month period will experience an improvement in headaches; of the remainder, the majority will stay the same and only a minority (<10%) will worsen. The improvement with analgesia withdrawal is maximal in patients with migraine, in whom two-thirds will improve.

Regular caffeine use of >200 mg (about the equivalent of three espressos) per day, over a period of at least 2 weeks may be associated with withdrawal headaches when interrupted or discontinued. This headache typically resolves within 7 days.

Other medications may provoke headache in their own right, notably nitroglycerin, atropine, digitalis, disulfiram, hydralazine, imipramine, nicotine, nifedipine and nimodipine.

### Headache caused by vascular disorders

Thunderclap headache is perhaps the most striking of the red flag symptoms suggesting secondary headache. It may arise from a number of vascular and non-vascular causes including arterial dissection, venous thrombosis, ischaemic stroke, pituitary apoplexy, reversible cerebral vasoconstriction syndrome and spontaneous intracranial hypotension, but the classic cause of thunderclap headache until proven otherwise is subarachnoid haemorrhage.

### Subarachnoid haemorrhage

Approximately 12% of patients presenting with an acute 'worst headache of my life' and normal clinical examination will be found to have had a subarachnoid haemorrhage. As early recognition and treatment leads to improved outcomes a high index of suspicion in such cases is essential. Prompt non-contrast CT has a sensitivity approaching 100% within 6 hours, but in cases of delayed presentation a lumbar puncture looking for evidence of blood or blood degradation products may be necessary. Some 85% of subarachnoid haemorrhage is aneurysmal and endovascular or surgical occlusion of the aneurysm is necessary to reduce the risk of rebleeding.

### Carotid and vertebral artery dissection

Arterial dissection may occur, particularly in susceptible individuals, in response to trauma of varying severity, though spontaneous cases are not uncommon. The presentation consists of pain in the neck and/or in the head and symptoms of ischaemia distal to the dissection, though 15% may present with headache alone, and ischaemia may be delayed. Neck pain with signs of posterior circulation ischaemia should raise the possibility of vertebral dissection, whereas an ipsilateral Horner's syndrome may be seen in carotid dissection, with or without carotid territory ischaemic symptoms.

### Giant cell arteritis

GCA occurs virtually exclusively in those over 50 years, and incidence rises with age, occurring 10 times more commonly in those over 80 compared to those in the 50–60 age group. It is 2–3 times more common in women than men. Symptoms of scalp tenderness as well as ischaemic pain in the muscles of mastication (jaw claudication) or the tongue (tongue angina) should raise suspicion of the diagnosis. ESR and/or CRP will be elevated in over 95% of cases and definitive diagnosis is established on temporal artery biopsy. Prompt treatment with steroids, typically at least 1 mg/kg initially will rapidly alleviate symptoms and protect against the risk of anterior ischaemic optic neuropathy (AION).

### Headache caused by disturbance of intracranial pressure Intracranial hypertension

A history suggestive of raised intracranial pressure should prompt urgent imaging to look for a structural cause such as a space-occupying lesion (e.g. tumour, abscess, haematoma, hydrocephalus) or venous sinus thrombosis. Once a space-occupying lesion has been excluded, a lumbar puncture may be required to clarify the pressure and lower it if needed. A CSF opening pressure of >250 mm CSF (in the lateral decubitus position) should prompt removal of CSF and the patient should maintain a careful diary of symptoms to establish any improvement in headache post-lumbar puncture.

Idiopathic intracranial hypertension is most commonly seen in young women with a high body mass index (BMI). Papilloedema is usual though cases without papilloedema are recognised. Treatment is directed at lowering CSF pressure to prevent visual loss. Ultimately,

reduction of BMI is usually curative but, as this is slow at best, pressure lowering strategies include drugs (e.g. acetazolamide, bendroflumethazide), repeated lumbar punctures and CSF shunting or optic nerve fenestration when necessary.

Other causes of raised CSF pressure include malignant meningeal infiltration and hypertrophic pachymeningitis and side effects of medications such as anabolic steroids, amiodarone, lithium carbonate, nalidixic acid, retinoids and tetracycline.

### Low pressure headaches (intracranial hypotension)

The most common cause of intracranial hypotension is iatrogenic, following lumbar puncture or inadvertently after epidural anaesthesia. Low CSF pressure (defined as <60 mm CSF in ICHD-III) results in headache that is usually worsened on standing and relieved by lying, though in persistent cases the postural variability may diminish over time. There may be associated neck pain, photophobia, tinnitus (or even hearing loss) and nausea. Some relief may be obtained from caffeine intake. Spontaneous CSF leakage may occur, often as a result of a tear in a spinal nerve root sheath, and the initial trauma may not always be recalled. Spontaneous CSF leakage may be more common in those with a collagen disorders such as hypermobility or Marfan's syndrome.

In post-dural (post LP) headache, where the aetiology is clear, resolution is usually spontaneous within 2 weeks and further investigation may not be required. Cranial MRI in low CSF pressure states may show cerebellar tonsillar descent, sagging of the brainstem, post-contrast enhancement of the meninges and occasionally subdural fluid collections (Figure 12.1). In spontaneous intracranial hypotension the site of CSF leakage is usually spinal and careful imaging with heavily T2-weighted spinal MRI (such as constructive interference steady state [CISS] sequences) or even CT myelography may be required to identify the site of leakage.

Where leakage has been identified, or inferred in the case of persistent post-dural puncture headache, epidural blood patching with autologous blood is the treatment of choice. Effective closure of the leak should result in resolution of the headache, though in refractory cases repeated blood patching and (rarely) operative repair may be required.

ICHD-III lists a very extensive list of other causes of secondary headache, beyond the scope of this chapter, and the reader is encouraged to refer to this to appreciate the broad spectrum of causes of secondary headache.

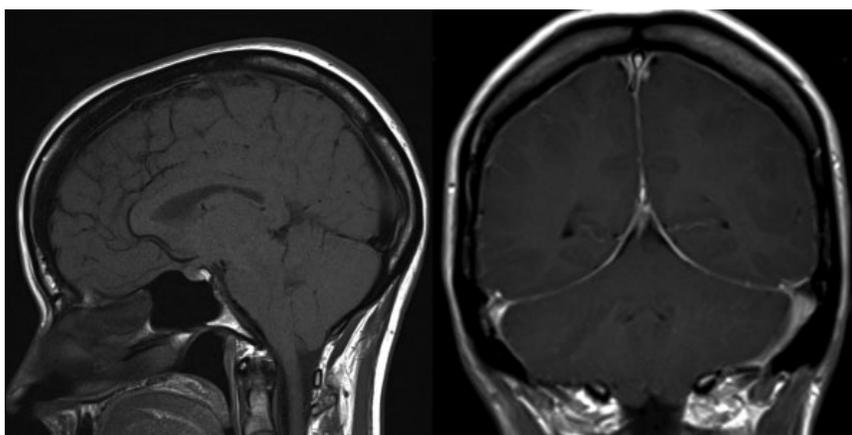

When evaluating a patient for secondary headache, bear in mind that with the exception of MOH, secondary headaches are rare and the reassurance of excluding a secondary cause should not be a substitute for diagnosing and treating a primary headache.

### Primary headaches

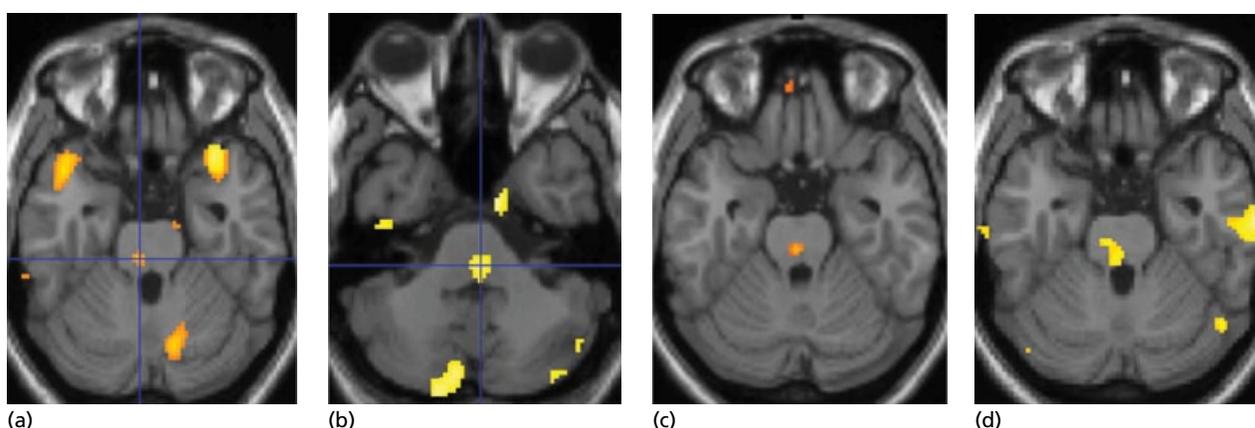

Primary headaches are disorders in which headache and associated features are seen in the absence of any exogenous cause. The common syndromes are tension-type headache, migraine and cluster headache.

### Anatomy and physiology of headache

The disabling primary headaches, migraine and cluster headache, have been studied extensively and are now relatively well understood. The detailed anatomy of the neural substrate of head pain is now well described. Surrounding the largest cerebral vessels, meningeal vessels, large venous sinuses and dura mater is a plexus consisting largely of small-diameter myelinated and unmyelinated fibres which arise

**Figure 12.1** Low cerebrospinal fluid (CSF) pressure headache: magnetic resonance image (MRI) showing tonsillar descent and diffuse meningeal enhancement.

mainly from the trigeminal nerve and the upper cervical dorsal roots. These fibres project centrally to synapse on second order sensory neurones in the trigeminal brainstem nuclear complex, composed of the principal trigeminal sensory nucleus and the spinal trigeminal nucleus. Projections from this trigeminocervical complex cross the midline and ascend in the contralateral quinto-thalamic tract to connections in the brainstem (peri-aqueductal grey; PAG) and diencephalon (hypothalamus), and thence ultimately to thalamic nuclei and cerebral cortex (Chapter 2). Cortical areas associated with nociception include primary and secondary somatosensory cortices, cingulate cortex, insulae, visual and auditory areas, and frontal cortices. A reflex connection exists between neurones in the pons in the superior salivatory nucleus, which results in a cranial parasympathetic outflow that is mediated through the pterygopalatine ganglia; this provides the basis for symptoms, such as lacrimation and nasal stuffiness, which are prominent in trigeminal autonomic cephalalgias. Transmission of pain is modulated by a powerful descending antinociceptive neural network extending from the frontal cortex and the hypothalamus through the PAG to medulla.

Primary headaches such as migraine and cluster headache are neurovascular disorders. The central underlying abnormality is a disorder of the endogenous pain modulating antinociceptive systems. The structures of the antinociceptive system, besides participating in nociceptive control, modulate other sensory modalities and can alter brain blood flow. The abnormality underlying primary headaches is hypothesised to result in an alteration of function of these systems – either activation of descending systems that facilitate processing of pain signals by trigeminocervical neurones, or suppression of descending pathways that inhibit such processing of pain signals or a combination of systems dysfunctions. The result is central hyperalgesia and an augmentation of the central perception of pain.

Functional neuroimaging studies have provided evidence of a role for brainstem dysfunction in migraine and hemicrania continua (Figure 12.2) and a region near the posterior hypothalamic grey matter, the site of the human circadian pacemaker cells of the suprachiasmatic nucleus in the pathogenesis of the TACS, including cluster headache (Figure 12.3).

## Migraine

Migraine is very common worldwide, affecting some 18% of the population, and is more frequent in women than men. It is a primary headache disorder which may be episodic or chronic. Migraine causes significant morbidity and lost productivity, and costs the United Kingdom over £2 billion a year in absenteeism alone. The Global Burden of Disease Survey recently estimated migraine to be the seventh greatest specific cause of disability globally. Despite this, it is frequently undiagnosed and undertreated. This section examines the features of migraine together with aspects of its management.

### Epidemiology

In England the 1-year prevalence of migraine has been estimated at 7.6% for men and 18.3% for women. The 1-year prevalence of episodic migraine in the North American population has recently been estimated at 11.7% (17.1% in women and 5.6% in men) based on a large postal questionnaire survey. The incidence of episodic migraine is less clear. Based on a Danish 12-year follow-up population study the annual incidence of episodic migraine was 8.1/1000 person years.

The prevalence of chronic migraine has been widely studied with estimates between 0 and 5.1% for 1-year prevalence being described for the general population. The incidence for chronic migraine has not been well studied. A figure of 14% has been given as the annual incidence of transformation of episodic to chronic migraine but this was made in specialist headache clinics so may not be applicable to the general population. In the community an estimated 2.5% of episodic migraineurs transformed into chronic migraine over a 1-year period in the United States.

### Clinical features

Migraine is usually episodic, with headaches occurring on less than 15 days per month. Chronic migraine involves headaches affecting the patient on 15 or more days a month for more than 3 months with features of migraine headaches on at least 8 days a month. It can be very helpful to ask patients how many headache *free* days they have had in the last month as well to pick up any additional lower level headaches, which are often described by patients as 'normal' headaches.

Migraineurs may have a warning that a headache is due to occur by premonitory symptoms up to 2 days before the headache, which can include yawning, increased micturition or fatigue. Estimates of the proportion of patients who experience premonitory symptoms vary widely, ranging from 7% to 87%. The migraine headache itself may have a variety of features and associated features. ICHD-III requires

at least five separate attacks each lasting 4–72 hours if untreated. The headache should have at least two of the following characteristics: unilateral location, pulsating quality, at least moderately severe, and aggravated by routine physical movement such as walking or climbing stairs. In addition there should be at least one of the following associated features during the headache: nausea with or without vomiting, or both photophobia and phonophobia. Importantly, there are caveats to the above criteria. While useful to define migraine for research purposes many migraineurs will not exhibit all of the above features. On the other hand, a patient may exhibit all the clinical features of migraine and yet have a secondary headache disorder. No one characteristic is critical for the diagnosis though duration of the headache can be one of the most helpful characteristics in distinguishing migraine from other primary headaches.

Just over 30% of migraineurs will experience auras with some or all of their headaches. Auras are recurrent episodes of reversible focal neurological symptoms typically developing gradually over 5–30 minutes and lasting for less than 60 minutes. They usually occur before or at the start of the headache. The auras are most commonly visual with positive symptoms, such as flashing lights or zig-zag lines and negative symptoms such as scotomata. Other relatively common types of auras include sensory and speech or language disturbance. Uncommon types of aura include motor (with hemiplegic symptoms) and brainstem (with dysarthria, vertigo, tinnitus, hyperacusis, diplopia, ataxia and decreased level of consciousness) disturbance for which careful exclusion of secondary causes is mandatory. The pathophysiology of the underlying auras is believed to involve a wave of cortical spreading depression in the relevant sensory area associated with initial hyperaemia followed by prolonged hypoperfusion. Less commonly, auras can occur with other primary headaches including cluster headaches, or even without headache at all, in which case it is especially important to exclude transient ischaemic attacks. Women who experience migraine with visual aura have an increased risk of stroke which is approximately trebled if they smoke and trebled if on the combined oral contraceptive pill.

### Assessment and investigations

Where a clear phenotype of long-standing and stable migraine has been established from the history together with a normal examination, imaging should not routinely be requested. However, focal neurological signs, atypical aura or prolonged aura may well justify MRI. While unusual (except for MOH), secondary causes do need to be borne in mind in patients with migrainous sounding headaches that are rapidly worsening.

Potentially significant abnormalities on MRI in patients with headache without neurological signs are found in less than 1%. However, even in healthy young adults, incidental changes on MRI are seen in nearly 10% of cases and may then require follow-up before being cleared as harmless. This usually generates considerable anxiety.

Keeping a diary each day to record headaches is often a helpful step. Recording should include the pain severity, duration of attacks and medications used. In females, the time of menses can also be recorded. Diaries should document the numbers of days abortive treatments are used to try and identify or avoid medication overuse. Disability can be assessed using a scale such as the Migraine Disability Assessment Scale (MIDAS), which is well validated and easy to use in clinical practice (Figure 12.4).

## Management

The management of migraine includes non-pharmacological strategies, pharmacological treatments (acute and preventive treatments) and, rarely, surgery.

### Non-pharmacological strategies

*Migraine triggers and predisposing factors* Migraineurs are often more sensitive to sensory stimuli than non-migraineurs. Thus, factors such as sleep disruption, skipping meals, perceived changes in stress levels or menstrual cycle sometimes can be significant factors in triggering or worsening migraine attacks. Therefore, patients should be advised to lead as regulated a life as is possible and acceptable. Healthy diets with regular eating patterns, good hydration, regular sleep, regular exercise, avoiding excessive caffeine and alcohol, and modifying or minimising stress will benefit most patients.

*Cognitive behavioural therapy (CBT)* CBT typically involves face-to-face meetings with a clinical psychologist although group sessions are sometimes used. It may seem rational to have some negative thoughts and emotions about a painful situation, but it can be helpful to explore the exact thoughts and emotions the patient experiences. These may be irrational, even involving catastrophising, and these beliefs may be then targeted and the patient encouraged to substitute these with more logical alternatives. Successful CBT can allow the patient to shift the locus of control from external chance to internal control. Rather than being seen as alternative to pharmacological treatments, behavioural therapies can be used successfully in conjunction with drugs. When successful, CBT can not only help the headache experience, but may also help to lessen some of the associated anxiety which can be co-morbid with migraine. It is advisable to be as specific as possible if asking others to refer on for CBT; patients may mistakenly end up having alternative approaches such as psychoanalysis offered.

*Acupuncture* This is commonly tried by patients even before being seen in specialty clinics. There are different techniques but at least some evidence for effectiveness. A recent study claimed similar results in chronic migraine to topiramate, although physician-patient interaction time was very different between the groups. While the evidence for efficacy is not overwhelming, acupuncture from an accredited practitioner is generally seen as safe and is included as an accepted treatment in the recent National Institute for Health and Care Excellence (NICE) headache guidelines for migraine prophylaxis.

*Acute attack treatments* General approaches to acute pharmacological treatment in migraine include either stepped or stratified

care. Stratified approaches develop a treatment plan for individual patients depending on the severity of the headaches while stepped approaches with treatment ladders provide a more generic approach starting at cheapest and safest options and build up as needed. Some pharmaco-economic evidence exists in favour of a stratified approach, which is more patient-centred.

Acute treatments are generally divided into non-specific (paracetamol, non-steroidal anti-inflammatory drugs, opioids), which may be effective for other pain types, or migraine specific (triptans or ergots) (Table 12.2). If an individual acute treatment is ineffective in at least two out of three trials, it is considered a treatment failure. While a useful rule of thumb, this 'three strikes and you're out' approach does not entirely exclude the possibility that a different formulation of the drug might sometimes work for that individual. Importantly, there may be different approaches to different types of headaches that the patient recognises.

While early treatment is important to success, some patients cannot predict early on which will be a severe headache and too frequent use of acute treatments may result in the dangers of medication overuse. Patients should be advised to limit the intake of paracetamol and NSAIDs to less than 15 days per month while triptans, ergots and any other combination of acute headache treatments should be limited to 10 days per month. The use of a headache diary is helpful to keep track of both the headaches and treatment days.

If an oral acute medicine is not effective a retrial with an antiemetic should be considered. In patients who have significant nausea or vomiting agents such as prochlorperazine 3–6 mg as buccal preparations, metoclopramide or domperidone can be used. Very importantly, however, antiemetics that have prokinetic action help counter the gastric stasis often seen in migraine which then aid absorption of the oral medication. These motility agents include metoclopramide 20 mg, or domperidone 10–20 mg. The use of motility agents with acute treatments can result in improved efficacy of the abortive treatment.

NSAIDs can be effective for migraine but high doses may be required, for example ibuprofen 400–800 mg or aspirin 600–1000 mg, ideally in a form to aid absorption such as effervescent tablets. Paracetamol can be added but opioids are generally discouraged for migraine, not least because of the dangers of developing medication overuse headaches. If nausea or vomiting is prominent, diclofenac suppositories (100 mg) have been used as well as antiemetics.

Migraine specific treatments are dominated by the triptans. Generally, they are fairly well tolerated although uncontrolled cardiovascular risk factors can be a contraindication. The recent NICE headache guideline has suggested that a triptan should be combined with an antiemetic and either paracetamol or an NSAID as an initial treatment if deemed appropriate. The response to one triptan does not predict the response to other triptans, hence they should be tried in turn until the patient can identify an effective agent. A common problem is the relapse of headaches in the first 24 hours after successful initial treatment. For this reason a second dose is often considered within 24 hours if there is relapse after at least 2 hours. Care again has to be taken to educate against the dangers of medication overuse. Triptans should be used for the headaches and not for any preceding aura.

Rather than randomly selecting triptans until all have been tried, an approach can be made to rationalise this by trying to opt first for those with better evidence of effectiveness, tolerability and price. The difficulty is that some triptans will be favourable for one or two of these criteria but not all. All prescription triptans have placebo-controlled evidence to suggest effectiveness in migraine.

## The Migraine Disability Assessment Test

The **MIDAS** (Migraine Disability Assessment) questionnaire was put together to help you measure the impact your headaches have on your life. The information on this questionnaire is also helpful for your primary care provider to determine the level of pain and disability caused by your headaches and to find the best treatment for you.

### INSTRUCTIONS

Please answer the following questions about ALL of the headaches you have had over the last 3 months. Select your answer in the box next to each question. Select zero if you did not have the activity in the last 3 months. Please take the completed form to your healthcare professional.

- \_\_\_\_\_ 1. On how many days in the last 3 months did you miss work or school because of your headaches?
- \_\_\_\_\_ 2. How many days in the last 3 months was your productivity at work or school reduced by half or more because of your headaches? (Do not include days you counted in question 1 where you missed work or school.)
- \_\_\_\_\_ 3. On how many days in the last 3 months did you not do household work (such as housework, home repairs and maintenance, shopping, caring for children and relatives) because of your headaches?
- \_\_\_\_\_ 4. How many days in the last 3 months was your productivity in household work reduced by half or more because of your headaches? (Do not include days you counted in question 3 where you did not do household work.)
- \_\_\_\_\_ 5. On how many days in the last 3 months did you miss family, social or leisure activities because of your headaches?
- \_\_\_\_\_ Total (Questions 1-5)

### What your Physician will need to know about your headache:

- \_\_\_\_\_ A. On how many days in the last 3 months did you have a headache? (If a headache lasted more than 1 day, count each day.)
- \_\_\_\_\_ B. On a scale of 0 - 10, on average how painful were these headaches? (where 0=no pain at all, and 10=pain as bad as it can be.)

**Scoring:** After you have filled out this questionnaire, add the total number of days from questions 1-5 (ignore A and B).

MIDAS Grade	Definition	MIDAS Score
I	Little or No Disability	0-5
II	Mild Disability	6-10
III	Moderate Disability	11-20
IV	Severe Disability	21+

**If Your MIDAS Score is 6 or more, please discuss this with your doctor.**

**Figure 12.4** MIDAS headache questionnaire. MIDAS score (add the total number of days from questions 1–5; ignore A and B) 0–5 little disability; 6–10 mild disability; 11–20 moderate disability; 21+ severe disability.

A meta-analysis has been performed to allow a comparison of triptans with results for sumatriptan 100 mg in terms of effectiveness and tolerability. While this acknowledged the greatest experience with sumatriptan, it suggested that rizatriptan 10 mg, eletriptan

80 mg and almotriptan 12.5 mg gave the highest likelihood of consistent success. Zolmitriptan 2.5 or 5 mg tablets were comparable to sumatriptan 100 mg. Naratriptan 2.5 mg showed lower efficacy but better tolerability. Frovatriptan was not included in this study, but the available data suggests that it has a lower efficacy but better tolerability than sumatriptan 100 mg.

Non-oral triptans may be of use with early vomiting or rapid onset headaches:

- Buccal: 'melt' forms of rizatriptan and zolmitriptan exist with evidence for their efficacy and speed of onset.
- Intranasal forms of sumatriptan and zolmitriptan exist. Importantly though, intranasal sumatriptan is still mainly absorbed enterally therefore not by-passing the problem of gastric stasis. This is less of a problem with zolmitriptan spray with about 30% of absorption occurring via the nasopharyngeal route.
- A subcutaneous triptan option only exists for sumatriptan. Subcutaneous sumatriptan can be extremely effective and rapid in onset.

Ergotamine can be effective but tolerability is a concern and is poorly absorbed orally with significant contraindications and side effect profile. The recent NICE guidelines specifically advised against the use of ergot-derived treatments for acute treatment of migraine.

The use of migraine-specific treatments in some special circumstances is summarised in Table 12.3.

**Table 12.2** Acute migraine treatments.

Non-specific treatments	Specific treatments
<b>Simple analgesics</b>	<b>Triptans</b>
Aspirin (600–1000 mg)	Sumatriptan (50–100 mg)
Paracetamol (1000 mg)	Almotriptan (12.5 mg)
	Rizatriptan (10 mg)
<b>NSAIDs</b>	Zolmitriptan (2.5–5 mg)
Ibuprofen (400–800 mg)	Eletriptan (40–80 mg)
Naproxen (500–1000 mg)	Frovatriptan (2.5 mg)
Tolfenamic acid (200 mg)	Naratriptan (2.5 mg)

Ergots and opiates should be avoided due to the risk of developing medication overuse headache.

Acute migraine treatments can be used with antiemetic/prokinetics such as domperidone, prochlorperazine or metoclopramide.

NSAIDs, non-steroidal anti-inflammatory drugs.

**Table 12.3** Acute treatments for migraine in special circumstances.

Clinical situation	Treatment options	Comments
Early nausea or vomiting	Rizatriptan MLT wafer 10 mg Sumatriptan nasal spray 20 mg Zolmitriptan nasal spray 5 mg Subcutaneous sumatriptan 6 mg	
Rapidly developing symptoms	Subcutaneous sumatriptan 6 mg	
Headache recurrence	Frovatriptan 2.5 mg Naratriptan 2.5 mg Almotriptan 12.5 mg Eletriptan 40 mg Ergotamine 1–2 mg	Ergotamine should not be used within 12 hours of a triptan
Poor tolerance of side effects	Naratriptan 2.5 mg Frovatriptan 2.5 mg Eletriptan 20 mg	Efficacy may be slightly less with these drugs
Menstrually related migraine – acute treatment	Triptans Dihydroergotamine nasal spray	Mini-prophylaxis with frovatriptan 2.5 mg twice daily, zolmitriptan 2.5 mg three times daily or naproxen 500 mg twice daily can be considered for 5–7 days starting 2 days before the period
Pregnancy	Paracetamol NSAIDs such as ibuprofen may be considered but still can cause problems especially in the third trimester with risk of bleeding or premature closure of the ductus arteriosus Sumatriptan has the most available data for use in pregnancy. From the available pregnancy registers no significant associations with major fetal abnormalities have been established though the data available is limited	The majority of women will experience improvement in their migraines as their pregnancy progresses

**Preventative treatments** Preventative treatment may help not only to reduce the frequency of headaches, but also to reduce severity of attacks and improve the effectiveness of acute medication. While typically having more than four headache days per month could lead to consideration of preventatives for some, less frequent headaches, especially if not responsive to acute treatment, may also be an indication for the use of such measures.

MOH has been discussed earlier, with evidence to support withdrawal to improve the headache. Another difficulty that may arise from medication-overuse is that patients may become less susceptible to preventatives. For much of the last decade fairly standard practice would be either to withdraw the medications being overused first for 1–2 months and then introduce a preventative or introduce a preventative at the same time as withdrawing. Recent analysis of evidence from trials in which topiramate or onabotulinumtoxinA appeared to benefit some patients in whom medication overuse was present has led to some debate on this issue.

Most preventatives had been developed for conditions other than headache and many have some evidence to support their use. Commonly used agents can be grouped into antiepileptic drugs, beta-blockers and tricyclic antidepressants. Other groups of agents used include serotonergic antagonists (pizotifen, methysergide), calcium channel antagonists (flunarizine), angiotensin modulators (angiotensin-converting enzyme inhibitors and angiotensin receptor inhibitors), nutrients and vitamins (co-enzyme Q10, riboflavin, magnesium) and herbal products such as feverfew.

The co-morbidities of the patient should be factored into choice, for example asthma excludes beta-blockers, a history of kidney stones or depression may contraindicate topiramate while topiramate may promote weight loss and therefore be favoured in patients with high BMI. Most preventatives have teratogenic potential although this is likely to be greatest for valproate. This is an important point, especially as many patients may be of childbearing age and some agents such as topiramate may increase likelihood of oral contraceptive failure.

The currently available evidence base is best for propranolol or topiramate. Valproate also has evidence for efficacy but has a significant side effect profile and teratogenicity is a particular concern. All three medicines were deemed to be effective in a recent American Academy of Neurology and American Headache Society report and can be considered for migraine prevention. Tricyclic antidepressants have long been used in migraine though the available evidence is difficult to assess because a range of doses, durations and drugs have been used in studies. A recent meta-analysis of randomised clinical trials of tricyclic antidepressants in migraine included 13 studies between 1966 and 2010 and concluded that the overall evidence was favourable. The options available for preventative treatments are covered in Table 12.4.

Whichever preventative is chosen, starting low and gradually increasing the dose typically over 2–4 weeks until either unacceptable side effects develop, a clear improvement emerges or until a maximum dose is reached. There can be a lag of up to 2 months after the optimum dose is achieved and therefore it is important to ensure that patients remain on these agents for a suitable duration of time.

In selected cases, combinations of preventatives can be beneficial where monotherapy has failed. Specific evidence exists for beta-blockers with topiramate, beta-blockers with valproate and

**Table 12.4** Preventive treatments in migraine.

Drug	Dose	Selected side effects
<b>Beta-blockers</b>		
Propranolol	40–120 mg twice daily	Reduced energy Tiredness
Metoprolol	100–200 mg/day	Postural symptoms Erectile dysfunction Contraindicated in asthma
<b>Antiepileptic agents</b>		
Topiramate	25–200 mg/day	Parasthesiae Cognitive dysfunction Weight loss Glaucoma Renal stones
Valproate	400–600 mg twice daily	Drowsiness Weight gain Tremor Hair loss Fetal abnormalities Haematological and liver abnormalities
<b>Tricyclic antidepressants</b>		
Amitriptyline	10–75 mg nocte	Drowsiness
Dothiepin	25–75 mg nocte	Dry mouth
Nortriptyline	10–75 mg nocte	Some patients are very sensitive and may only need a total dose of 10 mg, although generally 1–1.5 mg/kg body weight is required for a response
<b>Serotonergic modulators</b>		
Pizotifen	0.5–3 mg/day	Drowsiness Weight gain
Methysergide	1–6 mg/day	Drowsiness Leg cramps Hair loss Retroperitoneal fibrosis (a 1-month drug holiday is required every 6 months)
<b>Calcium channel antagonists</b>		
Flunarizine	5–10 mg/day	Lethargy Weight gain Depression Parkinsonism
<b>Angiotensin-based modulators</b>		
Lisinopril	10–20 mg/day	Persistent dry cough
Candesartan	8–32 mg/day	Hypotension
Telmisartan	20–80 mg/day	

Table 12.4 (continued)

Drug	Dose	Selected side effects
<b>Neutraceutical</b>		
Riboflavin	400 mg/day	Diarrhoea
Coenzyme Q10	300–600 mg/day	
Magnesium	600 mg/day	
<b>Controlled trials demonstrate no effect</b>		
Selective serotonin reuptake inhibitors (e.g. fluoxetine)		
Gabapentin		
Nimodipine		
Clonidine		
<b>No convincing controlled evidence</b>		
Verapamil		

topiramate with nortriptyline. While chronic migraine is also treated with preventative agents, the evidence base for preventatives is mainly focused on patients with episodic migraine. Specifically for chronic migraine there is evidence for topiramate, and OnabotulinumtoxinA as well as some limited evidence for acupuncture.

The two key PREEMPT studies looked at the effect of onabotulinumtoxinA (Botox) on chronic migraine versus saline placebo. The studies used 155–195 units of onabotulinumtoxinA injected at 31–39 sites around the head and neck. The pooled results of the two PREEMPT studies showed that from a similar baseline of around 19 days a month, after 24 weeks those who received Botox experienced a mean of 8.4 fewer headache days compared with a drop of 6.6 days in the placebo arm ( $P < 0.001$ ). A variety of other secondary end-points also favoured Botox over placebo.

For highly disabled chronic migraine patients who are intractable to medical treatments, there is emerging evidence that occipital nerve stimulation can be useful.

### Tension-type headache

Tension-type headache (TTH) is a relatively featureless headache, unlike migraine. Like migraine, TTH can be divided into episodic or chronic forms depending on whether patients have headaches on less or more than 15 days per month.

### Epidemiology

While TTH is more common in the community than migraine, affecting over 60% of the population in Europe, they are not often seen in isolation in specialist headache clinics unless coexisting with migraines. This reflects the lower severity of TTH compared with migraine. In secondary or tertiary care one should be careful before diagnosing TTH and carefully consider migraine first even if it does not have many migrainous characteristics.

### Clinical features

The episodic forms tend not to be severe, although chronic TTH can be associated with significant disability. The duration range is typically wider than for migraine. The ICHD-III (beta) definition lists the range as between 30 minutes and 30 days. TTH are not typically associated with the migrainous features such as photophobia, phonophobia, nausea and motion sensitivity. They are usually pressing or tightening headaches rather than throbbing.

### Investigations

Clear cases of episodic TTH with a normal examination do not require routine imaging. As with migraine, if there was rapid progression or abnormal signs on examination then imaging and even lumbar puncture may need considering.

### Management

Education and reassurance is especially important for TTH. Medical treatment may not even be needed but there is a potential danger of exacerbating the situation with excessive analgesia use. For acute treatment there is some evidence to support the use of NSAIDs such as naproxen and aspirin as well as paracetamol for episodic TTH.

Amitriptyline is often used where prophylaxis is required for TTH. A recent meta-analysis of tricyclic antidepressants found 17 randomised published studies focusing on TTH. Overall, the outcome was found to be similar to that for tricyclic antidepressants in migraine. Topiramate has also been shown to be potentially helpful in TTH. For frequent episodic or chronic TTH a course of acupuncture up to 10 sessions over 5–8 weeks may be beneficial.

### Trigeminal autonomic cephalalgias

The trigeminal autonomic cephalalgias (TACs) are a group of primary headache disorders characterised by unilateral head pain that occurs in association with ipsilateral cranial autonomic features. The TACs include cluster headache, paroxysmal hemicrania, short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT) and its closely related variant short-lasting unilateral neuralgiform headache attacks with cranial autonomic symptoms (SUNA) as well as hemicrania continua. The TACs differ in attack duration and frequency as well as the response to therapy (Table 12.5). The importance of recognising these syndromes resides in their excellent but highly selective response to treatment.

### Cluster headache

Cluster headache is an excruciating syndrome and is probably one of the most painful conditions known to mankind with female patients describing each attack as being worse than childbirth. The central feature of cluster headache is its striking circannual (cycles that recur each year) and circadian periodicity.

### Epidemiology

Cluster headache is a rare primary headache with a prevalence of 0.2%. There is a male predominance of 3.5–7 : 1.

### Clinical features

The headaches are strictly unilateral, though attacks of pain can switch sides. The pain is excruciatingly severe. It is located mainly around the orbital and temporal regions though any part of the head can be affected. The headache lasts between 15 minutes and 3 hours. The signature feature of cluster is the association with autonomic symptoms. ICHD-III (beta) require the cluster attacks to be accompanied by at least one of the following, which have to be present on the pain side: conjunctival injection, lacrimation, miosis, ptosis, eyelid oedema, rhinorrhoea, nasal blockage and forehead or facial sweating, or restlessness or agitation. The autonomic features are transient, lasting only for the duration of the attack, with the exception of partial Horner's syndrome; ptosis or miosis may rarely persist, especially after frequent attacks.

**Table 12.5** Clinical features of trigeminal autonomic cephalalgias.

	Cluster headache	Paroxysmal hemicranias	SUNCT/SUNA	Hemicrania continua

There are several descriptions of the full range of typical migrainous symptoms in significant proportions of cluster patients. Migrainous symptoms such as nausea, vomiting, photophobia, phonophobia and even aura symptoms have all been described in relationship to cluster attacks. However, in contrast to migraine, cluster headache sufferers are usually restless and irritable, preferring to move about, and looking for a movement or posture that may relieve the pain.

The cluster attack frequency varies between one every alternate day to three daily, although some have up to eight daily. The condition can have a striking circadian rhythmicity, with some patients reporting that the attacks occur at the same time each day. Alcohol, the smell of volatile substances, exercise, and elevated environmental temperature are recognised precipitants of cluster attacks.

Cluster headache is classified according to the duration of the bout. About 80–90% of patients have episodic cluster headache (ECH), which is diagnosed when they experience recurrent bouts, each with a duration of more than a week and separated by remissions lasting more than 4 weeks. The remaining 10–20% of patients have chronic cluster headache (CCH) in which either no remission occurs within 1 year or the remissions last less than 1 month. Most

patients with episodic cluster headache have one or two annual cluster periods, each lasting between 1 and 3 months. Often, a striking circannual periodicity is seen with the cluster periods, with the bouts occurring in the same month of the year.

### Investigations

The diagnosis of cluster headache is made entirely on the basis of a clinical history and neurological examination. However, it is very difficult to clinically dissect the secondary causes from primary cluster headache. MRI of the brain is a reasonable screening investigation.

### Management

The management of cluster includes using acute attack treatments, preventive agents and, rarely, surgical approaches.

**Acute attack treatments** The pain of cluster headache builds up very rapidly to such an excruciating intensity that most oral agents are too slowly absorbed to cure the pain within a reasonable period of time. The most efficacious abortive agents are those that involve parenteral or pulmonary administration (Table 12.6).

**Table 12.6** Acute attack treatments for cluster headache.

Good efficacy	Oxygen 100% at 7–12 L/min for 15–30 minutes Sumatriptan subcutaneous injection 6 mg (maximum twice daily for the duration of the cluster bout)
Moderate efficacy	Sumatriptan nasal spray 20 mg (maximum thrice daily for the duration of the cluster bout) Zolmitriptan 5 or 10 mg (for episodic cluster headache only)
Poor efficacy or unproven	Ergotamine tablets or suppository Intranasal lidocaine

Inhalation of oxygen is highly effective in the majority of patients. Oxygen needs to be used at a high concentration (100%) and flow-rate (7–12 L/min) for 15–20 minutes. Injectable sumatriptan 6 mg is the agent of choice for the acute treatment of cluster attacks. It has a rapid effect and high response rate with no evidence of tachyphylaxis. Though sumatriptan 20 mg and zolmitriptan 5 mg nasal sprays are effective in acute treatment, they are considerably less efficacious than injectable sumatriptan. However, they offer a useful option for patients who do not wish to self-inject regularly. There is no controlled evidence to support the use of oral sumatriptan in cluster headache. Oral sumatriptan 100 mg three times daily taken prior to an anticipated onset of an attack or at regular times does not prevent the attack and therefore it should not be used. Oral zolmitriptan 5 mg provides meaningful pain relief in episodic but not chronic cluster headache. However, its efficacy is modest and does not approach the efficacy or speed of subcutaneous sumatriptan or oxygen.

**Preventive treatments** The aim of preventive therapy is to produce a rapid suppression of attacks and to maintain that remission with minimal side effects until the cluster bout is over, or for a longer period in patients with chronic cluster headache.

Verapamil is the preventive drug of choice in both ECH and CCH. Clinical experience has demonstrated that higher doses than those used in cardiological indications are needed. Dosages commonly employed range from 240–960 mg/day in divided doses. Verapamil can cause heart block by slowing conduction in the atrioventricular node. Observing for PR interval prolongation on ECG can monitor potential development of heart block. After performing a baseline ECG, patients are usually started on 80 mg three times daily and thereafter the total daily dose is increased in increments of 80 mg every 10–14 days. An ECG is performed prior to each increment. The dose is increased until the cluster attacks are suppressed, side effects intervene or the maximum dose of 960 mg/day is achieved. About 20% of patients with cluster headache on verapamil have cardiac conduction problems and these can develop after months of stable dosing and are not dose-dependent. Thus, an ECG needs to be performed every 6 months with long-term therapy.

Other preventive treatment options include lithium and methysergide. Though topiramate, sodium valproate, pizotifen and gabapentin are often used, they are of as yet unproven efficacy.

**Transitional therapies** As preventative medications can take a number of weeks to exert their full effect, patients with short bouts or

patients in whom one wishes to quickly control attack frequency may benefit from a transitional or bridging treatment. These interventions are not suitable for long-term use and so may require concurrent use with traditional preventative agents. A short course of steroids is the most commonly used transitional agent but a greater occipital nerve block is another option.

**Surgery** This is a last-resort measure in treatment-resistant patients. Procedures may be destructive, such as pterygopalatine ganglion or trigeminal ganglion procedures, or even trigeminal nerve root section. Most recently, neurostimulation therapies with occipital nerve stimulation, sphenopalatine ganglion stimulation and deep brain stimulation of the posterior hypothalamic region have emerged. These approaches are very promising and especially occipital nerve stimulation and sphenopalatine ganglion stimulation offer a more acceptable side effect profile than destructive and invasive approaches.

### Paroxysmal hemicrania

Paroxysmal hemicrania is a rare syndrome that responds in a dramatic and absolute fashion to indometacin, thereby underlining the importance of distinguishing it from cluster headache, SUNCT and SUNA, which are not responsive to indometacin.

**Clinical features** The clinical phenotype of paroxysmal hemicrania is highly characteristic. Patients typically have unilateral, relatively brief, severe attacks of pain associated with cranial autonomic features that recur several times per day. The attacks have an abrupt onset and cessation. The pain is strictly unilateral and centred around the orbital and temporal regions though any part of the head can be affected. It is excruciatingly severe. The headache usually lasts 2–30 minutes. Attacks of paroxysmal hemicrania invariably occur in association with ipsilateral cranial autonomic features. Up to 85% of patients report at least one migrainous feature of photophobia, nausea or vomiting during an attack. Similar to cluster headache, patients are often restless or agitated during an attack. The frequency of attacks in paroxysmal hemicrania is high, ranging from 1 to 40 daily. The attacks occur regularly throughout the 24-hour period without a preponderance of nocturnal attacks as in cluster headache. While the majority of attacks are spontaneous, approximately 10% of attacks may be precipitated mechanically, either by bending or by rotating the head. Attacks may also be provoked by external pressure against the transverse processes of C4–5, C2 root or the greater occipital nerve. Alcohol ingestion triggers headaches in only 7% of patients.

**Investigations** The diagnosis of paroxysmal hemicrania is made entirely on the basis of a good clinical history and a detailed neurological examination. As a relatively high number of symptomatic cases have been reported, MRI of the brain should be routinely performed in all patients with paroxysmal hemicrania.

**Management** Indometacin leads to complete resolution of the headache. This is usually prompt, occurring within 1–2 days of initiating the effective dose. The typical maintenance dose ranges from 25 to 100 mg/day but may vary inter- and intra-individually between 12.5 and 300 mg/day. Therapy with indometacin can lead to gastrointestinal side effects. For patients who cannot tolerate indometacin one faces a difficult challenge. No other drug is consistently effective in paroxysmal hemicrania. Some

response is seen with a range of other NSAIDs, however, this is usually not helpful. Other therapies that have been reported to be effective in paroxysmal hemicrania include topiramate, verapamil, cyclooxygenase-2 inhibitors, and greater occipital nerve block blocks

### Short-lasting unilateral neuralgiform headache attacks

**Clinical features** This syndrome is characterised by moderate to severe, strictly unilateral pain that is usually centered over the orbital, supra-orbital or temporal region but can occur in other trigeminal distribution. The attacks last for 1–600 seconds and occur as single stabs, series of stabs or in a saw-tooth pattern. The attack frequency during the symptomatic phase varies immensely between patients and within an individual patient. Attacks may be as infrequent as once a day or less to more than 60 per hour. The pain is accompanied by prominent ipsilateral cranial autonomic features. The majority of patients can precipitate attacks by touching certain trigger zones within trigeminal innervated distribution and, occasionally, even from an extra-trigeminal territory. Precipitants include touching the face or scalp, washing, shaving, eating, chewing, brushing teeth, talking and coughing. Unlike in trigeminal neuralgia, most patients have no refractory period. This syndrome is very rare, with a prevalence of 1/15 000 population.

The disorder is further sub-classified into SUNCT or SUNA depending on the cranial autonomic features. SUNCT is diagnosed if patients have both conjunctival injection and lacrimation, while SUNA is diagnosed if only one or neither of these two autonomic symptoms are present. SUNCT and SUNA are likely to represent the same disorder but have been kept separate in ICHD-III until definitive evidence emerges to support this notion. These syndromes are very similar to trigeminal neuralgia and may indeed turn out to be variants of trigeminal neuralgia rather than distinct disorders in their own right.

**Investigations** Secondary forms of SUNCT and SUNA are typically seen with either posterior fossa or pituitary tumours. This emphasises the absolute need for cranial MRI, including adequate imaging of the pituitary. These patients should also have a basal (as opposed to dynamic) pituitary hormone screen. Recent studies suggest that in a high proportion of subjects with SUNCT/SUNA, brain MRI shows an arterial loop contacting or deforming the trigeminal nerve. Given the potential benefit of surgical decompression of the trigeminal nerve in trigeminal neuralgia the diagnostic work-up of SUNCT and SUNA should also include dedicated MRI cuts of the trigeminal nerves.

**Management** As the attacks are short-lasting, abortive therapies are not generally useful. For patients with acute severe debilitating attacks of SUNCT or SUNA, short-term prevention with an intravenous lidocaine infusion can be tried, though the headaches usually recur when the infusion is stopped. The mainstay of therapy in SUNCT and SUNA is preventive treatment. The most effective treatment based on open-label experience is lamotrigine. Other effective treatments include carbamazepine, topiramate and gabapentin. For patients who are refractory to medical treatments, surgical approaches can be useful. Trigeminal microvascular decompression can be useful in two-thirds of patients who have trigeminovascular conflict. Occipital nerve stimulation and posterior hypothalamic region deep brain stimulation can be highly effective in selected medically intractable patients.

### Hemicrania continua

Hemicrania continua, like paroxysmal hemicrania, is an indometacin-responsive headache. Unlike the other TACs, which are intermittent short-lasting headaches, hemicrania continua is a continuous headache.

**Clinical features** Hemicrania continua is a persistent headache that is exclusively unilateral without side-shifting though rare cases of side alternating attacks have been described. Patients describe a persistent background pain of mild-to-moderate intensity with superimposed exacerbations that can be very severe and are associated with cranial autonomic features, a sense of restlessness or agitation and aggravation of pain by movement. An absolute response to therapeutic doses of indometacin (at least 150 mg/day and increasing to 225 mg/day if necessary) is a prerequisite for diagnosis.

**Investigations** As with paroxysmal hemicrania, a relatively high number of symptomatic cases of hemicrania continua have been reported hence MRI should be routinely performed in all patients suspected to have hemicrania continua. Furthermore, systemic symptoms, atypical presentation or hemicrania continua which becomes unresponsive to indometacin over time should prompt careful search for a secondary cause.

**Management** Indometacin leads to complete resolution of symptoms but a significant minority are unable to tolerate the side effects. No other drug is consistently helpful in hemicrania continua. The treatment options in these cases include other NSAIDs, cyclooxygenase-2 inhibitors, topiramate, melatonin, verapamil, gabapentin, greater occipital nerve blocks and botulinum toxin type A injections. For patients who are intractable to medical treatments, occipital nerve stimulation can be considered.

### Other primary headaches

#### Primary cough headache

In cough headache, the pain arises moments after performing a Valsalva manoeuvre such as coughing, sneezing, straining, laughing or stooping. The pain reaches its peak almost immediately, and then subsides over several seconds to a few minutes although some patients experience mild to moderate headache for 2 hours. It is usually bilateral and posterior. Associated symptoms such as vertigo, nausea and sleep abnormality have been reported by up to two-thirds of patients. There is a significant correlation between the frequency of cough and the severity of the headache. This headache predominantly affects patients older than 40 years of age. The lifetime prevalence of benign cough headache is 1%.

The syndrome of cough headache is symptomatic in about 40% of cases, and the majority of patients in whom this is so have Chiari malformation type 1. Other reported causes include CSF hypotension, carotid or vertebrobasilar disease, middle cranial fossa or posterior fossa tumours, midbrain cyst, basilar impression, platybasia, subdural haematoma, cerebral aneurysms and reversible cerebral vasoconstriction syndrome. Diagnostic neuroimaging has an important role in the search for possible intracranial lesions or abnormalities.

The most consistently reported effective treatment is indometacin used at between 25 and 250 mg/day. Treatment should be withdrawn periodically to ascertain whether the symptoms have remitted. Other treatments reported to be effective include acetazolamide, topiramate, naproxen, propranolol, methysergide and

intravenous dihydroergotamine. In addition to medical therapy, there are several reports of high volume (40 mL) CSF removal by lumbar puncture. The response can be dramatic and long term. Any pulmonary disease causing coughing should be identified and treated if possible.

### Primary exercise headache

Exercise or exertional headaches are triggered by physical exercise. They are characterised by bilateral, throbbing pain that persists from 5 minutes to 48 hours. Exertional headaches are not usually associated with migrainous features, though exercise is also a fairly common trigger in some migraineurs for their typical migrainous headaches. Exertional headaches can be prevented by avoidance of excessive physical exercise, particularly in hot weather or at high altitude.

Case series report the presence of structural intracranial lesions in 10–40% of patients. The underlying abnormalities associated with exertional headaches include supratentorial and posterior fossa space-occupying lesions (both metastatic and primary), vascular abnormalities such as cerebral aneurysm or arteriovenous malformation, intracranial haemorrhage, intermittent obstruction of cerebrospinal fluid flow caused by a third ventricular colloid cyst, lateral ventricular tumour, or Chiari type 1 malformation, and previous traumatic injury. Extracranial causes of exertional headache include pheochromocytoma and cardiac cephalgia, which is a rare exertional headache secondary to cardiac ischaemia. Patients with exercise-induced headache should have brain MRI, and a neurovascular evaluation with intracranial magnetic resonance angiography. These patients should usually have an evaluation for coronary heart disease, particularly if headache occurs exclusively with exercise, lacks features suggestive of migraine, or radiates to or from the neck or jaw.

In situations where exertion cannot be predicted, treatment is prophylactic. If exertion can be predicted then pre-emptive therapy 30–60 minutes before exercise can be used. Indometacin at daily doses varying from 25 to 250 mg is generally very effective. Propranolol, naproxen and ergotamine derivatives have also been reported to be beneficial in some patients.

### Primary sex headache

Sex headache may be precipitated by both masturbation and coitus. Sex headache is of two types, preorgasmic and orgasmic, which have distinct clinical features. Preorgasmic headache is a bilateral occipital or generalised pressure headache that gradually intensifies with growing sexual excitement. Orgasmic headache has a sudden explosive onset followed by severe throbbing head pain that occurs just prior to or at the moment of orgasm. Sex headache tends to be short-lasting, with severe pain generally lasting between 10 minutes and 6 hours. Accompanying symptoms are uncommon. Some patients with preorgasmic headaches can terminate the attack by stopping sexual activity. In about 50% of patients benign sex headache will settle in 6 months. There is an association between sex headache and exercise headache as well as migraine.

Several symptomatic causes of sex headache have been reported including subarachnoid haemorrhage (underlining the importance of investigating for an underlying intracranial aneurysm), non-haemorrhagic stroke, pheochromocytoma and drugs such as cannabis, oral contraceptives and pseudoephedrine. Spontaneous low CSF pressure headache is another pressure-like positional type of headache that may arise during sexual activity. It is thus mandatory to exclude structural intracranial abnormalities in all cases of

sex headaches with appropriate neuroimaging. Evaluation for pheochromocytoma is warranted when symptoms such as prominent flushing, tachycardia and sweating are present remote from sexual activity.

Benign sex headaches are usually irregular and infrequent, hence management can often be limited to reassurance and advice about ceasing sexual activity if a milder warning headache develops. When sex headaches occur frequently, they can be prevented by propranolol (40–200 mg/day), diltiazem 60 mg three times daily or indometacin (25–250 mg/day). Triptans, ergotamine or indometacin (25–75 mg) taken 30–45 minutes prior to sexual activity can be helpful.

### Primary thunderclap headache

Thunderclap headache is characterised by the abrupt onset of a severe headache that reaches maximum intensity within 1 minute. Thunderclap headache is frequently associated with serious vascular intracranial disorders, particularly subarachnoid haemorrhage, as well as cerebral venous sinus thrombosis, arterial dissection, reversible cerebral vasoconstriction syndrome and acute cerebral ischaemia. It has also been reported with other pathologies including pituitary apoplexy, spontaneous intracranial hypotension, third ventricle colloid cysts, arterial hypertension and systemic or intracranial infections. Some longitudinal studies suggest that a benign form of recurrent thunderclap headache exists but the evidence for this is considered to be relatively poor.

It is not possible to differentiate between primary and secondary thunderclap headache on clinical grounds. Therefore all patient with thunderclap headache should be investigated. The first episode should be vigorously investigated with CT and CSF examination. For patients with thunderclap headache who have non-diagnostic head CT and lumbar puncture, we suggest obtaining brain MRI. Additional studies that may be indicated on a case-by-case basis include angiography and venography. Primary thunderclap headache should be a diagnosis of last resort, reached only when all organic causes have been demonstrably excluded.

Primary thunderclap headache is generally self-limiting, but can recur over months or years. For patients who have recurrent attacks nimodipine has been reported to be helpful.

### Primary stabbing headache

Primary stabbing headache is characterised by transient, sharp jabbing pains that occur within a small, localised area of the scalp. The pain can be unifocal or multifocal in site, predominantly within the first division of the trigeminal nerve. The attacks appear suddenly either as single stabs or in volleys of intense stabbing pain. The stabs last from 1 to 10 seconds and occur at irregular intervals from rarely to many times each day. The pain is spontaneous and without any additional features. The main differential diagnosis are SUNCT, SUNA and trigeminal neuralgia; primary stabbing headache is relatively easily differentiated from these conditions on the basis of presence of autonomic symptoms, triggerability and site of pain. Primary stabbing headache responds to indometacin, melatonin or cyclooxygenase-2 inhibitors.

### Nummular headache

Nummular headache is characterised by small circumscribed areas of pain on the head. The pain is generally of mild to moderate intensity and confined to a round or elliptical, sharp contoured, unchanging area 1–6 cm in diameter. The pain is continuous, although in a large minority of cases spontaneous remissions lasting weeks to

**Table 12.7** Differential diagnosis of new daily persistent headache.

	Post-traumatic headache
	Leptomeningeal metastasis

months may occur. Superimposed on the continuous pain, lancinating pain may occur that initially lasts seconds but may gradually increase in duration to minutes or hours. The affected area commonly shows variable combinations of hyperaesthesia, paraesthesia or allodynia. Structural and dermatological lesions need to be excluded with appropriate investigations. Treatment with gabapentin (900–1800 mg/day) can be effective, but nummular headache often becomes refractory to standard headache therapies.

### Hypnic headache

Hypnic headache, also known as ‘alarm clock headache’, is characterised by episodes of head pain that develop only during sleep and awaken the patient from sleep. The pain is usually mild to moderate in 80% of cases. It lasts from 15 minutes to 3 hours. The pain is bilateral in two-thirds of cases. The pain is usually featureless though nausea, photophobia, phonophobia and cranial autonomic features can rarely accompany the pain. Hypnic headache is one of the few headaches that occurs almost exclusively in later life, usually after the age of 50 years.

Other possible causes of headache developing during and causing waking from sleep should be ruled out, with particular attention given to sleep apnoea and medication overuse; intracranial structural disorders must be excluded with neuroimaging.

Simple analgesics tend to be effective abortive treatments. Preventive treatments reported to be effective include lithium, caffeine, melatonin, indometacin and flunarizine.

### New daily persistent headache

New daily persistent headache (NDPH) is a distinct headache that is daily and unremitting within 24 hours of onset, and lasts more than 3 months. Eighty per cent of patients can pinpoint the exact date their headache started. The pain lacks characteristic features, and in many cases the phenotype resembles migraine or, less often, tension-type headache.

NDPH can have both secondary and primary forms (Table 12.7). Diagnostically, it is important to first exclude secondary forms of NDPH. We recommend neuroimaging for all patients presenting with NDPH. Where available, we suggest brain MRI with gadolinium as the initial imaging study. For selected patients,

**Table 12.8** Causes of chronic daily headache.

Long-lasting (>4 hours/day)	Short-lasting (<4 hours/day)*
Chronic migraine <sup>†</sup>	Chronic cluster headache
Chronic tension-type headache <sup>†</sup>	Chronic paroxysmal hemicrania
Hemicrania continua <sup>†</sup>	SUNCT/SUNA
New daily persistent headache <sup>†</sup>	Hypnic headache
Nummular headache	

SUNA, short-lasting unilateral neuralgiform headache with cranial autonomic symptoms; SUNCT, short-lasting unilateral neuralgiform headache with conjunctival injection and tearing.

\* Patient with these disorders may have more than 4 hours/day of headache. This classification emphasises that the individual attacks last less than 4 hours.

<sup>†</sup> May be complicated by analgesia overuse, thereby resulting in concurrent medication overuse headache.

additional studies such as venography and lumbar puncture may be warranted

There are no controlled trials of treatment in primary NDPH. As noted earlier, the phenotype of primary NDPH often resembles primary chronic tension-type headache or a chronic migraine. Although evidence is lacking, it is intuitive to treat NDPH based on the phenotype. Thus, our suggested approach is to first classify the phenotype of NDPH as most similar to either migraine or chronic tension-type headache, and then treat with appropriate preventive headache therapy accordingly. NDPH may take either of two subtypes: a self-limited one, or a persistent form that can last years or decades and is challenging to treat.

### Chronic daily headache

The term chronic daily headache (CDH) remains in widespread usage, though it is not part of ICHD-III. It is defined as the presence of headache of any sort on at least 15 days per month for at least 3 consecutive months. As such, it is a heterogeneous entity which can indicate frequent or long-lasting headache of any cause; it may be a manifestation of primary headache, for example chronic migraine, tension type or cluster headache or secondary headache (notably MOH). A diagnosis of CDH is therefore not a substitute for a definite primary or secondary headache diagnosis. Secondary causes should be looked for where appropriate. Primary headaches that can result in CDH are listed in Table 12.8.

# Cranial Nerve Disorders

Jeremy Chataway, Charles Clarke, Robin Howard and Paul Jarman  
National Hospital for Neurology & Neurosurgery

This chapter reviews typical features of lesions of individual cranial nerves and conditions affecting them, and some combinations of cranial nerve lesions. Conditions affecting the optic nerves and cranial nerves III, IV and VI are discussed in Chapter 13. Neuro-otological conditions are discussed in Chapter 15 and the anatomy of the cranial nerves, their nuclei and central connections in Chapter 2.

## I. Olfactory nerve

Complaints about disorders of the sense of smell are relatively common; they are sometimes almost unnoticed by patients and tend to be downplayed by clinicians. Loss of olfaction is often an underestimated disability; it is of great importance in the professions where differentiation of complex odours is vital. Although seldom regarded as a major handicap, anosmia or hyposmia may be the first manifestation of a serious underlying disorder. Olfaction can be difficult to test in practice and is often not examined routinely.

### Functional anatomy

Humans have two nasal chemosensory systems: the olfactory nerve system responsible for detecting odours, and trigeminal afferents that respond to irritants, high concentrations of odorants and the sensation of coolness (e.g. menthol vapour). Thus, in patients with anosmia resulting from lesions of the olfactory nerve, the response to nasal irritation from ammonia or menthol is still preserved. The olfactory pathways and the subtleties of the complex mechanisms of olfaction are described in Chapter 2.

### Symptoms

Anosmia refers to complete loss of sense of smell and partial anosmia to loss of ability to detect certain smells. Hyposmia indicates generally diminished sense of smell. Dysosmia is distorted sense of smell (e.g. when pleasant odours smell unpleasant). Phantosmia refers to a sensation of smell that is constantly present, in the absence of objective odour.

Patients with impaired olfactory function also usually complain of loss of taste. This is because most of the perceived flavour of food is derived from smell rather than taste: try tasting food or drink with the nostrils occluded. The four basic tastes – sweet, sour, salty and bitter – are subserved by Vth, VIIth and IXth nerve afferents. *Umami*, the savoury, tomato-like taste recognised via

glutamate-specific receptors is distinct from the four common basic tastes and is rarely tested in clinical practice. These remain intact in the patient with anosmia. Many people with gradual loss of smell over many years are unaware of the problem. Dysosmia and phantosmia, often with perception of a foul or medicinal odour, may occur during olfactory epithelium degeneration and regeneration; this may follow an upper respiratory infection or paranasal sinus infection, or head trauma. These complaints are also noted frequently after cancer chemotherapy and cranial radiotherapy; recovery is uncertain.

It is important to determine the tempo of onset and to distinguish clinically between total bilateral loss of sense of smell and unilateral loss, rarely noticed by patients; the latter can point to a lateralised lesion of the olfactory system. A history of local nasal symptoms indicative of nasal congestion, allergic rhinitis or sinusitis should be sought. A recent upper respiratory tract infection may be relevant. Past history of head injury, exposure to toxic fumes, drugs, chemotherapy or radiotherapy, excessive alcohol, smoking and cocaine use, systemic diseases, and features of Parkinson's disease or cognitive impairment may all provide clues to aetiology. Kallmann's syndrome is a rare cause of anosmia resulting from failure of the olfactory lobes to develop, with secondary hypogonadism caused by gonadotropic hormone deficiency.

### Examination

Detailed smell testing is difficult in routine clinical practice. The usual assessment is to ask patients to sniff vials containing odours such as peppermint oil, cloves or coffee, using each nostril in turn with the other occluded. The examiner should be aware that even with a normal sense of smell it may be difficult for many people to identify these odours – the crux of the matter is to distinguish them. Non-organic anosmia may be suggested by the loss of ability to detect ammonia, which causes nasal irritation because of stimulation of trigeminal afferents within the nose; such testing with irritants should be carried out with particular care, if at all. However, all tests of this sort are relatively crude. More detailed testing of olfaction is possible using commercially available tests such as the University of Pennsylvania Smell Identification Test (UPSIT), a standardised panel of 40 microencapsulated 'scratch and sniff' odours with multiple choice identification of each. A percentile ranking, compared to age- and gender-matched controls is obtained

and olfactory function may be classified into one of six categories from anosmia to normal, and includes malingering. Other shorter quantitative smell testing kits are also commercially available. There are no readily available objective neurophysiological tests, although evoked responses are used in some research protocols.

In addition to testing olfaction, taste should be tested in patients with olfactory disorders, and the mouth, nose and sinuses examined. Endoscopic examination by an ENT specialist is usually necessary.

### Causes of anosmia

Olfactory disorders are caused either by transport disorders brought about by local obstruction of the nasal passages or sensori-neural impairment from damage to the olfactory neuro-epithelium, olfactory nerve or its central connections.

### Ageing

Age-related reduction in sense of smell is the norm. About half of the population between the ages of 65 and 80 years have significant impairment, a figure that rises to almost three-quarters after the age of 80. This diminution of smell with age may contribute to the loss of appetite that sometimes occurs in the elderly. The number of olfactory receptors and neurones decreases with age and there may be cumulative damage from viruses and degenerative change. In some cases bone growth around the ethmoid, leading to compression of the olfactory fila, may be a cause.

### Upper respiratory infections, nasal and paranasal sinus disease

Viral upper respiratory tract infections, including the common cold and influenza, are probably the most common cause of permanent loss of smell. Often the infection is more severe than usual and is remembered by the patient. Damage to the olfactory epithelium and receptors, including the basal cells from which receptor cells regenerate, is probably the cause. A wide variety of allergic and infective nasal disorders, including chronic rhinitis and sinusitis, as well as disorders causing nasal obstruction, may all be associated with anosmia.

### Trauma and surgery

Acceleration–deceleration of the brain following injury can shear the delicate olfactory fila as they pass through the cribriform plate of the ethmoid, with or without fracture of the cribriform plate itself. A fall on to the occipital region can cause this, without loss of consciousness, sometimes with frontal lobe contracoup injury. Anosmia is also associated with more severe traumatic brain injury with evident damage to the olfactory bulb and frontal cortical and subcortical structures; nasal trauma may also be a contributing factor in some cases. Transient dysosmia can occur soon after injury; recovery of olfactory function occurs in 30–40% but is unlikely if symptoms persist for longer than a year. Anosmia, unilateral or bilateral, can follow surgery to the sub-frontal region, sometimes with a persistent cerebrospinal fluid (CSF) leak and risk of meningitis.

### Neurodegenerative disorders

Impaired olfactory function has been well described in:

- Parkinson's disease
- Dementia with Lewy bodies
- Alzheimer's disease
- Huntington's disease
- Motor neurone disease
- Korsakoff's syndrome
- Multiple sclerosis (MS).

In Parkinson's disease, the anterior olfactory structures including the olfactory bulb and anterior olfactory nucleus have been shown to be involved, with Lewy body formation at an early stage of the disease. Similarly, in Alzheimer's disease, profound neuronal loss is seen in the olfactory bulb and limbic brain regions, areas that receive olfactory input become heavily laden with neurofibrillary tangles and plaques. In MS, olfactory loss is in direct proportion to the burden of demyelinating lesions in areas of the brain associated with olfactory processing (frontal and temporal regions).

In idiopathic Parkinson's disease, hyposmia predates the onset of motor symptoms, often by many years or even decades. Impaired olfactory function is found in up to 90% of patients with Parkinson's disease, irrespective of disease duration or severity. Perception of certain odours such as petrol, banana, smoke and cinnamon seem to be lost preferentially on detailed testing. Demonstration of hyposmia may be useful in the differential diagnosis of parkinsonian disorders, because other extrapyramidal disorders such as progressive supranuclear palsy, vascular parkinsonism and corticobasal degeneration are not associated with an increased prevalence of impaired olfaction compared to age-matched controls. However, hyposmia is sometimes seen in multiple system atrophy. There has been recent interest in olfactory testing as a biomarker of preclinical Parkinson's and Alzheimer's diseases.

### Other causes of olfactory dysfunction

Olfactory groove meningiomas are an important, if rare, cause of unilateral anosmia; impairment of smell may be the only or principal symptom of this tumour. Eventually, unilateral visual loss resulting from posterior extension to involve the optic nerve and dementia because of frontal lobe involvement may follow. Other structural lesions such as pituitary tumours and aneurysms may also compress the olfactory tract below the frontal lobes. Toxic exposure to a wide variety of industrial agents including acids, acetone, solvents and benzene have been anecdotally related to impaired smell, possibly because of direct damage to the olfactory receptor cells in some cases. The highly metabolically active receptor cells are also vulnerable to exposure to a number of drugs including antibiotics, anti-inflammatory agents, antithyroid drugs, antimetabolites and chemotherapeutic agents or radiotherapy – the latter two can irreversibly damage the ability of olfactory receptor cells to proliferate. Similarly, cigarette smoking impairs olfactory ability, usually with recovery after abstinence.

A variety of medical disorders such as cirrhosis, renal failure, hypothyroidism and vitamin deficiency (vitamins A, B<sub>6</sub> and B<sub>12</sub>) can cause impaired olfaction. Olfactory receptor cells may be congenitally absent in Kallmann's syndrome, Turner's syndrome and albinism.

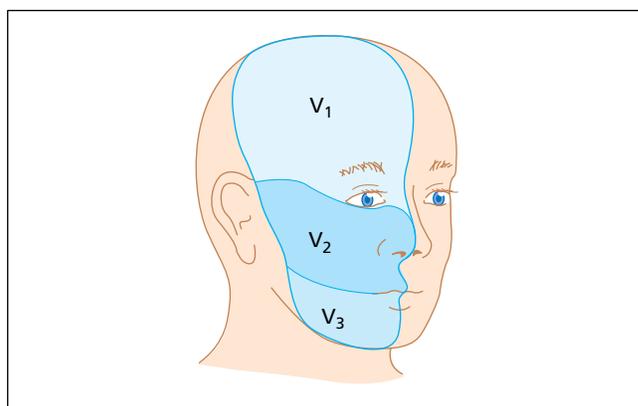

Damage to cortical structures involved in olfactory processing can lead to impaired odour identification or impairment of recognition memory but rarely to total anosmia. Olfactory hallucinations are well-recognised as part of the aura preceding a temporal lobe seizure; such hallucinations rarely occur as the sole manifestation of a seizure (Chapter 7). An unpleasant but stereotyped smell is usually described but it is rarely an identifiable odour. Olfactory hallucinations may also occur in depression, schizophrenia and alcohol withdrawal. The complaint of a constant foul smell, or of a distortion of smell with everything smelling unpleasant, may sometimes be a result of suppurative paranasal sinus infection, but is more often of psychotic origin or associated with depressive illness.

## V. Trigeminal nerve

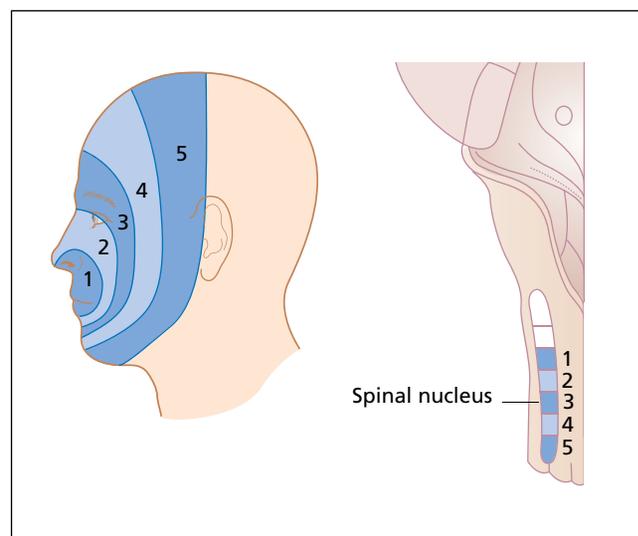

The trigeminal is the largest cranial nerve. It contains sensory and motor components, the sensory territory includes the face and head anterior to the vertex, the mucous membranes of the oral and nasal cavities, paranasal sinuses, the teeth, intracranial vessels and the dura of the anterior and middle cranial fossae. The motor root supplies the muscles of mastication. Detailed anatomy is considered in Chapter 2. The distribution of the three peripheral divisions of the nerve is shown in Figure 13.1 and the arrangement of the distribution of the spinal Vth nucleus in Figure 13.2.

### Examination

Motor and sensory functions of the trigeminal nerve need to be examined separately. Sensory examination should include examination of all three divisions of the nerve and comparison made with the other side. Cutaneous sensation including light touch, pin-prick and temperature should all be tested. In practice, temperature

**Figure 13.1** Cutaneous distribution of the three divisions of Vth nerve. Precise distribution varies amongst published sources. Source: Patten 1996. Reproduced with permission of Springer Science + Business Media.

**Figure 13.2** Distribution of spinal Vth nucleus. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

sensation is often quickly assessed with a cold metal tuning fork, asking if the patient can appreciate the cool temperature of the metal against the facial skin. Remember that the angle of the jaw is usually outside the trigeminal territory and that V<sub>1</sub>, the ophthalmic division includes the side of the nose and extends back to the vertex. The back of the scalp and angle of the jaw are supplied by the C2/3 dermatomes. Non-organic patterns of sensory loss may include the angle of the jaw or stop at the hairline but it is essential to recognise that organic disease may occasionally result in atypical patterns of sensory loss (e.g. in syringobulbia).

The corneal reflex (Chapters 2, 4 and 20) is elicited with a wisp of cotton wool or sometimes by wafting air gently over the cornea while shielding the other eye. The afferent arc is mediated by V<sub>1</sub> for the upper cornea and V<sub>2</sub> for the lower portion of the cornea (Chapter 2); the efferent arc is via the facial nerve (blink) and nervus intermedius (lacrimation). In the normal corneal response, there is discomfort when the cornea is touched, accompanied by tearing and conjunctival injection. Abnormalities of the corneal reflex may be an early sensitive sign of trigeminal nerve sensory dysfunction; neurophysiological recording of the related blink reflex is a useful way of quantifying an abnormality.

Tactile sensory loss on the face in the absence of a reduced or absent corneal reflex should raise suspicion of a non-organic cause. Parietal lobe lesions (involving the peri-sylvian portion of the post-central gyrus) can cause depression of contralateral corneal sensation.

The muscles of mastication are tested, first by asking the patient to clench the jaw, palpating the muscles and looking for fasciculation. Strength of jaw opening and lateral deviation against resistance are also examined. Unilateral lesions causing jaw deviation towards the affected side (contralateral pterygoid contraction) and inability to deviate the jaw to the opposite side. The jaw jerk is elicited with the jaw relaxed and slightly open. The afferent arc is via stretch receptors in V<sub>3</sub> and the efferent arc via the trigeminal motor fibres. An absent jaw jerk is rarely helpful. An exaggerated jaw jerk indicates bilateral supranuclear lesions of the cortico-bulbar pathways rostral to the pons (i.e. pseudo-bulbar palsy).

### Peripheral Vth nerve lesions

Lesions of individual divisions and peripheral branches produce well-demarcated areas of sensory loss on the face and sometimes considerable pain. Trauma is a frequent cause; the supra-orbital and infra-orbital branches of V<sub>1</sub> are among the nerves most commonly affected. Numbness of half of the tongue accompanied by occipital and upper neck pain on head turning is a feature of the neck-tongue syndrome, believed to be caused by compression of the ventral ramus of C2 that carries sensory fibres from the tongue via the hypoglossal nerve. The ophthalmic, maxillary and mandibular divisions may be affected individually or in combination as they exit the skull base (through the superior orbital fissure, foramen rotundum and foramen ovale) by malignant meningeal infiltration, infective or granulomatous meningeal processes, or bony metastases in the skull. The Gasserian ganglion may be affected by similar processes at the petrous tip, causing ipsilateral sensory disturbance in the face; the abducens nerve may also be affected in this area (Gradenigo's syndrome). Trigeminal schwannomas may arise from the region of the trigeminal ganglion, either as an isolated tumour or as part of the spectrum of neurofibromatosis type 2. The trigeminal nerve may be involved in cerebellopontine angle syndromes (see Cerebellopontine angle syndrome).

### Numb chin syndrome

Unilateral sensory disturbance affecting the chin and lower lip is a distinctive, important syndrome. It usually indicates a bony metastasis in the mandible involving the mental nerve. This can be a feature of a breast or prostate cancer recurrence, lymphoma or myeloma. Some cases are caused by more proximal infiltration of V<sub>3</sub>. Non-malignant disorders affecting the mandible can also present in this way. A variant is the numb cheek syndrome, is caused by compromise of the infra-orbital nerve in the infra-orbital foramen, or proximal involvement of V<sub>2</sub>.

### Superior orbital fissure syndrome

The ophthalmic division V<sub>1</sub> within the superior orbital fossa (SOF) may be involved in various combinations with the IIIrd, IVth and VIth cranial nerves (Chapter 14). The typical presentation is with ophthalmoplegia accompanied by sensory disturbance and often pain in V<sub>1</sub> distribution, sometimes in combination with proptosis with large orbital lesions. Horner's syndrome and visual loss may also occur if the sympathetic supply to the eye or optic nerve become involved, the latter suggesting extension to the orbital apex. Tumours, such as nasopharyngeal cancers, trauma, infections, e.g. epidural abscesses (see Intracranial epidural abscess) and mucormycosis spreading from a paranasal sinus and inflammatory disorders (e.g. sarcoidosis and Wegener's granulomatosis; Chapter 26) are important causes of the SOF syndrome.

### Cavernous sinus syndrome

This can be clinically indistinguishable from the SOF syndrome except that V<sub>2</sub> as well as V<sub>1</sub> may be involved in the cavernous sinus syndrome. Proptosis does not occur, except in the case of carotid cavernous fistulas (Chapter 14). Involvement of both the oculomotor nerve and the sympathetic supply to the eye may result in a mid position, non-reactive pupil, or the pupil may be dilated or miotic because of sympathetic or parasympathetic involvement in isolation. The causes are listed in Table 13.1. Cavernous sinus thrombosis is a serious condition that can follow infection of the face, paranasal sinuses (particularly the sphenoid sinus) or teeth. Spread to the opposite cavernous sinus usually occurs within a short time. The cavernous sinus syndrome is also discussed in Chapter 14.

**Table 13.1** Causes of cavernous sinus syndrome (ophthalmoplegia, orbital congestion, chemosis, peri-orbital oedema, proptosis, facial sensory loss, Horner's syndrome).

Vascular	Carotid aneurysms (aneurysms of the intracavernous portion of the carotid artery) Carotico-cavernous fistula Thrombosis (secondary to paranasal sinus infection, orbital cellulitis, facial infection)
Neoplastic	Metastases Nasopharyngeal carcinoma Pituitary adenoma (lateral expansion) Craniopharyngioma Meningioma Lymphoma
Inflammatory	Any inflammatory granulomatous process Sarcoidosis Wegener's granulomatosis Polyarteritis nodosa Tolosa-Hunt syndrome

### Nuclear Vth nerve lesions

As with other cranial nerves, trigeminal nuclear lesions resulting from intrinsic brainstem pathology, such as tumour, inflammatory or vascular lesions, frequently involve other brainstem structures. Because the lateral spinothalamic tract (which has already decussated) lies close to the trigeminal spinal tract and its nucleus, a common pattern is ipsilateral facial dissociated sensory loss (pain and temperature) with contralateral dissociated sensory loss in the limbs and trunk. Infarction of the lateral medulla (Wallenberg's lateral medullary syndrome; Chapter 5) is the most common cause.

The spinal trigeminal nucleus may be disrupted anywhere in the long course between the caudal pons and upper cervical cord. The somatotopic arrangement of the nucleus maps to an onion skin type distribution in the face, the nose and mouth being the centre of the onion, represented rostrally, with subsequent more posterior layers being more caudal in the nucleus (Figure 13.2). Thus, pontine nuclear lesions may result in intra-oral sensory loss with sparing of the face, while lesions of the lower part of nucleus (e.g. in syringobulbia) may be like a balaclava, sparing the muzzle area. The extension of the lower trigeminal spinal nucleus into the upper spinal cord means that lesions in this area may occasionally be a cause of facial pain and sensory disturbance.

Dorsal mid pons lesions involving the principal sensory nucleus and motor nucleus cause ipsilateral facial hemianaesthesia, usually to both light touch and pain/temperature, with paresis of muscles of mastication. There may be contralateral hemiplegia and spinothalamic sensory loss in the limbs. Ipsilateral tremor, internuclear ophthalmoplegia and Horner's syndrome can also occur with lesions in this area. Dorsal mid-pontine tumours can occasionally cause ipsilateral masticatory muscle spasm limiting jaw opening.

### Trigeminal neuralgia

Trigeminal neuralgia (TN) is the most common disorder of the trigeminal nerve. Although not life-threatening, TN can be extraordinarily distressing. Prevalence is difficult to determine; incidence is approximately 4/100000/year. Women are more frequently affected than men. TN, often termed idiopathic but frequently caused by neurovascular compression, starts typically in the sixth and seventh decades; younger patients are more likely to have symptomatic TN (e.g. caused by MS) or occasionally a mass lesion.

### Clinical features

The pain is usually quite characteristic, consisting of excruciating lancinating paroxysms in the face. This pain is severe, often described as shooting, stabbing, electric shock-like or as like a red hot needle. Paroxysms last for a few seconds or a minute at most; they tend to occur in bouts, sometimes with such frequency that paroxysms become indistinct. Often a refractory period of several minutes is seen after each attack, the duration being proportional to the severity and length of the paroxysm. The face may contort during an attack, hence the name *tic douloureux*. Patients are usually pain-free between attacks but in some a superimposed dull background pain may develop, often a sign of a poor response to treatment. Sensory triggering of pain by touching a specific affected part of the face (often no larger than a few millimetres), or by talking, chewing or even exposing the face to wind is very characteristic. Patients may be prevented from eating, drinking or brushing teeth; men may leave an area of the face unshaved. Weight loss can follow from pain triggered by eating. The mandibular and maxillary territories of the nerve are far more commonly affected than the ophthalmic division (only 5%); pain commencing in V<sub>1</sub> distribution

should lead to consideration of an underlying cause for TN. Bilateral TN is rare (3%) and usually caused by intrinsic brainstem pathology such as demyelination.

Spontaneous remissions occur, lasting months or even years, but the pain almost always recurs. Successive bouts tend to be worse and more frequent, with shorter remissions and the pain may spread to affect a wider area of the face over time, typically commencing in  $V_3$  distribution and moving to include  $V_2$  and  $V_1$ . Patients may become fearful during a remission that the pain will return. Examination can be difficult as the patient may be hesitant to allow the face to be touched. Subtle areas of cutaneous sensory loss over the affected area are seen in a minority of patients if careful examination is performed, but examination is typically normal. The presence of other neurological signs points to an underlying cause for TN. Careful scrutiny of the teeth and oral cavity is important, to identify other causes of facial pain.

The diagnosis of TN is often made erroneously in patients with other causes of facial pain. The presence of characteristic paroxysms of lancinating pain is needed to make the diagnosis, supported by sensory trigger areas. The main differential diagnosis of TN is dental disease, particularly dental abscess and the cracked tooth syndrome, both of which can mimic localised forms of TN. Most patients consult a dentist initially, and many will have had dental work, with no improvement in pain, before the diagnosis of TN is suggested. Some will date onset of symptoms to a dental procedure. Acute glaucoma, sinusitis, giant cell arteritis and angina with referred jaw pain should all enter the differential diagnosis. Temporomandibular joint dysfunction causing facial pain is rarely like TN, it is usually associated with jaw movements and is probably over-diagnosed. Trigeminal autonomic cephalalgias such as cluster headache (Chapter 12) typically affect only the eye and surrounding area and usually easily differentiated from TN. Distinguishing  $V_1$  TN from attacks of short-lasting unilateral neuralgiform headache with conjunctival injection and tearing (SUNCT) can be more difficult. The occasional occurrence of facial rather than eye pain in SUNCT may lead to particular problems. A useful distinguishing feature is the duration of attack. This is typically less than 5 seconds in TN and 5 seconds to 5 minutes in SUNCT. The younger age of patients with SUNCT with the presence of prominent autonomic features, or the finding on imaging of a vascular loop in patients with TN is helpful. Idiopathic stabbing headache may also enter the differential diagnosis of  $V_1$  TN.

Atypical facial pain is frequently mistakenly labelled as TN initially. Unlike TN, atypical facial pain tends to be constant rather than paroxysmal, aching rather than lancinating, diffuse and poorly localised, often affecting the whole face and even areas outside the trigeminal territory. Trigger zones are usually absent. There is frequently associated depression or anxiety, although this does not necessarily imply a causal relationship.

### Aetiology and pathogenesis

The main risk factors for apparently idiopathic TN are age and occasionally a history of hypertension. However, there is increasing evidence that in many cases TN is caused by compression of the trigeminal nerve root at or near the dorsal root entry zone by an ectatic vascular loop, often of the superior cerebellar artery. Abnormal ephaptic non-synaptic transmission between trigeminal axons, within areas of focal demyelination, caused by compression of the nerve has been proposed as the substrate of the pain, with increased excitability of the trigeminal-brainstem complex. High-resolution magnetic resonance imaging (MRI) studies demonstrate

a distinct vascular loop in contact with the nerve in some cases. Other cerebellopontine angle masses including tumours (vestibular schwannomas, meningiomas, epidermoids) and aneurysms may sometimes compress the nerve.

Intrinsic brainstem pathology, particularly plaques of pontine demyelination in patients with MS, can cause symptomatic TN, which is occasionally bilateral. Patients with MS have a 20 times higher risk of developing TN. Up to 5% of patients with MS develop TN; occasionally TN is a presenting symptom of MS. Rarely, small infarcts in the dorsal root entry zone in the pons, or infiltration of the trigeminal nerve or ganglion by amyloid or tumour may lead to TN.

MRI is not essential in typical cases of TN, although increasingly carried out. Imaging is indicated where a symptomatic cause is suspected, for example in younger patients, in those with sudden onset of pain, abnormal examination findings or when surgical treatment such as microvascular decompression is contemplated.

### Treatment

Until the advent of modern treatments patients were sometimes driven to suicide by the severity and distress of TN pain. A variety of effective medical and surgical treatments now exist, but evidence supporting their use is often observational rather than based on rigorous data.

Carbamazepine has been the first line drug for TN and it is effective or partially effective in 70% of cases (initially 100 mg every 12 hours, increasing gradually to 200 mg 6-hourly and occasionally to a total dose of 1.6 g/day in some patients). In practice, the problem is often achieving an effective therapeutic dosage quickly enough; side effects are often encountered in elderly patients when rapid titration regimes are used. Oxcarbazepine is used increasingly as a first or second line drug. It is as effective as carbamazepine and can be increased to an effective therapeutic dosage more rapidly and is often better tolerated (initially 300 mg 12-hourly increasing in increments to 2.4 g in divided doses). Other agents used alone or in combination include lamotrigine, baclofen, gabapentin and a variety of other anti-convulsant drugs. Conventional analgesics are not effective.

For patients with drug-resistant TN, or where drugs are not well tolerated, various surgical approaches are available. In general, surgery tends to be more effective than medical therapy. There is an increasing trend towards early surgical intervention, because sustained remission is the exception and natural history studies indicate TN often becomes gradually more severe and resistant to medical therapy. More than half of all patients with severe and intractable TN will require surgery.

*Gasserian ganglion ablative techniques* These techniques involve selective ablation of part of the trigeminal ganglion, using a percutaneous approach via the foramen ovale, by radio-frequency thermocoagulation, glycerol or balloon microcompression. These procedures, performed as day cases or with a short inpatient stay, have a low morbidity and immediate efficacy. However, some degree of postoperative facial sensory loss is almost inevitable and they may provide only temporary relief. Late recurrence is common. The extent of sensory loss is proportional to long-term efficacy; those with minor sensory loss tend to have recurrence of pain. Radio-frequency thermocoagulation is the most common modality used, destroying a selected part of the ganglion within Meckel's cave. Analgesia lasts on average 2 years and the procedure can be repeated. Glycerol injection is a simpler technique, usually associated with earlier recurrence of TN but it has fewer problems with postoperative numbness and pain than radio-frequency thermocoagulation.

Anaesthesia dolorosa, the distressing and sometimes very painful dysaesthesia in an anaesthetic area, occurs in around 1% of patients treated by ablation techniques; it is resistant to treatment.

**Microvascular decompression** This intracranial micro-neurosurgical procedure involves a general anaesthetic and the exposure of the trigeminal nerve at the brainstem. In some instances a vascular loop is seen to be compressing the nerve; the vessel is dissected away from the nerve and compression relieved, using Teflon felt or other material as a cushion. Decompression has a high long-term success rate, approximately 90% in published series, and has few frequent unwanted effects. Nevertheless, it is an intracranial procedure and carries a small risk of damage to other cranial nerves, especially unilateral deafness, as well as CSF leakage (2–5%) and, occasionally, cerebellar venous infarction.

**Gamma knife radio-surgery** High doses of focused irradiation are directed at either at the root exit zone or at the nerve itself within the pontine cistern, proximal to the Gasserian ganglion. Success rates for pain relief are reasonable, but the effects are usually delayed for several months. Long-term results and complications are not yet known.

**Choice of surgical technique** Ganglion ablation techniques are most appropriate for the elderly and infirm. For those able to undergo microvascular decompression, this is certainly the preferred option for TN affecting the ophthalmic division, where post-ablation corneal anaesthesia can lead to keratitis, and for patients with TN generally who prefer a more definitive procedure with a low risk of facial sensory loss. Symptomatic TN caused by MS is generally treated with medical therapy initially; ganglion ablation techniques are the preferred surgical technique, but decompression may be remarkably effective in some patients (40%) even in the absence of an identifiable vascular loop.

### Trigeminal sensory neuropathy

Facial sensory loss in the absence of a defined lesion of the trigeminal nerve or its central connections is usually described as idiopathic trigeminal sensory neuropathy and is probably a heterogeneous disorder.

Patients develop gradually evolving facial numbness, often preceded by positive sensory symptoms such as tingling, but usually without significant pain. In many cases initial symptoms are localised, typically in a circumoral distribution, with disregard for the divisional boundaries of the nerve. Gradual spread to involve the rest of the face, and sometimes the opposite side, is usual over a period of months or years. Tactile, temperature and pain sensation are usually diminished and taste sensation becomes impaired in the anterior two-thirds of the tongue in many. The corneal reflex is usually diminished or absent in those with  $V_1$  involvement; the blink reflex may be delayed or absent in neurophysiological recordings in some patients. The motor root is very rarely affected. A small subgroup have acute onset of sensory loss; this may represent a condition similar to Bell's palsy.

The association with autoimmune connective tissue diseases (CTDs) sometimes offers a clue to an underlying cause. Three conditions account for more than 90% of the CTDs associated with trigeminal neuropathy: undifferentiated connective tissue disease (47%), mixed connective tissue disease (26%) and scleroderma (19%). The condition is also seen in association with primary Sjögren's syndrome. Trigeminal neuropathy is seldom seen in the more common CTDs such as rheumatoid arthritis and systemic lupus erythematosus (SLE), and where it does occur in association with these disorders is more likely to be acute in onset with systemic and

other neurological involvement because of vasculitis. In a minority of patients, facial numbness develops before other rheumatological or systemic symptoms. Vasculitic damage to the trigeminal ganglion may explain trigeminal neuropathy in some cases without evidence of a CTD and there is speculation that tissue-specific autoimmune damage may explain some idiopathic cases.

Neuroimaging is usually normal. There are few pathological studies but the available evidence indicates a destructive inflammatory process at or near the Gasserian ganglion.

Generally, symptoms do not improve with time but few patients are severely disturbed by their symptoms, particularly once more serious neurological disorders have been excluded.

Non-specific, often intermittent, facial sensory symptoms are common in neurological practice, sometimes accompanied by sensory symptoms elsewhere in the body, and may sometimes be a feature of somatisation (Chapter 22). Non-organic patterns of sensory loss are typical; examination is normal. Investigations are negative. Distinguishing such patients from patients with trigeminal sensory neuropathy is usually possible on clinical grounds.

### Herpes zoster ophthalmicus

The lifetime risk of herpes zoster ophthalmicus (HZO) is about 1%. The other divisions of the trigeminal nerve are rarely affected. Elderly and immuno-compromised individuals are particularly at risk. Early ocular and later neurological complications are common and potentially serious.

As with shingles elsewhere, pain and sensory disturbance often precede appearance of vesicles. Vesicles over the side of the nose and medial to the eye indicate involvement of the nasociliary nerve and predict involvement of the eye itself (Hutchinson's sign). Most patients with HZO have conjunctivitis. Without antiviral therapy 50% of HZO patients will develop severe ocular complications, including keratopathy, episcleritis, corneal perforation and iritis, some of which result – potentially – in blindness. Corneal anaesthesia may lead to secondary damage to the eye. Retinal necrosis may occasionally occur in immuno-compromised patients.

All patients with HZO should receive oral antiviral therapy with aciclovir, valaciclovir or famciclovir as early as possible. The newer antiviral drugs may improve compliance, because dosing is three times daily rather than five times daily as with aciclovir. Treatment within 72 hours reduces the frequency of ocular complications from 50% to 20–30% and may reduce the duration of zoster-associated pain. Patients with eye involvement should be assessed by an ophthalmologist. Topical steroids may be indicated where there is anterior chamber inflammation. Taping of the lids is often helpful at night. There are some suggestions that steroids (oral and/or intravenous) in combination with antiviral drugs reduce the duration of pain and accelerate healing but there is no effect on the incidence of post-herpetic neuralgia (PHN). Steroids are not used routinely.

PHN is pain persisting more than 3 months after the rash (Chapter 23). This is the most common neurological complication of HZO. Overall, 7% of patients with shingles have PHN at 3 months and 3% at 1 year. PHN is much more common in the elderly, in whom HZO usually occurs, and 20% of HZO patients over the age of 60 years develop PHN, with 9% persisting at 1 year. However, after allowing for age, patients with HZO are no more likely to develop PHN than those with shingles affecting other dermatomes. Treatment of PHN is usually with tricyclic antidepressants (e.g. amitriptyline), or anticonvulsants, sometimes in combination. Topical capsaicin cream may also be helpful. PHN may be refractory to treatment and have a major impact on quality of life.

Rarer late neurological complications of HZO include cranial nerve palsies (optic neuropathy and III, IV and VI) and stroke as a result of granulomatous arteritis of the intracranial carotid artery or its branches, probably caused by direct viral invasion of the vessel. This usually develops 1–2 months after the rash.

### Atypical facial pain

Atypical facial pain is a residual diagnostic category for otherwise unclassifiable facial pain without an apparent structural cause. The features are of chronic facial pain, lasting months to years, usually unilateral and within trigeminal distribution, but without signs of Vth nerve sensory loss. The pain is described as deep and burning in quality. Paroxysms and trigger areas are typically absent. There have often been incorrect diagnoses, and invasive diagnostic or therapeutic procedures, sometimes multiple. Patients are typically over 50 years of age, and predominantly female. Depressive features are prominent but patients with atypical facial pain appear to have little in the way of other unexplained pain. Investigation is negative. Treatment, with tricyclic antidepressants and other similar drugs, although sometimes helpful, is frequently distinctly unsatisfactory. Attempts at invasive treatment usually cause the pain to increase.

## VII. Facial nerve

The facial nerve has a long and complex course and may be damaged at any point. Bell's palsy is seen commonly in primary care, at all ages, and worldwide.

### Functional anatomy

The facial nerve has motor, sensory and autonomic components and a tortuous course from pons to extracranial innervation of facial muscles, lacrimal and salivary glands, and visceral and somatic sensory territories. The anatomy is described in more detail in Chapter 2.

The majority of the upper motor neurone corticobulbar fibres decussate in the pons but the upper third of the face is said traditionally to receive bilateral cortical innervation, resulting in sparing of the brow and frontalis muscles with supranuclear lesions (e.g. after a stroke). The situation is more complex; the upper part

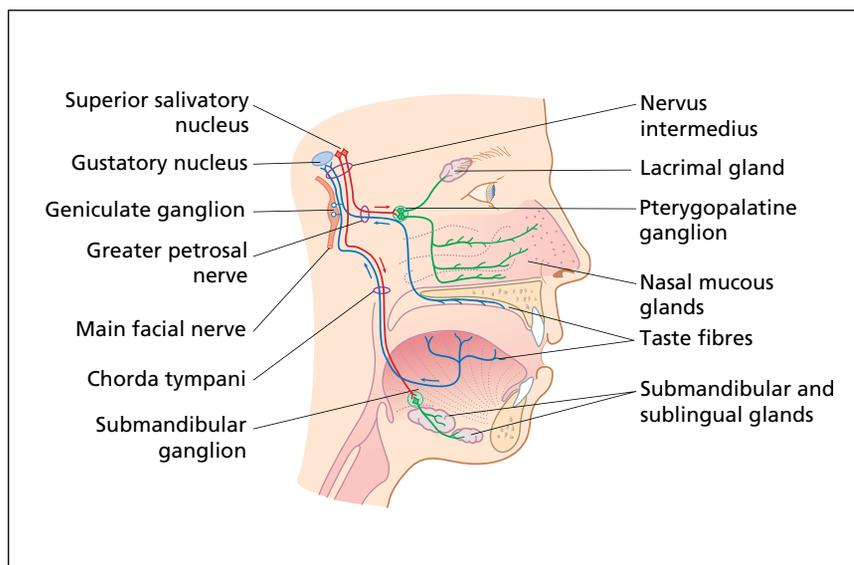

of the face probably receives relatively little direct cortical innervation. Separate supranuclear anatomical pathways subservise voluntary and emotional facial movements; as a result these movements may be dissociated. Thus, emotional movements such as smiling, which are separate from the internal capsule pathway, may be preserved when voluntary movements are affected following a stroke. The right cerebral hemisphere is dominant for expression of facial emotion.

The VIIth motor nucleus lies in the lower pons. The fascicle of efferent motor fibres travels backwards, before sweeping around in a U-turn around the VIth nerve nucleus, to emerge anteriorly from the lower border of the pons.

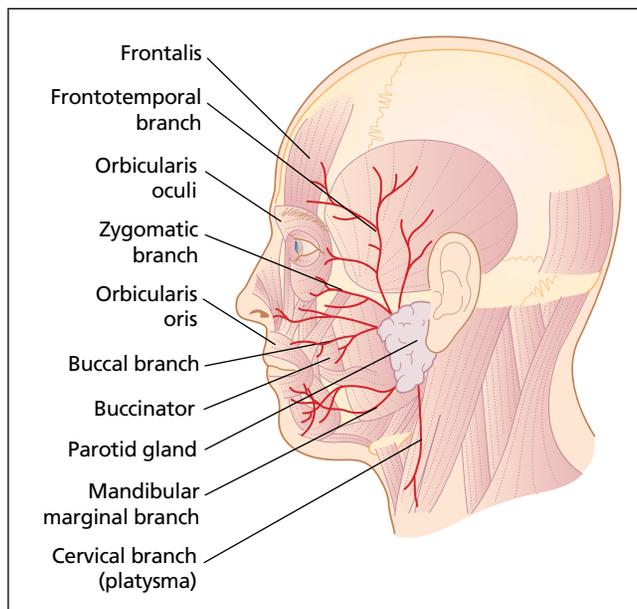

The nervus intermedius is the distinct sensory and autonomic component of the facial nerve that joins the motor fibres just after the internal genu (Chapter 2; Figure 13.3). After leaving the pons, the facial nerve traverses the cerebellopontine angle before entering the internal auditory meatus of the temporal bone with the nervus intermedius and VIIIth nerve. The facial nerve emerges from the skull via the stylomastoid foramen. After traversing the parotid gland the nerve divides into several branches that innervate the facial muscles, with the exception of the levator palpebrae superioris, supplied by the IIIrd nerve – which explains why facial palsy does not cause ptosis, but instead widens the palpebral fissure (Figure 13.4).

### Examination

Facial symmetry should be inspected, particularly forehead creases and nasolabial folds, remembering that a proportion of the normal population have some degree of facial asymmetry. Facial myokymia, synkinesis or hemiatrophy may be observed on careful inspection at rest and during facial movements. When assessing power, test frontalis (eyebrow elevation), as well as eye closure, lip closure and emotional facial movements such as smiling. Platysma is tested by asking the patient to bare their teeth and open the mouth at the same time. Asking the patient to blow out the cheeks and whistle are also useful. For patients with facial weakness, Bell's phenomenon (Chapter 4) is assessed. The ability to close the eye to protect the cornea needs to be examined specifically, to

**Figure 13.3** Nervus intermedius, greater petrosal nerve and chorda tympani. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

**Figure 13.4** Principal facial branches of VIIth nerve. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

avoid exposure keratopathy. Upper motor neurone lesions produce relative sparing of the frontalis and orbicularis oculi muscles because of their bilateral innervation; voluntary and emotional movements may be affected differentially. Unilateral upper motor neurone facial weakness is often less evident to patients and relatives than lower motor neurone weakness. Gradual onset weakness or even bilateral facial weakness is less noticeable than sudden unilateral weakness.

The four common primary tastes – sweet, salt, sour and bitter – can be tested using sugar, salt, vinegar and quinine dabbed separately on to the tongue, rinsing the mouth between each test substance (*Umami*: see p. 531). In cases of facial weakness, examination should include inspection of the oral cavity, tongue and external auditory meatus for vesicles indicating zoster or for evidence of nasopharyngeal carcinoma or fissured tongue (*lingua plicata*). The parotid should be palpated for evidence of tumour, infection or inflammation. Otoscopic examination of the external auditory canal and tympanic membrane should be performed to look for evidence of infection or cholesteatoma. The causes of unilateral and bilateral facial weakness are summarised in Table 13.2.

### Supranuclear facial weakness

Facial weakness caused by lesions of the upper motor neurones innervating the facial nucleus (e.g. following hemispheric stroke) are usually associated with ipsilateral limb weakness. In the face, the usual pattern is of relative sparing of the upper muscles because of their bilateral cortical representation and the fact that the cortical representation of the upper face is in the anterior cingulate gyrus rather than the motor cortex. Dissociation between voluntary and emotional facial movements may be seen; impairment of voluntary movement with relative sparing of emotional facial movements is more common than the converse.

In disorders such as progressive supranuclear palsy, disruption of supranuclear and brainstem mechanisms relating to facial movements may cause apraxia of eyelid opening; patients cannot voluntarily open eyes despite absence of overt facial weakness.

**Table 13.2** (a) Causes of facial palsy.

Bell's palsy
Herpes zoster (Ramsay Hunt syndrome)
Otitis media/cholesteatoma
<i>Borrelia</i> (Lyme disease)
Guillain–Barré syndrome
Sarcoidosis
Sjögren's syndrome
IgG4-related disease (Melkersson–Rosenthal syndrome)
Stroke
Multiple sclerosis
Other infections – HIV (usually associated with seroconversion), TB, polio
Vasculitis – Granulomatosis with polyangiitis (Wegener's), polyarteritis, Sjögren's syndrome
Tumour (usually involving temporal lobe, internal auditory canal, cerebellopontine angle, skull base or parotid gland):
• Schwannoma VIIth nerve
• Parotid gland tumour

**Table 13.2** (b) Causes of bilateral facial palsy.

Bell's palsy
Guillain–Barré/Miller–Fisher syndrome
Brainstem encephalitis
Pontine tumour
Meningeal infection / inflammation / infiltration
<i>Borrelia</i>
Sarcoidosis
Amyloidosis
HIV seroconversion
Herpes simplex / herpes zoster
Poliomyelitis
Motor neurone disease
Moebius syndrome
Neuromuscular junction / myasthenia gravis
Muscle / e.g. FSH, OPMD, Myotonic dystrophy

FSH, Facioscapulohumeral muscular dystrophy; OPMD, oculopharyngeal muscular dystrophy

### Nuclear VIIth lesions

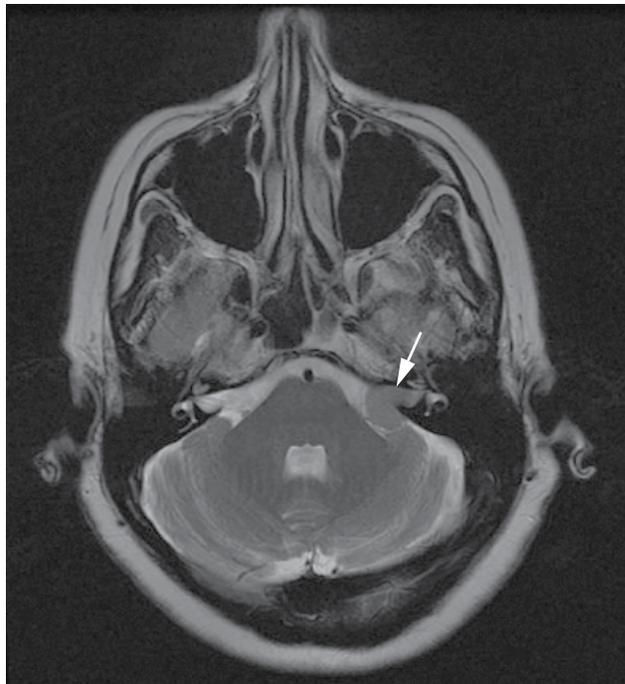

Vascular, inflammatory and occasionally infiltrative brainstem lesions can affect the facial nerve nucleus within the pons or the intrapontine fascicle. This produces a lower motor neurone type facial palsy. This rarely occurs in isolation and like most brainstem lesions usually involves adjacent structures. The VIIth nerve nucleus, around which the facial fasciculus sweeps, is often involved producing facial weakness and diplopia because of paralysis of lateral rectus on the same side. An associated contralateral hemiplegia (Millard–Gubler syndrome) is often caused by pontine vascular lesions; an ipsilateral gaze paresis reflects involvement of the paramedian pontine reticular formation.

### Cerebellopontine angle syndrome

The petrous temporal bone, lying laterally, completes the triangular recess between the cerebellum and the lower border of the pons (Table 13.3). The Vth nerve lies at the upper corner of the cerebellopontine angle (CPA), the IXth and Xth nerves at the lower, and the VIIth and VIIIth nerves between them (Figure 13.5). Mass lesions in the CPA cause combinations of an VIIIth nerve lesion, a Vth nerve lesion and a VIIth. Additional features develop when the adjacent cerebellar lobe is damaged, and occasionally a IXth nerve lesion, upper motor neurone signs in the limbs and exceptionally hydrocephalus with papilloedema.

**Table 13.3** Causes of cerebellopontine angle syndrome (invariably neoplasms; usually benign).

Vestibular schwannoma (most common)
Meningioma
Epidermoid
Cholesteatoma
Lipoma
Arachnoid cyst
Schwannoma of V, VII, IX, X or XI
Dermoid cyst
Hamartoma
Melanoma (primary or secondary)
Paraganglioma (glomus)
Choroid plexus papilloma
Primary CNS neoplasm
Lymphoma
Metastases (breast, prostate, lung and gynaecological)

**Figure 13.5** Vestibular schwannoma (MRI T2-weighted).

VIIIth nerve schwannoma (acoustic neuroma; Chapters 14 and 21) is the typical cause. Meningioma, cholesteatoma, metastasis or occasionally an aneurysm can also produce a CPA syndrome.

With an VIIIth nerve schwannoma there is a typical but not invariable sequence. High-pitched tinnitus, at first intermittent, is followed by progressive sensorineural deafness. Episodes of vertigo follow. Trigeminal facial sensory loss develops; initially this is symptomless – hence the importance of testing the corneal reflex. Facial weakness of lower motor neurone type follows. An IXth nerve lesion may be found. Later, as the tumour enlarges, cerebellar and other signs of brainstem involvement become apparent. In the elderly, when hearing loss has been neglected, hydrocephalus with raised pressure can be the presenting feature.

CPA lesions were sometimes hard to diagnose before the era of high-definition imaging but standard MRI sequences are now able to identify the great majority of CPA lesions.

### Facial canal syndrome

At the internal auditory meatus the VIIth nerve lies close to the VIIIth, and may be affected with it. Damage to the nerve within the facial canal is common and it is here that the VIIth nerve is believed to be affected in Bell's palsy. The first (labyrinthine) portion of the facial canal is the narrowest and the only segment lacking anastomosing arterial arcades, making it vulnerable to ischaemia and compression at this point. The clinical picture will depend on where within the canal the lesion occurs:

- Damage proximal to the first branch of the VIIth nerve, the greater superficial petrosal nerve to the lacrimal gland, will result in facial palsy with loss of lacrimation, hyperacusis (nerve to stapedius) and loss of taste in the anterior two-thirds of the tongue (chorda tympani).
- Lesions distal to the origin of the nerve to stapedius will not cause hyperacusis.
- Lesions distal to the chorda tympani will spare taste.

Head injury may cause damage to the facial nerve within the facial canal, usually as a result of a transverse fracture of the temporal bone. After the olfactory nerve, the facial nerve is the cranial nerve most commonly involved in head trauma. Surgical decompression and use of steroids are sometimes advocated but there is little evidence to support their use. Malignant otitis externa in diabetic patients, usually caused by *Pseudomonas* infection, and suppurative middle ear infection may spread to adjacent tissue and the skull base resulting in facial palsy. Temporal bone metastases, nasopharyngeal carcinoma and other tumours as well as disorders such as osteopetrosis and cholesteatoma may sometimes affect the facial nerve in this segment.

### Lesions at and distal to the stylomastoid foramen

The facial nerve or its branches can be damaged at or distal to its exit from the skull at the stylomastoid foramen. Parotid tumours or inflammatory parotitis resulting from infection or granulomatous disease such as sarcoidosis may cause facial palsy. Individual branches of the nerve may be damaged by surgery to the parotid or face, carotid endarterectomy, facial trauma or carotid dissection. Misplaced botulinum toxin injections, for cosmetic purposes or for hemifacial spasm, may also result in localised, but temporary, facial weakness.

### Bell's palsy

Bell's palsy is an acute peripheral facial palsy. A large retrospective study of almost 2500 cases presenting to UK GPs showed an incidence of 20/100 000 per year. Bell's palsy may occur in childhood; incidence increases steadily with age. There is no change in incidence

with season, latitude or geography and no evidence for familial clustering. Weak associations may exist with diabetes and hypertension. A viral aetiology has been postulated on the basis that decompression of the nerve in the acute phase usually reveals swelling of the facial nerve proximal to the geniculate ganglion, a finding confirmed by MRI, and detection of herpes simplex virus type 1 (HSV-1) DNA in endoneurial fluid in most patients. Both primary HSV-1 infection and reactivation of latent infection have been implicated. Microvascular ischaemic mononeuropathy of the facial nerve may also be causal in older patients. Bell's palsy has also been reported after immunisation. Bell's palsy should no longer be considered idiopathic.

**Clinical features** The clinical picture is stereotyped and familiar to most clinicians. Rapid onset of facial weakness progressing over 48 hours (and occasionally up to 5 days) is preceded or accompanied by diffuse retro-auricular pain in the region of the mastoid. In some patients, mastoid pain may be severe and persist for a week or longer. Facial weakness and asymmetry with drooling of liquids from the corner of the mouth on the affected side often lead the patient to suspect a stroke; most patients present promptly to primary care physicians. Not infrequently, patients mistakenly report that the contralateral unaffected side is the weak side. All facial muscles are usually equally affected. The palpebral fissure is widened on the affected side, eye closure and blinking are reduced or absent (with a visible Bell's phenomenon on attempted eye closure). Ectropion formation may lead to overflow of tears on to the cheek. The angle of the mouth droops with reduction of the nasolabial fold, smoothing of skin wrinkles; the platysma muscle is also involved. The extent of maximal facial weakness is variable, but is severe in the majority, although occasionally patients present with very mild facial weakness. For example, this may be noticed only because the patient is unable to form an adequate embouchure to play a wind instrument. However, a mild, painless, progressive or patchy facial weakness developing over several weeks is distinctly unusual in Bell's palsy, and suggests an underlying cause.

A vague alteration of sensation on the affected side of the face is relatively common in Bell's palsy, although the corneal reflex is preserved. Loss of taste, often described as a muddy or metallic taste, and hyperacusis (because of paralysis of stapedius) indicate involvement of the chorda tympani and the branch to stapedius, respectively.

Other causes of acute facial paralysis should be considered:

- The Ramsay-Hunt syndrome caused by varicella-zoster reactivation in the geniculate ganglion may be diagnosed by careful inspection of the external auditory meatus and palate for vesicles in these small somatic sensory territories of the facial nerve. Vesicles may be absent in some patients – zoster *sine herpette*. Other symptoms are common in the Ramsay-Hunt syndrome including tinnitus, hearing loss and nystagmus, indicating involvement of the VIIIth nerve and occasionally involvement of other cranial nerves such as the IXth and Xth.
- The ear should be examined for evidence of local pathology such as cholesteatoma or malignant otitis externa, and parotid tumours excluded.
- Lyme disease may possibly account for one-quarter of cases of facial palsy in endemic areas.
- Acute VIIth nerve lesions are sometimes seen at HIV seroconversion.

When a possible Bell's palsy appears to be unusual, for example a minor persistent facial weakness or slowly progressive weakness without pain, an underlying cause should be considered. A skull base tumour, such as a breast cancer metastasis can cause an isolated VIIth nerve lesion. In some cases there is also post-auricular pain.

**Investigation** Investigations are not required in typical cases. MRI may show contrast enhancement of the distal intra-canalicular and labyrinthine portions of the facial nerve. Imaging is not routinely indicated, unless a brainstem or other cause is suspected. Gradual onset of facial weakness over weeks, the presence of other neurological signs or failure to recover within 6 months should prompt further investigation, including imaging. In areas of high HIV prevalence, acute facial weakness is more often because of HIV seroconversion than the typical Bell's palsy seen in largely HIV-negative populations. In areas of high Lyme disease prevalence, testing for *Borellia* serology is appropriate.

CSF examination is not indicated in Bell's palsy and the CSF constituents are normal.

Neurophysiological stimulation of the facial nerve with measurement of facial compound motor action potential 3–20 days after onset may identify those with severe Wallerian degeneration of the nerve and a correspondingly poor prognosis for recovery. In practice this is rarely required.

**Management and outcome** Complete or almost complete recovery, without recurrence, over 3–8 weeks is the norm in at least 85% of cases, even without any treatment. Reassurance about the good prognosis and absence of recurrence is important. Inability to blink in severe facial weakness may lead to exposure keratitis and early evaluation should include assessment of the eye. Lubricating eye drops are often required and patients should be shown how to tape the eye closed at night. Severe facial weakness with complete inability to close the eye requires urgent ophthalmological assessment; lateral tarsorrhaphy and/or temporary insertion of a gold weight into the upper lid may be necessary.

Early treatment with steroids and antiviral agents remains contentious although this is now near standard practice. Some studies indicate a better outcome with steroids but a rigorous analysis as part of a Cochrane review concluded that there was insufficient evidence to support the use of steroids. Nevertheless, many clinicians choose to treat patients with oral prednisolone (typically 1 mg/kg for 7 days) if they present within a week of onset. Evidence to support use of antiviral agents is even more limited. The two largest clinical trials failed to show additional benefit for antiviral therapy and its use is no longer routinely recommended. However, it remains possible that the addition of antivirals is beneficial in the subgroup of patients with severe facial palsy (total paralysis) and it has been suggested that these patients should be given valacyclovir (1000 mg three times daily) in addition to prednisolone for 1 week. Treatment with an aciclovir–steroid combination could also be justified on the basis that HSV reactivation may be a frequent cause of Bell's palsy, and that some cases of Ramsay-Hunt syndrome may occur *sine herpette*.

Surgical decompression of the labyrinthine portion of the facial nerve in the acute phase has had its proponents, but there is little evidence to support this practice – now rarely performed in the United Kingdom. Over 80% of UK patients with Bell's palsy are managed in primary care; most receive no medical treatment.

The extent of early weakness is an important prognostic sign, with incomplete facial weakness indicating a better prognosis than total paralysis. For the majority of patients where recovery occurs within several weeks, conduction block and segmental demyelination, with intact axonal integrity within the facial canal, is presumed to be the basis of facial weakness. Where axonal loss and Wallerian degeneration have occurred, recovery follows after axonal regrowth. This is delayed by 4–6 months, or even longer. In these cases, recovery is usually incomplete, particularly for the more distal branches

supplying the brow and mouth, and often associated with contraction or tightness of facial muscles. Aberrant reinnervation of facial muscles and glands is common in late recovery, leading to synkinesis and the phenomenon of jaw-winking – involuntary eye closure with lip or mouth movement, known as the inverse Marcus Gunn phenomenon or Marin–Amat syndrome. Similarly, lip movement may occur on blinking. Aberrant parasympathetic reinnervation may lead to watering of the eye when eating (crocodile tears), caused by misdirection to the lacrimal gland of fibres destined for the submandibular salivary glands. These complications may be successfully treated with botulinum toxin injections either into the active muscle or the lacrimal gland.

For the minority left with severe facial weakness after a year, reconstructive facial surgery can be helpful. A variety of procedures may be considered: botulinum toxin for synkinesis, and into the contralateral side of the face to rebalance the cosmetic appearance, and highly specialised surgical procedures such as reanimation. The latter involves sural nerve grafting of a branch of the contralateral facial nerve, the aim being to innervate the paretic side. After 6 months (to allow axonal growth along the sural graft), this is followed by insertion of a revascularised pectoralis muscle flap into the affected side to improve function. In some patients, particularly older people, a simple muscle sling procedure improves cosmetic appearance, without improving movement.

### Recurrent facial palsy

Bell's palsy is rarely recurrent (<5% of cases) and should in any event prompt a search for an underlying cause, such as sarcoidosis.

**Melkersson–Rosenthal syndrome** This condition is a rare triad of intermittent VIIth nerve palsy, persistent or recurrent lip or facial swelling, and a fissured tongue (lingua plicata). The facial paralysis is identical to Bell's palsy, but has a distinct tendency to recur, and may be bilateral. These features are diagnostic clinically. Characteristic non-caseating granulomas are found on lip biopsy; the lip swelling is sometimes treated with local steroid injections. The aetiology was previously unknown, but now is thought to be associated with IgG4-related disease (Chapter 26).

### Bilateral facial weakness

Bilateral facial palsy is rare, accounting for fewer than 1% of cases of facial palsy, and is much more likely to be a manifestation of a systemic disease than a unilateral palsy, isolated or recurrent. Paradoxically, patients with bilateral facial weakness are often slower to present than those with obvious facial asymmetry.

In one large case series, bilateral Bell's palsy was the most common cause of bilateral facial palsy. Infective diseases such as bilateral mastoiditis and diphtheria have been replaced by HIV seroconversion, EBV infection and Lyme disease (Bannwarth's syndrome) as a cause of bilateral facial weakness. Lyme disease facial palsy is bilateral in one-quarter of cases and may be associated with a facial rash and CSF pleocytosis. Bilateral facial weakness may be a presenting feature of sarcoidosis. Other causes include trauma with skull base fracture, pontine glioma, tumours including bone metastases, leukaemic deposits within the skull base and malignant meningitis. These tend to cause gradually evolving facial weakness.

Bilateral facial weakness may be a feature of a more generalised neuromuscular disease. This occurs commonly in Guillain–Barré syndrome and the Miller Fisher variant, and is also a feature of disorders such as myotonic dystrophy, facioscapulohumeral dystrophy (sometimes presenting years before weakness of shoulder girdle muscles), myasthenia gravis, botulism, various congenital myopathies

and motor neurone disease. Möbius syndrome is a congenital disorder characterised by bilateral facial weakness, usually in association with abducens palsy and other neurological deficits. A rare form of familial amyloid polyneuropathy caused by gelsolin gene mutations may cause bilateral facial palsy with corneal lattice dystrophy.

### Hemifacial spasm

This is a benign, usually painless but often distressing condition, characterised by unilateral, involuntary, irregular tonic or clonic contractions of muscles supplied by the facial nerve. Prevalence is 14.5/100 000 and 7.4/100 000 in women and men, respectively. Onset is usually in the fifth and sixth decades.

In some patients the involuntary movements start in the orbicularis oculi muscle and gradually progresses over months or years to involve other facial muscles on the same side. In others, the problem begins with twitching around the mouth or the cheek. Movements are irregular in rhythm and degree but synchronous in all affected muscles. They may be spontaneous or triggered by voluntary facial movements including chewing and speaking, and they are made worse by stress or fatigue. Movements usually persist during sleep. Bilateral involvement is rare (3%), and when it occurs movements are never synchronous on the two sides. Examination is usually normal although subtle ipsilateral facial weakness is sometimes seen. It is now generally accepted that hemifacial spasm is usually caused by extrinsic compression of the root entry zone of the facial nerve, generally by vascular structures such as the vertebral or basilar arteries or their branches. Other mass lesions in the CPA, including tumours, are the cause in about 1% of cases. Secondary hemifacial spasm, following injury to the peripheral facial nerve or following Bell's palsy also occurs. High-resolution MRI with fine cuts through the region of the facial nerve root entry zone demonstrates a vascular structure in contact with the nerve in some cases. Imaging is not usually needed, except in atypical cases where onset is not around the eye, where there are abnormal findings on physical examination or when surgical treatment is being considered.

Botulinum toxin injection into affected muscles is now the first line for those patients who want treatment. Injections need to be repeated every 3–4 months and many patients eventually develop some degree of facial weakness and atrophy. Drug treatment with carbamazepine, gabapentin, clonazepam and baclofen are rarely very effective and seldom result in resolution of symptoms, certainly at tolerable doses. Microvascular decompression of the facial nerve in the posterior fossa involves interposing a non-resorbable sponge between the nerve and any adjacent vascular loop identified at operation. The procedure is sometimes claimed to give complete resolution of symptoms in some 60% of cases, but is associated with a risk of 3% facial weakness or 3% unilateral deafness.

Hemifacial spasm may occasionally occur with ipsilateral trigeminal neuralgia, one symptom usually preceding the other, a combination called *tic convulsif*. The paroxysms of pain and spasm occur independently. A compressive cause such as a vascular loop or other structural lesion is usually identified.

### Other involuntary facial movements

- Myokymia of orbicularis oculi, an irritating twitch usually of the lower eyelid, is a normal phenomenon, but sometimes a cause of anxiety. More extensive facial myokymia, with persistent worm-like wriggling of the chin and other facial muscles is more sinister. This is typically caused by intrinsic brainstem pathology such as MS, or a pontine glioma, in both cases it is usually progressive. Facial myokymia is also a hallmark of some inherited ataxias, particularly spinocerebellar atrophy type 3 (SCA3).

- Tics and tardive dyskinesia frequently involve facial or perioral muscles.
- Neuro-acanthocytosis may cause prominent oro-facial dystonia, often including the tongue.
- Blepharospasm is a form of focal dystonia affecting orbicularis oculi (Chapter 6). Fasciculation of facial muscles can develop in motor neurone disease (particularly Kennedy's disease).
- Focal motor seizures may affect facial muscles alone in some cases; epilepsy partialis continua (Chapter 7) is a cause of persistent clonic-tonic facial movements, which can be localised and difficult to recognise.

**Progressive hemifacial atrophy** Also known as Parry–Romberg syndrome, this rare condition consists of progressive hemifacial atrophy of skin, soft tissue and bone, sometimes with pathological changes within the brain. This begins in childhood, with gradual progressive atrophy, typically in one or more trigeminal nerve dermatomes. Facial sensation remains normal. There is no denervation. The condition is believed in some cases to be related to linear scleroderma. Sometimes a vertical fissure, known as a coup de sabre, separates atrophic areas from normal facial structures. Brain imaging shows ipsilateral grey and white matter lesions in some cases. Epilepsy sometimes occurs. The cause is unknown. There are suggestions that a chronic inflammatory process underlies the condition.

### Lower four cranial nerves: IX, X, XI and XII

An outline of the peripheral course of these four nerves is shown in Figure 13.6. Their complex central arrangement and nuclei are summarised in Chapter 2.

## IX. Glossopharyngeal nerve

### Functional anatomy

The IXth nerve (Chapter 2) is predominantly sensory but also contains motor and parasympathetic components. It arises from the lateral medulla as a series of small rootlets rostral to those of cranial

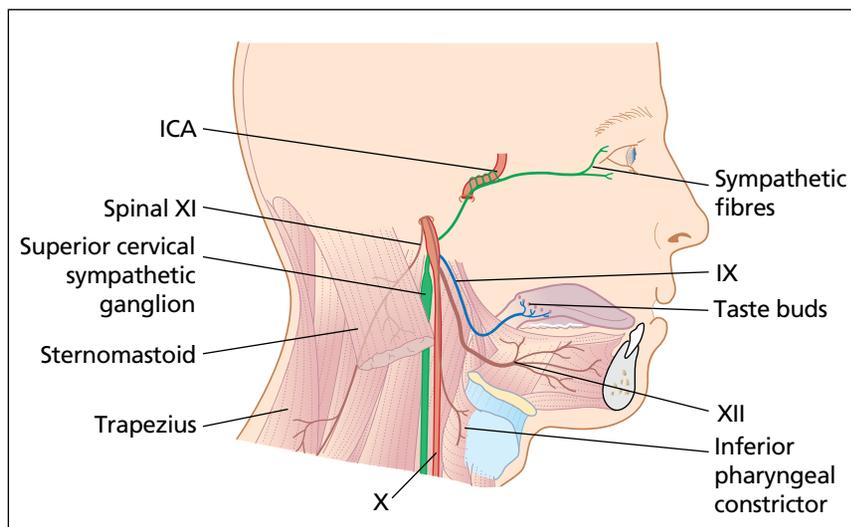

nerves X and XI. All three nerves then pass through the jugular foramen. At this point or just beyond, the IXth nerve divides into the superior and petrous ganglia, before descending the pharynx between the internal jugular vein and internal carotid artery. The small motor root supplies pharyngeal constrictors and elevators. The principal sensory root supplies taste and tactile sensation from the posterior one-third of the tongue, the posterior pharyngeal wall, Eustachian tube and tympanic membrane, and other targets such as the chemo- and baro-receptors. The parasympathetic fibres, from the inferior salivatory nucleus, leave the glossopharyngeal nerve at the petrous ganglion running in the tympanic and petrosal nerves. They terminate in the parotid gland, via the auriculo-temporal branch of the trigeminal nerve.

### Examination

Pharyngeal sensation can be tested with the end of an orange stick. In a IXth nerve lesion, there is altered sensation of the soft palate and pharynx. This is frequently difficult to diagnose in isolation, and rarely of great importance because other neighbouring nerves are also often affected. Loss of taste over the ipsilateral posterior third of the tongue is rarely symptomatic and cannot be tested. Isolated weakness of stylopharyngeus (which elevates the palate) is difficult to detect, with only mild dysphagia or asymmetry of the palatal arch at rest. Because the nerve supplies the afferent limb of both the pharyngeal and palatal reflex arcs, as well as the motor component of the former, a IXth nerve lesion has the potential to interfere with both these reflexes. Stimulating the normal pharynx, base of tongue or tonsillar area, with an orange stick, will result in pharyngeal elevation and constriction, with a degree of tongue retraction. In an isolated IXth nerve lesion the muscles of the pharynx supplied by the vagus continue to contract, making it impossible to diagnose an isolated IXth nerve lesion by this method.

### IXth nerve lesions, peripheral and central

An isolated peripheral glossopharyngeal nerve palsy is excessively rare and lesions can be generally identified by the additional structures involved. Unilateral supranuclear lesions cause no deficit because of the bilateral input to the nucleus ambiguus. It is only

**Figure 13.6** Distribution of IX, X, XI, XII and superior cervical ganglion. ICA, internal carotid artery. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

when there are bilateral corticobulbar lesions (as part of pseudobulbar palsy) that overt signs are seen which include tongue spasticity and dysarthria, with emotional lability.

Peripheral lesions usually occur as part of the jugular foramen and CPA syndromes. More distally the nerve can be injured in the retropharyngeal space by structural lesions (e.g. a primary tumour such as nasopharyngeal carcinoma or metastatic spread) and surgical complications (e.g. carotid endarterectomy).

### Glossopharyngeal neuralgia

Glossopharyngeal neuralgia is a rare condition. There is unilateral sharp stabbing pain in the ear or throat, lasting for seconds or minutes. Like trigeminal neuralgia, pain is triggered by movement of neighbouring structures, such as yawning or chewing. The pain is intense and paroxysmal. Bradycardia or even asystole with hypotension and syncope have been described in an attack. The cause often remains obscure, although CPA structural lesions, demyelination and possibly vascular loop compression of the posterior inferior cerebellar artery have been found. As with trigeminal neuralgia, carbamazepine and gabapentin may be effective. Microvascular decompression is usually curative but nerve section is also sometimes carried out.

## X. Vagus nerve

### Functional anatomy

The central origins and connections of the vagus and its relations to IX, XI and XII are outlined in Chapter 2. The vagus exits at the jugular foramen with the spinal accessory nerve and glossopharyngeal nerve. Two ganglia are formed (jugulare and nodose), and from this region a number of rami project: auricular (external ear), meningeal (posterior fossa dura mater) and pharyngeal (soft palate and pharynx). There are two principal laryngeal nerves, the superior and recurrent laryngeal nerves (Figure 13.7). The vagus carries the parasympathetic supply to many thoraco-abdominal organs,

with fibres from the nucleus ambiguus innervating the striated muscle of larynx, pharynx and soft palate, with the exception of stylopharyngeus (IXth) and tensor veli palati (Vth). Sensory input from the viscera and taste from the palate and epiglottis are carried back to the nucleus solitarius.

### Clinical features

Vocalisation, swallowing and palatal movement are the major functions observable clinically. Bilateral lesions cause complete palatal, pharyngeal and laryngeal paralysis resulting in severe dysphagia, dysphonia and respiratory compromise with stridor, inability to cough and high risk of aspiration. Tracheostomy is usually required in acute bilateral nuclear or peripheral lesions, which may otherwise be life-threatening.

Unilateral vagus nerve palsy is characterised by dysphonia – the voice is hoarse and weak, with variable, usually mild, dysphagia. The vocal cords cannot be opposed, causing the cough to be weak and dependent upon forceful expiration; this is described as bovine. There is difficulty clearing the throat; the voice can often sound wet, because of pharyngeal pooling of secretions. Clinical examination demonstrates soft palate droop on the affected side; there is failure of elevation of the ipsilateral palate and the uvula may be pulled towards the unaffected side on phonation. Unilateral depression of the gag reflex occurs with a lesion of one vagus nerve. Autonomic dysfunction can occur and is discussed in Chapter 24.

With bilateral vagus involvement the palate cannot elevate on phonation and it may droop depending on the function of the tensor veli palatini. The palatal gag reflex is absent bilaterally. There is nasal speech and nasal regurgitation of liquids.

With pharyngeal weakness dysarthria is usually minimal unless there is also weakness of the soft palate or larynx. Spontaneous coughing and the cough reflex are impaired. Dysphagia may occur but without the tendency to greater difficulty with liquids and nasal regurgitation that occurs with palatal weakness. Examination of the

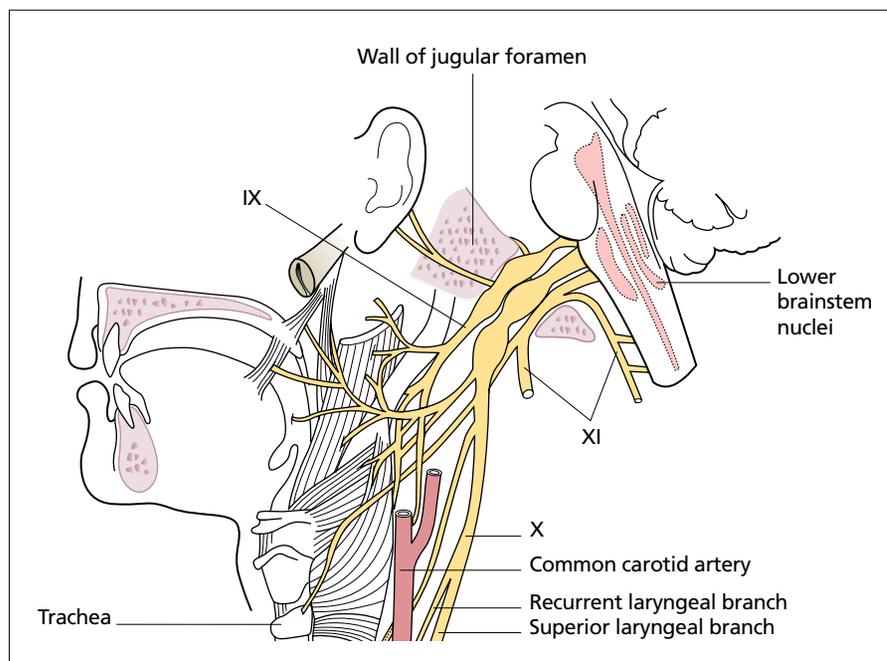

Figure 13.7 Scheme showing IXth, Xth, XIth nerves, skull base and brainstem.

pharynx includes observation of the contraction of the pharyngeal muscles on phonation, elevation of the larynx on swallowing and testing the pharyngeal gag reflex. Unilateral weakness of the superior pharyngeal constrictor may cause 'curtain movement' (Vernet's rideau phenomenon). With movement of the pharyngeal wall towards the non-paralysed side on testing the gag reflex or on phonation, the normal elevation of the larynx may be absent on one side unilateral lesions or on both sides in bilateral lesions.

Sensory examination is essentially impossible because of inaccessibility (meningeal structures) or co-innervation (e.g. the pinna).

### Causes and localisation of lesions

Major supranuclear lesions (e.g. acute hemispheric stroke), may cause transient swallowing difficulty, but the bilateral innervation of vagal brainstem nuclei means compensation usually occurs rapidly. Bilateral supranuclear lesions cause pseudobulbar palsy (see Pseudobulbar palsy). Nuclear lesions are usually accompanied by damage to adjacent structures within the medulla which may dominate the clinical picture. Brainstem stroke resulting from lesions of the vertebral artery or its branches may cause characteristic clinical syndromes of infarction, particularly affecting the lateral medulla (Wallenberg's lateral medullary syndrome; Chapter 5).

Involvement of the nucleus ambiguus leads to dysphagia and dysphonia accompanied by vertigo, ipsilateral cerebellar signs, Horner's syndrome and spinothalamic sensory loss of the contralateral half of the body and the ipsilateral face. Other structural and inflammatory disorders in this region can also affect long motor and sensory tracts; there are a number of eponymous syndromes (Table 13.4).

- Syringobulbia, motor neurone disease and vascular lesions can cause bilateral nuclear lesions affecting the vagus, producing a complete or partial bulbar palsy. Multiple system atrophy may affect the vagal nuclei causing stridor because of partial vocal cord paralysis as well as the autonomic disturbances characteristic of this condition.
- Peripheral lesions in the extramedullary intracranial region and as the nerve exits the skull through the jugular foramen often involve the IXth, XIth and XIIth nerves.
- Primary tumours (e.g. chordoma, skull base or meningeal infiltration by metastatic tumour and inflammatory disorders) may all be responsible (see Jugular foramen syndrome). Extracranial lesions of the nerve trunk in the neck, where it runs in the carotid sheath, may result from carotid dissection, surgery or lymph node inflammation (e.g. tuberculous) at the skull base.

**Table 13.4** Eponymous brainstem syndromes involving the cranial nerves.

Syndrome	Site	Artery	Neurology
Weber	Midbrain – base	PCA	<i>i/l</i> III, <i>c/l</i> pyramidal
Benedikt	Midbrain – tegmentum	PCA	<i>i/l</i> III, <i>c/l</i> pyramidal, ataxia, rubral tremor

*i/l*, ipsilateral; *c/l*, contralateral; PCA, posterior cerebral artery; PPRF, parapontine reticular formation.

- More distally, beyond the point at which the pharyngeal nerve arises high in the cervical region, a complete isolated vagal palsy causes unilateral vocal cord palsy and laryngeal anaesthesia but spares pharyngeal and palatal muscles. The superior laryngeal nerve, which arises just distal to the pharyngeal nerve, is primarily sensory and lesions tend to be asymptomatic; classically, cricothyroid dysfunction causes an inability to raise the vocal pitch, with a degree of hoarseness.

Lesions of the recurrent laryngeal nerve are more common than isolated vagus trunk lesions. These cause degrees of dysphonia, which may be transient if unilateral, or severe if bilateral. The left recurrent laryngeal nerve is more frequently involved than the right because of its longer intrathoracic course making it vulnerable to mediastinal lesions such as lung malignancy, left atrial enlargement and aortic arch aneurysm. A wide variety of pathological processes (e.g. thyroid masses, lymph node and oesophageal malignancy) can affect the recurrent laryngeal nerves as they ascend through the neck and they are vulnerable during thyroid and parathyroid surgery. In a significant proportion of cases, however, the cause of an isolated recurrent laryngeal nerve palsy often remains undetermined, even after extensive investigation; spontaneous recovery may occur.

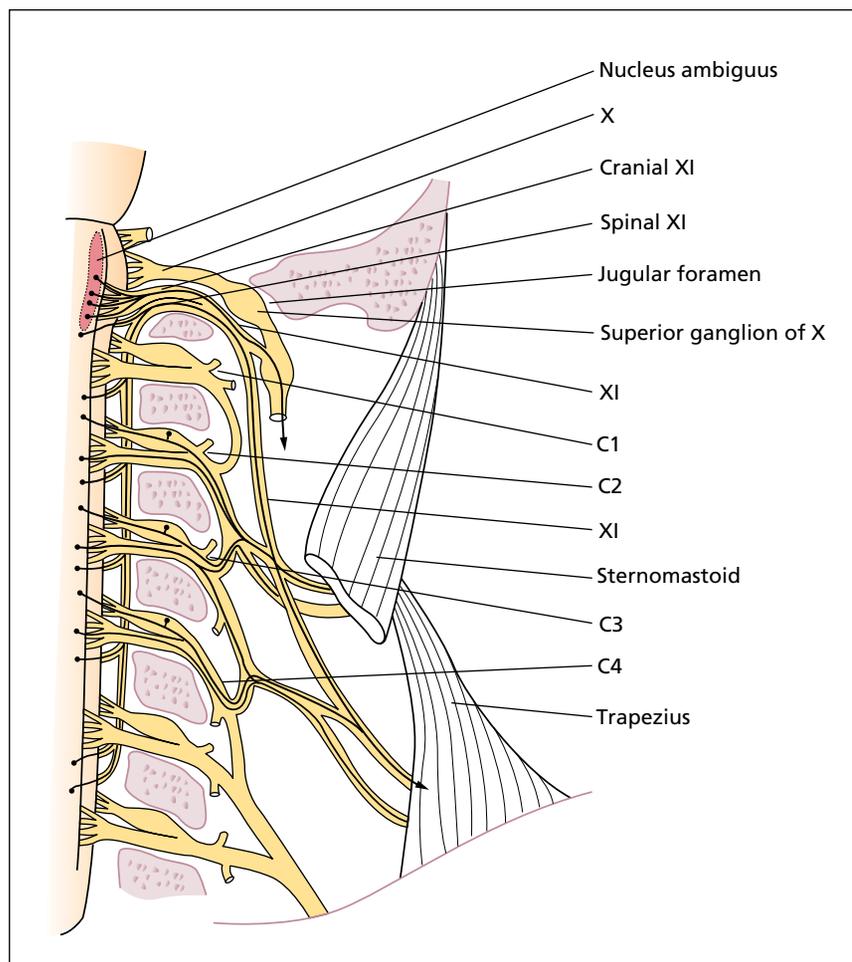

### Investigation

This is based around comprehensive ENT evaluation, with appropriate MRI and CT imaging of brainstem, skull base, neck and upper thorax. If no structural pathology is identified, CSF examination may be needed. The clinical picture will help to localise the lesion and guide targeted investigation. In practice, when confronted with a patient with a vocal cord palsy, the clinician needs to establish if there is evidence of other brainstem signs or involvement of other lower cranial nerves and to look for associated pharyngeal and palatal paralysis.

## XI. Accessory nerve

### Functional anatomy

The spinal accessory nerve is the motor nerve to the upper portion of the trapezius and sternocleidomastoid muscles. Unusually, the XIth nerve has twin origins: the caudal portion of the nucleus ambiguus forms the internal ramus (minority), and the accessory nucleus of the upper cervical spinal cord (C1–6), the spinal root and external ramus (majority). The pathway begins by ascent of the spinal root through the foramen magnum and the nerve then exits from the skull via the jugular foramen (Figure 13.8). From there, the

**Figure 13.8** Jugular foramen (left), X and XI (AP view, cord and medulla).

internal ramus supplies the larynx and pharynx with the Xth nerve; the external ramus supplies the sternocleidomastoid and trapezius muscles. Strictly speaking, the fibres of the cranial root of the nerve destined to form the internal ramus are functionally and anatomically part of the vagus nerve; thus, the accessory nerve is primarily a spinal nerve with an intracranial course rather than a true cranial nerve. Afferent twigs from the cervical and thoracic nerves combine with spinal XI as it pierces trapezius – an anomalous arrangement (Chapter 2). The spinal accessory nerve has an intimate relationship with the internal jugular vein (IJV): one surgical series of neck dissections for cancer found that in 96% it was lateral to the IJV at the level of the superior border of the posterior belly of digastric, in 3% medial and in 1% spinal XI travelled through the IJV.

### Examination and localisation of lesions

The right sternomastoid is tested by asking the patient to turn the head to the left against resistance; both sternomastoids contracting together produce head flexion. The trapezius raises the abducted arm above horizontal, and is responsible for much of the scapular movement. This is tested by asking the subject to shrug their shoulders.

The clinical picture is relatively straightforward for unilateral peripheral lesions. The shoulder droops lower on the affected side, with wasting of the upper trapezius, accompanied by weakness of shoulder elevation and arm abduction above 90°. Winging of the scapular is seen, particularly when the arm is moved laterally, as opposed to damage of the long thoracic nerve when the winging is seen with forward movement of the arms against a flat surface, because of serratus anterior weakness. The so-called scapular flip sign is a cluster of shoulder girdle depression, trapezius atrophy, and active shoulder abduction limited to less than 90° with the postulated mechanism being the unopposed pull of the external humeral rotators by the inactive lower and middle trapezius.

Isolated bilateral sternocleidomastoid lesions are extremely rare but generalised neuromuscular processes such as myotonic dystrophy, inflammatory myopathies, some muscular dystrophies and myasthenia gravis also affect these and other neck muscles and are a more common cause of neck flexion weakness.

With central hemispheric lesions, the trapezius is weak on the side of the hemiparesis, while the sternomastoid is weak ipsilateral to the cortical lesion (so head turning is weak towards the side of the hemiparesis). Dissociated weakness has also been described, mainly indicating brainstem or upper cervical pathology.

### XIth nerve lesions

The leading cause of damage to the XIth nerve is iatrogenic trauma during operations such as lymph node biopsy in the posterior cervical triangle and other surgery in this region. Historically, tuberculosis of the neck was a major cause. Vascular procedures such as carotid artery endarterectomy and internal jugular vein cannulation are also well-recognised causes, especially with the intimate relationship to the IJV described earlier (Table 13.5).

These lesions cause weakness of trapezius but spare the sternomastoid. The trapezius weakness following XIth nerve lesions is sometimes associated with persisting severe local shoulder pain and/or deep pain in the trapezius, possibly caused by mechanical factors relating to shoulder droop and scapular winging, or to the anomalous afferents described earlier. Neurophysiology studies can confirm the site of the peripheral lesion, followed if needed by imaging. Surgical intervention has a distinct place in management, using direct grafting, end-to-end repair or neurolysis. There are also instances of spontaneous accessory neuropathy, perhaps allied

to neuralgic amyotrophy with pain in the lateral neck or shoulder, which subsides over several weeks followed by weakness and wasting. Recovery is rare. A recurrent variant has been described, with one individual experiencing two episodes over 8 years.

The spinal nucleus of XI may be affected by local structural and inflammatory cord pathologies. In the posterior fossa, the intracranial portion of the nerve can be damaged, often in combination with the glossopharyngeal and vagus nerves (Table 13.4; see Jugular foramen syndrome).

## XII. Hypoglossal nerve

### Functional anatomy

Glossal muscles, both intrinsic and extrinsic, are supplied by the hypoglossal nerve; the peripheral route travelled is illustrated in Figure 13.9. The styloglossus elevates and retracts the tongue, the hypoglossus convexus and the genioglossus protudes the tongue. The nucleus is beneath the floor of the 4th ventricle, and the nerve

**Figure 13.9** Peripheral distribution of XIIth nerve and other principal structures.

emerges as a series of rootlets between the olive and pyramid, in the ventrolateral sulcus. In the posterior cranial fossa, the XIIth nerve exits the skull through the hypoglossal foramen, close to the jugular foramen. Its proximity to both the internal carotid artery and internal jugular vein is important.

### Localisation of lesions

Observation of the tongue in both resting and active states is essential, the latter including forward–backward and side–side movements. A variety of signs of unilateral or bilateral wasting can be seen: furrowing, atrophy, fissuring, discoloration and fibrillation. Tongue fibrillation, seen typically bilaterally in motor neurone disease, should only be diagnosed with the tongue at rest within the mouth; the normal tongue often has some flickering movements visible when protruded. The tongue can be spastic, with a small triangular appearance when protruded and slow clumsy movements (see Pseudobulbar palsy).

Peripheral pathology affecting one XIIth nerve causes the tongue to deviate to the side of the lesion on tongue protrusion. Subtle weakness is detected by asking the patient to press the tongue against the inside of each cheek (weakness is evident when the tongue is pressed against the cheek on the same side as the lesion). Typically, unilateral wasting and atrophy follow.

Unilateral upper motor neurone lesions can result in deviation of the tongue contralateral to the lesion, without evidence of wasting, although caused by the bilateral representation; this is uncommon (Chapter 2). Bilateral lower motor neurone lesions result in an inability to protrude the tongue, mild dysphagia and severe dysarthria (see Bulbar palsy).

### Causes of XIIth nerve lesions

The causes of hypoglossal nerve lesions are summarised in Table 13.6. A variety of tumours account for half, mainly peripherally in the skull base or neck, with half of those being malignant (e.g. nasopharyngeal carcinoma, lymphoma and metastatic carcinoma).

Nasopharyngeal carcinoma commonly involves the Vth and VIth nerves and can spread within the cavernous sinus to involve the IIIrd nerve. In a series of approximately 1000 patients with nasopharyngeal carcinoma, 22% presented with cranial nerve involvement, in which the XIIth nerve was involved in 19%, rising to nearly one-third at follow-up. Trauma is an important cause of XIIth nerve damage, in particular bullet, shrapnel and knife wounds. Damage from infection is rare but when there is evidence of sepsis, osteomyelitis of the clivus should be suspected, in particular in patients with diabetes who have *Pseudomonas* infection originating in the ear (malignant otitis externa). An isolated XIIth nerve lesion, usually associated with neck pain, is sometimes seen as part of carotid artery dissection (Chapter 5) or following carotid endarterectomy.

The proximity of the XIIth nerve to the other lower cranial nerves in the posterior fossa and neck has already been mentioned and combinations of cranial nerve palsies are frequently seen.

### Investigation

Imaging of the skull base and neck is essential, predominantly using MRI and fine-cut CT, usually with contrast enhancement. If no cause is revealed, then CSF analysis looking for inflammatory and infiltrative causes may be needed. Electrophysiological studies can be useful (e.g. in motor neurone disease or Guillain–Barré syndrome).

### Cranial nerve injury following carotid endarterectomy or carotid angioplasty with stenting

Cranial nerve injury is a common problem following carotid procedures and, in the authors' experience, often understated to patients prior to surgery (Table 13.7). In a recent Cochrane review of trials of carotid intervention, carotid endarterectomy compared to carotid artery stenting carried a higher risk of cranial nerve injury, 5.5% versus 0.3% (n = 7000 evaluated). The nerve most frequently affected is the hypoglossal.

**Table 13.6** Causes of tongue weakness.

### Jugular foramen syndrome

This pattern of IXth, Xth and XIth nerve lesions is known as Vernet's syndrome but cranial nerve involvement may be more extensive (Table 13.8a). Figure 13.8 and Figure 13.9 demonstrate how

**Table 13.7** Common nerve lesions following carotid endarterectomy and stenting.

Nerve involved	Effect	Usual outcome
Cervical sympathetic chain	Horner's syndrome	Permanent
Hypoglossal (XII)	Tongue deviation	Recovery
Recurrent laryngeal (X)	Hoarseness, dysphagia	Variable
Cutaneous cervical branches	Sensory loss around neck	Some numbness: common
Accessory (XI) – unusual	Weak sternomastoid; pain	Variable

**Table 13.8** Causes of jugular foramen syndrome.

(a) Variants	
Vernet	Ipsilateral involvement of CN IX, X, XI

Villaret	Collet–Sicard + Horner's (due to carotid sympathetics)
(b) Causes	
Tumours	Glomus tumour (paraganglioma, chemodactoma) Schwannoma Meningioma Ependymoma Glioma (ectopic) Chordoma Plasmacytoma Metastasis
Infection	Malignant otitis externa Retropharyngeal abscess Herpes zoster
Vascular	Thrombosis of the jugular bulb Giant cell arteritis
Trauma	

structural disease at the jugular foramen can damage this trio of cranial nerves. As predicted, the presentation is dysphagia, dysphonia, sensory loss over the posterior third of the tongue, soft palate, pharynx and larynx (IXth and Xth) and ipsilateral sternomastoid/trapezius atrophy and weakness (XIth). The causes are listed in Table 13.8b.

An analysis of jugular foramen schwannomas found:

- Mean age at presentation was 40 years
- 2 : 1 left : right
- Common symptoms: hearing loss, tinnitus, hoarseness, dysphagia and ataxia, and
- Complete removal was possible in 80% but 7% recurred.

Schwannomas arose from the glossopharyngeal nerve in 24%, vagus in 13% and cranial XI in 6%. Postoperative complications included facial and lower cranial nerve palsies occurred in around 25%.

## Bulbar and pseudobulbar palsy

These terms refer to impairment of function of muscles supplied by lower cranial nerves (IX, X, XI and sometimes XII). The nuclei of these nerves lie in the medulla (the medullary bulb), within the brainstem. Lesions involving the descending corticobulbar pathways (from cortex to nucleus) cause pseudobulbar palsy and lesions of the nuclei, fasciculi, cranial nerves or muscles themselves produce bulbar palsy. In pseudobulbar weakness, there is no lateralisation. Bulbar weakness can be unilateral, though it is typically bilateral. The most obvious manifestation of diminished muscle movement is usually choking and neurogenic dysphagia, but both bulbar and pseudobulbar palsy include a constellation of characteristic associated clinical features. Patients with severe Parkinson's disease also have poverty of movement of bulbar muscles, and cerebellar disease causes disordered swallowing.

### Normal swallowing

The normal swallow is a complex sequence of coordinated events requiring intact lower cranial nerve function. A pre-oral phase is associated with the sight, smell and taste of food that triggers saliva production and prepares for the food or liquid bolus. In the oral phase the lips close to form a seal (VII); the tongue and rotatory action of the jaw (XII, V) grind food, mixing it with saliva. The velum sits on the base of the tongue to seal off the nasal cavity. When the bolus has been formed the tongue raises against the hard palate, a central groove forms (XII) and the stripping motion of the tongue moves the bolus backwards. When the bolus reaches the faucial arches, the swallowing reflex is triggered. The pharyngeal stage is entirely involuntary. The soft palate rises to block off the nasal cavity (X). As the swallow is triggered the larynx rises and tilts forwards. The airway is protected by apposition of the true and false cords and of the arytenoids against the base of the epiglottis (the sphincteric action of the larynx). The epiglottis inhibits direct contact of the bolus with the laryngeal vestibule (all X). Upward and forward movement of the hyoid and larynx (V, VII, C1–3) enhance airway protection and pull open the relaxed upper oesophageal sphincter. The bolus moves over the closed airway and the cricopharyngeal sphincter relaxes. In the oesophageal stage the bolus passes through the cricopharyngeal oesophagus by peristalsis. Breathing is centrally inhibited during the swallow (deglutition apnoea); afterwards, structures return passively to their original positions, or with the aid of the infrahyoid muscles.

It is increasingly clear these swallowing reflexes are influenced by significant descending control to the medulla. Clinical observation in cerebrovascular disease and cortical mapping using transcranial magnetic stimulation and functional imaging indicate a role for the cerebral cortex (primary motor, inferior frontal gyrus and insula) with probable left hemispheric dominance. Dysphagia is also common in basal ganglia and cerebellar disorders – these systems are clearly also involved in descending control.

### Bulbar palsy

While bulbar palsy may be unilateral or bilateral, swallowing impairment usually only occurs with bilateral weakness (Table 13.9). Bulbar muscle weakness causes a nasal dysarthria, dysphagia with nasal regurgitation, a wasted atrophic tongue with fasciculation and slow tongue movement. There may also be associated facial weakness, dysphonia and limited jaw movement. There is consistent absence of both palatal and pharyngeal reflexes in bulbar palsy. Unilateral pharyngeal wall paresis causes the paralysed side to move

towards the healthy side (Vernet's movement *de rideau*). It is not possible to distinguish reliably between IX and X nerve lesions, but lack of posterior pharyngeal sensation can have important implications in stroke. A unilateral XII nerve lesion causes tongue deviation – on retraction towards the healthy side (unopposed action of the styloglossus), and on protrusion towards the affected side (genioglossus). Impaired swallow can easily lead to poor dietary intake and dehydration, aspiration and bronchopneumonia – secretions pool in the pharynx.

### Pseudobulbar palsy

Pseudobulbar palsy describes an upper motor neurone pattern of weakness affecting muscles innervated by the bulbar nuclei (Table 13.10). It is usually caused by bilateral involvement of the descending corticobulbar and/or cortico-pontine pathways anywhere from the insular cortex to the medulla. Pseudobulbar palsy is characterised by spastic dysarthria, slow and limited tongue movements with no wasting or fasciculation, an exaggerated jaw jerk and pharyngeal weakness. There may be complete anarthria with an

inability to open the mouth, protrude the tongue, swallow or move the face at will or on command. Patients with pseudobulbar palsy show a striking incongruity with loss of voluntary movements of muscles innervated by the motor nuclei of the lower pons and medulla (inability to swallow, phonate, articulate, move the tongue forcefully, close the eyes) but preservation of reflex ponto-medullary actions: yawning, coughing, throat clearing, spasmodic laughter and crying. Pseudobulbar affect describes the combination of emotional lability and profound motor retardation. There may be associated frontal release signs and primitive reflexes; the jaw jerk, facial and pharyngeal reflexes can be particularly brisk, with clonic jaw movements or clamping down on a wooden tongue blade. Occasionally, these clinical features occur in isolation with no other manifestations of pseudobulbar palsy. In particular, isolated inappropriate spasmodic laughing or crying, unrelated to surrounding circumstances or stimulation and with no corresponding emotional feeling may be the first feature sign of pseudobulbar palsy. Movements of the palate and pharynx on phonation are variable but often reduced.

Pseudobulbar palsy may be divided into three forms:

- 1 Cortical:** caused by lesions in the opercular region and characterised by isolated weakness of the face, pharynx and tongue with dissociation between automatic and voluntary function. This is associated with anarthria, a complete loss of swallow and hypotonic paralysed muscles. Emotional lability is unusual.
- 2 Striatal:** caused by lesions in the descending corticobulbar tract in which the characteristic cortical features are associated with pyramidal signs, emotional lability and cognitive impairment.
- 3 Pontine:** in which all these features occur with cerebellar signs and emotional lability but no cognitive impairment.

### Dropped head syndrome

Certain clinical appearances narrow diagnostic possibilities. The dropped head syndrome (Figure 13.10) is one of these. A variety of neuromuscular diseases cause this syndrome (Table 13.11); motor neurone disease is one of the most common.

**Figure 13.10** Dropped head syndrome in a patient with motor neurone disease. Source: Gourie-Devi 2003. Reproduced with permission of BMJ.

The condition is particularly distressing and difficult to help. Various supports and frames are sometimes suggested and some patients find a high-backed chair or a tailored U shaped cushion is more comfortable than a soft collar. Advice from an occupational therapist with experience of palliative care is helpful. Severe neck pain often accompanies the weak muscles.

### Multiple cranial neuropathies

Multiple cranial neuropathies (MCNs) are either caused by local lesions such as tumours, vascular causes, trauma and infection, which affect clusters of neighbouring nerves, or by underlying systemic conditions. Some combinations of cranial nerve lesions have been mentioned already; others are described in Chapters 14 and 21. Some MCNs have a benign cause, such as a CPA tumour. However, when no such lesion is evident on initial imaging, MCNs should be regarded as ominous, because of the high chance of underlying malignancy (metastasis, primary tumour and malignant meningitis) or other serious systemic disease often affecting the clivus or the skull base (Table 13.12). Careful scrutiny, a review of detailed imaging and CSF analysis are needed, and may need to be repeated after an interval. Images of the skull base are sometimes particularly difficult to interpret; fine-cut CT, with bone windows is

of particular value. The advice and expertise of an ENT surgeon and an ophthalmologist with experience of neurological conditions is invaluable.

One large series of over 1000 cases of MCNs found that tumours were responsible for 30%. Schwannomas, generally from the VIIIth nerve, followed by metastases were the most common neoplasms. The majority of vascular cases were lateral pontine or medullary infarcts. There were a small number of arteriovenous malformations and carotico-cavernous aneurysms. Infection made up 10% of the

Neuropathy	Guillain–Barré, Miller–Fisher, idiopathic cranial polyneuropathy
Metabolic	Diabetes mellitus
Inflammatory	Sarcoidosis, Behçet's, amyloidosis
Vasculitis	Wegener, PAN, Churg–Strauss, lymphomatoid granulomatosis, giant cell arteritis, granulomatous angiitis
Connective tissue disease	Systemic lupus erythematosus, Sjögren's, scleroderma, mixed connective tissue disease
Pituitary	Apoplexy, lymphocytic hypophysitis
Vascular	Aneurysm, dissection, endarterectomy
Radiotherapy	
Bone disease	Osteopetrosis, Paget's disease, hyperostosis cranialis, fibrous dysplasia

CMV, cytomegalovirus; EBV, Epstein–Barr virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; HTLV-1, human T-cell lymphotropic virus; HZV, herpes zoster virus; PAN, polyarteritis nodosa; TB, tuberculosis.

series, caused by meningitis (bacterial, tuberculous, cryptococcal). Other causes included botulism, mucormycosis, viral encephalitis and cysticercosis. The main causes of multiple cranial nerve palsies are summarised in Table 13.13.

#### Other causes of MCNs

Other causes of MCNs are sarcoidosis, infection and vasculitides (Chapters 9 and 26). Nasopharyngeal carcinoma is also an important cause of MCN; usually branches of V are involved initially, but with tumour spread the VIIth, VIth and lower cranial nerves become affected.

#### Multiple recurrent cranial neuropathy of unknown cause

A recurrent multiple cranial neuropathy of unknown cause is seen particularly in South-East Asia. Clusters of MCNs, such as IIIrd, Vth and VIIth nerve lesions, develop, remit and recur over several years. Some of these cases are responsive to steroids.

#### Intracranial epidural abscess

Pyogenic intracranial epidural abscess is a rare cause of progressive sequential multiple cranial nerve lesions on one side. This occurs typically in the elderly, and in diabetic and cachectic patients. For example, deafness with a discharge from the external auditory meatus can be followed by a VIIth nerve palsy and progressively by lower cranial nerve palsies, to include the XIIth. The abscess, a thin sheet of pus, little more than 1 mm in thickness, can also track

upwards to involve the Vth nerve, the three oculomotor nerves and even the optic nerve, the process taking weeks or months. In the early stages, these abscesses can be hard to visualise on imaging. Surgical exploration is usually required, and high doses of antibiotics, but the condition carries a high mortality.

## Acknowledgement

Professor M.J. Turlough FitzGerald, Emeritus Professor, Department of Anatomy, National University of Ireland, Galway, kindly agreed that figures and information from the award-winning textbook *Clinical Neuroanatomy and Related Neuroscience* (FitzGerald MJT, Folan-Curran J. 4th edition, 2002; WB Saunders, Edinburgh) were made available for use in the first edition. This cooperation proved invaluable. Details from figures in the subsequent *Clinical Neuroanatomy and Neuroscience* (FitzGerald MJT, Gruener G, Mtui E. 6th edition, 2012; Elsevier Saunders) have been used here, again with permission from Professor FitzGerald. The *Queen Square Textbook* authors and editors are most grateful for this continuing cooperation.

Patients generally relate visual disorders to the eye itself rather than recognising that the problem might be with the brain. In the United Kingdom, when a patient complains that he/she has impaired vision the first port of call is frequently an optometrist and if spectacles are not the answer a further referral is made to a hospital through the general practitioner. In many other countries without extensive service provision by optometrists and general practitioners the patient will seek the advice of an ophthalmologist directly.

A significant proportion of patients presenting with symptoms of visual abnormalities have primary neurological disorders or require neurological assessment. Therefore, ophthalmology and neurology should rightly be closely related disciplines; the eye is, after all, a part of the brain and many disorders of the brain have direct effects on vision.

The neuroanatomy of the visual pathway is outlined in Chapter 2. The basic examination of the visual and ocular motor system is dealt with in Chapter 4.

## Unilateral visual failure

### History

#### Mode of onset

In taking a history from a patient complaining of visual loss in one eye it is first essential to establish whether the onset was acute, subacute or gradual and whether, since the patient noticed the problem, the vision has deteriorated, improved or remained static. It is best to establish exactly how and in what circumstances he/she first became aware of the problem because the patient may suddenly become aware of vision loss that has been coming on for some time. Some people do not seem habitually to close one eye unless having a specific reason to do so – such as acquiring a foreign body in one eye or during a visit to the optometrist. Thus, a reported abrupt onset of unilateral visual loss, in contrast to when both eyes are affected, may be spurious and the precise circumstances need to be reviewed with an appropriate degree of scepticism. Once it is clear that the loss of vision was genuinely abrupt, painless and with no subsequent change, a vascular cause (e.g. central retinal artery occlusion or anterior ischaemic optic neuropathy) is almost certain but it is important to remember that some vascular syndromes can cause progressive or fluctuating loss of vision.

Subacute loss over days, with pain, is in keeping with an inflammatory cause (e.g. optic neuritis) but the differential diagnosis remains wide unless there has been spontaneous recovery of vision because a number of compressive lesions are capable of producing the same syndrome: notably, anterior communicating artery aneurysm, infections or mucocoele of the paranasal sinuses. The consequences of missing compressive optic neuropathy (e.g. pituitary tumour) can be disastrous as early intervention is required to prevent permanent visual loss. The general rule is that in demyelinating optic neuritis, associated with multiple sclerosis (MS), the pain precedes the loss of vision. Indeed, the pain often abates as the visual loss is noticed by the patient. Furthermore, the pain is not severe, rarely disturbing sleep and it may only be present on eye movement or even only on movement in a particular direction. Therefore an unusual degree of persistent pain would be a feature that should alert the clinician to possible compressive granulomatous or infective causes.

In many patients, the more typical history of gradually progressive loss of vision produced by a compressive lesion will be clear: in others, it may be necessary to acquire optometrist's records to confirm the tempo of the visual failure. Paradoxically, in some instances, loss of vision which would clearly have been abrupt at onset may not be noticed for some time – such as following a vascular occlusion that affected a part of the field only or following trauma. Again, any previous records of visual acuity or visual field testing will be invaluable. Another situation that causes confusion is when a patient is referred with asymptomatic unilateral visual field loss. Usually, visual acuity is normal in this situation and the patient presents with a visual field defect sparing central vision. It is first necessary to establish whether the patient had ever had a previous perimetric examination; if not, the loss could be congenital. If it is clear that the loss has been acquired at some time between two examinations it may require some detective work to decide the cause based on the examination findings and on occasion serial perimetry to determine whether or not the defect is static. Unilateral visual field defects that present in this way are commonly caused by focal retinal pathology, congenital optic nerve defects, glaucoma, optic disc drusen, previous trauma, compressive lesions and as chronic sequelae of subclinical branch retinal artery and vein occlusions or demyelinating optic neuritis.

### Positive symptoms

Positive symptoms are not commonly reported in optic nerve disease. Occasionally, patients with optic neuritis report that on eye movement a brief flash is perceived. Of interest, these flashes are not seen except in the dark, indicating that the perception is washed out by natural illumination. This is in contrast to positive stimuli generated in the occipital lobes which appear equally bright in the dark and in brightly lit surroundings. Patients who report continuous phosphenes (again appreciated more in low light levels) will have retinal disease and this is particularly true of cases of local retinitis such as the idiopathic big blind spot syndrome and acute zonal occult outer retinopathy. These two conditions are almost always unilateral and often referred as suspected optic nerve disease because the retina appears normal on fundus examination but there are discrete scotomas typical of retinal disease and within which the patient is aware of a more or less constant flickering.

### Effect of light level

Humans have a duplex retina in which two independent systems of photoreceptors – the rods and cones – are specialised for low and high light levels, respectively. Indeed, in extreme low light levels the cone photoreceptors make no contribution to vision and at photopic levels the rods do not function. Hence, conditions that affect more or less independently the two classes of photoreceptor result in visual loss that is much more marked at low light levels (nyctalopia, e.g. rod dystrophies) or at high light levels (e.g. cone dystrophies); these disorders are rarely unilateral. However, post receptorally the rod and cone signals are shared (multiplexed) by the same pathways (bipolar cells and retinal ganglion cells). Hence, in optic nerve disease marked variation in visual performance at different light levels is not generally observed. There are exceptions to this and some patients with optic neuropathy may report seeing better in bright or dim light although it may be difficult to understand why. A more specific situation which occurs in demyelinating optic neuropathy is deterioration in bright light which patients describe as ‘fading’. The pathophysiological basis of this is not known.

### Direct questions

The following are a few direct questions worthwhile asking any patient with unilateral visual loss.

- *Subjective visual field changes* ‘If you are viewing with that eye alone, is the entire field of vision affected, or only a part?’ Central scotomas are frequently reported as appearing as if there is a cloud or other patch in front of the eye, saying: ‘If only I could see around it my eyesight would be normal.’ Patients with altitudinal field defects may have normal visual acuity but be aware that they cannot see above or below what they are looking at and this is highly suggestive of either anterior ischaemic optic neuropathy or a branch retinal artery occlusion.
- *Provoking factors* ‘Does vision deteriorate after exertion or a hot bath?’ In Uhthoff’s symptom vision deteriorates with a rise in body temperature, returning to normal when the body cools down. This phenomenon is almost pathognomonic of demyelinating (MS-associated) optic neuritis. The loss of vision may be total or partial but recovery always occurs after a few minutes of resting. Most commonly, the symptom is noticed by patients who have recovered from acute optic neuritis but it may also occur in the acute phase or in patients who do not report an acute episode at all, that is to say as a result of subclinical demyelination.
- *Associated symptoms* ‘Have you noticed any change in your sense of smell?’ In cases of anterior cranial fossa masses (usually

meningiomas) anosmia may precede loss of vision by several years and may well have passed without any neuroimaging being carried out.

- *Double vision* ‘Have you had double vision?’ The ocular motor nerves enter the orbit through the superior orbital fissure while the optic nerve enters through the optic canal and the combination of an optic neuropathy with a IIIrd, IVth or VIth cranial nerve lesion would indicate either an extensive lesion (and this can occur with meningiomas and granulomas) or the pathology must be within the orbit itself and on examination the neurologist should look particularly for orbital signs.
- *Distortion* ‘Do you see distortion of anything that you are looking at, do straight lines appear crooked or do objects appear larger or smaller than they are?’ Rarely, spatial distortion of images can occur with occipital lobe disease. This does not occur with optic nerve disease but is very commonly seen with retinal disease. A distorted photoreceptor layer will result in an equivalent geometric distortion of the perceived image. Thus, elevation of the retina will result in separation of the photoreceptors and the perceived image will be diminished in size. Central serous retinopathy in younger patients or age-related macular degeneration in older patients are the disorders that are most commonly confused with optic nerve disease and this simple question can provide an important clue.

### Examination

#### Visual acuity

The first step for the neurologist is to decide whether unilateral visual loss is caused by refractive error, disorders of the lens and ocular media or retinal pathology and hence would require onward referral for appropriate management. Some knowledge of optometry is essential because the presence of emmetropia, myopia or hypermetropia and presbyopia has a marked effect on how patients respond to changes in vision resulting from neurological disease and also on the interpretation of findings on examination including the appearance of the fundus. Visual acuity examination for near and distance, with and without refractive correction, should be carried out under standardised conditions using correctly illuminated Snellen or equivalent charts at the correct distance.

#### Colour vision

The testing of colour vision can be performed simply by asking the patient to judge the saturation of a coloured target. ‘Saturation’ in chromatic terms refers to how far the colour is from white and it is generally the case in optic nerve disease that colours will appear less saturated – that is to say, closer to white. Quite simply, in unilateral optic nerve disease if a coloured target is held up to the affected eye and a comparison made with the unaffected eye this difference in colour will be reported. At the extreme the colour may be lost altogether and the object will appear white or grey depending upon its luminance/brightness. Tests are available in which patients are shown a series of discs of the same hue varying in saturation. The patient is asked to arrange them in order of increasing saturation which will indicate the least saturated disc that is perceived as being different from white. The degree of saturation can be quantified in this way.

Across the visual field this change can be observed regionally so that in a patient with a central scotoma which is relative the colour saturation of the target may be restored as it is moved from an abnormal to an unaffected region of the visual field. This is of particular importance when a hemianopic or altitudinal field defect is suspected as this change in colour saturation will appear abruptly as the target is moved across the vertical or horizontal meridian, respectively.

The Ishihara pseudoisochromatic plates are commonly utilised for the assessment of colour vision in ophthalmic and neurological practice. The term 'pseudoisochromatic' refers to the fact that the individual coloured dots which make up the figure are varied in brightness, thus making it impossible to use luminance differences to identify the figure. The advantage of this in the assessment of unilateral visual loss is that impairment of colour vision in optic nerve disease is much greater (for an equivalent loss of acuity) than in the case of retinal disease. The explanation for this is not known but it may in part be related to a selective effect of compressive and demyelinating optic pathology on the parvocellular pathway (these are the retinal ganglion cell axons that project to the parvocellular layers of the lateral geniculate nucleus and which subserve colour vision). In retinal disease the extent to which colour vision is affected can be predicted from the degree of involvement of the macular and paramacular regions of the retina. In other words, if acuity is reduced and there is a large enough central scotoma then colour vision will be affected. At the limit, patients with visual acuity of 6/60 cannot read even the control plate in the Ishihara test. This plate does not require any colour vision to read but indicates that the patient has adequate visual acuity to perform the test. In optic nerve disease, a patient with a visual acuity of 6/6 or 6/9 is likely to have significantly impaired colour vision and this would be very unusual in retinal disorders with the exception of the cone dystrophies.

The Ishihara plates were developed for the assessment of congenital colour anomalies (Daltonism) and so there is considerable detail in the testing that is not relevant to optic nerve disease where the losses do not follow the specific patterns seen in Daltonism but show instead largely global losses. Furthermore, specific illumination conditions are required for an accurate interpretation of errors. Therefore, loss of colour vision can be broadly quantified by recording the number of errors made on the charts but there is normally little to be gained from recording the individual errors. An exception to this is if the patient misses all of the numbers on the left or right-hand side of the double figure numbers as this may indicate a hemianopic defect on that side in that eye. It is also worth observing the speed with which the patient is able to read the numbers. This should be instantaneous and any reduction in the speed of reading in one eye is certainly significant. Some appreciation of the effect of Daltonism on performance on these plates is necessary so that results can be interpreted in the patients (female : male ratio 1 : 17) who are so affected.

### Amsler's test

The Amsler grid is a very useful tool as patients may be able to visualise scotomas or report distortion (see Unilateral visual failure: direct questions). The findings can be recorded and used for serial monitoring of any defect. In fact, it is common practice to use the recording sheet (a black grid on a white background) for testing as well as recording rather than the test plates which are considerably more sensitive being a white or red grid on a black background.

### Visual field testing

Confrontation perimetry remains an essential skill. A rapid assessment of the visual field can be obtained in any situation and any clinical environment. A normal confrontation test is usually an accurate assessment of a normal field. Monitoring of fixation is straightforward (even if the patient's cooperation may be problematic) because the patient is asked to fix on the tester's eye. In the case of unilateral visual loss not only should the visual loss in the affected eye be plotted, but the other eye should be tested carefully for any evidence of a contralateral temporal hemianopic visual field defect

as this immediately gives the location of the lesion as involving the prechiasmatic portion of the optic nerve and the chiasm itself. Such defects are best demonstrated looking for colour desaturation. There is considerable discussion in the literature regarding junctional visual field defects (i.e. defects affecting the junction of the optic nerve and chiasm) and readers may have heard of the 'junctional scotoma' and 'Wilbrand's knee' of optic nerve fibres which loop forward into the contralateral nerve before crossing in the chiasm. Suffice to say that the junctional scotoma (first described by Traquair, ophthalmologist in Edinburgh, 1875–1954) is a temporal hemianopic scotoma found in an eye that shows signs of optic neuropathy: an upper temporal hemianopic defect in the fellow eye was described by Wilbrand (ophthalmologist in Hamburg, 1851–1935). Whatever the anatomical explanation of these phenomena, the essential practical point is that a temporal hemianopic defect in either eye of a patient with unilateral visual loss immediately places the problem to the chiasm.

It is beyond the scope of this chapter to give detailed descriptions of other perimetric techniques such as Goldmann and Humphrey automated perimetry but it is helpful to appreciate their respective advantages and disadvantages. In a patient with unilateral visual loss either method can be used but in certain respects the information provided is complementary.

The Goldmann perimeter uses kinetic testing – the target is moved from an area where it is invisible to a seeing area and the patient is asked to report when he/she sees it, usually from the periphery towards the centre in plotting isopters (lines of equal sensitivity) for any particular size and brightness of target: thus, a scotoma can be plotted (including the physiological blind spot) by moving the target from within the scotoma to its borders. The Goldmann perimeter can also be used for static testing. The target spot is flashed on at a particular location in the visual field and the patient asked whether or not it was detected. The brightness of the target can then be adjusted to determine the *threshold* – the smallest increment of the target over the background that the subject can detect. To cover the entire visual field in this way can be extremely arduous and the method of plotting isopters to kinetic targets remains the most efficient way of screening the visual field; however, some static points should be tested within the central field to look for any evidence of central or paracentral scotomas.

The Humphrey and Octopus automated perimeters are in use in most ophthalmology departments and at the time of writing the manually operated Goldmann perimeter is no longer being manufactured. The automated perimeters are based on the Goldmann in that the target size employed is the same as one of the standard settings on the Goldmann (size III) and indeed the field plot produced for the Humphrey perimeter is the same scale as the Goldmann charts (they can be overlapped and held up to the light to compare them). The test is automated and the operator is needed to monitor fixation and encourage the patient to concentrate a task which they may find quite challenging. The most commonly used plot that the reader will come across is limited to the central 30° of the field and threshold sensitivity is measured along a grid of points covering the area. These automated machines are being modified to permit the kind of kinetic testing that is carried out on the Goldmann but this will be more time-consuming.

Interpretation of visual fields requires considerable knowledge. An understanding is required of refraction and it is necessary to be familiar with many potential artefacts and what happens when the subject is fatigued, and so on. For the general neurologist the most useful skill is to be able to carry out competent confrontation

fields but for a detailed consideration of complex cases and strategies for monitoring it will be necessary to turn to colleagues with neuro-ophthalmic expertise.

### Fundus examination

The primary interest is in the appearance of the optic disc and there are some important rules. The emphasis traditionally has been on the observation of a pale optic disc as evidence for optic neuropathy but there is considerably more detailed information to be obtained. First, it is important to observe the morphology of the optic disc and in particular the size of the cup. In the management of glaucoma the degree of cupping of the optic disc is of fundamental importance and it is essential to know the difference between normal cupping and pathological cupping in optic nerve disease including glaucoma. In hypermetropia there tends to be a small cup or none at all (crowded optic disc) while in myopia the disc can be very large so it is necessary to be familiar with identifying the neural elements within the disc circumference which is defined by the scleral opening.

Furthermore, we are interested not only in pallor of the disc but more directly with loss of the optic nerve fibres which is the primary pathology leading to the development of atrophy. The retinal nerve fibre layer is the closest layer to us as we examine the retina with the ophthalmoscope. The vessels, the arterioles and venules of the retina itself are in this same layer and it is the retinal nerve fibres (the retinal ganglion cell axons) that fill in the space between the vessels, altering in a subtle way the optical properties of the retinal surface. With some practice it is possible to observe thinning of this layer and the disappearance of sectors and slits associated with focal pathology at the disc.

Once familiar with the variations in morphology of the disc in health and disease and the changes that occur in the optic nerve fibre layer we can be confident in ascribing loss of vision to disc-related pathology (e.g. glaucoma, optic disc drusen, papilloedema) or to retrobulbar disease (optic neuritis or compressive optic neuropathy). It must be remembered also that severe retinal disease (especially retinal dystrophies) can lead to loss of retinal ganglion cells and thence to the appearance of optic atrophy. Another important fact is that it takes 4–6 weeks for the loss of retinal nerve fibres and optic atrophy to appear following an acute insult to the optic nerve. If a patient presents with a history of visual loss of less than a month but optic atrophy is already visible then the pathological process must predate the first symptom. This indicates that either the patient noticed the loss of vision sometime after the onset (as occurs in compressive optic neuropathy) or that there has been a previous subclinical event (as might occur in MS).

Swelling of the optic disc occurs in a number of pathological situations such as acute optic neuritis, acute ischaemia, retinal vein occlusion and in raised intracranial pressure. The disc may also appear swollen in hypermetropic crowded discs or with buried drusen (pseudopapilloedema).

The vessels are also of interest, not only in primarily vascular disease but also in compressive optic neuropathies because of the development of retinochoroidal collaterals (previously, and erroneously, known as optico-ciliary shunt vessels). In order to understand this phenomenon it is necessary to understand that there are two possible routes for venous blood to leave the retina:

- The ophthalmic vein, which is the continuation of the central retinal vein, and thence to the cavernous sinus, and
- The choroidal veins, which drain into the vortex veins and thence to the cavernous sinus indirectly.

Any pathology that gives rise to retinal venous hypertension will tend to lead to the opening up of collaterals between the retinal branch veins and the choroidal veins. Occlusion of the central retinal vein is a common cause of this but any pathology that compresses the central retinal vein within the optic nerve – typically, optic nerve sheath meningioma – will result in the formation of these collaterals. Papilloedema is another cause because the central retinal vein has a short course in the subarachnoid space of the optic nerve sheath and a rise in intracranial pressure will lead to retinal venous hypertension.

In inflammatory disorders of the optic nerve there may be evidence of periphlebitis or vitritis; these changes are more marked in sarcoidosis than in MS.

The macula is inspected primarily to look for any evidence of a maculopathy that could mimic optic nerve disease such as central serous retinopathy or a cone dystrophy. Exudates around the macula (a ‘macular star’) are seen in neuroretinitis. The clinical features resemble optic neuritis but the inflammation must be very anterior, possibly involving the ganglion cell layer, for sufficient retinal oedema to be generated for the macular star to result.

### Associated features

Thorough general ophthalmological and neurological examinations must be undertaken but signs of orbital disease should also be sought, such as proptosis or motility defects. The sense of smell must be tested. Evidence of sinus disease should be sought and clues to any pre-existing central nervous system (CNS) dysfunction such as caused by MS.

The causes of transient unilateral visual loss are summarised in Table 14.1 and those of sudden fixed unilateral visual loss in Table 14.2.

**Table 14.1** Causes and underlying conditions in transient monocular blindness.

Vascular*	Central retinal artery emboli Retinal or choroidal ischaemia Partial retinal vein occlusion Carotid artery stenosis or occlusion (e.g. atherosclerotic plaque, thromboembolism, dissection, radiation damage) Arterial vasospasm
Migraine	Uncertain whether monocular visual loss occurs in migraine
Hypoperfusion	Hypotension, hyperviscosity, hypercoagulability, carotid disease, giant cell arteritis
Ocular	Intermittent angle closure glaucoma Retinal detachment
Vasculitis	Giant cell arteritis
Others	Inflammatory – Uhthoff’s phenomenon Idiopathic Psychogenic
Obscurations†	Papilloedema due to raised intracranial hypertension causes transient visual obscurations Optic nerve tumours (e.g. gaze-evoked amaurosis in optic sheath meningioma)

\*Duration: several minutes.

†Duration: seconds only.

**Table 14.2** Sudden onset fixed monocular visual loss.

<b>Vascular</b>
Non-arteritic anterior ischaemic optic neuropathy (posterior non-arteritic ischaemic optic neuropathy is rare)
Arteritic anterior and posterior ischaemic optic neuropathy
Branch or central retinal artery occlusion
Branch or central retinal vein occlusion
<b>Inflammatory</b>
Systemic inflammatory disease
Traumatic optic neuropathy
Retinal detachment
Vitreous haemorrhage
Functional visual loss

## Bilateral visual failure

The diagnostic problem of progressive bilateral visual loss is usually solvable with a clear understanding of the knowledge of the visual pathways, patterns of visual symptoms and careful examination. Visual loss in both eyes may develop over months, weeks or days:

- 1 If visual loss > 6/9 develops on a background of previously normal visual acuity, this should be investigated initially by an optometrist and/or an ophthalmologist and, if visual loss remains unexplained, by a neurologist.
- 2 Progression of visual loss or progressive visual symptoms should always be investigated.
- 3 Accurate measurement and recording of visual acuity is essential. A 2 or 3 m hand-held Snellen chart is useful, even though these are less accurate than the standard 6 m wall chart. A pin-hole (this corrects up to 4 dioptres of refractive error) is essential.
- 4 As with unocular visual loss, substantial diminished vision is sometimes an almost incidental finding in the context of vague visual complaints.

The principal issue is to distinguish between ocular disease and disease of the neural pathway, for example:

- Refractive errors, cataracts, uveitis, macular degeneration, bilateral retinal disease
- Optic nerve disease
- Conditions affecting the optic chiasm, and beyond, to the cortex.

Post-chiasmal conditions, such as optic tract lesions, are relatively rare. Others, such as optic radiation lesions, visual association area and bilateral occipital lobe infarction, tend to present acutely. Bilateral visual loss, with progression, which does not have an organic basis is relatively common. Its features are characteristic and need to be recognised. Non-organic visual impairment must be distinguished from cortical visual loss.

For the general neurologist, matters can be compounded by unfamiliarity with the fine detail of ophthalmology and relative inexperience of ocular and retinal conditions. Conversely, for the ophthalmologist, chiasmal compression and other neurological problems will be less familiar than the patterns of common ocular disease. The causes of progressive bilateral visual loss include the following:

- 1 *Ocular and retinal conditions*  
Refractive errors and cataracts

**Table 14.3** Sudden onset fixed bilateral visual loss.

Occipital lobe infarction
Acute basilar artery occlusive disease
Posterior circulation hypoperfusion (posterior watershed (border-zone) infarction)
Sagittal sinus thrombosis
Pituitary apoplexy
Posterior reversible encephalopathy syndrome
Toxic encephalopathy (caused by drugs, e.g. ciclosporin, methotrexate, vincristine)
Head trauma
Functional visual loss

Macular degeneration

Uveitis

Retinal disease:

Diabetes and other retinal vascular disease

Retinal dystrophies

Paraneoplastic degenerations.

### 2 *Bilateral optic nerve disease*

Leber's hereditary optic neuropathy

Other bilateral optic nerve lesions

Papilloedema as a cause of visual failure

Toxins, drugs and radiation.

### 3 *Chiasmal disease*

Chiasmal compression by mass lesions

Chiasmal (and optic nerve) glioma and meningioma.

### 4 *Post-chiasmal disease*

Optic tract and radiation lesions

Visual association area lesions

Cortical visual loss.

### 5 *Non-organic visual failure*

The causes of sudden onset fixed bilateral visual loss are summarised in Table 14.3 and progressive visual loss in Table 14.4.

**Table 14.4** Neurological causes of bilateral progressive visual loss.

Anterior visual pathway inflammation	Optic neuritis Sarcoidosis Meningitis Neurosyphilis
Anterior visual pathway compression	Tumours Aneurysm Dysthyroid
Hereditary optic neuropathy	Leber's Dominant optic atrophy
Optic nerve drusen	
Low tension glaucoma	
Papilloedema	
Toxic and nutritional optic neuropathy	
Drugs (Table 14.5)	
Radiation damage	
Paraneoplastic retinopathy	

## Special investigations in neuro-ophthalmology

### Optical coherence tomography

Optical coherence tomography (OCT) permits non-cross-sectional imaging of internal structures in biological tissues using near infra-red light. All the layers of the retina can be studied in high magnification and consecutively. Quantitative analysis of retinal nerve fibre layer (RNFL) atrophy may serve as a biomarker for axonal loss in generalised neurological disease and has important applications in MS and neuromyelitis optica (NMO) (Figures 14.1, 14.2 and 14.3). This equipment has become widely adopted in general ophthalmology departments with facilities for the assessment and treatment of retinal disease.

### Ultrasound

Real-time B-mode ultrasound can be used to study the optic nerve head; for example, it is very useful in demonstrating echogenic buried drusen in cases with elevated optic discs, giving the correct diagnosis without the need for more invasive investigations (Figure 14.4).

### Clinical electrophysiology of the eye

The visual evoked potential (VEP) is a sensitive means of detecting optic nerve dysfunction. However, VEP abnormalities are not specific for optic nerve disease and can reflect dysfunction anterior to

the optic nerve. Macular disease, in the presence or absence of fundus change, commonly causes VEP delay.

Full-field electroretinogram (ERG) will ascertain the nature of possible generalised retinal disease if the pattern ERG (PERG) suggests a macular abnormality (Figure 14.5).

### Visual field testing

Visual field testing retains central importance in the localisation of defects in the visual system, and for monitoring natural history and responses to therapy. Qualitative confrontation testing with a red target remains useful, with quantitative recording provided by kinetic and static perimetry (Figures 14.6, 14.7, 14.8 and 14.9).

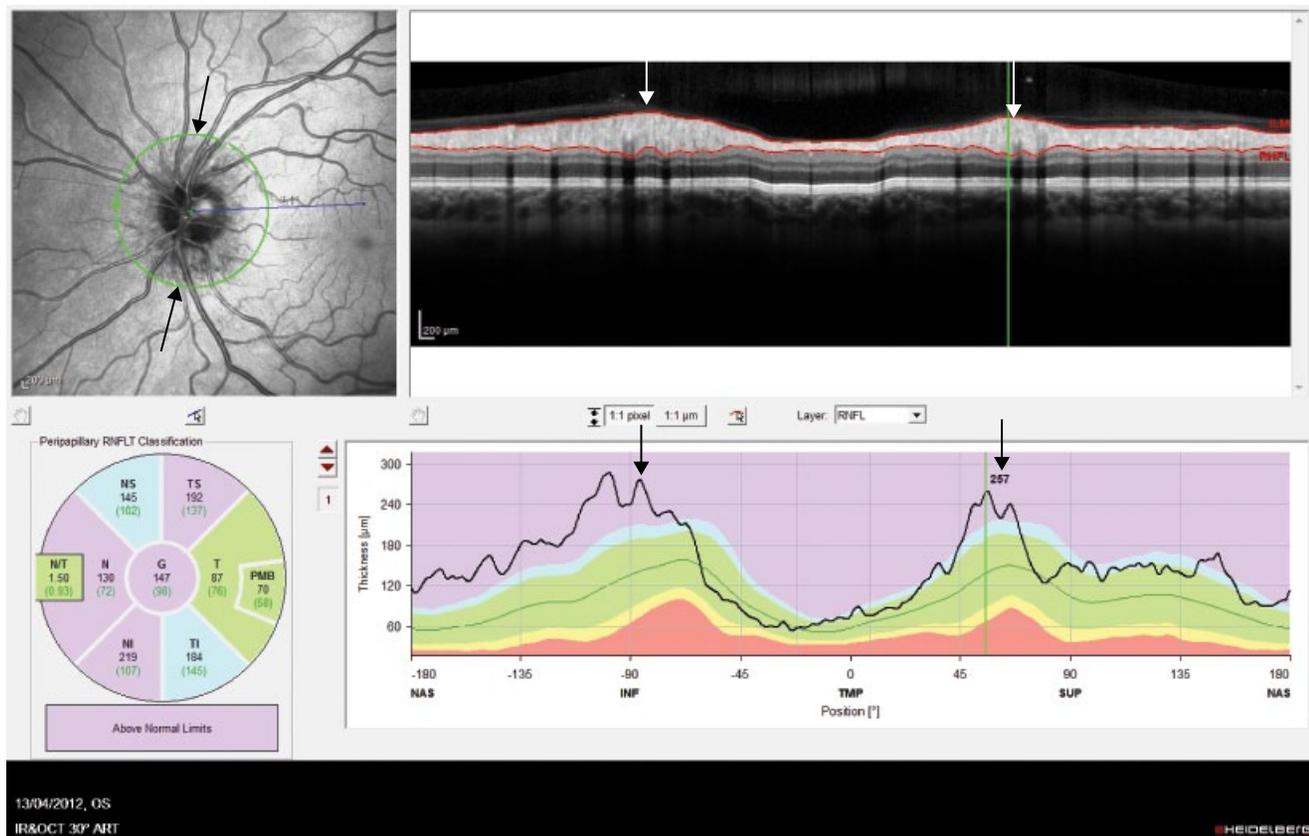

### Fundus fluorescein angiography

Fundus fluorescein angiography (FFA) remains important in neuro-ophthalmology for certain specific situations (Figures 14.10, 14.11 and 14.12).

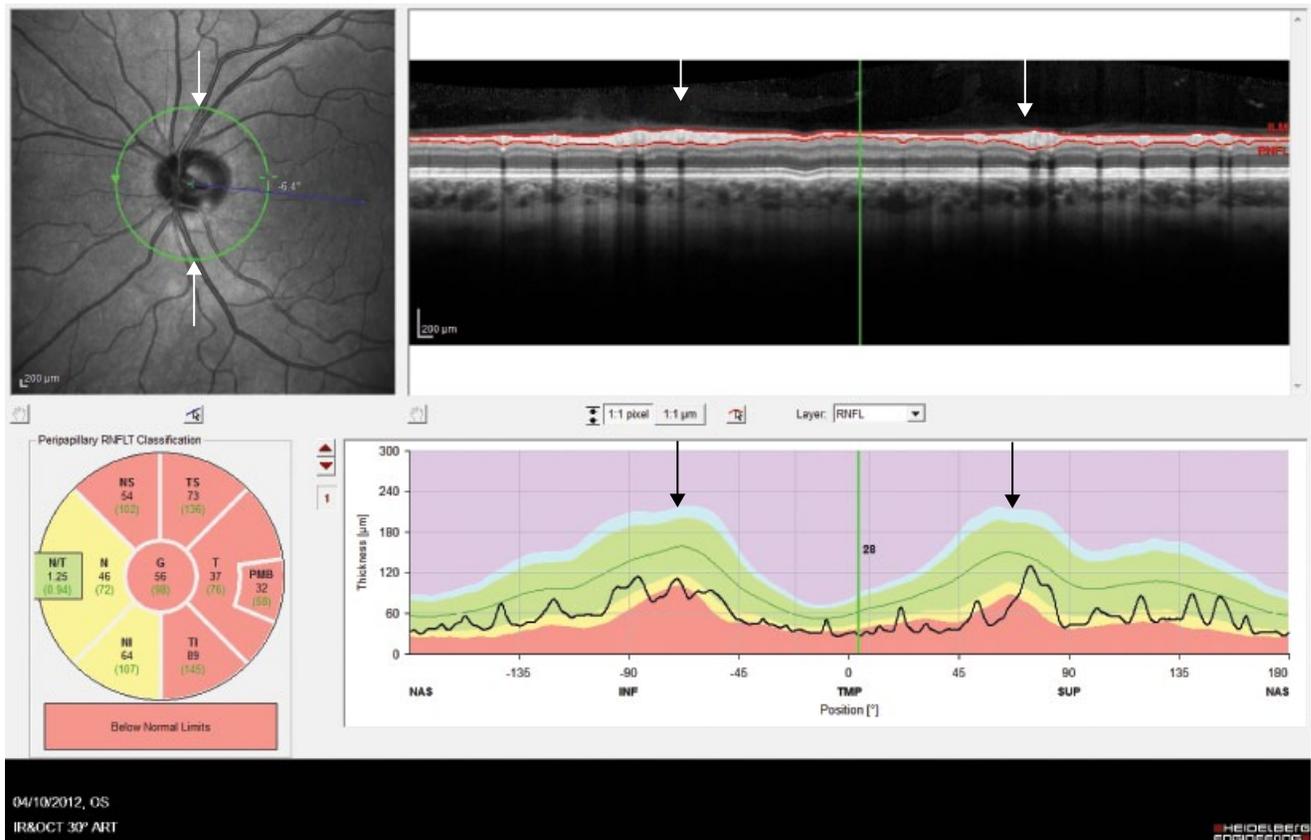

## Optic nerve disease

### Optic neuropathy

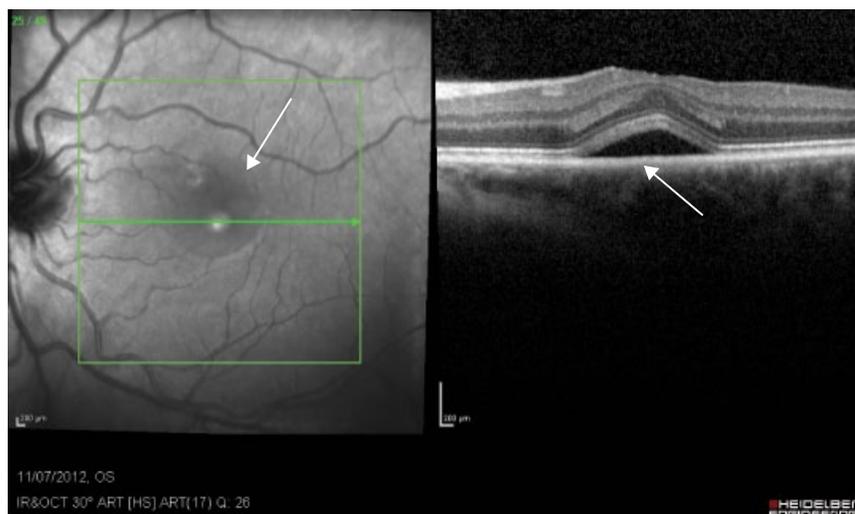

Optic nerve lesions generally lead to monocular visual loss and pain is a frequent accompanying feature. The causes of optic nerve disease are listed in Table 14.5.

**Figure 14.1** Fourier-domain optical coherence tomography (OCT) of the retina in a patient with acute optic neuritis showing mild retinal nerve fibre layer (RNFL) swelling around the optic disc which correlates with ophthalmoscopic disc swelling. This is most prominent at the superior and inferior poles (arrows).

**Figure 14.2** Repeat study on the same patient 4 months later shows that the peri-papillary RNFL swelling has resolved and is replaced by with measurable reduction of thickness of the peri-papillary RNFL on cross-sectional imaging (arrows).

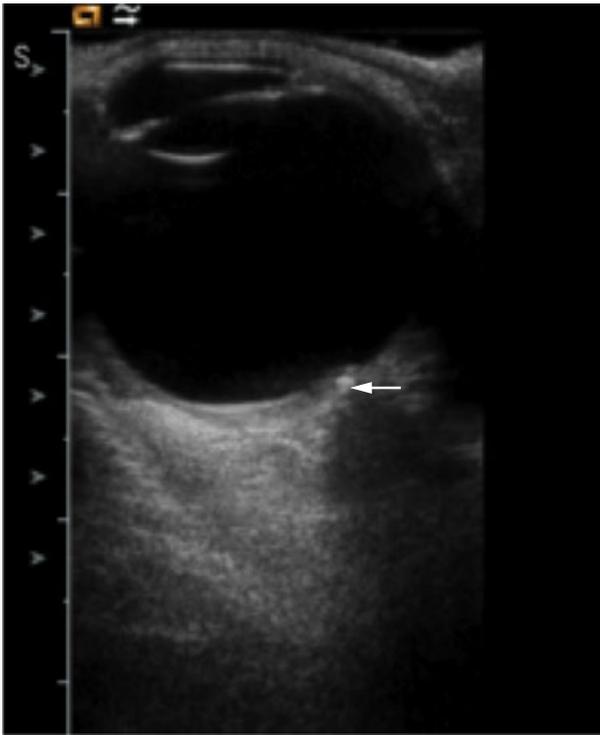

**Figure 14.3** Not all patients with central visual acuity loss and an apparently normal fundus have retrobulbar neuritis. On closer examination this patient with systemic lupus erythematosus had a focal serous detachment of the neurosensory retina at the fovea, seen on biomicroscopy and demonstrated clearly on OCT (arrows).

### Inflammatory optic neuropathies (optic neuritis)

*Nosology of optic neuritis* There is no consistent terminology in literature for describing optic neuritis. It is sometimes categorised by clinical presentation into typical and atypical forms, where typical indicates optic neuritis associated with

multiple sclerosis in white populations. This has a characteristic tempo of recovery and visual loss tends not to be severe. An alternative classification describes optic neuritis by aetiology and this system is predominantly adopted in this chapter (Table 14.6). The most common form in white populations is

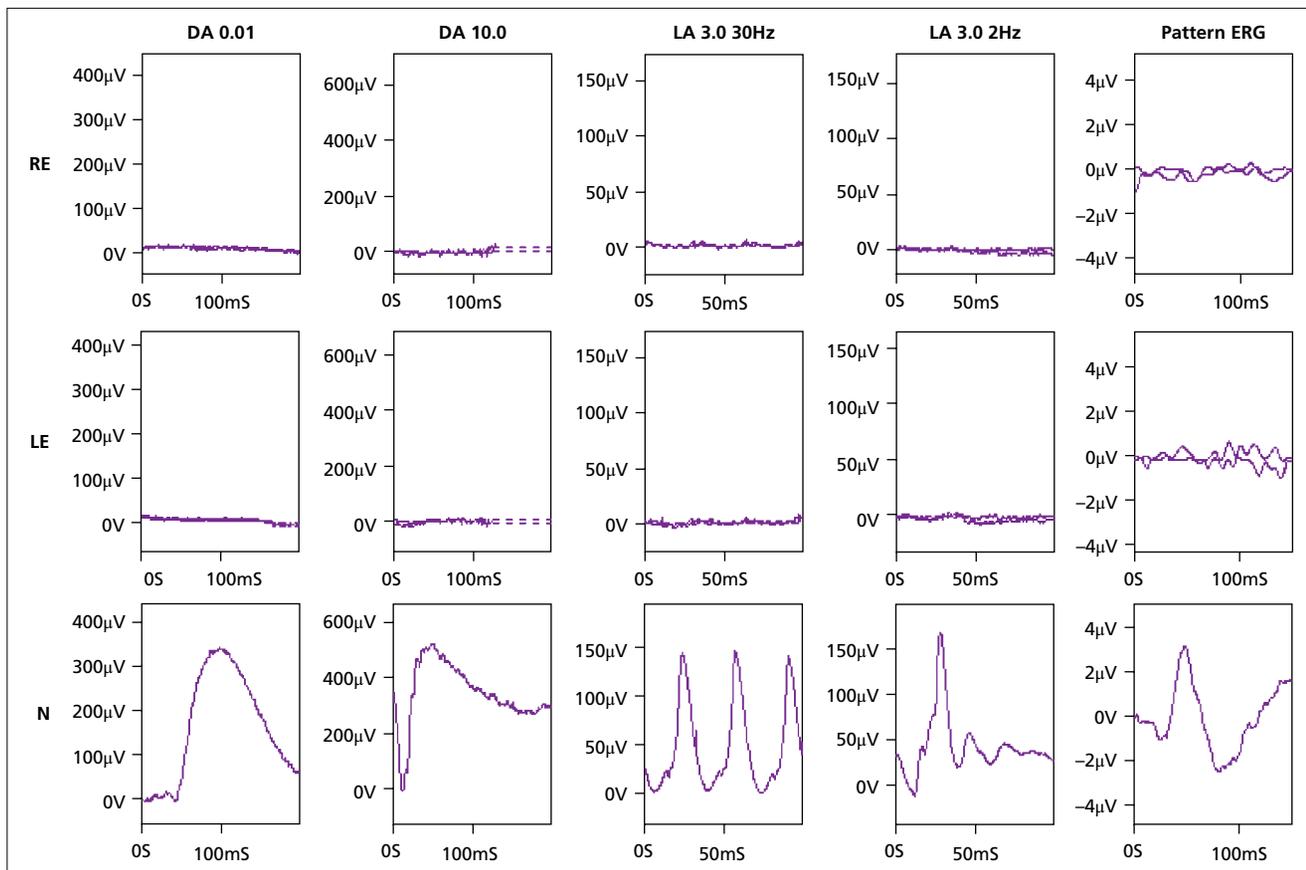

**Figure 14.4** B-mode ultrasound: echogenic buried optic disc drusen (arrow).

multiple sclerosis associated optic neuritis (MS-ON) with the understanding that it can also occur as a demyelinating clinically isolated syndrome (CIS). Optic neuritis associated with neuromyelitis optica (NMO-ON) is an important cause of atypical optic neuritis, described later. These form part of a group of immune-mediated causes of optic neuritis, which can have no systemic features of inflammation (e.g. MS, NMO) or be related to certain systemic inflammatory disorders (e.g. sarcoid, lupus, vasculitis). Certain conditions closely related to optic neuritis, which do not fit neatly by aetiological classification, are described (neuroretinitis and optic perineuritis) at the end of this section.

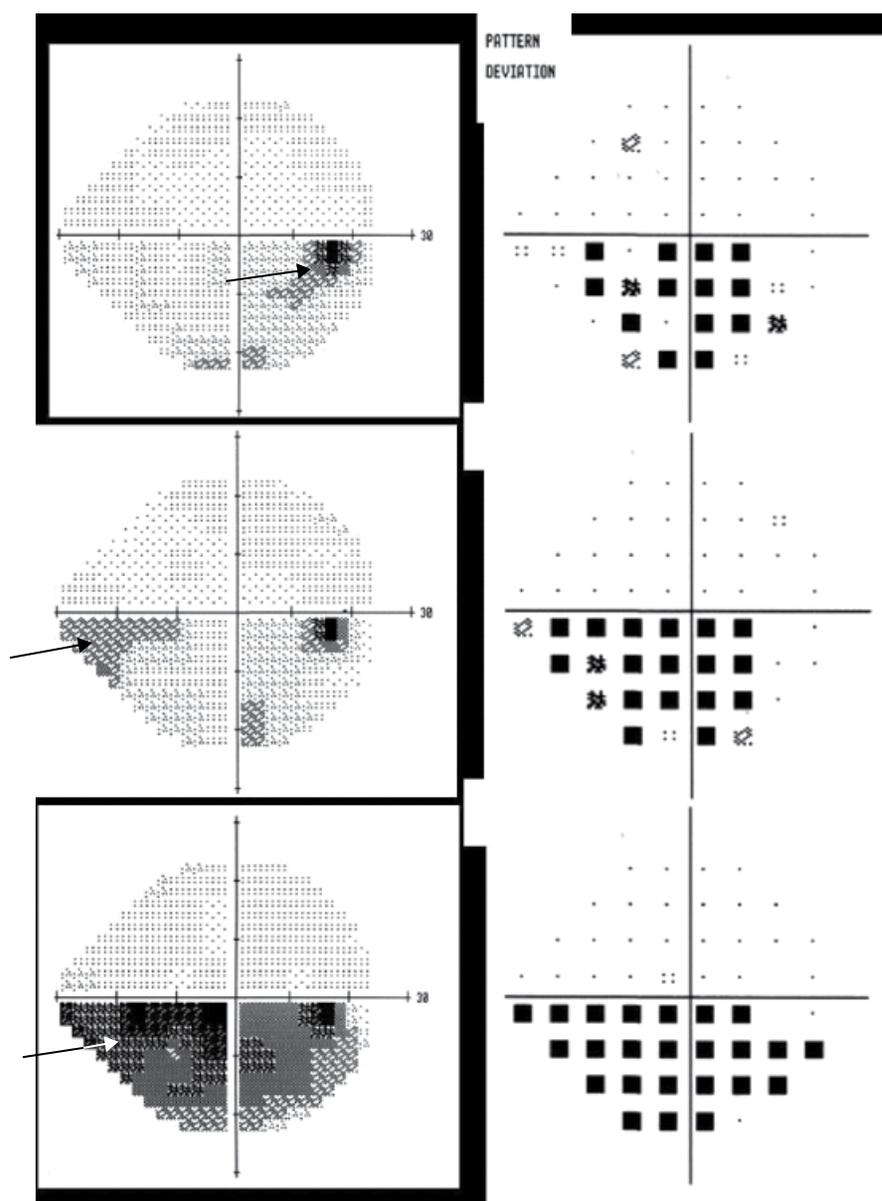

#### Optic neuritis associated with multiple sclerosis

**Clinical features** Optic neuritis is one of the most common causes of subacute unilateral visual loss in young adults. It is first essential to distinguish optic neuritis associated with MS from other causes. In Caucasian populations in temperate latitudes, MS will be the most common form of optic neuritis seen but in other parts of the world and in non-Caucasian populations this may not be the case.

Almost all patients experience pain on eye movement prior to noticing loss of vision but this is rarely severe and as a general rule will not interfere with sleep. Severe or persistent pain should lead to a consideration of other disorders such as a granulomatous optic neuropathy or NMO-ON. If the nerve is affected entirely intracranially there will be no pain but this occurs

**Figure 14.5** Flat electroretinogram (ERG) in left eye (LE) and right eye (RE) in both dark adapted (DA) and light adapted (LA) conditions, compared with normal (N) in a case of paraneoplastic retinopathy due to remote cancer.

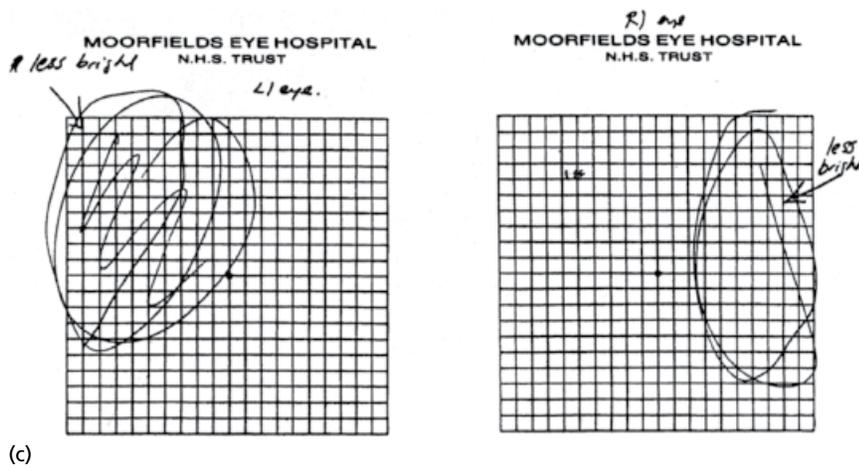

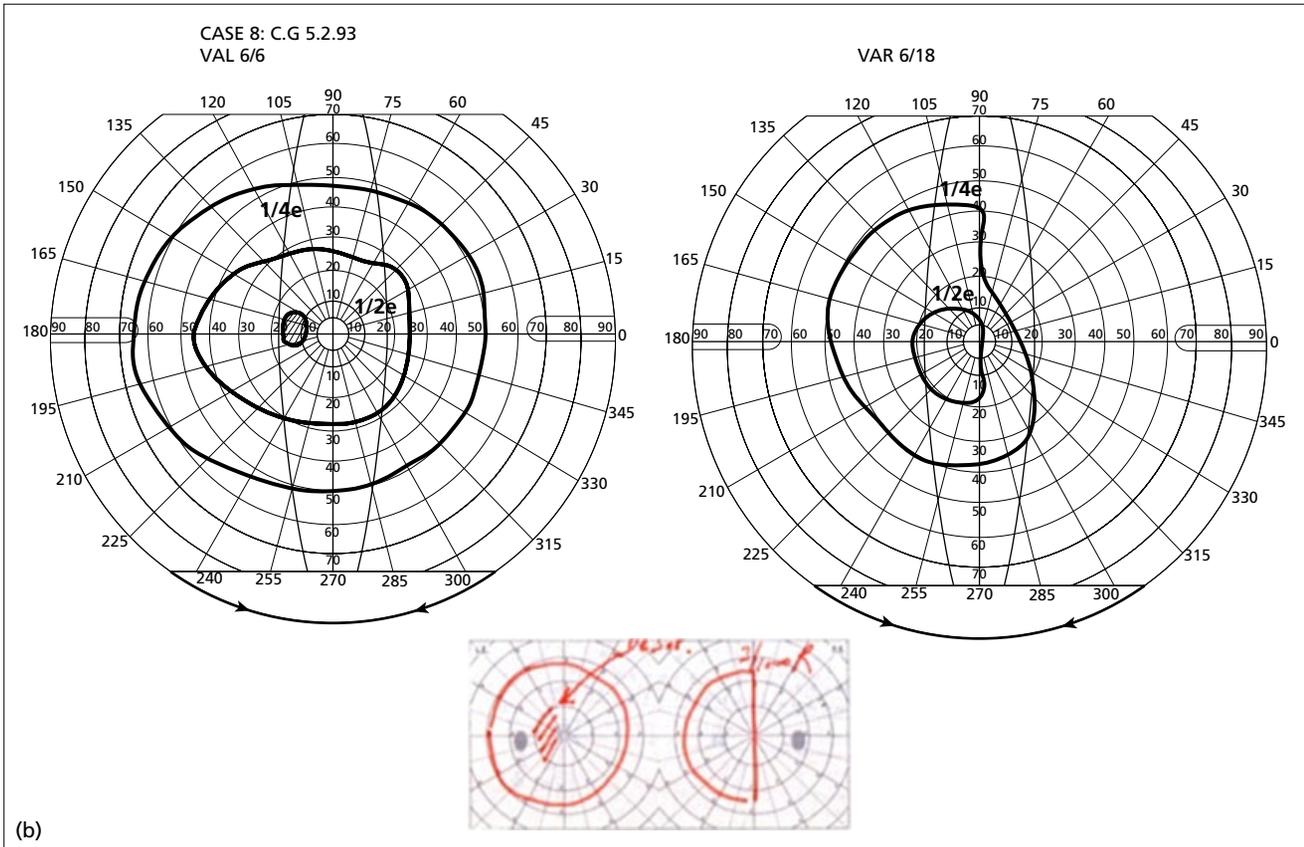

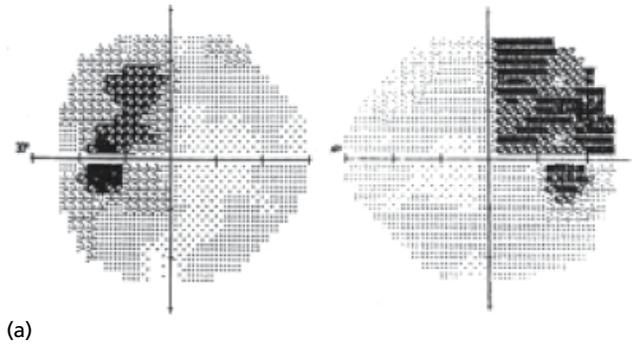

**Figure 14.6** Progressive lower altitudinal scotoma evolving over 2 weeks in anterior ischaemic optic neuropathy: shown here on static automated perimetry equipment (arrows).

in only 10% of cases. Loss of vision typically progresses over days and can be minimal (indeed it may not be noticed by the patient) or, at the other extreme, lead to no light perception. Colour vision and the pupil light reflex are impaired disproportionately to the acuity loss. Central visual field defects are typical but not found universally. There is nearly always a degree of spontaneous recovery and 95% of cases will recover to a visual acuity of 6/9 or better. Disc swelling is seen acutely in one-third of cases, the disc appearing normal (retrobulbar neuritis) in two-thirds. After recovery, many patients exhibit some degree of disc pallor.

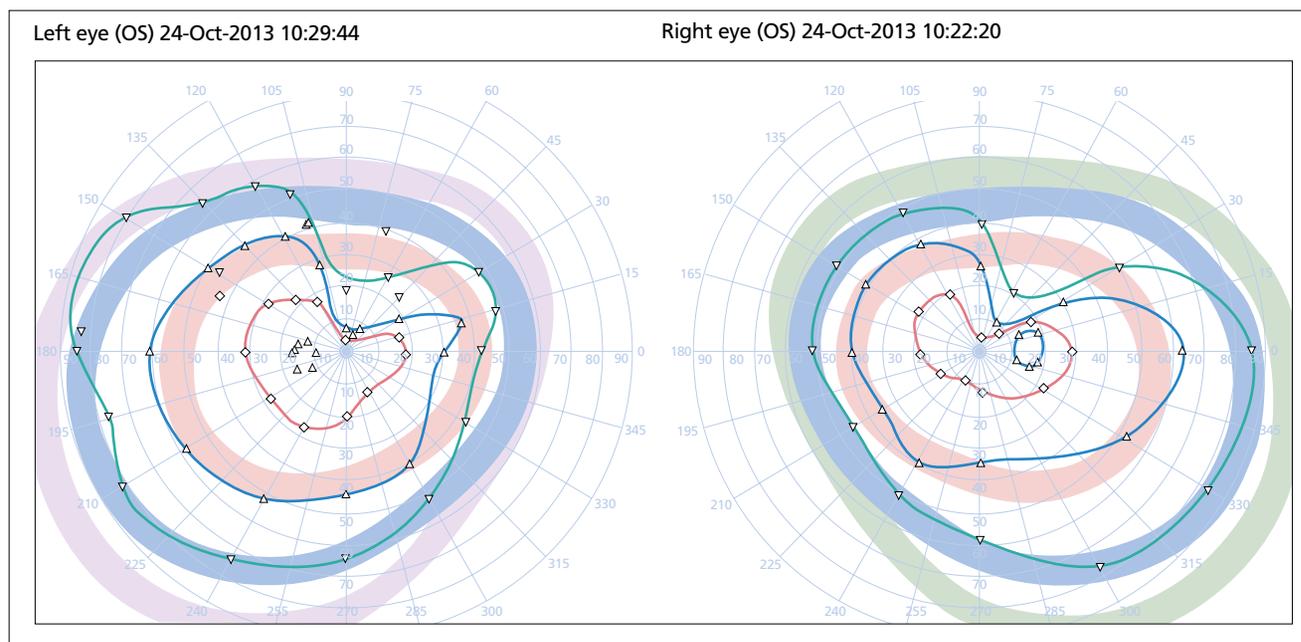

**Investigations** In patients where the clinical context and symptomatology point to a diagnosis of MS-ON, the diagnosis can usually be made on clinical grounds. However, there may be

uncertainty and the investigations should follow the protocol given below for atypical forms of optic neuritis. It is customary to check the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), and perform a chest X-ray and syphilis serology. MRI of the optic nerves will almost always show high signal in the affected optic nerve on T2-weighted (or STIR) orbital images (Figure 14.13) with gadolinium enhancement. In cases of diagnostic uncertainty, visual evoked potentials with pattern electroretinograms and optical coherence tomography can help to confirm optic nerve involvement or exclude maculopathy as a cause of the visual loss.

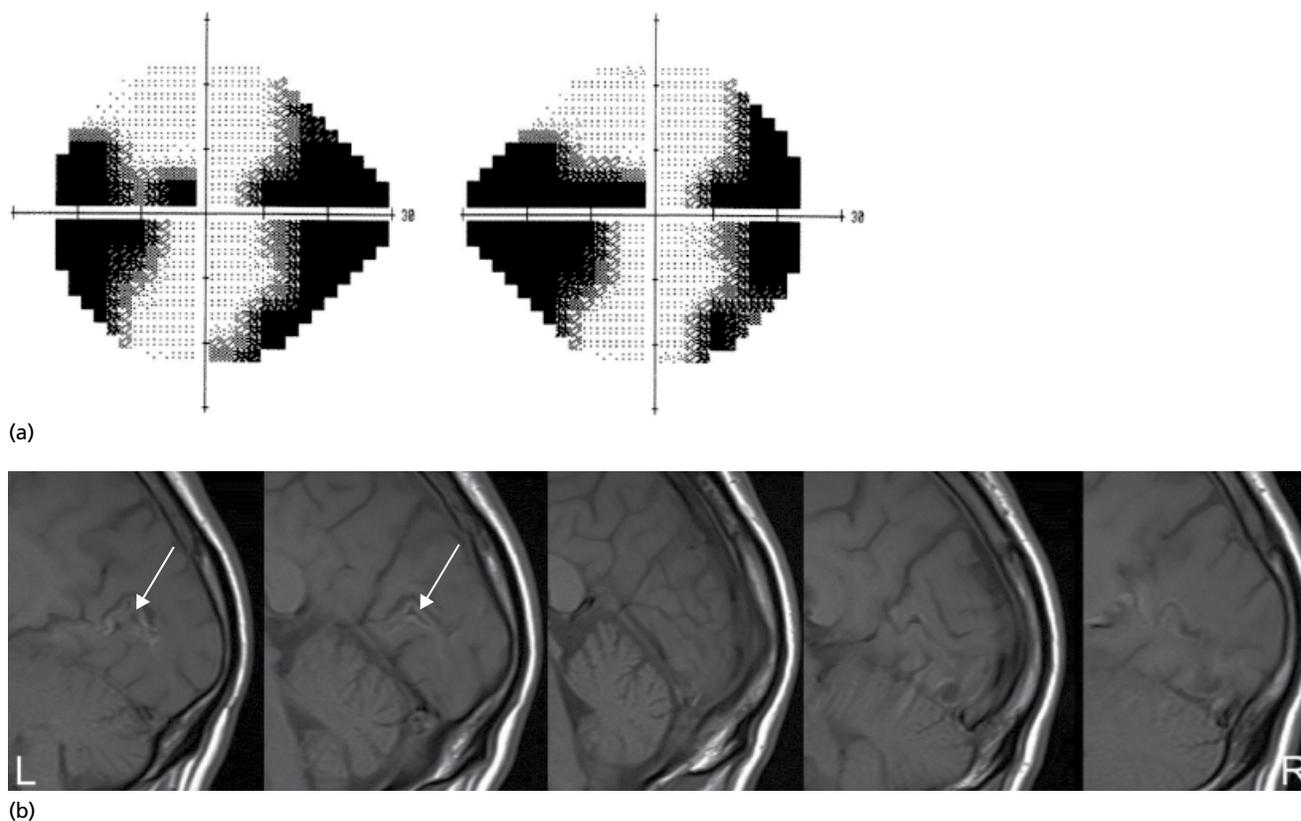

In CIS, the risk of future conversion to multiple sclerosis can be stratified with brain MRI and this should be routinely discussed with or offered to the patient (chapter 11). Abnormal brain MRI may show disseminated white matter lesions suggestive of

**Figure 14.7** Bi-temporal hemianopia signifying chiasmatal compression shown in different field testing formats. (a) Bilateral temporal defects on automated perimetry grey-scale. (b) Asymmetric temporal defects on Goldmann kinetic perimetry clarified on red target testing. (c) Amsler grid central visual field showing bi-temporal hemianopic scotomas due to chiasmatal compression: as represented by the patient.

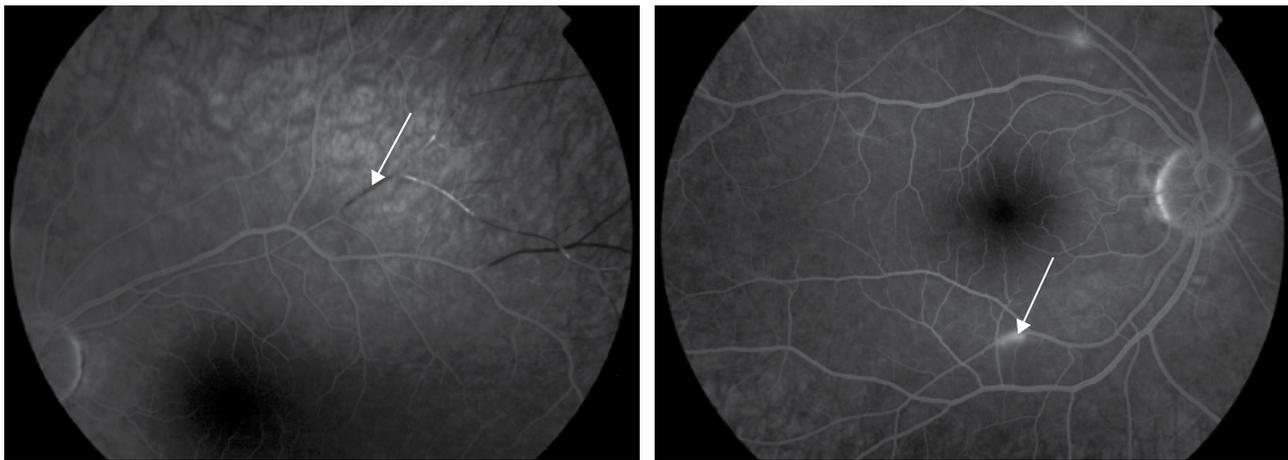

**Figure 14.8** Upper quadrantic hemianopia after temporal lobectomy: automated full field kinetic perimetry.

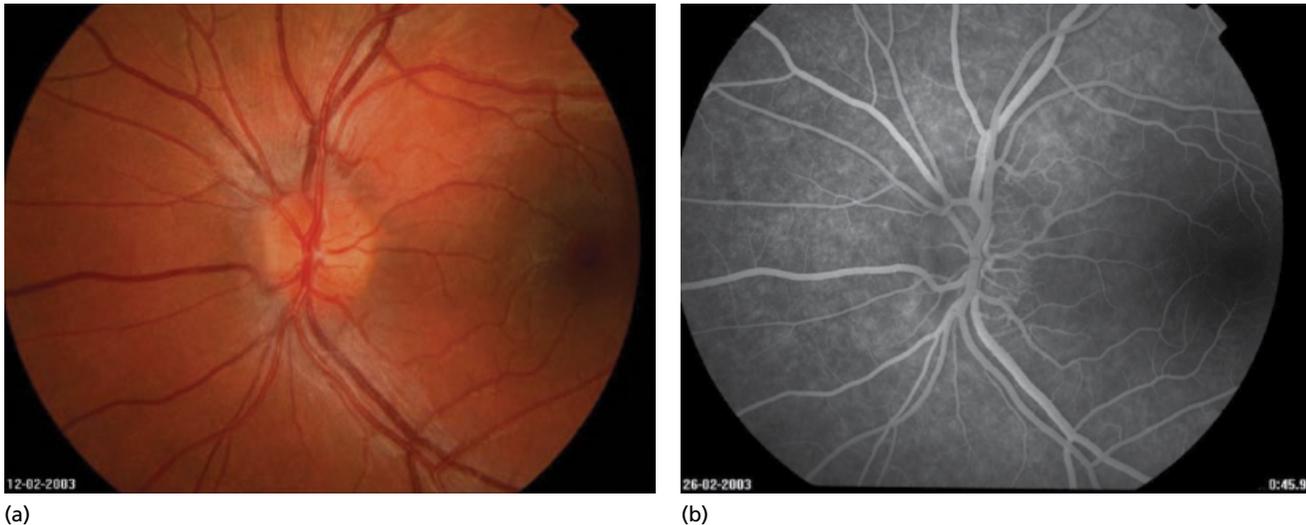

**Figure 14.9** Bilateral macular sparing hemianopias: (a) automated visual fields; (b) MRI showing bilateral anterior calcarine fissure lesion (arrows).

demyelination. In the North American Optic Neuritis Treatment Trial (ONTT), 72% of patients with optic neuritis with abnormal baseline MRIs developed clinically definite MS after 15 years compared with 25% with normal baseline MRIs. Even the lower risk is

not insignificant, hence patients should receive appropriate counselling. The longest prospective follow-up of CIS (ON, cord and brainstem) was for 20 years and reported a conversion rate to clinically definite MS of 82% for baseline abnormal MRIs compared

**Figure 14.10** Recurrent branch retinal artery occlusions with hyperfluorescence at remote artery bifurcation sites in Susac's micro-angiopathy of eye, brain and cochlea. (a) Fundus fluorescein angiography (FFA) showing occluded branch retinal artery (arrow). (b) FFA showing hyperfluorescence at a different branch artery bifurcation (arrow).

**Figure 14.11** Hyperaemia and likely optic disc swelling in a patient with subacute monocular visual loss. (a) Colour photograph of optic disc. (b) FFA showing absence of dye leakage supporting diagnosis of Leber's hereditary optic neuropathy and against diagnoses of ischaemic or inflammatory optic neuropathy.

with 21% for those with normal baseline MRIs. More recently, developments in MRI criteria can now allow the diagnosis of MS to be made after a single episode of MS-ON and after a single MRI brain with contrast in certain cases.

**Treatment** Many studies have confirmed that a short course of high-dose corticosteroids reduces the time taken for recovery in acute MS-ON but does not alter the eventual outcome. Methylprednisolone administered 1 g/day for 3 days intravenously or 500 mg/day orally for 5 days is usually recommended. However, approximately 10% of patients are left with acuities of 6/12 or worse. There is interest in developing neuroprotective or remyelinating therapies which potentially could improve visual outcome and several trials are in progress.

### Optic neuritis associated with neuromyelitis optica (Devic's syndrome)

**Clinical features** (Chapters 11 and 16) NMO-ON can present with atypical ON features such as severe peri-ocular pain or severe visual loss, which are rarely seen in MS-ON. It is essential to recognise the possibility of NMO early, as prompt treatment can save vision. Spontaneous clinical recovery is less likely without treatment.

The disorder is more common in parts of the world where MS is less frequently the cause of optic neuritis and is likely to be related to the 'Asian optico-spinal form of multiple sclerosis' seen in East Asia. Although very few epidemiological studies have been performed, it is thought to be more common in non-Caucasians and has a greater female preponderance. Other autoimmune conditions (e.g. lupus, Sjögren's syndrome) may co-exist with

**Figure 14.12** Fundus photograph and FFA in greater magnification: small peripheral retinal haemangioma in von Hippel-Lindau disease.

NMO-ON. Patients may have or develop other features of NMO (e.g. longitudinally extensive myelitis) or have an NMO spectrum disorder.

**Investigations** Aquaporin 4 (AQ4) antibody should be sought in any case of atypical optic neuritis. There are no absolute features of optic nerve imaging although the lesion is more likely to be posterior along the optic nerve and involve the chiasm. Patients with both optic neuritis and the typical spinal cord lesions of NMO are more likely to have AQ4 antibodies. There is also a small subgroup of patients who have recurrent optic neuritis alone without myelitis and who have the same antibody, about 5–10% of cases of optic neuritis for whom no specific cause (including MS) can be identified. However, the diagnosis is an important one to make because the management of NMO is quite different from the management of MS. Brain MRI may be normal or may show white matter lesions that look atypical for MS. Hypothalamic and peri-aqueductal grey matter lesions have also been seen. CSF may show a lymphocytic pleocytosis and oligoclonal bands are less likely to be found than in MS-ON. Post-acutely, OCT tends to show more severe retinal nerve fibre layer thinning than after MS-ON.

There is an emerging NMO phenotype found in a sub-group of AQ4 Ab-negative NMO patients who are positive for myelin oligodendrocyte glycoprotein (MOG) Ab. These patients are more likely to be male, have bilateral simultaneous optic neuritis, have spinal lesions lower down in the cord and tend to demonstrate better functional recovery.

**Treatment** Acute attacks are treated with high dose corticosteroids (intravenous methylprednisolone 1 g/day for 3–5 days) followed by a prolonged oral tail weaning over 4–6 months. Relapses during weaning can be treated by increasing the oral dose or providing a further intravenous course. Plasmapheresis should be considered for those patients who do not respond to steroids in the acute phase. Steroid sparing immunosuppressants should be commenced for long-term relapse prevention. No randomised controlled evidence exists but azathioprine and methotrexate are typically considered as first line agents. Rituximab is gaining favour as an alternative first line agent. Second line agents include mycophenolate. Future treatments may include tocilizumab and eculizumab (Chapter 11).

**Table 14.5** Causes and classification of optic neuropathy.

#### Anterior optic neuropathy with disc swelling

(Disorders causing visible axonal swelling at the optic nerve head: often monocular)

- Anterior ischaemic optic neuropathy
  - Arteritic
  - Non-arteritic
- Optic neuritis (papillitis)
- Neuro-retinitis
- Diabetic papillopathy
- Papillophlebitis/venous papillopathy
- Compressive optic neuropathy
- Infiltrative optic neuropathy
- Medication-associated (e.g. amiodarone, beta-interferon)
- Raised intracranial pressure
- Accelerated hypertension

#### Anterior optic neuropathy without disc swelling

(Disorders causing primary retinal ganglion cell failure: typically bilateral and symmetrical)

- Toxic/nutritional optic neuropathy
  - Drugs (e.g. ethambutol, isoniazid, linezolid, chloramphenicol)
  - Toxins (e.g. methanol, ethylene glycol, toluene, heavy metals)
- Nutritional (e.g. vitamin deficiency B<sub>1</sub>, B<sub>12</sub>, folate deficiency)
- Endemic (Tanzanian, Jamaican)
- Recreational (e.g. ethanol, tobacco)
- Hereditary optic neuropathy
  - Leber's hereditary optic neuropathy
  - Dominant optic atrophy
- Syndromic (e.g. Friedreich's, Wolfram's, mitochondrial disease, storage diseases, hereditary motor sensory neuropathy)

#### Posterior (retrobulbar) optic neuropathy without disc swelling

- Retrobulbar neuritis
- Traumatic optic neuropathy
- Radionecrosis
- Compressive optic neuropathy
- Obstructive hydrocephalus
- Posterior ischaemic optic neuropathy

#### Pseudopapilloedema

(Disorders mimicking acquired causes of optic neuropathy with disc swelling)

- Optic disc drusen
- Optic disc hamartomas
- Optic disc dysplasia and dysversions
- High refractive error
- Myelinated nerve fibres

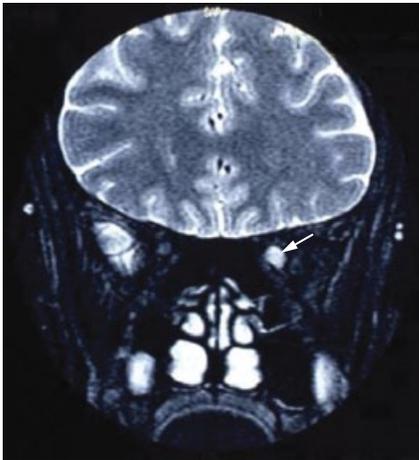

#### Optic neuritis: chronic relapsing inflammatory optic neuropathy

Chronic relapsing inflammatory optic neuropathy (CRION) is a condition that is not yet clearly defined and has an unknown aetiology. Presentation is with painful subacute visual loss but the pain is frequently more severe and prolonged than in MS-ON. In most cases the second eye is involved but not simultaneously.

**Table 14.6** Causes of optic neuritis.

Immune-mediated	No systemic inflammation	MS-ON (if first episode then called clinically isolated syndrome) NMO-ON Solitary, isolated optic neuritis Recurrent isolated optic neuritis Chronic relapsing inflammatory optic neuropathy Post-viral/post-immunisation Acute disseminated encephalomyelitis
	Systemic inflammation	Sarcoidosis Connective tissue disease – lupus, Sjögren's syndrome Vasculitis – polyarteritis nodosa, Wegener's granulomatosis, Churg–Strauss
Infective	Bacterial	Borrelia, syphilis, mycoplasma, tuberculosis, Whipple's disease
	Viral	Herpes simplex/zoster, EBV, CMV, Coxsackie, hepatitis A and B, measles, mumps, rubella
	Parasitic	Toxoplasmosis, cysticercosis, toxocara
	Fungal	Cryptococcus, aspergillus, mucormycosis, candida
Other associated conditions	Perineuritis (contiguous sheath inflammation) Sinus disease (mucocoele, pyocoele) Neuroretinitis Extrinsic tumour (e.g. meningioma)	

CMV, cytomegalovirus; EBV, Epstein–Barr virus.

**Figure 14.13** Coronal MRI showing high signal in the left optic nerve (arrow) in a case of demyelinating optic neuritis.

However, the essential point is that there is not only a response to corticosteroids but a relapse when these are withdrawn. This is in contrast to MS-ON where it is possible to give very short courses of high-dose steroids (even as short as 3 days) without fear of relapse when the course is completed. However, relapse is also common in sarcoid-related optic neuropathy and NMO-ON. Another feature often seen in CRION is late improvement (i.e. a long-standing optic neuropathy that appeared static can show recovery with corticosteroid therapy).

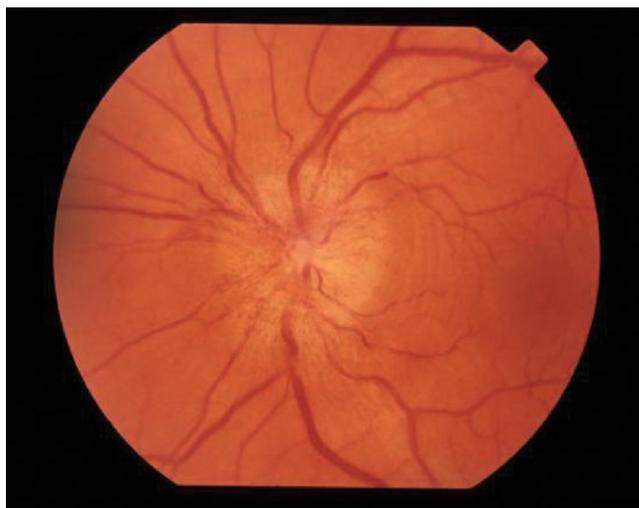

**Investigations** By definition, investigations are normal. Any evidence for an underlying systemic condition such as a vasculitis or

granulomatous disorder must be excluded. There is no evidence of MS or NMO. A small number of patients with this phenotype do appear to have NMO antibodies.

**Treatment** The response to immunosuppression suggests that the essential difference between CRION and MS-ON is that in the former there is ongoing inflammation whereas in MS-ON there is a brief period of inflammation of acute onset which then subsides moving to a recovery phase. CRION is therefore appropriately treated with long-term immunosuppression and steroid-sparing agents. It is important to bear in mind that relapses can be associated with irreversible visual loss unless treated promptly.

#### Optic neuritis: infective disorders

**Clinical features** It is important to recognise these causes of optic neuritis because they require immediate and aggressive management. Viral infections can give rise to optic neuritis either by direct infection of the optic nerve or as a post-infectious syndrome. Bacterial infection of the optic nerve or sheath, such as in pneumococcal meningitis, can result in devastating visual loss as can fungal invasion (e.g. with *Aspergillus fumigatus*). Optic neuritis is one of many possible ophthalmic complications of neurosyphilis (Figure 14.14) and of another spirochaetal disease, Lyme disease, caused by *Borrelia burgdorferi*. In most cases there will be some clear evidence of the causative infective process for instance herpes zoster ophthalmicus, or bacterial meningitis. Vigilance is required for instances of underlying infection such as syphilis, tuberculosis, sinus disease or fungal disease. Atypical features of optic neuritis such as orbital signs or prolonged and severe pain should alert the physician to these possibilities. In many of these infective cases the optic nerve sheath is involved rather than the optic nerve itself and

**Figure 14.14** Optic neuritis in secondary syphilis.

the presenting syndrome is one of optic perineuritis (see Optic neuritis: optic perineuritis).

**Investigations** Serological testing for syphilis should be undertaken in every case of optic neuritis presenting as an isolated syndrome. Other serological tests will depend on the clinical presentation. Tuberculin testing may be required as may lumbar puncture, sinus biopsy and, occasionally, optic nerve biopsy. MRI of the optic nerve may give important clues in that the appearance may be of optic perineuritis rather than of swelling and inflammation affecting the intrinsic optic nerve and there may be evidence of infection elsewhere in the orbit, the paranasal sinuses or intracranially.

**Treatment** The management of these disorders is discussed in Chapter 9.

#### Optic neuritis: sarcoid-related optic neuropathy

**Clinical features** In neurosarcoidosis, optic neuropathy is not uncommon. Some patients have a syndrome indistinguishable from MS-ON with spontaneous recovery but more commonly the optic nerve is infiltrated with granulomata. This process may be visible at the optic disc and there is much greater likelihood of a vitritis and of peri-phlebitis than in MS-ON. The optic nerve may also be compressed extrinsically by a granulomatous mass causing contiguous involvement of nearby structures, for example leading to diabetes insipidus arising in sarcoid chiasmitis with associated orbital signs (Figure 14.15). Sarcoidosis is also a cause of optic perineuritis (see Optic neuritis: optic perineuritis).

**Investigations** On MRI, when there is intrinsic optic nerve disease the optic nerve is more likely to be enlarged than in MS-ON. There may be a granulomatous mass and features of optic perineuritis.

**Treatment** Corticosteroids are used in the acute phase. It is essential that steroid treatment is given over many weeks in slowly reducing doses. The treatment of neurosarcoidosis is reviewed in Chapter 26.

**Figure 14.15** CT showing bilateral thickening of optic nerve sheaths (arrow) in sarcoid granulomatous optic neuritis.

**Figure 14.16** Swollen optic disc with hard exudates in retinal nerve fibre layer due to acute neuro-retinitis in a case of cat-scratch fever.

#### Optic neuritis: neuroretinitis

**Clinical features** This condition presents in similar fashion to MS-ON but the pathology is more anterior. The optic disc is swollen and within a few weeks a macular star develops. The macular star (exudates in a radial pattern around the macula) indicates that there has been oedema affecting the retina itself and it may be that this syndrome results from inflammation more of the retinal ganglion cell layer than of the optic nerve itself (Figure 14.16). It is an important diagnosis to make because it is not associated with MS.

**Investigations** This disorder commonly occurs after an infection and therefore appropriate serological tests may be revealing (e.g. *Bartonella* infection – cat scratch disease). In acute neuroretinitis the optic nerve does not show the features of demyelinating optic neuritis on MRI such as swelling, increased T2 hyperintensity

or enhancement on gadolinium-enhanced MRI, and there are no CNS abnormalities (Figure 14.16).

**Treatment** Corticosteroids are usually given in more severe cases with vision reduced to 6/60 or worse.

### Optic neuritis: optic perineuritis

**Clinical features** Optic perineuritis describes the situation in which the optic nerve is not directly involved in the inflammatory process, but rather the optic nerve sheath. Presentation can be much as any other form of optic neuritis but there may be considerable and sustained pain; in some cases the patient is reluctant to move the eye at all. There may be orbital signs of congestion or inflammation and disc swelling is almost universal. Peripheral visual field loss is more common than a central defect. The pathology is a meningeal-based process and is caused by infective disorders such as tuberculosis and syphilis or infiltration with a neoplastic process, particularly lymphoma or malignant meningitis. In some cases the condition is a component of orbital inflammatory disease with or without associated scleritis.

**Investigations** MRI shows a thickened and enhancing optic nerve sheath often with involvement of the orbital fat. Investigations are directed towards excluding a systemic condition. Rarely, a biopsy of the optic nerve sheath may be necessary. CSF examination should include careful cytology for neoplasia.

**Treatment** Treatment depends upon the exact cause, if this can be determined. All investigations should be carried out within 48 hours so that corticosteroid therapy can be instituted promptly if no other cause is found as any delay in treatment may result in a poor visual outcome.

### Ischaemic ocular syndromes

#### Nosology of ischaemic syndromes

It is essential to have an understanding of the vascular supply to the intracranial and intraorbital portions of the optic nerve, to the optic nerve head and to the outer and inner layers of the retina. The ganglion cell layer of the retina is supplied in most individuals entirely by the central retinal artery which is a branch of the ophthalmic artery and is an end artery. Occlusion of this artery results in total visual loss and this is a common consequence of retinal embolism. In around 15% there is a branch of the choroidal circulation (cilio-retinal artery) which is usually solitary and supplies the macula. Occlusion of this artery will give rise to a scotoma extending from the blind spot to the macula. This is a rare event in isolation but can occur in association with central retinal vein occlusion.

The prelaminar (most anterior) portion of the optic disc is supplied by the short posterior ciliary arteries which are several in number. These are also branches of the ophthalmic artery but these are not end arteries because there is an anastomosis (the circle of Zinn–Haller) around the optic nerve itself immediately behind the globe where the arterioles pierce the sclera to supply the optic nerve head and the choroid. Ischaemic events in posterior ciliary artery territory therefore are not related to embolic or arteriolar occlusive disease as is the case with the central retinal artery but to low perfusion. The optic disc is especially vulnerable in this respect because it is at a watershed between different branches of the short posterior ciliary vessels from the ophthalmic artery.

The anastomoses between the internal and external carotid artery in the orbit are extensive and for this reason occlusion of the ophthalmic artery in isolation does not result in any ischaemic consequence

because the branches of the external carotid can take over the supply to all of the orbital structures. Similarly, occlusion of the internal carotid artery, in the presence of an adequate external carotid artery supply will not result in any ischaemic complications in the orbit and indeed the flow in the ophthalmic artery can be reversed.

The retrolaminar portion of the optic nerve and the remainder of the intraorbital nerve are supplied by pial vessels and by penetrating branches of the ophthalmic artery. The intracanalicular portion of the nerve is supplied by penetrating branches of the ophthalmic artery and the intracranial portion by pial vessels.

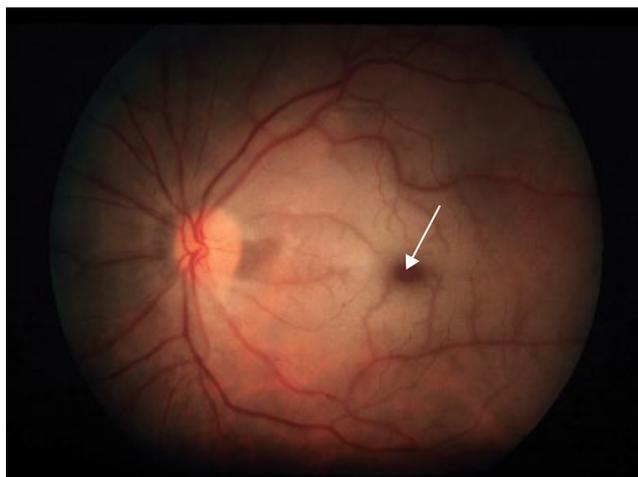

### Central and branch retinal artery occlusion

**Clinical features** In central retinal artery occlusion (CRAO) abrupt loss of vision may be reported or loss of vision noticed on waking. Occasionally, the loss of vision may go unnoticed by the patient, more commonly in branch retinal artery occlusion (BRAO; Figure 14.17). There is no pain. In BRAO the field defects respect the fact that the branch arterioles of the central retinal artery do not cross the horizontal raphe of the retina so that altitudinal defects, or portions thereof, are the rule. Any portion of the retina supplied by a cilio-retinal artery (most commonly the macula) will be spared. Acutely, there is retinal oedema (cloudy swelling; Figure 14.17) which is the hallmark of infarction of the inner layers of the retina which includes the ganglion cell layer. The 'cherry red spot' at the macula is in fact normal in colour; it is simply that this is a zone that is free of capillaries and ganglion cells, hence the red spot results from the intact choroidal supply, thrown into contrast by the surrounding pale and infarcted retina (Figure 14.18). If flow in the central retinal artery is restored within a matter of minutes following the occlusive event, then transient monocular blindness will result. If it is restored some time later, when infarction has occurred, then the appearance of the fundus can return remarkably to normal except that there is total loss of the retinal nerve fibre layer.

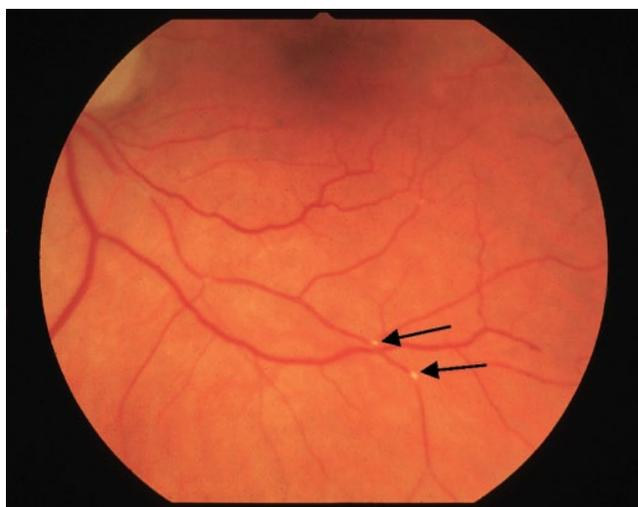

Of particular value is the search for the various types of embolus – calcific, cholesterol (Figure 14.19) or platelet/fibrin – as this can give some clue as to the source of the embolus. Not all retinal artery occlusions are caused by embolic disease, however, and CRAO can occur in giant cell arteritis and other causes of vasculitis. Some cases

**Figure 14.17** Branch retinal artery occlusion. Note the sectorial cloudy retinal swelling in the superior retina (arrow).

**Figure 14.18** Central retinal artery occlusion with cherry red spot in Afro-Caribbean patient (arrow).

**Figure 14.19** Cholesterol emboli (arrow).

are seen of recurrent BRAO and in this situation a more extensive vasculopathy should be suspected such as Susac's syndrome where recurrent arteriolar ischaemic events occur in the retina, the brain and the cochlea. Clearly, in these situations it is the systemic associated features that often give the clue (Chapter 26).

**Investigations** If a calcific embolus is seen as a cause of a CRAO then a cardiac source should be suspected, whereas platelet or fibrin embolus or cholesterol is more likely to have originated in atherosclerotic disease of the ipsilateral internal carotid or aortic arch.

**Treatment** Treatment of acute CRAO is attempted if seen early enough. Administering acetazolamide intravenously and performing ocular massage with or without paracentesis to lower intraocular pressure and improve perfusion is established practice but has no evidence base. Even cases with a blind eye for some hours can experience partial recovery spontaneously and it would be difficult to set up a controlled trial of such treatment. Local intra-arterial thrombolysis has not proved superior to conservative treatment and is associated with a risk of intracranial haemorrhage.

**Figure 14.20** Central retinal vein occlusion showing scattered deep retinal haemorrhages.

### Central and branch retinal vein occlusion

**Clinical features** Patients usually present complaining of painless abrupt onset of blurred vision or there may be no symptoms. The appearance of a central retinal vein occlusion (CRVO) is easily recognised – there is swelling of the optic disc and congestion of the retinal veins with extensive nerve fibre layer haemorrhages. Partial retinal vein occlusion (venous papillopathy or papillophlebitis) can cause diagnostic confusion because the patient may present with unilateral disc swelling with minimal haemorrhages and be investigated for raised intracranial pressure or an optic nerve tumour (Figure 14.20).

**Investigations** For the neurologist the task is usually to exclude any underlying prothrombotic disorder in the absence of obvious vascular risk factors such as hypertension or diabetes. CRVO can occur in young fit people and dehydration may have a part to play in some of these. Otherwise, most studies have shown an association between CRVO and various vascular risk factors particularly when recurrent. There is no need for imaging but it must be remembered that some optic nerve tumours (particularly malignant glioma of the optic nerve) can present with a picture resembling a CRVO but in these cases there is usually progression of visual loss and progression to arterial occlusion.

**Treatment** There is no treatment for the acute disorder but referral to the ophthalmologist is necessary because if there is significant retinal ischaemia new vessel formation can occur with all its attendant complications. Otherwise, management is limited to prevention of recurrence as with all occlusive vascular disease.

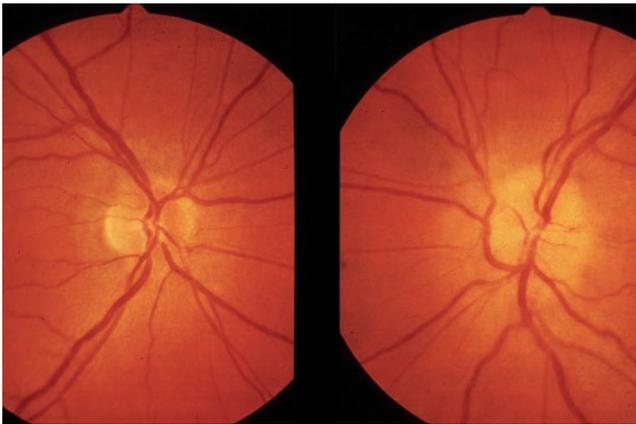

### Non-arteritic anterior ischaemic optic neuropathy

**Clinical features** Ischaemia at the level of the posterior short ciliary artery supply to the prelaminar optic nerve head results in anterior ischaemic optic neuropathy (AION). By definition, the optic disc will be swollen acutely. Indeed, it should always be insisted that the diagnosis is not made unless the patient was seen acutely and the disc observed to be swollen. The common form of AION is non-arteritic. The pathogenesis of this condition is not understood but the condition may be caused by a drop in the perfusion pressure

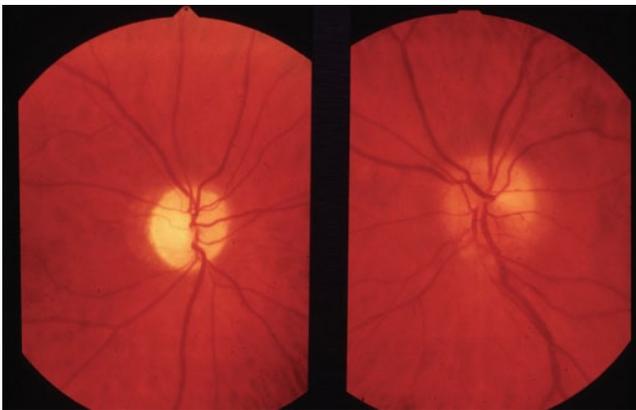

of the optic nerve head. It is almost never brought about by embolic disease, with the rare exception of atrial myxoma. Associations therefore include systemic hypotension, especially blood loss, during surgery and during renal haemodialysis, and obstructive sleep apnoea/hypopnoea syndrome. The other factor that influences perfusion of the optic disc is intraocular pressure and angle closure glaucoma may precipitate AION.

The morphology of the optic disc is of particular importance, the majority of cases have small 'crowded' optic discs, usually also hypermetropic (i.e. the scleral opening is small and the optic nerve has little or no cup; Figure 14.21). Therefore, if a minor degree of ischaemia leads to swelling of the optic nerve head, the ischaemia will be exacerbated and lead to infarction.

In non-arteritic AION the most common field defect is a lower altitudinal one – hence, the upper part of the optic disc is more vulnerable, a feature also in favour of the critical perfusion hypothesis. The optic disc will be swollen throughout initially but after 4–6 weeks the upper pole will become atrophic as the nerve fibres disappear while the lower pole remains swollen. A few weeks later sectoral optic atrophy is seen with loss of optic nerve fibre from the upper pole of the disc corresponding to the visual field defect (Figure 14.22).

**Figure 14.21** Left eye non-arteritic anterior ischaemic optic neuropathy with 'crowded disc at risk' in fellow right eye. The left disc is swollen and the right has an absent physiological cup.

**Figure 14.22** Pseudo-Foster Kennedy syndrome with swollen optic disc on left and optic atrophy on right.

Patients most commonly complain of sudden or subacute visual loss with some progression over hours to days, they may notice the loss on waking, or it may pass unnoticed until the visual field defect or optic atrophy is picked up some time later. AION rarely affects the same eye a second time but some cases show stepwise progression sometimes over many weeks. Unfortunately (and possibly related to the vulnerable optic disc morphology), there is a risk of the same process occurring in the other eye in about 20–40% of cases. Second eye involvement is usually within months to years, bilateral simultaneous involvement suggests systemic hypotension as the cause.

**Investigations** Non-arteritic AION is rarely associated with embolic disease and only exceptionally associated with disease of the ipsilateral carotid artery; in which case it is usually in the context of disease of both the internal and external carotid arteries and inadequate perfusion of the entire globe. Thrombophilic conditions, most of which cause venous rather than arterial occlusions, are rarely implicated. Investigations are limited to a general screen for vascular risk factors with consideration of nocturnal hypotension or obstructive sleep apnoea as cofactors.

Many patients with non-arteritic AION are relatively young and do not have extensive evidence of generalised vascular disease and in these patients the disc morphology may be the only predisposing factor.

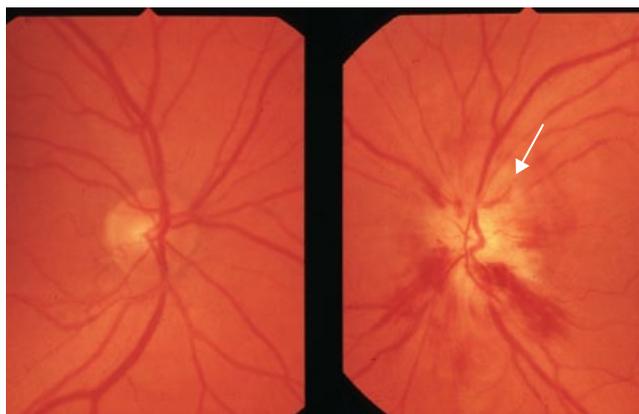

**Treatment** Management is treatment of any underlying cause and of general vascular risk factors. There is no treatment known to influence the visual deficit although drugs to lower the intraocular pressure are sometimes used. Neither has it been shown that prophylactic aspirin can reduce the risk to the other eye but it seems reasonable to prescribe it as general secondary prevention.

#### Anterior ischaemic optic neuropathy in giant cell arteritis and other vasculitides

There is an extensive literature on factors which help distinguish between arteritic and non-arteritic AION. The argument is centred on the need to diagnose giant cell arteritis (GCA) and to prevent blindness. While the importance of this cannot be overemphasised, the arteritic versus non-arteritic AION dichotomy is only a part of the story. It is essential to realise that AION is not the only cause of visual symptoms and visual loss in GCA, furthermore there are other systemic inflammatory conditions that can lead to AION.

**Clinical features** By definition, all causes of AION will be associated with disc swelling but in GCA the loss of vision is more profound than in non-arteritic AION, indeed total blindness of the affected eye in a matter of hours is the rule. The swollen disc will look pale early – often within days – whereas in non-arteritic AION the disc only becomes pale as optic atrophy supervenes (Figure 14.23). Premonitory transient visual loss occurs in GCA but never in non-arteritic AION; this is not embolic but a result of poor perfusion. Usually, patients are aware that the loss of vision lasts seconds only and tends to come on with change of posture from sitting or lying to standing. This phenomenon is related to the pathological difference between the two conditions. Indeed, all of the distinctions between the two can be explained in these terms.

First in GCA, many arteries and arterioles are involved, hence there is more extensive ischaemia. The central retinal artery and the choroidal vessels may be involved, the entire globe or indeed entire orbit may be ischaemic because branches of both the internal and external carotid artery are affected. Secondly, GCA is a vascular occlusive disorder which accounts for the more profound visual loss

**Figure 14.23** Vasculitic anterior ischaemic optic neuropathy (AION) showing haemorrhagic disc swelling.

as there is no collateral or anastomotic supply which may help to preserve vision. However, in GCA, the occlusion is generally not thrombotic and the lumen is occluded by the intimal hypertrophy which is the pathological hallmark of the disease.

Apart from the severity of the visual loss, for example, preceding symptoms – both visual and systemic – should be sought in any patient with visual loss that might be brought about by GCA. Headache and tenderness of the extracranial arteries, especially the superficial temporal and occipital arteries are important clues to the diagnosis as is other evidence of ischaemia in the territory of the branches of the external carotid artery (ischaemic jaw pain on chewing, scalp or tongue necrosis). Polymyalgia rheumatica often occurs in the same individuals and may precede or follow GCA by some years. The disease is rare below the age of 50 years.

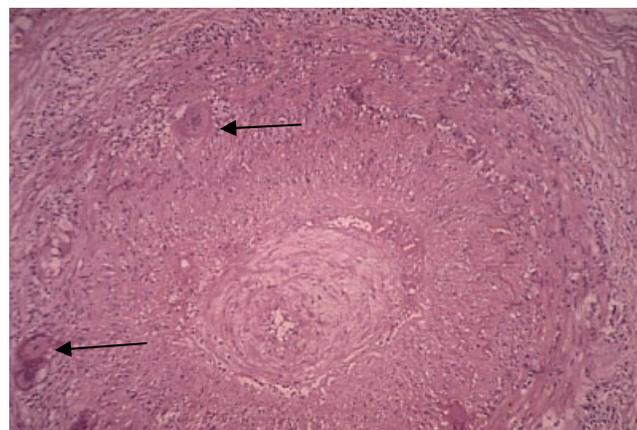

An often neglected clinical sign is the palpation of the superficial temporal, occipital and facial arteries (Figure 14.24). In a severe case of GCA these arteries will be thickened, pulseless and tender. In the appropriate clinical context this confirms the diagnosis. In other cases they may be normal or thickened but still with a pulse. False positives are possible because arteriosclerosis alone can result in similar findings.

AION can occur in other true vasculitides where there is inflammation in the vessel wall especially where arterioles are affected (e.g. polyarteritis nodosa, Churg–Strauss syndrome and ANCA-positive vasculitis). It can also be seen where there is vascular occlusion because of antigen–antibody complex deposition in arterioles and capillaries such as in systemic lupus erythematosus. These conditions have characteristic systemic features but it is beyond the scope of this chapter to list them all. An important clinical point, however, is that these disorders lie somewhere between GCA and non-arteritic AION in their clinical features – visual loss may be intermediate in severity, for example. The importance in recognising these conditions is that, unlike non-arteritic AION and the vast majority of cases of GCA, there is some possibility of visual recovery if treatment is administered promptly.

**Investigations** A normal ESR and CRP do not exclude the diagnosis but in most cases these are reliable screening tests with all the usual concerns regarding false positive and false negative results. In clinically definite cases of GCA one needs to disregard blood tests, but they are usually helpful when monitoring the response to steroid therapy. A biopsy should be carried out if possible

**Figure 14.24** Giant cell arteritis with superficial scalp necrosis.

**Figure 14.25** Giant cell arteritis histology. Granulomatous inflammation across vessel wall with fragmentation of the internal elastic lamina and occlusion of the lumen (arrows).

because it is always helpful to future management to have that result in the notes (Figure 14.25). The rapidity of the response of headache to steroids (usually measured in hours after the first dose) is also useful circumstantial evidence.

**Treatment** Therapy with oral prednisolone, at 1 mg/kg body weight, should be commenced urgently in any suspected case of GCA. Intravenous methylprednisolone to initiate therapy may have advantages if the second eye becomes involved. There is a time window of a few days in which visual loss can occur in the other eye even after treatment with steroids has been initiated. A delay of even hours can make a difference in preventing blindness. Unfortunately, the chances of recovery in an eye already showing signs of AION are low. It is possible to demonstrate that the lumen recanalises in affected arteries – simply by palpating the superficial temporal arteries again in a week or two when the pulse will be restored. In clinical practice the main problem is the need to minimise the adverse effects of corticosteroids and discontinue the treatment safely without risking relapse. In most cases it is possible to discontinue steroids after 18 months to 2 years.

### Posterior ischaemic optic neuropathy

Posterior ischaemic optic neuropathy (PION) should only be diagnosed in the context of GCA or following severe hypotension, or for example following spinal surgery. A compressive disorder is erroneously diagnosed as PION more commonly than vice versa, a situation that has more serious potential consequences.

**Clinical features** There is acute or subacute painless loss of vision with variable patterns of visual field loss with, in the acute phase, a normal fundus although optic atrophy develops later. Where visual loss has occurred in the context of spinal surgery or blood loss the loss of vision is more likely to be bilateral (see Bilateral visual failure).

**Investigations** In the appropriate context, the investigations for arteritic AION are as those described earlier. In recovery from peri-operative visual loss little needs to be done except to exclude an unlikely compressive lesion by appropriate imaging. There is little information on the MRI appearances of the optic nerve in acute PION, there is no need to carry out this investigation in GCA and cases of spontaneous PION are very rare. There is often high signal and gadolinium enhancement of a segment of the nerve.

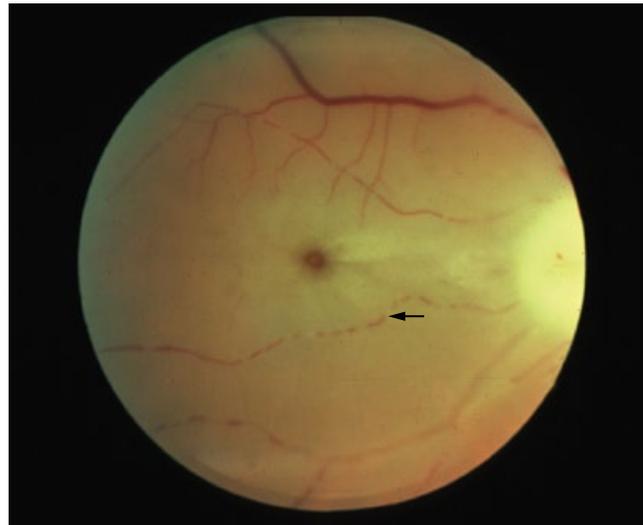

**Treatment** Treatment of GCA is discussed earlier. There is no treatment for PION in other contexts.

### Chronic ocular ischaemic syndromes

**Clinical features** In a number of situations there may be chronic ischaemia of the retina, the optic disc or the entire globe. As far as the optic disc is concerned chronic ischaemia at the capillary level will lead to disc swelling with a variable degree of visual loss. The classic example is known as ‘diabetic papillopathy’ where a chronically swollen disc is seen in poorly controlled diabetes. Disc swelling in accelerated hypertension has a similar aetiology and can persist for some time without significant loss of vision. In both instances there is a risk of infarction of the optic nerve which will lead to permanent loss of vision. In the case of accelerated hypertension this may occur if the blood pressure is treated too aggressively.

‘Slow flow retinopathy’ is seen when there is poor perfusion of the retina. This situation occurs when there is severe impairment of both the internal and external carotid artery supply to the orbit.

Patients may complain of transient loss of vision, particularly associated with change from a sitting to a standing posture and on moving to bright illumination particularly sunlight. On examination, vision may be only mildly impaired but there is congestion of retinal veins, haemorrhages in the mid-periphery

**Figure 14.26** Arteritic AION + central retinal artery occlusion (CRAO) with cattle trucking in branch retinal artery (arrow) in a patient with GCA.

(characteristically petal-shaped) and macular oedema (‘cattle-trucking’) (Figure 14.26). The central retinal artery collapses with minimal digital pressure on the globe and indeed may show spontaneous pulsation because in diastole the pressure is lower than the intraocular pressure. In more severe cases the entire globe may be ischaemic, this leads to the formation of new vessels at the iris – rubeosis – which in turn leads to glaucoma.

**Investigations** The task is to confirm that the problem is with occlusion of the ipsilateral carotid artery. The principal differential diagnosis is GCA which can also give rise to an ocular ischaemic syndrome.

**Treatment** The evidence that carotid endarterectomy is effective in these disorders is not compelling and many cases, if followed, will not deteriorate nor develop significant visual loss, except in the case of rubeotic glaucoma which should be treated by an ophthalmologist.

### Tumours affecting the optic nerve

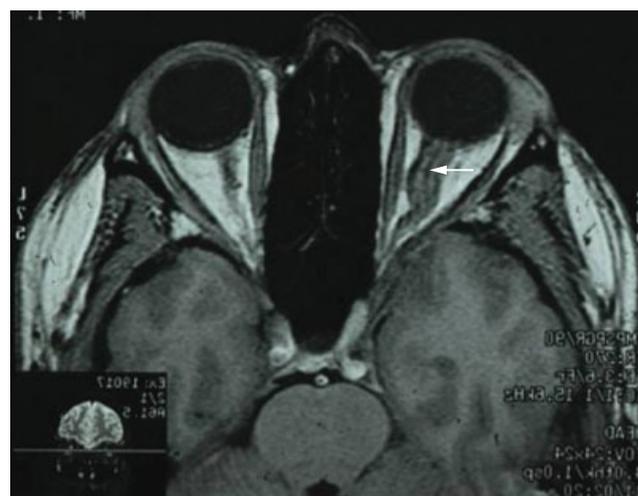

#### Compressive or infiltrative optic neuropathy

Visual loss may be unilateral or bilateral. In unilateral cases there will be a relative afferent pupillary defect, the disc may be normal, swollen or infiltrated. When the visual impairment is bilateral the lesion is almost always intracranial or in the paranasal sinuses and the optic discs appear normal at presentation although progressive loss of colour vision and an afferent pupillary defect may occur. The disc may develop collateral vessels to bypass the retinal circulation. Locally invasive tumours such as optic glioma and optic nerve sheath meningioma compress the optic nerve and directly cause axonal backflow. Systemic malignancies such as leukaemia, lymphoma and metastases can directly infiltrate the optic nerves usually via the dura and cause both compression and papilloedema leading to abrupt or rapidly progressive visual loss (Figure 14.27; Table 14.7).

**Primary optic nerve sheath meningiomas** Primary optic nerve sheath meningiomas arise from the arachnoid cells of the optic nerve sheath. Their origin is generally in the orbital portion of the nerve but intracranial extension may occur. Primary optic nerve

**Figure 14.27** Neoplastic infiltration of the optic disc with associated central retinal artery occlusion (CRAO) causing a cherry red spot at the macula.

**Figure 14.28** Peri-optic meningioma causing thickening of left optic nerve sheath (arrow).

Meningeal carcinomatosis and malignant meningitis	
Non-neoplastic	Sarcoidosis

sheath meningiomas are more common in middle-aged females and are generally unilateral but may be bilateral or multifocal particularly in neurofibromatosis type 2. They may present with features of a slowly progressive optic neuropathy leading to loss of acuity, impairment of colour vision with a central scotoma and a relative afferent pupillary defect. Fundal examination shows unilateral optic atrophy but there may be chronic disc oedema with retinochoroidal venous collateral vessels indicating chronic

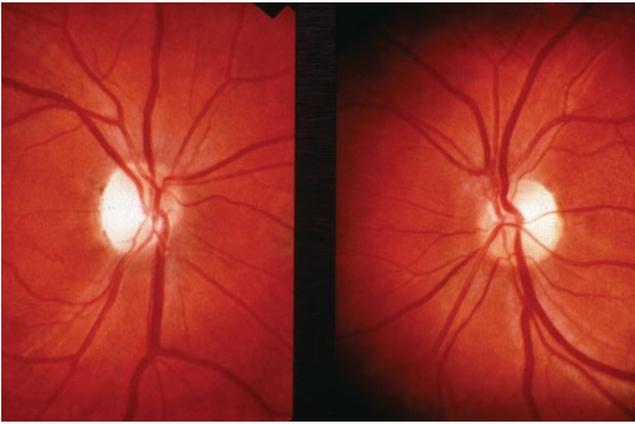

retinal vein obstruction. Progressive visual loss is likely regardless of treatment but intracranial extension is rare (Figure 14.28). Stereotactic radiotherapy can slow progression in selected cases.

**Other forms of meningiomas** Meningiomas may also arise from the sphenoid wing, tuberculum sellae or olfactory groove. They cause visual failure by direct compression of the intracranial portion of the optic nerve or chiasm but they may invade the optic canal and orbit. Large olfactory groove or sphenoid wing meningiomas can cause optic atrophy in one eye due to compression and papilloedema in the other eye due to raised intracranial pressure (Foster Kennedy syndrome). Imaging of sphenoid wing meningioma shows sphenoid hyperostosis and contrast enhancement on CT if there is orbital extension of the intracranial mass. Complete surgical excision is rarely possible but vision can be improved or stabilised by decompressing the optic canal and the posterior orbital segment of the optic nerve, sometime combined with adjuvant radiotherapy.

#### Optic and optochiasmal glioma

Primary glial tumours of the anterior visual pathway (optic glioma) occur either as benign gliomas of childhood or rarely as malignant glioblastoma in adults.

Benign optic gliomas of childhood arise in the chiasm more often than within the orbit or the canal. Patients present with proptosis and visual field loss which is generally bilateral and either scotomatous or bitemporal. There may be horizontal or rotatory nystagmus with head nodding. The optic disc is swollen or atrophic leading to fluctuations in visual function which may improve spontaneously in some patients. It is essential to exclude neurofibromatosis type 1. Optic glioma of childhood may be associated with hypothalamic or thalamic involvement and there may be hydrocephalus or signs of raised intracranial pressure and leptomeningeal spread may occur. The management is controversial as these tumours are slow-growing. Surgery is confined to palliative treatment for intraorbital tumours and chiasmal gliomas. Radiotherapy results in significant tumour shrinkage and improvement in visual function but carries a risk of radionecrosis of the optic nerve. However, surgical intervention may be required for hydrocephalus, decompression of intraneural cyst, in instances of significant exophytic extension, or biopsy.

**Figure 14.29** Autosomal dominant optic atrophy causing temporal optic disc pallor in both eyes.

Primary malignant gliomas of the optic nerve generally arise in males aged 40–60 years and patients present with rapid monocular visual loss, retrobulbar pain and disc oedema with transient improvement on corticosteroids, signs mimicking optic neuritis. However, within several weeks of treatment visual function deteriorates again and contralateral visual loss develops. There may be an associated central retinal vein or artery occlusion as a result of vascular compression. Radiotherapy and adjunctive chemotherapy may slow progression somewhat but spread along the optic nerve sheath usually occurs within a few months with a uniformly poor prognosis.

### Hereditary optic neuropathies

#### Autosomal dominant optic atrophy

Autosomal dominant optic atrophy typically commences in childhood or the teenage years and is characterised by insidious binocular visual loss which is highly variable. It commonly affects the papillo-macular nerve fibre bundle causing loss of central vision manifest as impaired visual acuity with a bilateral symmetrical central or centro-caecal scotoma and mild impairment of colour vision. Optic atrophy is often localised to the temporal portion of the optic nerve (Figure 14.29) and there may be associated sensorineural hearing loss. The condition is transmitted as an autosomal dominant with high penetrance although there is variability even within families. The gene responsible (*OPA1*) is located on the long arm of chromosome 3 although there is considerable genetic heterogeneity.

#### Leber's hereditary optic neuropathy

Leber's hereditary optic neuropathy (LHON) typically presents in young adults with subacute painless loss of central vision which develops over 3–6 months; however, there is considerable variability in the age of onset and rate of progression. While the onset may be bilateral and symmetrical, in up to 50% of patients one eye is affected initially followed by similar loss in the fellow eye developing within 4–6 weeks. The rate of visual loss is considerably quicker than in dominant hereditary optic atrophy and progressively worsens over several weeks although sudden and complete visual loss may occur.

On examination there is marked impairment of visual acuity and colour vision, with a central or centro-caecal scotoma with preservation of the peripheral field (Figure 14.30). The disc may appear normal but the condition is characterised by a triad of hyperaemia with swelling of the optic nerve fibre layer around the

**Figure 14.30** Acute Leber's hereditary optic neuropathy (LHON); optic disc shows hyperaemia and telangiectatic vessels (arrow).

**Figure 14.31** Bitemporal optic disc pallor in established LHON.

disc ('pseudopapilloedema'), telangiectatic vessels on the disc and in the circumpapillary region with the absence of leakage on fluorescein angiography. Optic nerve involvement progresses to optic atrophy with non-glaucomatous cupping, pallor and attenuation of the arterioles (Figure 14.31). The optic disc abnormalities may be present for many years prior to the onset of visual loss and may be seen in unaffected carriers of the mutation.

Some patients may have cardiac conduction defects or other neurological features including pyramidal signs with brisk reflexes, cerebellar ataxia and tremor, movement disorders, distal sensory neuropathy or encephalopathy and some patients have been reported to develop MS. It is therefore important to exclude LHON in patients with severe visual loss resulting from MS. The prognosis for restoration of vision is poor but some patients do recover vision spontaneously many years later.

LHON is a mitochondrial disorder that is maternally inherited. It is caused by point mutations within the mitochondrial genome at nucleotide positions 11778, 3460 and 14484 in genes that encode subunits of the respiratory chain. The 11778 mutation is the most common and has the worst visual prognosis with a 4% improvement rate. However, 25–40% of patients with mutations at sites 14484 and 3460 experience improvement in visual acuity and the field deficit.

It is important to consider the diagnosis in any patient with painless, relatively rapid visual loss particularly with an asymmetrical onset and to distinguish the condition from toxic nutritional optic neuropathy.

### Toxic and nutritional optic neuropathies

Toxic and nutritional neuropathies are often considered together because it is difficult to distinguish the relative contribution, particularly in tobacco- or alcohol-related amblyopia. Clinically toxic and nutritional deficiencies present with subacute bilateral central visual loss with impaired acuity, centro-caecal scotomata and impaired colour vision. Toxic and deficiency optic neuropathies are almost always bilateral although one eye may be affected before the other. The optic disc appears hyperaemic at onset but temporal pallor develops as a later finding and there is selective vulnerability of the papillo-macular bundle. The loss of vision usually evolves slowly over months, with moderate to severe impairment of acuity although complete blindness may result from methanol toxicity.

Tobacco-alcohol amblyopia is usually associated with excessive tobacco consumption with or without alcoholism or poor nutritional intake. A similar syndrome is associated with vitamin B<sub>12</sub> deficiency and may occur with vitamin B<sub>12</sub> levels that remain in the low normal range. Nutritional optic neuropathy may occur in a number of settings including chronic alcohol abuse, starvation, malabsorption syndromes or depression.

Toxic amblyopia (Chapter 19) is particularly associated with amiodarone, ciclosporin and digoxin and may develop with other neurological manifestations including peripheral neuropathy, ataxia and tremor. In Cuban epidemic optic neuropathy there is an associated peripheral neuropathy, myelopathy and sensorineural hearing loss.

### Traumatic optic neuropathy

Traumatic optic neuropathy typically results from damage to the optic nerve and its blood supply from pial vessels within the optic canal following an indirect blow to the bony orbital rim. Less commonly there is penetrating orbital trauma. Orbito-cranial fractures may be absent even when optic nerve function is significantly affected (Figure 14.32). Visual loss is variable but may be severe. There is no evidence for improvement following corticosteroids or decompression of the optic nerve.

### Radiation-induced optic neuropathy (Chapters 19 and 21)

This can occur in up to 15% of patients who have received radiotherapy with doses up to 5000 cGy but may occur with smaller doses if there has been coexisting chemotherapy or diabetes mellitus. Visual loss occurs 4 months to 8 years after radiotherapy with a relatively rapid progression in one or both eyes. The optic disc is initially normal but pallor develops. There is no effective treatment but single case reports describe improvement in response to corticosteroids, anticoagulants and hyperbaric oxygen therapy. A transient and self-limiting form may occur which is usually treated with corticosteroids.

### Swollen optic disc

Optic disc swelling (Figure 14.33) is the end result of many pathological processes (Table 14.8). A swollen disc implies axonal distension and elevation of the optic disc. Papilloedema is the term used when the cause is elevated intracranial pressure, but local disease of the optic nerve itself and intraocular processes may produce a similar ophthalmoscopic picture.

Figure 14.32 Traumatic optic nerve avulsion from scleral canal.

**Pseudopapilloedema (Table 14.5)**

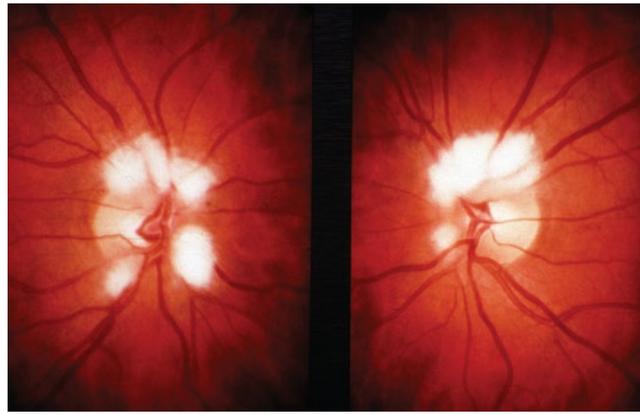

NB The term papilloedema should be reserved for cases of optic disc swelling caused by raised intracranial pressure.

**Figure 14.34** Optic disc drusen visible on disc surface (arrow).

The optic disc may also appear swollen because of bilateral anomalous disc appearances. Local causes for disc swelling (e.g. optic neuritis, ischaemic optic neuropathy and compressive lesions; Table 14.8) are frequently unilateral and often present with ipsilateral visual loss and a relative afferent pupillary defect.

**Specific optic disc anomalies**

**Optic disc drusen** These are small hyaline concretions on the surface or 'buried' beneath the optic nerve head causing elevation of the optic disc but no other features of true swelling. They are usually bilateral and drusen may be easily visible. Up to 70% of patients with this anomaly have a field defect including enlargement of the

**Figure 14.35** Myelinated retinal nerve fibres.

blind spot and arcuate or infero-nasal defects but central vision is preserved. Drusen may be associated with retinitis pigmentosa and are transmitted as an autosomal dominant trait (Figure 14.34).

**Tilted disc** This is a non-hereditary condition characterised by bilateral elevation of the supero-temporal disc, posterior displacement of the infero-nasal disc, situs inversus of the retinal vessels and bitemporal visual field defects. The elevated superior disc may be mistaken for segmental swelling but there is no hyperaemia or obscuration of the peri-papillary vessels.

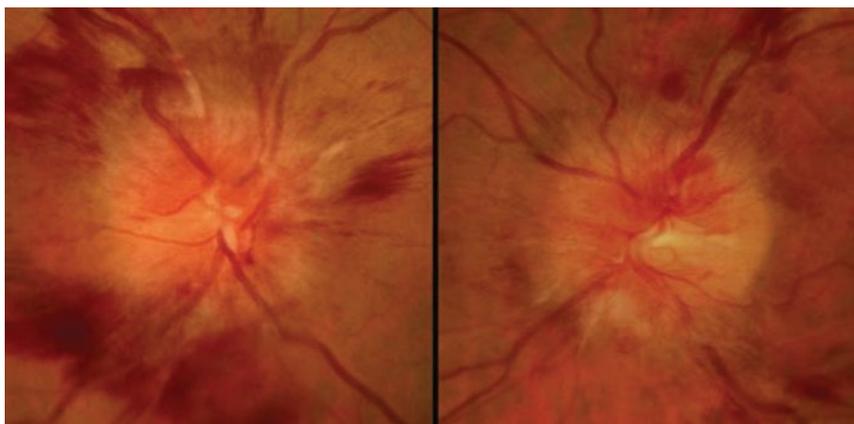

**Myelinated nerve fibres** These appear as white striated patches, often at the upper and lower poles of the optic disc, which typically spare the papillomacular bundle. They rarely affect acuity or visual field (Figure 14.35).

**Papilloedema**

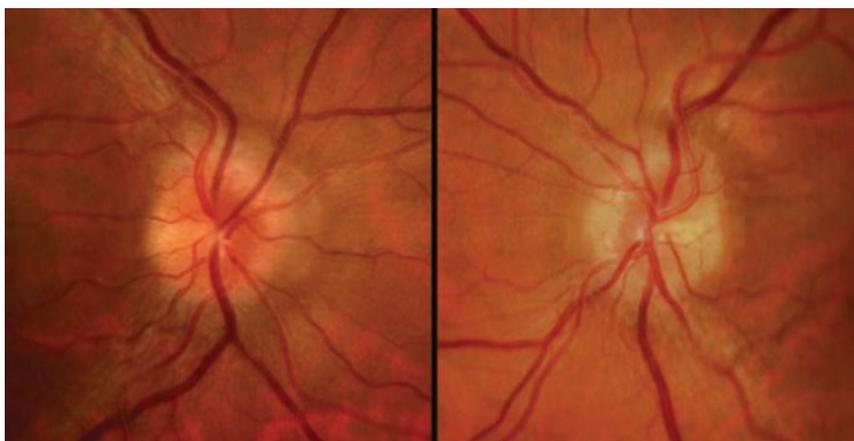

Papilloedema is the most common cause of optic disc swelling without visual loss and is caused by raised intracranial pressure (Figure 14.36). This may occur as a result of the following:

- 1 An intracranial mass (e.g. tumour, abscess or haemorrhage)
- 2 Excessive production of CSF (e.g. choroid plexus papilloma)
- 3 Blockage of arachnoid villi by blood or protein (e.g. infection, sarcoidosis, carcinomatous meningitis)
- 4 Obstruction of flow of CSF through the ventricles (e.g. aqueduct stenosis)
- 5 Decreased flow of venous blood through the dural sinuses (venous sinus thrombosis)
- 6 Idiopathic intracranial hypertension (see Idiopathic intracranial hypertension).

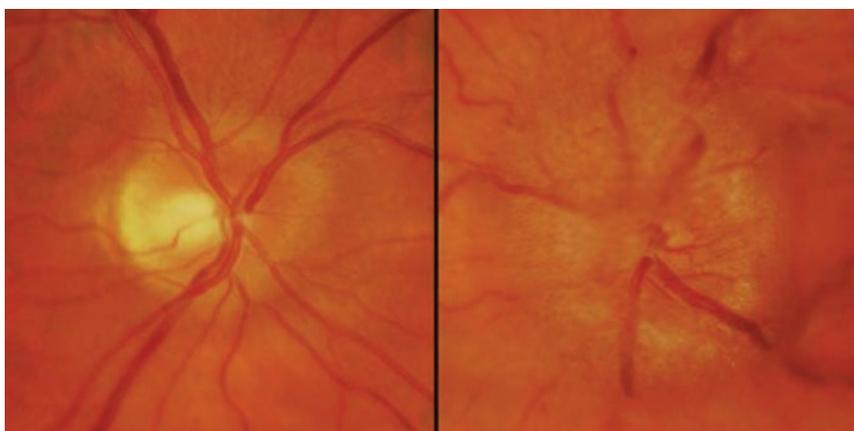

Patients with papilloedema may report transient binocular visual obscurations which occur occasionally or many times a day and are often related to changes in posture. There may be diplopia caused by unilateral or bilateral VIth nerve palsy. In the early stage, visual loss only occurs if haemorrhages, exudates and oedema develop over the macula or in the subretinal fluid or if there is a mass lesion involving the optic nerve or chiasm. On examination the visual field is initially normal but as disc swelling worsens, there is an enlarged blind spot. If intracranial pressure is severe enough to cause compression and axonal loss an arcuate scotomatous defect develops and with continued damage generalised field constriction occurs although visual acuity remains preserved unless the field loss is severe. It is unclear why the papillomacular bundle (i.e. the portion of the ganglion cell layer subserving central vision) is spared until late.

**Figure 14.36** Acute haemorrhagic papilloedema.

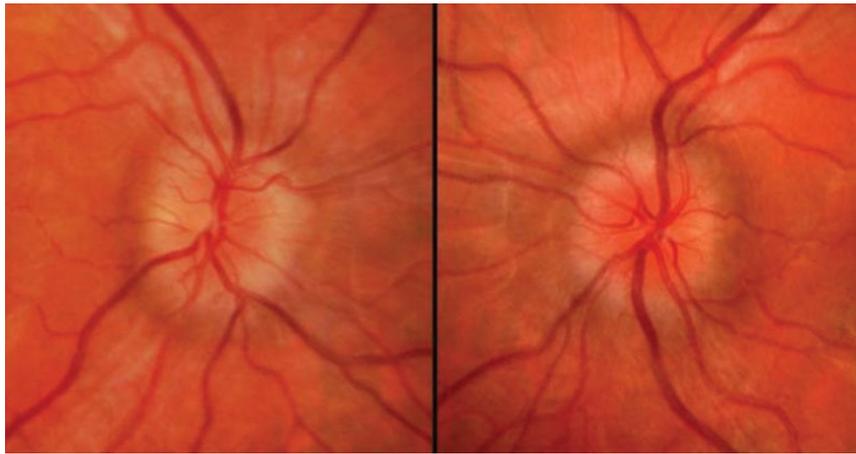

**Figure 14.37** Early papilloedema.

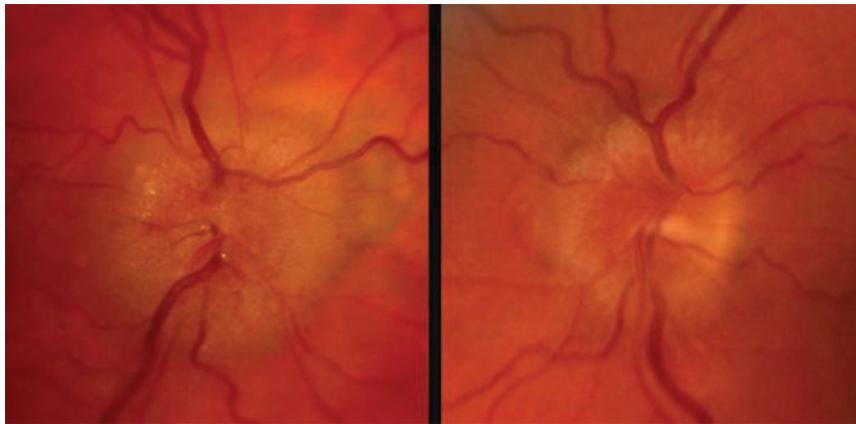

**Figure 14.38** Asymmetric bilateral papilloedema.

The disc appearance varies with severity. In early papilloedema there may be only mild swelling of the optic disc with no evidence of haemorrhages or dilation of retinal veins (Figure 14.37). However, as papilloedema worsens the discs become increasingly swollen and hyperaemic and the vessels become obscured by swollen tissues and spontaneous venous pulsation is lost. Peri-papillary flame-shaped haemorrhages may appear with folds in the retina and/or macula

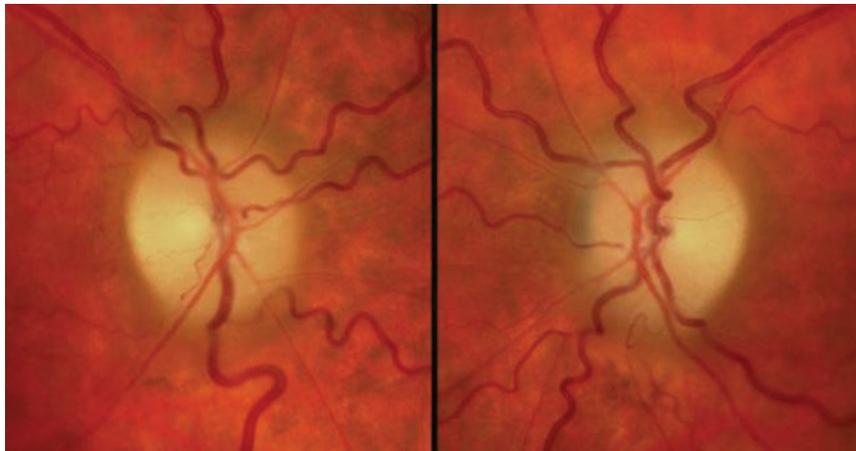

which rarely compromise vision. When papilloedema is fully developed visual acuity and colour vision are normal but the blind spot is enlarged and severe field constriction is present. With chronic papilloedema the discs become pale and the margins clearer, haemorrhage resolves but the constricted visual field persists (Figures 14.38, 14.39 and 14.40). Eventually, atrophic papilloedema occurs when the swelling has resolved and led to the death of nerve

**Figure 14.39** Chronic compensated papilloedema.

**Figure 14.40** Vintage papilloedema with corpora amylacea.

**Figure 14.41** Atrophic papilloedema.

fibres (Figure 14.41). The optic discs are pale, visual acuity is reduced and the visual fields are severely constricted.

Papilloedema can only develop if there is patency of the subarachnoid space surrounding the optic nerve. If these spaces are blocked by adhesions, papilloedema does not occur. Loss of the nerve fibres in optic atrophy will also prevent the development

of papilloedema. Development of papilloedema depends on increased pressure in the distal optic nerve sheath, decreased perfusion of the axons exiting through the lamina cribrosa and possibly elevated central retinal venous pressure. Disturbance of both slow and fast axoplasmic transport are a feature of papilloedema.

### Idiopathic intracranial hypertension

Idiopathic intracranial hypertension (IIH) is a disorder of elevated intracranial pressure of unknown cause which may lead to visual loss due to papilloedema. The condition usually occurs in obese women of childbearing age.

The diagnosis depends on fulfilling the modified Dandy criteria:

- 1 Symptoms and signs of elevated intracranial pressure in an awake and alert patient.
- 2 No localising symptoms or signs other than a VIth nerve palsy.
- 3 Normal neuroimaging apart from changes due to the raised pressure itself.
- 4 Lumbar puncture showing elevated opening pressure (>250 mm/H<sub>2</sub>O) but normal fluid analysis.

Intracranial hypertension may be idiopathic or may develop secondarily to a number of underlying conditions, particularly venous sinus thrombosis. The clinical features of idiopathic and secondary intracranial hypertension may be identical. However, the treatment of the secondary form depends on the underlying cause and it is therefore extremely important to exclude another underlying cause before making a final diagnosis of IIH.

Clinically, IIH presents with headache in >90% of patients, it is characteristically severe, daily and pulsatile; nausea and vomiting may be present. There may be retrobulbar pain with eye movements and radicular pain in the neck and shoulders radiating down the arms. Transient visual obscurations lasting for seconds or minutes and associated with postural changes are present in up to 70% of patients. Tinnitus is common and some patients develop hearing loss. Diplopia, usually horizontal is present in up to 40% of patients usually resulting from a VIth nerve palsy. Other symptoms include impaired coordination and sense of smell and numbness or motor weakness.

On examination only 15% of patients who present with IIH have impairment in visual acuity but significant visual field loss is common. An afferent pupillary defect suggests asymmetric visual loss and is present in the eye with the greatest amount of field loss. VIth nerve palsies are relatively common because of stretching of the nerve by intracranial hypertension. A IIIth nerve palsy may occur in IIH but other causes must be excluded. Signs of optic disc swelling include elevation and blurring of the disc margin, a peripapillary halo, venous congestion and tortuosity, retinal exudates and retinal infarcts (cotton wool spots). Significant visual loss is likely when there are nerve fibre layer haemorrhages, subretinal neovascularisation, cotton wool spots, choroidal folds or macular oedema. Papilloedema may be unilateral or asymmetrical, and optic nerve atrophy suggesting long-standing papilloedema may be present in up to 10% of patients. The appearances may be striking enough to mimic Foster Kennedy syndrome or AION.

Visual field abnormalities are frequent; enlargement of the blind spot and constriction of the fields are the most common manifestation. Other visual field defects include arcuate or centro-caecal scotomatous lesions, nasal visual field loss or loss of visual acuity alone. Visual field testing shows a greater sensitivity when compared with visual acuity and contrast sensitivity.

Venous sinus thrombosis leads to increased pressure within the dural sinuses which, in turn, causes poor absorption of CSF through the arachnoid granulations and this leads to papilloedema and headache. Venous sinus thrombosis is discussed in Chapter 5. The most important causes include:

- Hypercoagulable states
- Thrombocythaemia
- Behçet's disease
- Oral contraceptive use

- Pregnancy
- Local infection
- Iatrogenic trauma (e.g. subclavian vein thrombosis following catheter insertion)
- Mass lesions in the venous sinus (e.g. meningioma, metastases or cystic lesions).

IIH has been associated with a number of aetiological factors although clear evidence of a causal relationship is lacking. Endocrine disorders are likely to be important because of the strong female bias, association with obesity and the relationship of IIH to hypoparathyroidism and thyroid disorders, Addison's disease and Cushing's disease. IIH is also associated with obstructive sleep apnoea, medications including antibiotics (naladixic acid, ciprofloxacin, tetracyclines, minocycline and nitrofurantoin), hormonal medications including growth hormone and the oral contraceptive, and corticosteroids. The strongest link of IIH is with hypervitaminosis A or retinoid excess. Stopping the medication relieves the symptoms.

**Investigations** MRI shows that up to 70% of patients have an empty sella, presumably caused by long-standing effects of pulsatile high-pressure CSF causing downward herniation of the arachnoid through a defect in the diaphragm sellae. Other features include reversal of the optic nerve head, flattening of the posterior sclera, enhancement of the prelaminar optic nerve, distension of peri-optical subarachnoid space, vertical tortuosity of the orbital optic nerve and intraocular protrusion of the prelaminar optic nerve.

Poor prognostic features for visual loss include long-standing swelling of the optic disc with atrophy, visual field or acuity loss at first examination, delay in treatment, systemic hypertension, older age, male gender and increased intraocular pressure. Pre-existing disc anomalies such as drusen and an optic pit may also worsen the prognosis for visual outcome.

**Management** Medical treatment of the underlying condition includes weight loss with restriction of calorie, salt and fluid intake. Repeat lumbar punctures may be necessary and in self-limiting disease this approach may tide patients over until spontaneous remission.

Symptomatic therapy is routinely used. Acetazolamide is a strong carbonic anhydrase inhibitor that reduces CSF production and is highly effective in IIH. The dose is gradually increased to 0.5–1 g/day although higher doses are occasionally necessary. Many patients develop evidence of toxicity with digital or peri-orbital tingling, anorexia or a metallic taste. Other diuretics such as bendroflumethazide and can be used if acetazolamide is not tolerated. High-dose corticosteroids are normally only given in rare instances of severe visual failure in the short term, prior to CSF diversion surgery.

Surgical options, when required for intractable headache or progressive visual loss, include shunting and optic nerve sheath decompression (ONSD). The preferred shunt technique (normally either lumbar–peritoneal or ventricular–peritoneal) varies according to local expertise but effective shunting remains the best way of controlling headache and/or severe visual loss. ONSD is often used in instances when headache is minimal and visual loss is less severe, meaning that more invasive shunting procedures can be avoided.

### Ocular involvement in other neurological disease

#### Uveomeningitic syndromes

Uveomeningitic syndromes are a group of disorders in which there is involvement of the uveal tract (either the iris, ciliary body or the choroid), the retina and the meninges. The causes are listed in Table 14.9.

**Table 14.9** Causes of uveomeningitic syndromes.

Inflammatory	Vogt–Koyanagi–Harada Sarcoidosis Beçhet’s syndrome SLE Wegener’s granulomatosis
Infections	Borrelia, syphilis, TB, leprosy, <i>Neisseria meningitidis</i> Fungi – candida, coccidiomycosis CMV, herpes simplex, HZV, HIV, hepatitis B SSPE
Neoplasia	Primary B-cell lymphoma Large cell or intravascular lymphoma Leukaemia Metastatic carcinoma, paraneoplastic
Primary ophthalmological	Acute posterior multifocal placoid pigment epitheliopathy Multiple evanescent white dot syndrome Posterior scleritis

CMV, cytomegalovirus; HZV, herpes zoster virus; SLE, systemic lupus erythematosus; SSPE, subacute sclerosing panencephalitis; TB, tuberculosis.

**Sarcoidosis** Up to 60% of patients with sarcoidosis may have ocular involvement and this may be the presenting feature (Chapter 26). Conjunctival nodules and uveitis are commonly associated conditions and posterior segment inflammation is particularly seen with neurological involvement. The optic nerve appears swollen because of the intraocular inflammation but may be directly involved by granulomas or meningeal change. Retinal abnormalities in sarcoidosis include periphlebitis with haemorrhages and choroidal granulomas.

**Behçet’s disease** Inflammatory ocular disease can occur in 70% of patients and usually manifests itself as a bilateral panuveitis (Chapter 26). The pathognomonic features of the uveitis are a hypopyon in the anterior chamber and retinal infiltrates in the posterior segment. Recurrent attacks of retinal vein occlusion also occur and after sequential attacks optic atrophy and permanent visual loss ensue.

Inflammation of the optic nerve is unusual, but intracranial hypertension and papilloedema may develop in isolation or secondary to venous sinus thrombosis. Historically, visual prognosis has been poor as the ocular inflammation responds poorly to regular immunosuppressives but the introduction of biological agents such as rituximab and infliximab is changing the outcomes.

**Vogt–Koyanagi–Harada disease** Vogt–Koyanagi–Harada disease (VKH) is a granulomatous multi-system inflammatory disorder that affects the eyes, the auditory system, meninges and the skin. The cause is unknown. There may be meningism, tinnitus and a CSF pleocytosis; skin involvement is characterised by alopecia, poliosis (whitening of the eyebrows) and vitiligo. Early ocular involvement is characterised by uveitis and serous retinal detachment. Late manifestations are usually bilateral and include choroidal and retinal depigmentation.

**Table 14.10** Causes of retinal involvement in neurological disease.

Retinitis pigmentosa	Hereditary Neurodegenerative disorders – abetalipoproteinaemia (Bassen– Kornzweig syndrome), Refsum’s disease, adrenoleukodystrophy
Salt and pepper retinopathy	Kearns–Sayre syndrome Hallervorden–Spatz disease
Cone–rod dystrophy	Multiple system atrophy Spinocerebellar atrophy type 7 Juvenile Batten’s disease
Cherry red spot	Tay–Sachs disease Niemann–Pick disease Sialidosis
Paraneoplastic retinopathy	Cancer-associated retinopathy Melanoma-associated retinopathy
Viral retinitis	Acute retinal necrosis

**Multiple sclerosis** In MS (Chapter 11) the most common ocular manifestation is optic neuritis; however, symptomatic uveitis may occur in up to 3% of patients and asymptomatic changes in the retinal vessels including periphlebitis and sheathing or cuffing of the retinal veins with lymphocytes and plasma cells can be demonstrated on fluorescein angiography in a greater number. Visual loss in MS is therefore not always a result of optic neuritis but may, albeit rarely, be caused by uveitis with macular oedema, previous haemorrhage or retinal vascular change with neovascularisation.

**Retinitis pigmentosa** Retinitis pigmentosa may occur as an isolated genetic defect or as part of a variety of other diseases in particular mitochondrial disorders (Table 14.10). Isolated hereditary forms of retinitis pigmentosa may be autosomal recessive (<60%), autosomal dominant (<25%) and, rarely, X-linked. The X-linked and recessive forms are typically more severe than the autosomal dominant form. More than 20 genes coding for this disorder have now been recognised but the most common abnormality lies in the genes for rhodopsin and peripherin.

The initial loss in the rod dystrophy form of retinitis pigmentosa occurs in the mid-peripheral visual field with an inability to see as clearly in dim light as in bright light (nyctalopsia). There is then a progressive loss of the peripheral visual field. The fundus initially shows a grey discoloration of the retinal pigment epithelium but with progression pigmented cells migrate into the retina leading to a characteristic bone spicule appearance with ‘waxy’ pallor of the optic nerve and attenuated retinal vessels.

In contrast, cone dystrophies are caused by involvement of the photoreceptors in the region of the macula. These cause blurred vision and an inability to see as clearly in bright light as in dim light. There is loss of the central field of vision manifest as a reduction in visual acuity or a central scotoma with loss of colour vision. Initially the fundus appears normal but as the condition progresses there is pigmentary degeneration of the macular (‘bull’s-eye maculopathy’). Eventually, optic disc pallor develops which mimics primary optic nerve disease.

Retinal pigmentary changes are associated with several forms of mitochondrial disease including neurogenic muscle weakness, ataxia and retinitis pigmentosa (NARP), myoclonic epilepsy, lactic acidosis, stroke-like episodes (MELAS) and Kearns–Sayre syndrome. In NARP, retinal involvement is manifest as a cone–rod dystrophy with variable involvement of each form of photoreceptors. The severity of the disease correlates with the extent of the mutation in mtDNA. Pigmentary change is noted in the first or second decade of life and associated with bilateral symmetrical ptosis. The macula is often affected initially followed by the peripheral retina with pigment clumping, atrophy and a ‘salt and pepper’ retinopathy. The visual acuity and fields are only mildly affected. There may be systemic and neurological involvement (Chapter 10). Retinal involvement has also occasionally been reported in subacute necrotising encephalopathy (Leigh’s disease) which is also ascribed to a mitochondrial respiratory chain deficiency. Retinitis pigmentosa has also been associated with a variety of metabolic abnormalities affecting amino acid protein or lipoprotein metabolism (Chapter 19).

### Neoplasia

Metastatic disease is the most common form of intraocular malignancy. Lesions may involve the choroid, retina or vitreous humor. The lung and breast are the most common primary sources. Primary intraocular lymphoma occurs in up to 25% of patients with primary CNS lymphoma but ocular involvement may occur in isolation. Ocular lesions are variable. There may be a posterior uveitis with vitreous cellular infiltration. The characteristic lesion is a subretinal infiltrate which appears creamy yellow and is associated with retinal pigment epithelial detachment. There may be discrete pale retinal lesions or vascular changes including vasculitis.

Paraneoplastic syndromes include carcinoma-associated retinopathy in which a progressive subacute bilateral visual loss is associated with pigmentary retinal change and arteriolar narrowing with sheathing. Patients who have the paraneoplastic disorder characterised by the IgG autoantibody CRMP-5 may present with progressive visual loss caused by a combination of vitritis, retinitis and optic neuritis. The optic disc becomes swollen, there is diffuse leakage from all retinal vessels and histologically lymphocytes are found throughout the retina, although on funduscopy there is no frank area of white fluffy retinitis.

### The phakomatoses in neuro-ophthalmology

The phakomatoses comprise a group of dominantly inherited diseases in which tumours both benign and malignant arise in different organ systems and in which tissues of ectodermal origin (CNS, skin and eye) are prominently involved.

#### Neurofibromatosis types 1 and 2 (Chapters 16 and 26)

Neurofibromatosis type 1 (NF1) is the most common with a frequency of about 1 in 3000. The gene has 100% penetrance but variable expression. NF1 is inherited as an autosomal dominant trait but about 50% of new cases are considered to be new mutations. The diagnostic criteria for NF1 are met if a person has two or more of the following:

- Six or more café au lait spots over 5 mm in greatest diameter in prepubertal individuals and 15 mm in post-pubertal individuals
- Two or more neurofibromas or one plexiform neuroma
- Axillary or inguinal freckles
- Optic glioma
- Two or more iris nodules

**Figure 14.42** Iris hamartomas (Lisch nodules) in neurofibromatosis type 1 (NF1) (arrows).

- Distinctive osseous lesion (e.g. sphenoid dysplasia)
- A first degree relative with NF1.

Ocular features of NF1 include iris hamartomas, known as Lisch nodules (Figure 14.42) or melanocytic naevi which are detectable in about 50% of 5-year-olds, 75% of 15-year-olds and 95–100% of adults over 25 years. Individuals with NF1 may also have congenital glaucoma, anterior subcapsular cataract, posterior segment hamartomas, retinal vascular occlusions and pulsating exophthalmos due to sphenoid dysplasia. Retinal and choroidal hamartomas are occasionally seen, but these are a more typical feature of neurofibromatosis type 2 (NF2). Up to 70% of optic gliomas arise in patients with NF1 – typically these present in early childhood and have a benign histology and clinical course.

The gene for NF1 is located in the long arm of chromosome 17 – band q11.2. Within this gene is an area coding for a GAP-like protein which may act as a growth regulator interacting with an oncogene to produce benign and occasionally malignant tumours. The unpredictability of disease severity even in the same NF1 gene mutation makes genetic counselling difficult.

NF2 is a much rarer disease than NF1 with a population incidence of 1/33 000–40 000. At least 50% of new cases appear to be new mutations. Like NF1, NF2 has an extremely high penetrance. The hallmark of NF2 is the presence of bilateral vestibular nerve schwannomas; diagnostic criteria are met if a person has either of the following:

- 1 Bilateral VIIIth nerve masses seen with appropriate imaging
- 2 A first degree relative with NF2 and either unilateral VIIIth nerve mass or one of the following:
  - Neurofibromas
  - Meningioma
  - Glioma
  - Schwannoma
  - Juvenile posterior subcapsular lenticular opacity.

Patients with NF2 tend to develop tumours of neural coverings and sheaths – meningiomas including optic nerve sheath meningiomas, schwannomas and ependymomas whereas those with NF1 tend to develop neural or astrocytic tumours – astrocytomas and gliomas. Although presentation in NF2 is typically the result of hearing loss, more than 75% of patients with NF2 have posterior subcapsular cataract, and occasionally optic nerve sheath meningioma. Other ocular findings include combined retinal pigment epithelial and retinal hamartomas, epiretinal membranes, optic disc gliomas, retinal haemangiomas, medullated nerve fibres,

choroidal naevi, uveal melanoma and choroidal hamartoma. Lisch nodules are occasionally seen.

The NF2 gene is located on chromosome 22q band 11.2. In sporadic forms of the disease the vestibular schwannomas develop at a later age and may occur unilaterally.

### Von Hippel–Lindau disease (Chapter 26)

Von Hippel–Lindau (VHL) disease is a pleiotropic autosomal dominant inherited familial cancer syndrome characterised by a predisposition to develop haemangioblastomas of CNS and retina, renal cell carcinoma, pheochromocytoma and renal, pancreatic and epididymal cysts. The minimum birth incidence in the United Kingdom is 1/36 000. The gene for VHL disease has been mapped to chromosome 3p25–p26, and the clinical importance lies in the fact that long-term morbidity and mortality can be reduced by pre-symptomatic diagnosis of ocular, CNS and renal involvement.

Although clinical heterogeneity is common, retinal angiomas is the most frequent initial manifestation and develops in more than 70% of patients by the age of 60 years. Retinal haemangiomas (or more correctly, haemangioblastomas) are most commonly seen in the peripheral retina but may also occur on the optic disc itself. Ophthalmological screening requires dilated direct and indirect funduscopy together with fluorescein angiography for the detection of nascent, preclinical lesions.

Current criteria for diagnosis of VHL are as follows.

A. Without family history, two of the following:

- Retinal or CNS haemangioblastoma
- Pheochromocytoma
- Renal cell carcinoma, or
- Renal/pancreatic/epididymal cysts.

B. Positive family history, one of the above.

Current screening recommendations in an affected individual are:

- 1 Annual physical examination and urinalysis including 24-hour vanillylmandelic acid levels (VMAs)
- 2 Annual ophthalmological examinations
- 3 Brain imaging 3-yearly to age 50, then 5-yearly
- 4 Annual renal ultrasound and 3-yearly abdominal CT scanning.

When screening of an at risk relative is required, this protocol is modified so that the eyes are examined from age of 5 years (with fluorescein angiography from age 10), brain imaging is undertaken 3-yearly from age 15 to 40 and then 5-yearly, and abdominal imaging is commenced from age 20.

### Tuberous sclerosis

The triad of epilepsy, retinal tumours and adenoma sebaceum referred to as tuberous sclerosis or Bourneville's disease has now been widened and the term tuberous sclerosis complex (TSC) is applied. All tissues are involved, most typically brain and retina but also skin, heart, kidneys and lungs. TSC is inherited as an autosomal dominant trait showing marked genetic heterogeneity. It appears that different families may have different mutations: in some pedigrees the mutation location is at chromosome 9q34.1–q34.2 and in others it is at 11q14–q23. Diagnosis is based on the presence of:

- 1 Cortical tubers, or
- 2 Multiple hamartomas associated with cortical tubers:
  - Subependymal nodules
  - Facial angiofibromas
  - Renal angiomyofibroma

and three other associated lesions:

- Giant cell astrocytomas
- Retinal hamartoma

**Figure 14.43** Retinal hamartomas in a patient with tuberous sclerosis.

- Ungual fibroma
- Fibrous forehead plaque.

Fifty per cent of patients have retinal or optic nerve hamartomas: other ocular abnormalities include adenoma sebaceum on the eyelids and colobomas. A wide range of neuro-ophthalmic features including retrochiasmal field defects, ocular motility abnormalities and papilloedema reflect intracranial involvement. The retinal hamartomas may be calcified or non-calcified lesions of both glioblastic and angioblastic origin – patches of focal congenital retinal pigment epithelial hypertrophy may also be seen (Figure 14.43). In contrast to VHL disease, retinal hamartomas in TSC are only rarely associated with visual loss. The differential diagnosis of non-calcified hamartomas includes retinoblastoma in infants, and calcified hamartomas on the optic nerve may resemble florid calcified peripapillary disc drusen seen in retinitis pigmentosa.

### Sturge–Weber syndrome (encephalo-trigeminal angiomatosis)

Sturge–Weber syndrome (SWS) is a further vascular neuro-cutaneous syndrome often classed alongside the phakomatoses, but without a familial basis or associated tumours. Typically, angiomas involve the meninges and the skin of the face, typically the ophthalmic ( $V_1$ ) and maxillary ( $V_2$ ) distributions of the trigeminal nerve, giving rise to the cutaneous facial port-wine stain. Ipsilateral intracranial calcifying meningeal lesions affect the ipsilateral parietal and occipital regions leading to epilepsy, developmental delay, learning disability and homonymous visual field loss. Ocular involvement is characterised by glaucoma as well as haemangiomas of the choroid, conjunctiva and episclera. In type 1 SWS, both facial and leptomeningeal angiomas arise and patients may have glaucoma; in type 2, facial angiomas and glaucoma arise without leptomeningeal involvement, and in type 3 there is isolated leptomeningeal involvement without a facial angioma or glaucoma.

## Abnormalities of eye movements

### Diplopia

Disturbances of eye movements may occur as a consequence of either reduced or excessive ocular motility. Diplopia results from:

- Dysfunction of the extraocular muscles, caused by local factors
- Impairment of neuromuscular junction

- Disturbance of the cranial nerves at any point throughout their long course
- Lesions at a nuclear or supranuclear level within the brainstem or central pathways.

Oscillopsia (illusory movement of static objects) results from nystagmus or saccadic intrusion. Binocular diplopia is caused by ocular misalignment and therefore resolves if one eye is covered and is absent if there is severe monocular visual impairment. Monocular diplopia persists if one eye is closed and is generally caused by local eye disease, refractive error or functional disorders.

The character and pattern of diplopia should be established by history and examination. It is important to clarify whether the separation of images is maximal on vertical, horizontal or oblique gaze, whether any corrective head position is favoured and whether the diplopia is worse at a distance (typically in a VIth nerve palsy) or for near objects (e.g. medial rectus palsy). Diplopia is worse when looking in the field of action of a paretic muscle or in the opposite field to a restricted muscle (i.e. when it is being stretched). Diplopia may be absent, despite ocular misalignment, if there is impaired acuity in one eye, if the separation is particularly wide or narrow and the false image can be suppressed or if the ocular misalignment is long-standing or has been present from birth. The presence of pain on eye movement suggests a local orbital or myopathic process while orbital or peri-orbital pain is characteristic of vascular, neoplastic, inflammatory or infective disorders.

The principles of examination of the extraocular movements are outlined in Chapter 4. The presence of pupillary asymmetry or impaired reactions may be important (e.g. a fixed dilated pupil may indicate parasympathetic involvement in a compressive IIIrd nerve palsy). Involvement of other cranial nerves (e.g. II, V, VII and VIII) is important in localising lesions and a proptosis suggests thyroid ophthalmoparesis or a structural lesion of the orbit. Ocular alignment should be assessed by the corneal light reflex or cover test and the eye movement examination includes assessment of ocular motility in each eye in the nine positions of gaze. The presence of associated local factors (e.g. orbital swelling or dry eyes) or neurological features (e.g. other cranial nerve lesions) may be of localising importance.

Vertical diplopia is present when the patient sees two images displaced vertically or diagonally and suggests impairment of any or all of the superior or inferior recti or oblique muscles. Torsional diplopia from underaction of the oblique muscles is associated with an angular head tilt. Horizontal diplopia, in which the images appear side by side, is usually brought about by involvement of the medial or lateral rectus muscles.

### Orbital disease

The principal causes of restrictive ophthalmopathy are summarised in Table 14.11.

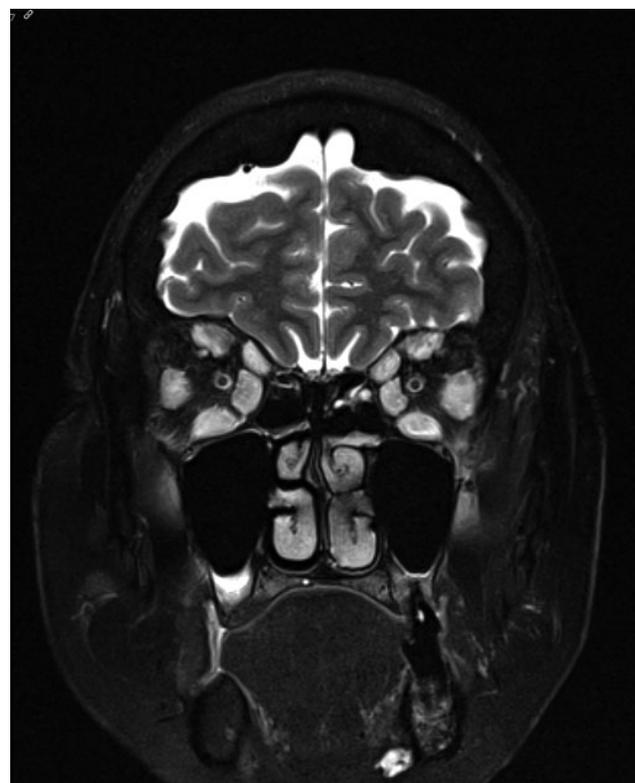

#### Thyroid ophthalmopathy

Thyroid ophthalmology is a common cause of proptosis with horizontal or vertical diplopia. It is associated with Graves' disease in >50% of patients and most of these patients are hyperthyroid at the time of diagnosis (Figure 14.44).

Two phases of the disease are recognised: active and fibrotic. In the active phase, the patient develops lid changes (upper lid retraction and lid lag, puffiness), conjunctival congestion

**Table 14.11** Causes of restrictive ophthalmoplegia (progressive infiltration and fibrosis of extraocular muscles).

Dysthyroid eye disease	
Orbital pseudotumour (myositis)	
Primary or metastatic orbital tumours	Lymphoma
Other orbital masses	Paranasal sinus mucocoele
Intracranial masses extending into orbit	Sphenoid wing meningioma
Infiltration of extraocular muscles	Sarcoidosis, amyloidosis, acromegaly, infection
Entrapment of extraocular muscle due to trauma	
Caroticoavernous fistula	

**Figure 14.44** MRI scan (T2-weighted) showing extraocular muscle thickening in thyroid eye disease.

(chemosis), orbital congestion (proptosis) and extraocular muscle swelling (ophthalmoplegia) in association with water and glycosaminoglycan deposition in the orbital structures together with an inflammatory infiltrate. Vision may be compromised either by such severe proptosis as to cause corneal exposure, or by optic nerve compression at the orbital apex leading to visual failure. Choroidal folds or optic nerve swelling may be seen although fundal examination may be normal.

In the fibrotic phase of the disease, evidence of inflammation (pain, conjunctival congestion, vascular engorgement at the site of tendon insertions into the globe) resolves leaving the patient with variable degrees of proptosis, lid lag and ophthalmoplegia. The limitation of eye movements in the fibrotic phase is principally caused by the healing with fibrosis of the inflammatory infiltrate of the acute phase leaving a restrictive myopathy. In some patients the acute phase is florid and readily diagnosed; in others it is limited and subclinical so that the patient presents later with a restrictive myopathy. The disease may be highly asymmetric or unilateral; extraocular muscle involvement may be selective or generalised. The inferior and medial recti are the two most commonly involved muscles. The diagnosis is made from the history and typical physical signs. Sometimes orbital signs are minimal or absent so that the patient may present with diplopia, most commonly vertical but lid retraction is still usually present.

Treatment of the endocrine disorder rarely affects the thyroid ophthalmology, and although ocular motility defects and lid problems may be treated by elective surgery, compressive optic neuropathy requires high-dose corticosteroids and sometimes urgent endoscopic surgical decompression.

### Orbital inflammatory syndromes

Non-specific idiopathic inflammatory disorders cause double vision associated with marked local pain and may be classified according to their mode of onset, anatomical localisation and physical signs or histopathological subtype. In particular they may be divided into:

- *Orbital pseudotumour* when the inflammation primarily involves the structures in and around the orbit (sclera, ocular muscles and lids).
- *Tolosa–Hunt syndrome* when the inflammation primarily involves the cavernous sinus and superior orbital fissure.
- *Orbital inflammation*: the cellular component of the infiltrate is highly variable but includes mature T lymphocytes, plasma cells, macrophages, eosinophils and polymorphonuclear leukocytes. Connective tissue may show oedema, fibrosis or sclerosis. Clinically, orbital inflammation is associated with localised ipsilateral pain, conjunctival injection, unilateral lid oedema and erythema, proptosis, ophthalmoplegia and a palpable orbital mass.

In Tolosa–Hunt syndrome, involvement of the superior orbital fissure is characterised by:

- Proptosis
- Ophthalmoplegia
- Trigeminal sensory loss
- Horner's syndrome.

Ophthalmoplegia without proptosis suggests cavernous sinus involvement.

Orbital myositis is often unilateral and occasionally only a single muscle is affected but any combination of extraocular muscles may be involved. Symptoms may be caused by paresis or restriction but conjunctival injection and pain on eye movements are characteristic.

Imaging is essential to assess possible orbital mass lesions and paranasal sinus disease: extraocular muscle enlargement in thyroid ophthalmology spares the tendon insertions into the globe in contrast to other inflammatory diseases. The course of orbital inflammatory pseudotumour, orbital myositis and Tolosa–Hunt syndrome is usually one of prompt response to systemic steroids but then relapse as the steroids are reduced which may prompt the use of additional steroid-sparing agents such as azathioprine, methotrexate or mycophenolate mofetil.

Lymphoid tumours are the most common orbital neoplasms and are the most important differential diagnosis of the inflammatory orbital syndromes. If prompt response to steroids does not occur then a biopsy should be considered. Other primary and systemic syndromes must be considered in the differential diagnosis of orbital inflammatory syndromes. Inflammatory disease of the orbit may be infective, particularly in children when it is a medical emergency. In orbital cellulitis, ophthalmoplegia is associated with fever and lid swelling. Proptosis occurs with paranasal sinus or metastatic infection.

Mucormycosis (Chapter 9) is an acute fungal infection which occurs in the immuno-compromised patient and is particularly associated with diabetic ketoacidosis, haematological malignancy and organ transplantation. Rhino-orbital cerebral mucormycosis develops by inhaling spores onto the oral and nasal mucosa following which direct invasion of the orbits occurs via the paranasal sinuses or the brain and via the sphenoid sinus, superior orbital fissure, cribriform plate or via the orbital vessels and nerves. The condition is characteristically unilateral with an acute onset of fever, headache, sinusitis, peri-orbital pain, cellulitis, rhinorrhoea and trigeminal anaesthesia. Ophthalmic involvement is a result of direct fungal infiltration or ischaemic infarction and this leads to acute ophthalmoplegia, proptosis, peri-orbital oedema and blindness from central retinal artery occlusion or an optic neuropathy. Mucormycosis may cause an orbital apex or cavernous sinus syndrome. Neurological involvement may lead to internal carotid artery occlusion, meningitis or cerebral abscess. Radiology shows mucosal thickening, orbital infiltration, bony destruction or ophthalmic vein thrombosis. However, tissue diagnosis is usually established by nasal biopsy demonstrating large branching hyphae that invade the vessels. Mucormycosis carries a high mortality rate and requires aggressive antifungal treatment and surgical debridement.

Inflammatory disease of the orbit may be caused by granulomatous disease (tuberculosis, sarcoidosis), systemic vasculitis (granulomatous polyangiitis) or neoplasm (lymphoma or metastasis). Metastatic cancer (particular breast) may spread to the orbit causing unilateral or bilateral inflammatory masses. Lymphoid neoplasm tends to develop at a later age, is often bilateral and is less characteristically associated with pain or ophthalmoplegia.

### Cavernous sinus thrombosis

A number of conditions may lead to thrombosis within the cavernous sinus. Infection may spread from local structures either directly or via vascular pathways (e.g. facial and dental infections, sinusitis, otitis media or orbital cellulitis). Underlying medical conditions that may predispose to cavernous sinus thrombosis include diabetes mellitus, malignancy and collagen vascular disease. There is usually peri-orbital pain with proptosis, chemosis, ptosis and ophthalmoplegia.

Patients may present with headache, nausea and vomiting, occasionally encephalopathy and early involvement of the VIth nerve occurs before total ophthalmoplegia develops. With increasing venous stasis optic disc swelling may develop leading to optic neuropathy or retinal ischaemia. Meningitis or cerebral abscess is associated with extension beyond the cavernous sinus. The CSF may show meningitis and imaging confirms involvement of the cavernous sinus and superior ophthalmic vein. Other causes of lesions of the cavernous sinus are considered later.

### Carotico-cavernous fistula

Carotico-cavernous fistula (CCF) is an abnormal arteriovenous communication between the carotid artery and the cavernous sinus. The fistula is considered:

- *Direct*: if the arterial supply is derived from the internal carotid artery itself, or
- *Indirect*: if the supply is via the extradural meningeal branches of the internal or external carotid artery.

The fistula is indirect in >90% of cases and may be located anywhere along the course of the intracavernous carotid artery. It may project anteriorly or posteriorly.

The most common cause of CCF is head trauma which may be either penetrating or non-penetrating and not necessarily associated with a fracture of the skull base. Other causes include rupture of an intracavernous aneurysm, systemic vasculopathy, Ehlers–Danlos syndrome or fibromuscular dysplasia. Direct CCF may present within a few days of trauma but indirect CCF may be delayed and manifest with mild signs such as red eye and subtle orbital congestion. If the blood escapes posteriorly through the superior and inferior petrosal sinuses, ocular signs may be minimal although an expanded inferior petrosal sinus will cause direct compression of the VIth cranial nerve. However, anterior flow of high pressure arterial blood into the orbital veins leads to raised episcleral venous pressure, reduced arterial perfusion pressure and venous stasis. Although the signs are usually ipsilateral, the contralateral eye may be involved because of the variable connections between the two cavernous sinuses.

In an anterior direct CCF there is pulsatile proptosis associated with chemosis, arterialisation of the conjunctival vessels and an orbital bruit. Ophthalmoplegia may be a result of compression of the cranial nerves within the cavernous sinus or direct muscle involvement with orbital hypoxia and oedema due to venous stasis. Visual loss occurs as a result of retinal ischaemia, ischaemic optic neuropathy, intracranial optic nerve compression or corneal ulceration. These effects result from a reduction in retinal blood flow, because of a drop in effective ophthalmic artery perfusion pressure, together with venous stasis caused by arterialisation of the orbital venous circulation. Fundal examination shows features of a slow flow retinopathy with mild disc swelling, blot haemorrhages and micro-aneurysms, venous congestion and tortuosity. Central retinal vein occlusion, glaucoma, retinal detachment and vitreous haemorrhage may occur. The diagnosis is established on imaging by enlargement of the superior ophthalmic vein. Rapid diagnosis is essential because high intracranial venous pressure may cause venous haemorrhage. Transarterial balloon embolisation is the most effective treatment.

Indirect CCFs are low-flow dural-based arteriovenous malformations which are typically non-traumatic. Symptoms are often mild with conjunctival injection, mild ophthalmoplegia and elevated intraocular pressure or retinal vasculopathy which may threaten vision. Rarely, orbital congestion may become severe if there is thrombosis of the superior ophthalmic vein. MRI may show distension of the cavernous sinus, of the superior ophthalmic vein and enlargement of the extraocular muscles. Endovascular treatment is indicated if there is significant posterior venous hypertension with the risk of associated cortical venous thrombosis, or if there is significant intraocular pressure rise and risk of visual loss.

### Myopathy

Myopathy involving the extraocular muscles leads to progressive ophthalmoparesis termed chronic progressive external ophthalmoplegia. This syndrome is brought about by a number of causes,

each associated with limitation of eye movements and ptosis but normal pupillary function. Because of the slowly progressive and painless onset, patients are often asymptomatic. Oculocephalic and caloric stimulation do not increase the range of movements reflecting the infranuclear origin of the limitation and there is often symmetrical ptosis and moderate orbicularis oculi weakness.

### Mitochondrial disease

Mitochondrial myopathy (Chapter 10) is an important cause of chronic progressive external ophthalmoplegia (CPEO) (Table 14.12) which may be an isolated finding in cases with mitochondrial or Mendelian autosomal recessive or dominant transmission. Sporadic mitochondrial DNA deletions or duplications are more common than maternally inherited cases. Dominant and recessive forms are associated with genetic mutations in *ANT1*, *POLG*, *POLG2* and *PEO* genes. There may be an associated ‘salt and pepper’ retinopathy or a symptomatic field constriction with bone spicules and disc pallor typical of retinitis pigmentosa.

In Kearns–Sayre syndrome, CPEO, ptosis and retinitis pigmentosa (developing before the age of 20) are associated with cardiac conduction deficit (heart block often requiring a pacemaker), cerebellar signs and a raised CSF protein. CPEO is also prominent in mitochondrial gastrointestinal encephalomyopathy. Muscle biopsy shows the presence of ‘ragged red fibres’ within a population of relatively normal fibres on modified Gomori trichrome staining representing degenerate mitochondria. Electron microscopy confirms abnormal morphology of the mitochondria. A deletion in the mitochondrial DNA can be detected in >90% of patients with Kearns–Sayre syndrome and in 50% with CPEO alone.

### Oculopharyngeal dystrophy

This is an inherited dystrophy affecting extraocular and bulbar muscles which is usually transmitted in an autosomal dominant pattern but rarely may be recessive. Bulbar weakness, if prominent, leads to severe dysarthria and dysphagia, predominantly affecting liquids with marked nasal regurgitation. There is bilateral ptosis, progressive ophthalmoplegia and facial weakness with occasional involvement of the jaw muscles leading to difficulty chewing. Muscle biopsy shows characteristic vacuolar myopathy with tubules.

**Table 14.12** Causes of progressive external ophthalmoplegia.

Mitochondrial myopathy – Kearns–Sayre
Myopathy
Congenital – central core, multicore, centronuclear, myotubular, nemaline
Congenital oculopharyngeal
Myotonic dystrophy
Neuromuscular junction – Myasthenia gravis, Botulism
Neurogenic disease
aBetalipoproteinaemia
Spinocerebellar ataxia

Other causes of myopathy affecting the extraocular muscles include abetalipoproteinaemia (Chapter 19) which is characterised by childhood onset of CPEO, retinopathy and chronic fatty diarrhoea. There is malabsorption, low serum cholesterol and complete absence of beta lipoprotein.

### Neuromuscular junction abnormalities

Ocular myasthenia gravis is discussed in Chapter 10. The ophthalmoparesis is variable and may mimic any abnormal eye movement. It often fluctuates with prominent fatigability and variable ptosis. Nystagmus of an abducting eye mimicking internuclear ophthalmoplegia may occur and can develop rarely in the absence of extraocular muscle limitation. Weakness of orbicularis oculi is usually associated. In long-standing ocular myasthenia there may be a severe fixed ophthalmoplegia with ptosis which may be difficult to distinguish from myopathy or mitochondrial disorder. Extraocular muscle involvement may be found in congenital myasthenia but is not common in paraneoplastic Lambert–Eaton myasthenic syndrome.

Botulism (Chapters 9 and 20) is associated with external ophthalmoplegia and ptosis which may precede the development of dilated, poorly reactive pupils and paralysis of accommodation. The presence of associated gastrointestinal symptoms and muscarinic anticholinergic effects helps to distinguish botulism from myasthenia gravis.

### Cranial nerve palsies

#### Oculomotor nerve (IIIrd nerve palsy)

The IIIrd nerve originates in several subnuclei in the dorsal midbrain (Table 14.13). The fascicles exit the brainstem ventrally in close relation to the red nucleus and cortico-spinal tract. The nerve traverses the subarachnoid space and passes through the lateral wall of the cavernous sinus (Table 14.14). Just before entering the orbit via the superior orbital fissure, it divides into a superior branch, which innervates the levator palpebrae superioris and the superior rectus, and an inferior branch which innervates the inferior and medial recti, the inferior oblique and the iris sphincter and ciliary muscle. In the subarachnoid space and cavernous sinus the pupillomotor fibres

**Table 14.13** Causes of oculomotor (IIIrd) nerve palsy.

Location	Clinical features	Aetiology
Nucleus	III (i/l) but with c/l superior rectus involved. Ptosis either bilateral or absent	Infarction Haemorrhage Trauma Tumour Infection

Infection	Herpes zoster
Inflammatory	Tolosa–Hunt syndrome, vasculitis, Granulomatosis with polyangiitis (Wegener's granulomatosis)

of the IIIrd nerve lie superficially and dorsally and are vulnerable to compression from above. The IIIrd nerve supplies the medial rectus, inferior oblique, inferior rectus and superior rectus muscles, the lid levator and the parasympathetic innervation of the pupillary sphincter and ciliary body. Patients with a IIIrd nerve palsy complain of binocular diplopia. With a complete lesion there is ptosis, a fixed dilated pupil and the eye is deviated 'downward and outward' with residual function only in abduction (lateral rectus) and intorsion (superior oblique). Elevation, depression and adduction of the eye are impaired. With partial lesions involvement of extraocular muscles is incomplete and the pattern may resemble myopathic or restrictive disorders. In microvascular disease, the perforating vasa nervorum are primarily occluded affecting the central fibres and extraocular movements, and sparing the pupillomotor fibres.

Aberrant reinnervation (oculomotor synkinesis) is relatively common following oculomotor nerve injury or prolonged compression as with meningioma or aneurysm. A number of characteristic patterns are seen. These include co-contraction of the levator and medial rectus on attempted adduction or co-contraction of levator and inferior rectus on attempted down-gaze and pupillary constriction on medial or downward eye movement.

### Abducens (VIth) nerve palsy

Abducens nerve palsy causes binocular horizontal diplopia due to ipsilateral rectus paresis with a primary position esotropia. The causes are summarised in Table 14.15.

The VIth nerve nucleus is located in the caudal paramedian pontine tegmentum beneath the floor of the IVth ventricle. The facial nerve loops around the nucleus and the medial longitudinal fasciculus (MLF) passes medially. The fascicle has a long intrapontine course and lesions are frequently associated with other neurological signs. It emerges from the brainstem ventrally and traverses the subarachnoid space in close relationship to the anterior inferior cerebellar artery. Within the cavernous sinus it lies free in the body unsupported by the sinus wall (unlike III and IV) before passing through the annular segment of the superior orbital fissure to innervate the lateral rectus muscle.

### Trochlear (IVth) nerve palsy

Trochlear nerve palsy causes binocular vertical diplopia with tilting of objects (torsional diplopia) which is worse on looking down and is caused by ipsilateral superior oblique weakness (Table 14.16). There is elevation of the affected eye with vertical diplopia and head tilt away from the side of the lesion.

The trochlear nerve originates in the dorsal midbrain. The fascicle passes laterally to the aqueduct and exits the midbrain dorsally. The nerves cross in the superior medullary velum before passing around the midbrain tectum to reach the free end of the tentorium and then pass forward into the wall of the cavernous sinus. The nerve enters the orbit through the superior orbital fissure and innervates the contralateral superior oblique muscle.

Congenital trochlear palsy is relatively common and may be caused by aplasia of the nucleus or a developmental anomaly of the superior oblique tendon in the orbit. The trochlear nerve is rarely involved by intrinsic brainstem lesions because of the short intramedullary course of its fascicle. Isolated trochlear nuclear lesions cause a contralateral superior oblique palsy. There is usually also a Horner's syndrome ipsilateral to the lesion because of the proximity of sympathetic fibres. Bilateral IVth nerve palsy may be caused by a lesion in the superior medullary velum.

The most common cause of trochlear palsy is trauma, possibly because the tectum of the midbrain shifts as a result of contre-coup trauma and may compress the IVth nerve either in the superior medullary velum or against the tentorial notch. Microvascular ischaemic disease may also cause IVth nerve palsy. Other causes of IVth nerve palsy are summarised in Table 14.16.

### Painful and combined ophthalmoplegia

Multiple ocular motor palsies are usually unilateral and result from lesions in the cavernous sinus or superior orbital fissure. The principal causes are summarised in Table 14.17.

Bilateral lesions suggest a diffuse disorder of muscle (see Myopathies), a neuromuscular abnormality (e.g. myasthenia gravis) or a neurogenic cause (e.g. Guillain–Barré syndrome, Miller Fisher syndrome), diffuse infiltrative brainstem lesions, infection or neoplastic disease affecting the meninges. Painful combined ophthalmoplegia is usually caused by inflammatory, neoplastic or vascular disease; other causes are summarised in Table 14.18.

### Central disorders of eye movements

Normal vision requires the ability to shift gaze rapidly to bring an object of attention into foveal vision (saccadic system) and a system to stabilise the new image on this area even if there is movement of the object (smooth pursuit and vergence) or of the head and body (vestibulo-ocular and opto-kinetic reflexes). The anatomical and physiological basis of these systems is discussed in specialised texts.

Supranuclear eye movement abnormalities result when the cerebral, cerebellar and brainstem afferent inputs to the ocular motor nuclear are disrupted.

### Saccadic eye movements

The assessment of saccadic eye movements is mentioned briefly in Chapter 4. They are best examined by telling the patient to fixate alternately between two targets: saccades in each direction can be examined in each field of gaze in both horizontal and vertical planes. The examiner notes whether the saccades are of normal velocity, promptly initiated, accurate and conjugate.

**Table 14.15** Causes of abducens (VIth) nerve palsy.

c/l, contralateral; i/l, ipsilateral; ICA, internal carotid artery; SLE, systemic lupus erythematosus; TB, tuberculosis; VZV, varicella zoster virus.

Disorders of saccadic eye movements consist of abnormalities of velocity, accuracy, initiation, premature termination of gaze during saccades and the presence of saccadic intrusions and oscillations.

**Velocity** Slow saccadic movements occur either in the direction of a paretic extraocular muscle or, if there is an internuclear ophthalmoplegia, in adduction. Slow saccades with a full range of movement occur in degenerative disorders affecting the parapontine reticular formation: spinocerebellar ataxia, Alzheimer's, Parkinson's and

Huntington's diseases. Slowing of vertical saccades is characteristic of progressive supranuclear palsy (PSP) while prolonged latency of saccadic movements is seen in corticobasal degeneration. In myasthenia the initial velocity of the saccade may be abnormally fast with fatigue during the course of the movement.

**Accuracy** Dysmetric (inaccurate) saccades are seen in cerebellar disorders, neurodegenerative conditions or as a consequence of drug toxicity (particularly anticonvulsants). In lesions of the

cerebellar vermis and brachium conjunctivum, saccades may have an abnormally large amplitude (hypermetric) away from the side of the lesion. Saccadic hypermetria leads to macro-saccadic oscillation around the target. These oscillations may also be associated with hypometric saccades.

**Initiation** Delayed initiation of saccadic movements and prolonged latency may be caused by lesions anywhere within the saccadic pathways, particularly frontal, collicular or pontine damage. Saccadic latency is increased in PSP and cortico-basal degeneration. Ocular motor apraxia is characterised by loss of voluntary control of saccadic and pursuit eye movements with preservation of reflex movements, especially slow and quick phases of the vestibulo-ocular reflex. Patients have difficulty in making horizontal and vertical saccades to command although reflex and random saccades are normal. Ocular motor apraxia may be congenital but when acquired indicates bilateral hemispheric disease and is particularly associated with Balint's syndrome and cortical visual loss (see Visual cortex). Abnormalities of saccadic initiation are also common in parkinsonian syndromes and progressive ataxia.

**Impersistence and gaze distractibility** Saccadic movements are often abnormal in neurodegenerative disease, particularly Alzheimer's, when large amplitude saccadic intrusions deviate the eyes away from the intended direction of gaze. There may also be a distractibility of gaze in which there is an inability to fix on a target while being distracted by an alternative peripheral target. On head turning there may be an ocular deviation with skew and the complete absence of saccadic movements. In neurodegenerative disorders period alternating gaze deviation with tonic deviation of the eyes and the head to one side may also occur followed by a slow deviation over 10–15 seconds to the other side.

**Intrusions** Saccadic intrusions may take several forms. Square wave jerks occur during fixation when there is a conjugate displacement of the eye followed by a refixation saccade. These are seen in

**Table 14.18** Causes of painful ophthalmoplegia.

ICA, internal carotid artery.

cerebellar disease and PSP but are also described in many other neurodegenerative disorders. High-amplitude macro-square wave jerks are seen in cerebellar disorders, multiple system atrophy and Chiari malformation. In ocular flutter, which occasionally occurs in MS, there are bursts of saccades with no intersaccadic interval. Opsoclonus (saccadomania) suggests brainstem (particularly pontine) disease. This is a multi-directional sequence of conjugate saccadic eye movements of large amplitude which persist during eye closure and sleep. It occurs as a paraneoplastic or post-infective phenomenon and may be associated with drug ingestion.

### Horizontal gaze palsy

Horizontal gaze palsy refers to a restriction of conjugate eye movements that affect both eyes in a symmetrical manner. Unilateral restriction of horizontal voluntary gaze is usually caused by a contralateral frontal or ipsilateral pontine lesion.

Frontal lobe lesions occur acutely as the result of a cerebrovascular event affecting ipsilateral horizontal smooth pursuit and causing a sustained ipsilateral horizontal gaze deviation with head rotation – the patient is said to be looking towards the side of the lesion and away from the hemiparesis. The gaze palsy can be overcome by oculo-cephalic stimulation and usually resolves over several days although residual impairment of saccadic and smooth pursuit persists. Frontal horizontal gaze palsy is usually caused by an extensive vascular lesion often haemorrhagic involving the post-Rolandic cortex or subcortical fronto-parietal region and the internal capsule. Adversive eye deviation is associated with an epileptic focus but this often resolves rapidly.

Lesions of the posterior parietal cortex and temporo-occipital parietal region cause ipsilateral horizontal gaze preference and decrease the gain and maximum velocity of smooth pursuit eye movements towards the side of the lesion. Contralateral sensory and visual inattention may be associated.

Thalamic lesions cause abnormalities of horizontal and vertical gaze with conjugate deviation of the eyes away from the side of the lesion and towards the hemiparesis. Pontine lesions involving the paramedian pontine reticular formation (PPRF) or the VIth nerve nucleus lead to a horizontal gaze palsy with the eyes deviated away from the side of the lesion and an inability to move either eye beyond the midline towards the side of the lesion. The palsy may be incomplete. Oculo-cephalic stimulation by passive horizontal

rotation of the head directly stimulates the VIth nerve but will not overcome the gaze palsy caused by pontine nuclear or infranuclear lesions. Horizontal gaze palsy in the pons may be a result of ischaemia, infarction, acute infection or inflammatory change, tumours or trauma.

### Vertical gaze palsy

Vertical gaze palsy may be caused by lesions affecting the visual pathway from the cortex (frontal and parieto-occipital) to the vertical gaze centre in the rostral midbrain. Rarely, non-dominant hemispheric lesions may cause up-gaze palsies and thalamic lesions have also been associated with vertical gaze palsy.

Midbrain disorders most commonly result in disturbances of vertical eye movements that can be related to involvement of the posterior commissure, the rostral interstitial nucleus of the MLF (riMLF) or the interstitial nucleus of Cajal (iC). Lesions in the posterior commissure cause loss of up-gaze and Parinaud's syndrome (dorsal midbrain or pretectal syndrome) which includes lid retraction (Collier's sign) and occasionally ptosis, down-gaze preference, disturbance of vergence eye movements including convergence–retraction nystagmus, skew deviation and pupillary light near dissociation (see Convergence–retraction nystagmus in Parinaud's syndrome). The lesion is usually bilateral and Parinaud's syndrome is caused by tumours (pinealoma, glioma, metastases), obstructive hydrocephalus (dilation of the 3rd ventricle and aqueduct) and by vascular occlusion (perforating branches of posterior cerebral artery) or thalamic and midbrain haemorrhage.

Up-gaze palsy resulting from lesions of the rostral midbrain nuclei is associated with hypersomnolence and impaired consciousness because there is involvement of the reticular activating system. There may be behavioural disturbances, associated with thalamic impairment, including amnesia, apathy, slowness of thought and akinetic mutism. This clinical pattern is seen as part of the 'top of the basilar syndrome'.

Bilateral defects in the riMLF result either in paralysis of down-gaze or loss of downward saccades. This is seen in a number of neurodegenerative or metabolic storage diseases including PSP, Niemann–Pick disease type C, Whipple's disease, Wilson's disease and Wernicke's syndrome. Combined loss of up-gaze and down-gaze for all eye movements suggests extensive bilateral rostral midbrain impairment involving riMLF and interstitial nucleus of Cajal.

### Oculogyric crises

Oculogyric crises are episodes of fixed conjugate upward (and occasionally lateral) deviation of the eyes first described in encephalitis lethargica. The crises are accompanied by behavioural disturbances including obsessive thoughts or depression and dystonic or dyskinetic limb movements. The episodes occur most commonly in association with metoclopramide or neuroleptic medication but are also described with other forms of brainstem encephalitis, parkinsonian syndromes or as a paraneoplastic phenomenon. The anatomical basis remains unknown.

### Internuclear ophthalmoplegia

Internuclear ophthalmoplegia (INO) is caused by a lesion of the MLF which lies between the VIth nerve nucleus and the contralateral medial rectus oculomotor subnucleus. The abducens nerve and the MLF coordinate conjugate horizontal eye movements with co-contraction of the contralateral medial rectus and ipsilateral lateral rectus. If there is a lesion of the MLF the horizontal PPRF can communicate with the adjacent ipsilateral VIth but the other

pathway to the contralateral IIIrd nerve nucleus is interrupted. This leads to impaired adduction (incomplete and decreased velocity) of the eye ipsilateral to the MLF lesion and ataxic nystagmus of the contralateral eye. The nystagmus may be the most prominent feature. Convergence is usually preserved because the IIIrd nerve and medial rectus continue to work normally if conjugate movements are not required. When INO is bilateral there is usually vertical nystagmus on up-gaze. INO is a characteristic sign of demyelination resulting from MS or other forms of inflammation but is also common in brainstem vascular disease. It is also seen in Wernicke's encephalopathy and can occur as a paraneoplastic sign.

### One and a half syndrome

This is associated with a unilateral lesion of the dorsal pontine tegmentum affecting the ipsilateral PPRF, MLF and VIth nerve nucleus. There is dysconjugate horizontal gaze palsy and an internuclear ophthalmoplegia leading to complete impairment of horizontal gaze in the direction of the lesion and impaired adduction when looking in a contralateral direction. Vertical movements and convergence are spared. This condition is usually caused by a pontine infarct or MS although any structural lesion may be responsible.

### Wall-eyed bilateral internuclear ophthalmoplegia

Wall-eyed bilateral internuclear ophthalmoplegia (WEBINO) occurs if, in the presence of bilateral internuclear ophthalmoplegia, both eyes deviate laterally rather than remaining aligned in the primary position, convergence is often absent. This is caused by extensive lesions involving each MLF.

### Internuclear ophthalmoplegia of abduction

This describes paresis of ipsilateral abduction occasionally associated with adducting nystagmus in the contralateral eye. This has been associated with ipsilateral rostral pontine and mesencephalic lesions. The paresis of abduction may be prenuclear and suggests an ipsilateral inhibitory correction between the PPRF and oculomotor nucleus.

### Disconjugate vertical gaze palsy

A number of disconjugate vertical gaze palsies have been described. These include mononuclear elevator paresis in which the eyes are straight in the primary position of gaze but the affected eye will not elevate. Full elevation on eye lid closure confirms the supranuclear origin of the defect. It is associated with a lesion immediately rostral to the oculomotor nucleus. A vertical one and a half syndrome may also occur in association with vertical up-gaze palsy and monocular paresis of down-gaze associated with thalamo-mesencephalic infarction.

### Skew deviation and ocular tilt reaction

Skew deviation is a vertical misalignment caused by an acquired supranuclear or vestibulo-ocular dysfunction. Hypertropia may be the same (concomitant) in all positions of gaze or may vary with eye position or alternate in left and right gaze. Non-concomitant skew deviation can mimic a single extraocular muscle paresis but there are usually accompanying brainstem signs. Skew deviation represents an imbalance in the otolith input because of a peripheral or central lesion. There is generally a downward and outward rotation of the eye on the side of the lesion and upward and inward rotation of the opposite side. Skew deviation is often associated with an INO. In some patients, skew deviation may be associated with ocular torsion which can be sustained (tonic or paroxysmal) and give rise

to a compensatory head tilt – the ocular tilt reaction. Skew deviations are seen commonly in disruptions of the otolith-ocular pathways as a result of acute peripheral disease, and lesions of the vestibular nerve and nuclei, intrinsic brainstem lesions affecting the MLF and cerebellar disorders.

## Nystagmus

### Horizontal nystagmus

Nystagmus is an involuntary rhythmic regular oscillatory movement in one or both eyes in any field of gaze. It usually consists of alternating phases of slow drift with a quick corrective fast 'jerk' saccade in the opposite direction (jerk nystagmus). In some cases the movements have the same speed in both phases which is usually slow and sinusoidal (pendular nystagmus). Nystagmus reflects a disorder in the mechanisms that maintain steady gaze. Nystagmus occurring in the comatose and critically ill patient is discussed in Chapter 20.

### Nystagmus in normal subjects

Some normal subjects show endpoint gaze evoked nystagmus on extreme lateral or vertical gaze. This may be asymmetrical having a greater amplitude in the abducting eye but tends to wane after several seconds (Table 14.19). Optokinetic nystagmus (OKN) is a jerk nystagmus induced by moving repetitive visual stimuli across the visual field. It is composed of an initial slow pursuit eye movement and a compensatory fast saccadic movement that shifts the eyes back towards fixation. This is a physiological form of nystagmus and the amplitude in the two eyes is equal regardless of the direction in which the stimulus is moved. The optokinetic response is reduced in association with lesions of the deep parietal lobe. Reduced OKN amplitude of an affected eye in adduction is a valuable way of demonstrating an internuclear ophthalmoplegia. Normal OKN pattern is retained with functional visual loss.

### Jerk nystagmus

Jerk nystagmus is characterised by an initial slow drift away from the fixation target followed by a fast correcting phase back towards the target. The abnormal slow phase is mediated by the smooth pursuit system and the fast phase by the saccadic system. It is the direction of the fast component that defines the direction of the nystagmus. The amplitude is normally increased on gaze in the direction of the fast component (Alexander's law). Nystagmus in the primary position is defined by its trajectory (i.e. horizontal, torsional, upbeat, downbeat or mixed) and by the direction of the fast phase.

### Pendular nystagmus

In pendular nystagmus both phases of the oscillation are symmetrical. The movement is usually vertical with a torsional component superimposed but may be horizontal, oblique or rotatory.

**Table 14.19** Nystagmus in normal subjects.

Endpoint nystagmus
Fatigue nystagmus
Optokinetic nystagmus
Voluntary nystagmus

It is usually present in the primary position and does not vary with gaze direction. The movements may fluctuate, be different in both eyes or may be monocular. Occasionally, saccadic or fast phases may be superimposed upon a pendular nystagmus. It may be congenital but in acquired cases typically causes severe oscillopsia which interferes with reading and is associated with impairment of visual acuity and visual blurring. Specific forms of pendular nystagmus include spasmus nutans, oculo-palatal myoclonus, see-saw nystagmus and oculo-masticatory myorhythmia (in Whipple's disease). Acquired pendular nystagmus arises as a late manifestation of MS and it may also be associated with lesions in the pontine tegmentum particularly with brainstem stroke and encephalitis.

### Nystagmus in childhood

Latent nystagmus (fusional maldevelopment nystagmus syndrome) in childhood is a congenital jerk nystagmus that only appears when one eye is covered (Table 14.20). It is a conjugate jerk nystagmus beating with the fast phase towards the fixating eye. When the other eye is covered, the nystagmus reverses its direction. Latent nystagmus may become manifest as oscillopsia in patients with strabismus, amblyopia or acquired visual loss who are only able to fix monocularly (manifest latent nystagmus).

Congenital nystagmus (infantile nystagmus syndrome) is noted at birth or in early infancy but may rarely emerge in teenage years or adulthood. The oscillations are generally horizontal and conjugate in all directions of gaze and are either pendular or a mix of jerk and pendular wave forms. The movements diminish with vergence and increase on attempted fixation. The amplitude can vary in different gaze positions but the direction of the nystagmus does not fluctuate. Some patients adopt a compensatory head turn to use the position with the lowest amplitude of ocular movement. Patients with congenital nystagmus show an inversion of OKN in which the quick phase is directed in the same direction as the drum is rotating. Congenital nystagmus is absent during sleep. It is usually idiopathic but may be associated with structural ocular lesions, retinal dystrophies or optic neuropathies. The nystagmus block syndrome refers to a form of conjugate horizontal congenital nystagmus that is absent or minimal when the fixating eye is in adduction but becomes more marked when it is in abduction.

### Pendular nystagmus from visual loss

Vertical pendular nystagmus can result from any condition that causes visual loss in early childhood (Table 14.20). In adults, vertical pendular nystagmus may develop many years after visual loss. Nystagmus is usually low amplitude and low velocity and may resolve if vision is restored.

**Table 14.20** Types of nystagmus in children.

Congenital nystagmus	
Acquired nystagmus	Secondary to structural brain lesion
	Secondary to any condition causing reduced vision
	Monocular – optic glioma
	Spasmus nutans
	Nystagmus block syndrome

### Spasmus nutans

This is a rare and benign syndrome that develops in infancy (<14 months) and resolves by 3 years. It is characterised by nystagmus, head nodding and abnormal head posture. The nystagmus is usually horizontal and pendular although it may be oblique. It is usually of low amplitude and high frequency and characteristically either monocular or markedly disconjugate. The head nodding usually appears first and disappears with sleep or changes in head position. The condition is often transient with good residual visual acuity although it can occasionally be associated with structural lesions causing impaired visual acuity.

### Monocular nystagmus

This is often caused by spasmus nutans or uniocular visual loss from optic glioma. However, in practice it is more usually brought about by an asymmetrical congenital nystagmus.

### Vestibular jerk nystagmus

This is caused by abnormalities in the peripheral or central vestibular system causing an imbalance in the mediation of the smooth pursuit eye movements. Diseases of the peripheral vestibular system involving the labyrinth or vestibular nerve result in a unidirectional horizontal or mixed horizontal jerk nystagmus with the fast phase directed away from the side of the lesion. The amplitude of the nystagmus increases as the eyes are turned in the direction of the fast phase. It is reduced by visual fixation and intensified by factors causing loss of visual fixation including the dark, wearing Frenzel goggles or by sudden changes in head position. Clinical correlates of peripheral labyrinthine disturbance include tinnitus, vertigo, deafness and falling in the direction of the lesion.

### Gaze evoked or gaze paretic jerk nystagmus

Gaze evoked nystagmus is induced by holding gaze in an eccentric position. It is the most common form of nystagmus encountered in clinical practice. The eyes are unable to maintain the eye position and the orbital elastic tissue causes them to drift back into the primary position. This is followed by a corrective saccadic eye movement giving rise to the nystagmus. If an associated paresis of gaze is present, either because of a peripheral or central disturbance, the nystagmus is termed gaze paretic. Gaze evoked nystagmus is usually asymptomatic and is only rarely associated with oscillopsia or poor balance from gait ataxia. It is a relatively large amplitude nystagmus which beats in the direction of gaze and is associated with rebound nystagmus on return to primary position and impairment of horizontal smooth pursuit movements. An associated fatigue nystagmus may occur in normal subjects or in myasthenia gravis after extended maintenance of eccentric gaze. Gaze evoked nystagmus is associated with many medications including antiepileptic drugs, sedative and alcohol and may also be caused by structural lesions of the vestibulo-cerebellum or the brainstem.

### Caloric nystagmus

Cold water instilled into the external auditory meatus results in a jerk nystagmus with the fast phase beating away from the irrigated side when the head is maintained at a 30° angle. Irrigation induces repetitive slow phases that are corrected by opposite directed saccadic quick phases. The presence of normal caloric nystagmus indicates that the brainstem vestibulo-ocular connections and the IIIrd and VIth cranial nerves are intact. Disturbances of caloric nystagmus have been discussed in more detail in Chapter 15.

### Torsional nystagmus

This is usually caused by a brainstem lesion affecting the central projections from the anterior and posterior semicircular canals and the otolith, therefore interrupting the vestibular input to the ocular motor centres. Torsional nystagmus usually beats away from the side of a brainstem lesion and is a conjugate movement associated with oscillopsia. There is generally an associated skew deviation and impairment of smooth pursuit movements. There may also be an internuclear ophthalmoplegia and associated midbrain lesion affecting vertical gaze. Torsional nystagmus is usually caused by infarction of the brainstem but may be associated with MS, tumours or rhombencephalitis.

### Central vestibular horizontal nystagmus

This is a low amplitude nystagmus in the primary position which is seen in patients with reduced pursuit movements because of large cerebral lesions. Lesions of the vestibular nuclei or cerebellar flocculus result in a variety of forms of nystagmus which may be bidirectional or purely vertical (upbeat or downbeat) but less commonly may be torsional or horizontal. Fixation does not reduce the amplitude and Frenzel goggles or darkness do not intensify the oscillations. Central vestibular nystagmus is usually associated with vascular lesions, MS or brainstem tumours. The fast phase of the nystagmus is directed towards the side of the lesion. Patients with cerebellopontine angle lesions may manifest both a gaze paretic nystagmus to the side of the lesion, as a result of a horizontal pontine gaze paresis, and a faster beating nystagmus in the opposite direction associated with vestibular involvement.

### Vertical and other forms of nystagmus

#### Downbeat nystagmus

This is a jerk nystagmus in which there is a fast phase saccadic movement beating in a downward direction (Table 14.21). This occurs in the primary position and increases with downward and lateral gaze. It causes blurred vision, oscillopsia and gait imbalance. It is associated with lesions of the dorsal medulla leading to loss of tonic downward vestibular input causing the eyes to drift upwards or of the cerebellar flocculus which removes its tonic inhibition of upward vestibular eye movements. Downbeat nystagmus is therefore associated with gaze

evoked and rebound nystagmus and abnormal smooth pursuit movements. Lower brainstem involvement may cause a coexisting internuclear ophthalmoplegia or skew deviation.

Downbeat nystagmus is particularly associated with lesions at the cervico-medullary junction (e.g. Arnold–Chiari malformation) but is also seen in spino-cerebellar degeneration and in association with drug toxicity in particular antiepileptic drugs, lithium and alcohol.

#### Upbeat nystagmus

Upbeat nystagmus is a jerk nystagmus characterised by a slow downward drift and a saccadic correcting fast phase beating upward (Table 14.22). It is associated with midline lesions of the ponto-medullary or ponto-mesencephalic junctions causing loss of vestibular upward eye movement input. Oscillopsia is less frequent than with downbeat nystagmus and patients are either asymptomatic or complain of blurred vision. Upbeat nystagmus occurs in the primary position and increases with up-gaze. Impaired upward pursuit is seen and the condition is often associated with poor horizontal pursuit, gaze evoked nystagmus and rebound nystagmus. If the cause is a low brainstem lesion there may also be a skew deviation and an internuclear ophthalmoplegia. Upbeat nystagmus is caused by cerebellar degeneration, brainstem or cerebellar strokes and demyelination but may also occur with toxicity and Wernicke's encephalopathy.

Other forms of vertical eye movement disorders may be seen in states of impaired consciousness and are discussed in Chapter 20.

#### Nystagmus in oculopalatal tremor

This may be associated with an asymptomatic palatal tremor. More commonly, palatal tremor is symptomatic and follows brainstem infarction or cerebellar degeneration. The nystagmus is usually a slow vertical regular pendular movement, synchronous with the palatal movement. Oculopalatal tremor is associated with brainstem involvement and is often seen with a horizontal gaze or lower cranial nerve palsy, cerebellar dysarthria or damage to the spinothalamic tract. It is associated with lesions of the dentato-rubro-olivary region (Mollaret's triangle) which lead to denervation of the inferior olive which appears hypertrophied on MRI.

**Table 14.21** Causes of downbeat nystagmus.

Craniocervical abnormalities	Arnold–Chiari malformation, basilar invagination, syringobulbia, Paget's disease, platybasia
Toxic – metabolic	Antiepileptic drugs lithium, alcohol (Wernicke's encephalopathy)
Cerebellar degeneration	Spinocerebellar atrophy, paraneoplastic, familial episodic ataxia, multiple system atrophy
Raised intracranial pressure	
Infarction	
Infection	
Demyelination (rare)	
Cerebellar tumour	
Head trauma	
Heat stroke	

**Table 14.22** Causes of upbeat nystagmus.

Infarction	Medulla, cerebellum or superior cerebellar peduncle
Posterior fossa tumour	
Demyelination (common)	
Wernicke encephalopathy	
Brainstem encephalitis	
Behçet's disease	
Meningitis	
Congenital	Leber's neuropathy
Toxins	Tobacco Antiepileptic drugs Ciclosporin
Paraneoplastic	

### See-saw nystagmus

In see-saw nystagmus there is alternating elevation and intorsion of one eye while the opposite eye falls and extorts. Both components of the movements are pendular and they occur in rapidly alternating sequence. It is usually present in all positions of gaze but maximal in down-gaze. This form of nystagmus is associated with bitemporal hemianopia usually from a large suprasellar mass such as a craniopharyngioma or pituitary adenoma. The lesion often causes expansion of the 3rd ventricle. It is also associated with vascular disease, particularly affecting the rostral mesencephalon.

### Oculomasticatory myorhythmia

Oculomasticatory myorhythmia is a continuous slow rhythmic convergent–divergent nystagmus (i.e. the eyes oscillate horizontally towards and away from each other). There are synchronous diffuse muscle contractions particularly involving masticatory or facial muscles and occasionally the palate and mouth. This form of nystagmus is associated with Whipple's disease and occurs in about 20% of patients. There is often also a supranuclear gaze palsy affecting vertical and then horizontal eye movements with eventual loss of all eye movements.

### Periodic alternating nystagmus

Periodic alternating nystagmus may occur as a congenital or acquired manifestation; it is a spontaneous horizontal jerk nystagmus that is present in primary position of gaze. It is present in one direction for around 120 seconds, it then stops for 5–20 seconds before beating in the other direction for a similar duration. In the interval between direction change, there may be a vertical nystagmus or square wave jerks. The horizontal nystagmus is least when looking in the direction of the slow phase. A complete cycle takes approximately 4 minutes and therefore may be missed on routine clinical examination. Periodic alternating nystagmus may be congenital or acquired in association with impairment of the vestibular cerebellar pathways. It is particularly seen with Arnold–Chiari malformation or cerebellar degeneration but may also be associated with MS or brainstem tumours.

### Convergence–retraction nystagmus in Parinaud's syndrome

This is characterised by rapid convergence movements of both eyes which also retract in the globe. It is best seen on attempted up-gaze or with a downward moving optokinetic drum and is caused by co-contraction of the horizontal recti on attempted convergence or up-gaze. Patients may have difficulty with upward saccadic movements but vertical pursuit is intact. It occurs with pupillary light near dissociation and bilateral lid retraction and is associated with lesions of the dorsal rostral midbrain which involve the posterior commissure (e.g. pineal tumours).

### Voluntary nystagmus

Normal individuals may be able to perform high-frequency horizontal conjugate eye movements which appear to be pendular. Occasionally they are vertical or circumrotatory. The movements tend to fatigue after more than a few seconds.

### Eye lid nystagmus

Eye lid twitches may occur in synchrony with vertical nystagmus and may also be provoked by convergence. Similar eye lid twitches are seen with the fast phase of horizontal nystagmus on lateral gaze.

Rarely, lid nystagmus may occur in isolation and it is particularly associated with medullary disorders. Irregular lid flutter may also be seen with weakness of up-gaze or in parkinsonism.

### Medical treatment of nystagmus

A proportion of patients with neurological nystagmus develop visually disabling and intrusive oscillopsia which is sometimes responsive to medication. Examples of drugs that may help include gabapentin for particular acquired pendular nystagmus in multiple sclerosis, baclofen for acquired periodic alternating nystagmus and aminopyridine for downbeat jerk nystagmus.

## Chiasmal and retrochiasmal visual pathways

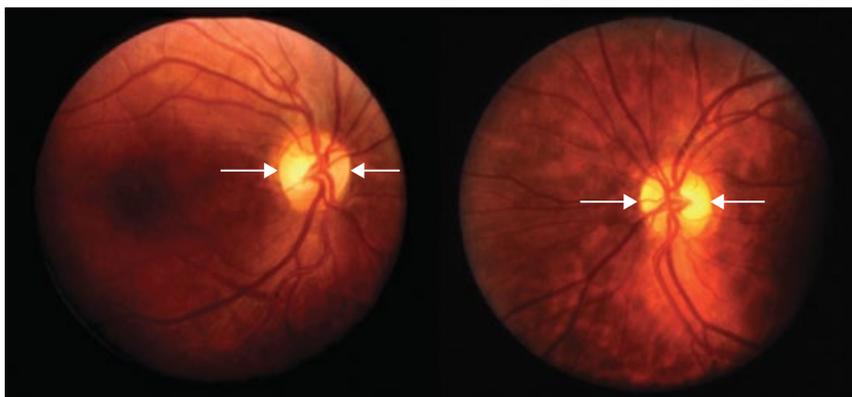

### Chiasmal disease

At the optic chiasm the nerve fibres from the temporal retina (nasal visual field) maintain their relative position in the lateral chiasm before passing into the ipsilateral optic tract while the nerve fibres from the nasal retina (temporal visual field) decussate in the chiasm and pass into the contralateral optic tract. The separation of the two hemifields occurs at the fovea so that the visual field is split at the point of fixation into the right and left halves, thus the macular fibres are both crossed and uncrossed in the optic chiasm. Bitemporal hemianopia is the characteristic clinical sign of chiasmal disease.

In some individuals the intracranial portion of the optic nerve is relatively long and the chiasm is formed in the posterior cistern (post-fixed) with the consequence that expanding sellar lesions may cause compression of the optic nerve and anterior aspect of the chiasm. Lesions of the anterior chiasm can result in a contralateral temporal hemianopic field defect with an ipsilateral central scotoma. This is referred to as a junctional field defect. A central scotoma with a temporal hemianopic scotoma in the same eye is also a junctional pattern but is less often identified.

Conversely, the chiasm may be pre-fixed so that mass lesions of the pituitary fossa may impinge on the posterior aspect of the chiasm or optic tract. Lesions of the posterior chiasmal notch may selectively involve only dorsal crossing fibres which predominantly serve central vision thus resulting in a bitemporal hemianopic scotoma. However, macular fibres, which form at least 30% of all fibres despite serving only 5° of field, are present throughout the chiasm and therefore any form of chiasmal lesion usually causes a defect in central vision (e.g. acuity or colour vision) in one or both eyes as part of the bitemporal field loss.

Patients with bi-temporal hemianopia may present with double vision despite normal eye movements. When there are dense temporal field defects, binocular fusion is not supported by overlapping temporal hemifields in the visual cortex. As a result, latent phorias may readily break down leading to variable vertical or horizontal diplopia. In other instances there may be difficulty in performing tasks requiring depth perception and judgement. The phenomenon of post-fixational blindness occurs when the subject with a bi-temporal hemianopia fixates on a near target, causing objects beyond the target to project on to both nasal hemiretina and therefore be invisible. In chiasmal disorders, diplopia may also be caused by direct cranial nerve involvement, either because of compression or direct invasion of the cavernous sinus or as a consequence of raised intracranial pressure.

**Figure 14.45** Bow tie or band atrophy in both discs with bi-temporal hemianopia caused by chiasmal transection (arrows).

The characteristic appearance of the optic disc in pure bi-temporal hemianopia is 'band' or 'bow-tie' atrophy. This occurs because exclusively crossing fibres enter the disc at the nasal and temporal poles. At all other locations there is a mixture of crossing and non-crossing fibres. Hence, if only crossing fibres are lost a 'band' of total atrophy results which is rarely seen in a complete form except in chiasmal transection caused by trauma (Figure 14.45).

Management of lesions in the pituitary region is described in Chapter 21.

### Homonymous hemianopia

Homonymous hemianopia is caused by unilateral lesions of the visual pathway posterior to the optic chiasm (i.e. optic tract, lateral geniculate body [LGB], optic radiation and cerebral cortex). Clinically, these are often disabling causing difficulty with reading and visual scanning. Patients may fail to notice relevant objects or obstacles on the affected side causing collisions particularly in complex environments (e.g. with approaching people). Driving, reading, shopping, applying make-up and food preparation are the most commonly affected activities of daily living. Transient homonymous hemianopia may occur in migraine, transient ischaemic attacks or seizures. The most common cause is vascular but homonymous hemianopia may result from tumours, trauma or surgery.

### Optic tract

Each optic tract contains crossed and uncrossed nerve fibres subserving the contralateral visual field, in particular nasal fibres subserving the temporal visual field of the contralateral eye and ipsilateral temporal fibres subserving the nasal visual field. Therefore, the left optic tract contains fibres carrying information for the right half of the visual field from both the right and left eyes. Lesions of the optic tract cause homonymous visual field defects of the contralateral visual field. The optic tract lies in close proximity to the internal capsule, cerebral peduncle and basal ganglia. Optic tract lesions are rare and are usually associated with other visual system abnormalities. Tract lesions typically occur with suprasellar lesions (craniopharyngiomas, aneurysm, optic chiasmal glioma and rarely, pituitary tumours) which extend posteriorly especially when there is a pre-fixed chiasm.

Involvement of the optic tract may lead to a homonymous hemianopia which may be complete or incomplete. When incomplete the visual field loss is often non-congruent. Optic atrophy occurs in

a 'bow-tie' distribution (band atrophy) in the eye with the temporal hemianopia because the fibres at the temporal poles of the disc are exclusively crossing fibres, where fibres crossing from temporal hemifields to enter the disc at both lateral poles are preferentially lost. A contralateral relative afferent pupillary defect may be present because the temporal hemifield served by the nasal hemiretina carries a greater number of ganglion cells that drive the light reflex than does the nasal hemifield. Lesions of the optic tract may be associated with hypothalamic involvement and contralateral hemiparesis from internal capsular damage.

### Lateral geniculate nucleus

Most of the nerve fibres of the optic tract (>80%) project to the ipsilateral lateral geniculate nucleus in the midbrain. Other optic tract fibres innervate the Edinger–Westphal nucleus in the pretectum, providing the afferent limb of the pupillary light reflex. The axons from the ipsilateral eye terminate in the second, third and fifth laminae of the lateral geniculate body while the axons from the contralateral eye terminate in the first, fourth and sixth laminae. The nerve fibres are believed to form a precise retinotopic map of the LGB.

Isolated lesions of the LGB are extremely uncommon and are caused by occlusive vascular disease involving the dual supply from the posterior cerebral and inferior choroidal arteries. Such lesions are often associated with contralateral hemiparesis from involvement of the adjacent posterior limb of the internal capsule or contralateral hemisensory loss from thalamic involvement.

Horizontal bands of the ganglion may be destroyed resulting in a specific hemianopic wedge field defect (known as geniculate hemianopia or sectoranopia) that straddles the horizontal meridian, although congruous or non-congruous hemianopia are more common. The wedge-shaped defects are located near the horizontal meridian either involving or sparing fixation. Pupillary reactions are normal. There may be associated signs resulting from involvement of the ipsilateral thalamus and/or pyramidal tract.

### Optic radiation

The neurones originating from the LGB form the optic radiation or the geniculo-striate tract and end in the primary visual cortex in the occipital lobe. The first part of the optic radiation is associated with the posterior limb of the internal capsule and lies in close proximity

to the cortico-spinal and cortico-bulbar tracts as well as the thalamus and cortical fibres. Lesions of the optic radiation in this region typically produce contralateral and usually complete homonymous hemianopia associated with contralateral hemianaesthesia and hemiplegia. Relative afferent pupillary defects may occur in lesions that are close to the lateral geniculate body.

The inferior fibres that subserve the superior visual field initially course anteriorly, superior to and around the temporal horn of the lateral ventricle. They then pass laterally and posterior to the striate cortex forming Meyer's loop. It is believed that as these fibres approach the occipital cortex their retinotopic order increases and the left and right eye fibres representing common visual loci separate into ocular dominance columns in the striate cortex. Lesions of the optic radiation in the temporal lobe usually result in a congruous homonymous hemianopia primarily affecting the superior quadrant with preserved visual acuity and pupillary light reflexes. The defect may be incomplete, incongruous and either confined to the superior quadrants ('pie in the sky') or more dense superiorly than inferiorly. This field defect is associated with aphasia, memory deficits and visual hallucinations. It is caused by intrinsic tumours such as gliomas, metastases or large demyelinating plaques rather more frequently than vascular occlusion.

More dorsal fibres pass through the parietal lobe. Lesions of the optic radiation in this region lead to incomplete or mildly incongruous homonymous hemianopia which is either limited to the inferior visual field or is more dense inferiorly than superiorly. However, more extensive lesions may produce a complete homonymous hemianopia with macular splitting, preservation of visual acuity and normal pupillary reflexes. There may be associated disruption of optokinetic nystagmus. Contralateral hemifield neglect is also seen in lesions of the non-dominant parietal lobe and should be distinguished from a visual field defect although sometimes both co-occur. There can be an associated sensory defect and lesions extending into the dominant angular gyrus produce Gerstmann's syndrome (finger agnosia, agraphia, acalculia, right-left disorientation).

### Visual cortex

The anatomical structure of the visual cortex and the associated striate and extrastriate cortex is described in Chapter 2. The primary visual cortex (V1, calcarine cortex, striate cortex, Brodmann area 17) is believed to be retinotopically organised, based on visual information from the corresponding retinal loci from the two eyes. The posterior pole of the occipital lobe is concerned with the central visual field while the peripheral visual field is represented in the most anterior part of the striate cortex. The upper lip of the calcarine cortex receives projections from the inferior visual field. The striate cortex is surrounded by the visual association areas (V2-6, Brodmann areas 18 and 19). These areas are also believed to be retinotopically arranged with over-representation for the central visual field as in the primary visual cortex.

Various specific patterns of acquired field defect occur with lesions of the primary visual cortex. Occipital lobe lesions are the most common cause of homonymous hemianopia and are usually a result of infarction in the distribution of the posterior cerebral artery. Other aetiologies include venous infarction, haemorrhagic arteriovenous malformations and fistulas, tumours, abscess and trauma.

The most peripheral 30% of temporal field viewed by both eyes is not overlapped by corresponding nasal fields in the other eye (temporal crescent). This portion of the field therefore has a monocular representation in the anterior part of the contralateral

visual cortex. Lesions of the anterior striate cortex cause a congruous homonymous scotoma with unilateral loss of the temporal crescent. This is the only example of a monocular visual field defect caused by a retrochiasmal lesion although a uniocular temporal scotoma is much more commonly caused by a peripheral retinal lesion. More commonly, when the anterior portion of the visual cortex is spared by an occipital lobe lesion, there is a complete homonymous hemianopia except for sparing of the temporal crescent in the contralateral eye.

Superior and inferior homonymous visual field defects respecting the vertical and sometimes the horizontal meridians occur with lesions of the occipital cortex selectively damaging either the inferior or superior banks (usually infarcts).

Macular sparing is rarer than macular splitting hemianopias. Mammals in general and humans in particular are foveo-centric, that is much of the occipital cortex (two-thirds) given over to central (0-5°) vision which is why macular sparing hemianopias are rarer than those that involve central vision. The mechanism of macular sparing has been debated with some arguing that the macula is bilaterally represented in the occipital cortex but the weight of evidence supports the theory that macula sparing is caused by incomplete damage to the striate cortex on the affected side, probably because of sparing of some of the four main branches of the posterior cerebral arteries (PCA) which supplies visual cortex. Conversely, homonymous visual field defects preferentially involving the macular may occur. These respect the vertical meridian and are limited to the central 30° and are usually enclosed within an area of normal peripheral visual field. The cause is most commonly occipital tip injury resulting from hypotension or ischaemic stroke. However, larger lesions involving the occipital radiations and optic tract have also been associated with this deficit.

### Bilateral homonymous hemianopia

This may occur with bilateral lesions of the occipital cortex either simultaneously or consecutively. The extent of the visual field defect depends on the involvement of the striate cortex. Bilateral occipital cortex lesions are relatively frequent because the two posterior cerebral arteries are terminal branches of a single basilar artery and therefore basilar occlusion will cause occipital infarction and cortical blindness. This may also occur in metabolic, neurodegenerative or inflammatory disease. A variety of bilateral homonymous lesions may occur ranging from complete bilateral homonymous hemianopia (cortical blindness), to bilateral macular sparing hemianopia (ring scotoma), quadrantanopias or scotomatous and altitudinal defects.

Anton's syndrome is particularly associated with occipital cortex lesions extending to the calcarine cortex and including visual association cortices (Brodmann areas 18 and 19). Acute bilateral and extensive lesions of the occipital lobe lead to sudden visual loss. Patients with cortical blindness are sometimes unaware of their visual loss, deny any difficulty and confabulate about what they are able to see often being able to direct their gaze to auditory stimuli.

### Blindsight and stato-kinetic dissociation

Blindsight or residual vision in an apparently blind hemifield (V1 scotoma) can be demonstrated in some patients. There is evidence that reflex motor responses may be generated in response to stimuli in the blind field. The underlying substrate for this is uncertain but is likely to involve subcortical visual pathway, the pulvinar of the thalamus and callosal connections. There is also a

direct projection from the LGB to area 5, which may subserve preserved perception of movement. The Riddoch phenomenon of stato-kinetic dissociation may be demonstrated on Goldmann perimetry: a stimulus is perceived on movement in the periphery of a homonymous hemianopia despite failure to see colour or static forms.

#### Visual association areas (extrastriate cortex areas V2–6)

Lesions affecting the human area V1 often extend into underlying white matter in the prestriate area and adjacent parietal and temporal regions causing an inferior quadrantic field defect which respects the horizontal as well the vertical meridian. The pre-striate pathways or visual association areas can be considered as two separate systems: first, a ventro-mesial pathway which occupies the occipital lobe below the calcarine fissure and adjacent temporal lobes (the visual 'what' pathway) and, secondly, a dorsolateral area which is located in the occipital lobe above the calcarine fissure and in the adjacent parietal and temporo-parietal region (the 'where' pathway). The clinical significance of this is that there may be functional partitioning of the pre-striate cortex in such a way that focal lesions may result in selective impairment of aspects of higher visual function.

Lesions of the ventro-mesial pathway in the occipito-temporal cortex result in defects of object recognition colour vision and reading affecting the contralateral hemifield. These include cerebral dyschromatopsia, pure alexia and prosopagnosia (see Other disorders of visual perception). Hemianopic field defects are commonly found, often bilateral inferior quadrantanopia as a result of damage to the adjacent ventral portion of the optic radiation. Lesions of the dorso-lateral pathway may cause visuo-spatial neglect, Balint's syndrome, visual agnosia and, very rarely, cerebral akinetopsia (see Other disorders of visual perception).

## Disorders of higher visual function

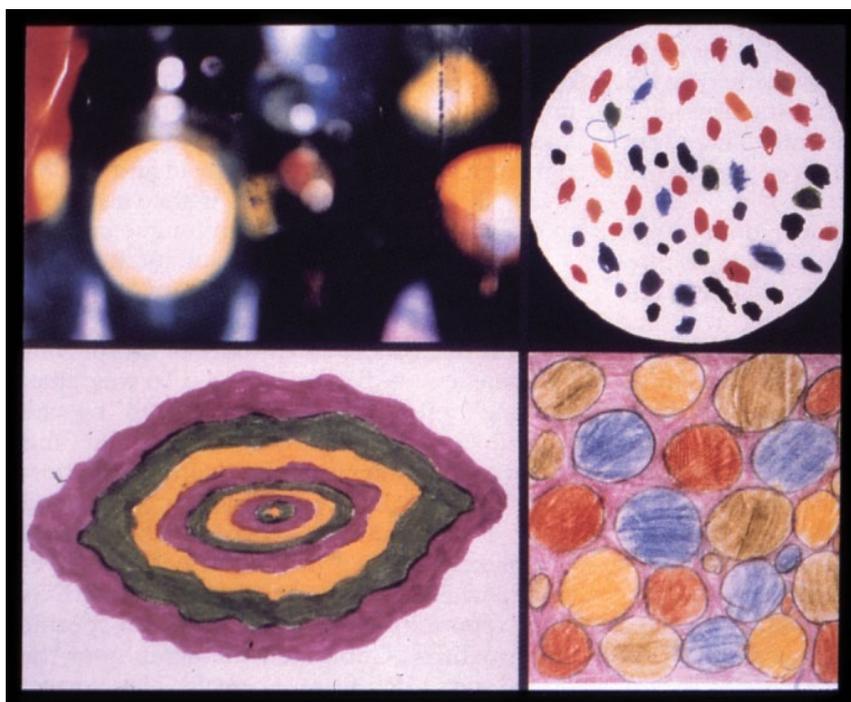

### Visual hallucinations

Visual hallucinations are formed or unformed images perceived when in reality there is no stimulus present and are the result of endogenous neural activity. Illusions are the misperception or distortion of a stimulus present in the external environment.

Visual hallucinations may occur in medical, neurological or ocular disorders. In contrast to auditory hallucinations, they are not usually a result of psychiatric disorders. Simple visual hallucinations may consist of single discrete or flickering flashes of light (phosphenes or photopsia) which may result from lesions of the retina, choroid or optic nerve. There may be lines of different colours in the form of simple patterns (circles, fortification or zig-zag patterns) which may be associated with a defect in the field of vision and usually caused by migraine or occipital epilepsy. Simple visual hallucinations include brief vertical flashes of light (Moore's lightning streaks) which predominantly occur in the temporal field in association with eye movements and are associated with vitreous detachment. Spontaneous flashes precipitated by eye movement or loud unexpected sounds may be a manifestation of demyelination or other causes of optic neuropathy.

Migraine is the most common cause of visual hallucination and illusion. The disturbances may vary from elementary, predominantly black and white, visual disturbances, elementary positive (phosphenes or geometrical forms) or negative (scotomas) disturbances with more complex visual hallucinations and illusions. In particular, fortification spectra (teichopsia), scintillating lights and lines or zig-zag waves may occur and frank distortions including geometric forms, micropsia, macropsia and metamorphopsia. These may also occur in migraine without headache.

Visual hallucinations are particularly associated with simple and complex seizures arising in the occipital lobe with or without secondary generalisation (Figure 14.46). These seizures may be

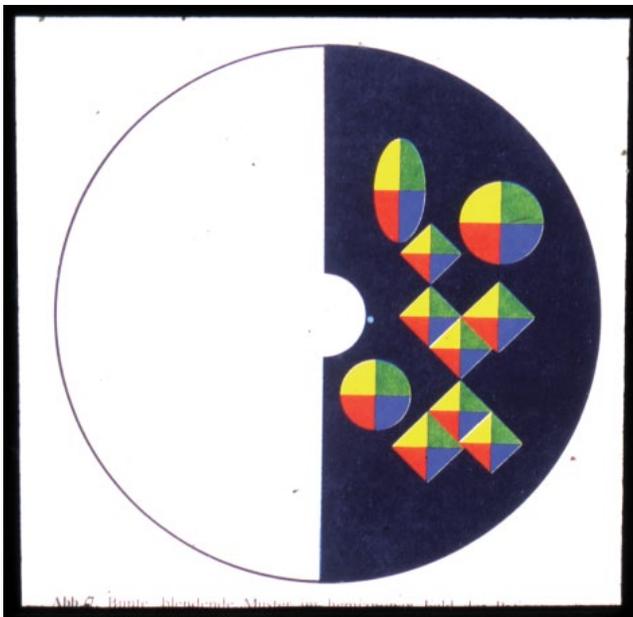

**Figure 14.46** Visual phenomena recorded by four patients with occipital epilepsy. Source: Panayiotopoulos 1999. Reproduced with permission of John Libbey Eurotext.

associated with multiple types of hallucinations or illusions. In contrast to migraine, the hallucinations are usually brief, stereotyped and fragmentary and are usually multicoloured and occasionally complex with circular or spherical patterns. They are generally seen in the contralateral temporal field but may begin centrally. They may be prolonged in non-convulsive status and are sometimes perceived as unreal and associated with anxiety and an affective disturbance. It may be difficult to distinguish from migraine because a migraine-like headache may occur after an occipital lobe seizure, usually coming on several minutes after the hallucinations have stopped. Occipital and temporal lobe epilepsy may also be associated with distortions, particularly changes in size both micropsia and macropsia.

In transient visual loss caused by occipital ischaemia there may be coloured bright flashes (scintillations). Occipital lobe tumours may give rise to uniform visual hallucinations in one hemifield often associated with exercise, which are probably ictal in origin. Visual hallucinations may occur with posterior cerebral infarction involving the occipital lobe and thalamus (Figure 14.47).

Complex visual hallucinations are usually related to temporal lobe dysfunction. They may involve hallucinations of colour, face, texture and objects and correlate with cerebral activity in the ventral extrastriate visual cortex and their content reflects the functional specialisation of the particular region of occipital cortex affected.

Hallucinations and illusions occur in a variety of other neurological disorders (Chapter 8). They are frequently seen in delirium from any cause when they are associated with an alteration in attention, concentration and the level of consciousness with disrupted sleep-wake cycle and agitation. The symptoms characteristically fluctuate. In diffuse Lewy body disease there are characteristically vivid visual hallucinations and similar phenomena may also be seen in Parkinson's disease particularly in the older and more cognitively impaired patient taking dopamine agonists.

**Figure 14.47** Geometric hallucinations within a hemianopic field defect recorded by the patient. Source: Kölmel 1985. Reproduced with permission of BMJ.

These hallucinations are often colourful, complex, involving scenes of people and animals. There may also be associated paranoid delusional disturbances. Visual hallucinations are less commonly seen in Alzheimer's disease, Pick's disease, Huntington's chorea and vascular dementia. Hypnogogic and hypnopompic hallucinations lasting several minutes are associated with narcolepsy. These are often colourful vivid images involving people, animals or landscape scenes and may be difficult to separate from reality.

### Visual hallucinations associated with impaired vision (Charles Bonnet syndrome)

In patients with impaired visual acuity from a variety of primary ophthalmological disorders, particularly in the elderly, recurrent vivid hallucinations may occur despite normal cognition and insight. They may be more likely to occur in low light and are seen in the blind portion of the visual field. They are not stereotyped and often consist of vivid scenes which are predominantly coloured and often involve animals, flowers and people which are sometimes said to have a cartoon-like appearance. They may have normal proportion or be altered in size and may change shape when the subject reaches out to them. They can usually be stopped by opening and closing the eyes or by rapid eye movements. The patient invariably realises that the hallucinations are unreal.

This syndrome may result from lesions throughout the visual pathway but is particularly associated with age-related degenerative retinal or neurological disease and is considered to be a release phenomenon of the ventral occipito-temporal cortex.

### Peduncular hallucinosis

This occurs with lesions of the thalamus and upper midbrain (usually bilateral). These are vivid and usually well-formed colourful hallucinations or people, animals or complex scenes. There may be illusionary micropsia and the scenes are often considered to be pleasant. The hallucinations can last for minutes to hours and usually occur in the evening. There may be associated auditory and tactile hallucinations but insight is well preserved.

Other visual illusions may be experienced by patients with partial visual loss (Table 14.23).

**Table 14.23** Visual illusions in patients with partial visual loss.

Tesselopsia	Regular repeating patterns
Dendropsia	Branching patterns
Hyperchromatopsia	Hyperintense brilliant colours
Polyopia	Seeing a single target as multiple
Macropsia	Seeing objects enlarged
Micropsia	Seeing objects reduced in size
Metamorphopsia	Seeing distortion of perceived objects
Palinopsia	Persistence or recurrence of the visual image despite removal of the object
Allesthesia	Transportation of an object seen in a visual field to the contralateral visual field
Oscillopsia	Illusion of movement of the environment

### Polyopia

Polyopia, in which a single target is seen as multiple, is a rare manifestation of lesions of the occipital cortex or central visual pathway and occurs with monocular viewing. The number of objects seen may vary from two to hundreds. The true image is seen and the false images are similar but tend to reduce in intensity, colour and size. Polyopia tends to develop several seconds after fixation and does not resolve with a pin-hole.

### Palinopsia

Palinopsia is also associated with occipital or occipito-temporal disease and may occur as an ictal phenomenon. The image tends to recur immediately after the object has been removed or the gaze has been diverted, it is usually without colour and remains despite eye closure. Palinopsia may develop during recovery from cortical blindness and is particularly associated with non-dominant focal occipito-parietal lesions. It also occurs in association with a variety of medications, drug withdrawal and neurodegenerative disorders.

### Other disorders of visual perception

#### Pulfrich's phenomenon

Pulfrich's phenomenon is loss of stereoscopic depth perception that causes objects to appear to cross the midline. It is caused by a difference in the latency of transmission in the optic nerve between the two eyes usually because of delay in conduction associated with demyelination or compression of the optic nerve.

#### Hemifield slide

Bi-temporal hemifield slide is caused by loss of overlapping regions of the binocular visual field. This may cause a disturbance to reading because there is a vertical break in horizontal lines of text. Similarly, a left homonymous hemianopia may impair the transition from the end of line of text to a new line on the left-hand side of the page.

#### Tilt

Environmental tilt is particularly seen following lateral medullary infarction. The tilt in the field of vision may be 90° or 180° and come on abruptly. Severe tilts tend to be brief in duration while smaller deviations may persist for longer periods.

#### Visual synaesthesia

Visual synaesthesia occurs when auditory, tactile or gustatory stimuli produce visual images and is associated with illusions throughout the visual pathway. Visual dysaesthesia occur when various unpleasant visual sensations are experienced when looking towards a blind field. They are often associated with lesions of the optic radiation.

#### Visual agnosia

Visual agnosia refers to an inability to recognise objects visually despite preservation of visual acuity, intellectual function, attention and language abilities. However, object recognition deficits may also occur as a result of visual form imperception despite normal acuity. These patients are unable to detect differences in object matching tasks. True visual object agnosia may occur at the level of perceptual analysis (apperceptive agnosia) or at the level of semantic analysis (associative agnosia). Apperceptive agnosia is observed in patients with lesions of the right dorsal posterior cortex and associative agnosia with left ventral lesions. Patients with apperceptive agnosia cannot copy a line drawing well; those with associative agnosia can copy the drawing but are unable to explain it. Both syndromes are seen most commonly in

degenerative disorders, specifically Alzheimer's disease and a rare variant, posterior cortical atrophy.

#### Prosopagnosia

Prosopagnosia is a circumscribed form of visual agnosia in which there is failure to recognise previously familiar faces or to learn the appearance of new faces. In its severe form patients rely on individual facial features (e.g. glasses, beard or hairstyle) or non-visual clues (e.g. voice) to recognise others. However, some patients are able to judge age, gender and emotional expression. Prosopagnosia can be congenital or associated with bilateral lesions particularly affecting the ventral visual system, a milder form may occur with unilateral right hemisphere lesions.

#### Disorders of colour vision

Inability to recognise colours as a consequence of cortical deficits occurs in several different clinical patterns. In cerebral achromatopsia patients are not able to read Ishihara plates or sort colours according to hue. There is complete loss of colour vision with colours appearing as shades of grey. This is associated with bilateral lesions or involvement of the non-dominant occipito-temporal lobe and there is usually a superior quadrantic field loss with involvement of the inferior striate cortex or optic radiations. There is often accompanying visual agnosia.

#### Cerebral metamorphopsia

Patients notice distortion of images which may be caused by spatial remapping around homonymous scotomas in which case it can be mapped in a predictable fashion. In other instances the distortions are bizarre, often frightening and specific to faces and hands (Figure 14.48).

#### Visual simultanagnosia

This syndrome may occur in isolation or in association with cortical visual loss. There is an inability to understand the visual field as a whole while individual elemental parts are attended and recognised. If the patient is presented with several figures he/she is able to recognise them individually but sees only one when they are presented in a group. Formal testing is difficult because patients use only macular vision and fail to keep their eyes focused on the target. The syndrome appears to be associated with an inability to sustain visuo-spatial attention. It is particularly associated with the visual field defects involving unilateral or bilateral inferior quadrantic field and may occur as a sequelae of posterior circulation watershed infarction in Balint's syndrome. Dorsal (visuo-spatial) and ventral (visual agnosias) variants occur. Patients can be severely visually impaired despite a normal performance on tests of visual acuity.

#### Cortical visual impairment

Balint's syndrome is characterised by the following:

- 1 *Ocular motor apraxia*: an inability to shift gaze on command because of difficulty initiating voluntary saccades to redirect attention to visual targets despite an unrestricted range of eye movements.
- 2 *Optic ataxia*: the inability to benefit from visual guidance when reaching for a target under visual control; the inability to benefit from visual guidance when reaching. It is manifest as clumsiness of movement of the hand performed under visual guidance. This is present throughout the range of movement in contrast to cerebellar ataxia.

**Figure 14.48** Metamorphopsia recorded by a patient following occipital lobe surgery. Source: Mooney et al. 1965. Reproduced with permission of Elsevier.

**3** *Reduced visual attention manifest as simultanagnosia* (see Cortical visual impairment): there may also be a reduction in visual attention with functional constriction in the fields and altitudinal neglect.

Balint's syndrome is associated with bilateral posterior watershed lesions in the convexity of the hemispheres. It is also associated with Gerstmann's syndrome although the strength of associations with these defects as a syndrome remains open to question.

Occipital cortical visual disturbances may also occur as a consequence of posterior presentation of Alzheimer's disease which tends to come on at a young age with relatively preserved visual acuity and colour appreciation. There is often difficulty reading and marked visuo-spatial difficulties. MRI shows prominent occipitoparietal atrophy.

### Neglect

This is different from hemianopia in the sense that it is not confined to one hemifield or the other, but rather is best considered as a disorder of attentional allocation over space, with a spatial gradient.

Right parietal lesions are the most common cause with severe and persistent cases usually associated with widespread fronto-parietal damage. Patients preferentially respond to stimuli on the right leading to visual extinction. Cancellation tests are often used to diagnose the condition (patients with hemianopia alone will be slow but accurate in these tests); the more difficult the test that is, the more targets and distracters, the more a patient's tendency to only report stimuli to the right. Neglect can also affect interpersonal space with patients not recognising their own body parts in extreme cases.

### Alexia

This is the loss of reading ability in previously literate subjects. When associated with other language disturbance (aphasia) it is known as central alexia, or as Dejerine called it 'alexia with agraphia' (patients with aphasia are usually agraphic). This is usually caused by a lesion affecting the dominant MCA territory. Peripheral alexia or 'alexia without agraphia' occurs in the face of otherwise normal language abilities (speaking, hearing speech, writing). The most common form is hemianopic alexia where a macular splitting hemianopia causes

problems with text reading by robbing the reader of information about upcoming words. For texts, like this one, written and thus read from left-to-right, a right-sided hemianopia is more disabling. 'Pure' alexia is caused by lesions affecting the dominant fusiform gyrus and its connections. These patients have difficulty with single word reading and, in the more severe cases, resort to a letter-by-letter reading strategy. At the most severe end of the spectrum are patients who have problems at the single letter level: global alexia. Such patients retain their writing ability, at least to some degree, leading to the odd sign of a patient being able to write a sentence which, after a suitable gap to interfere with verbal recall of what they have just written, they cannot subsequently read.

## Abnormalities of the pupil

The pupil is abnormal in a number of ocular as well as neurological disorders; only the latter is considered in this chapter. The importance of pupillary change is not so much the fact that they cause serious symptoms (they usually do not), but that they may indicate serious underlying neurological disease.

A knowledge of the anatomy of the direct and indirect light reflexes and of the sympathetic supply are important in understanding pupillary change (Chapter 2), and abnormalities of pupillary function can be very helpful in localising neurological disorders.

The size of the pupil is determined by the balance between parasympathetic drive (which determines the tone in the iris sphincter muscle) and sympathetic drive (which determines the tone in the iris dilator muscle). The size of the pupils is affected by the ambient lighting and many other factors including the level of alertness and emotional factors. Sometimes the pupils are naturally of slightly unequal size without any underlying pathology (physiological anisocoria). Physiological anisocoria describes clearly perceptible inequality of pupillary size and is present in 20% of the population. It varies from day to day and can even reverse in some people. Its physiological nature can be confirmed by the observations that the measured inequality is similar in light and dark, and by the fact that the direct and indirect light reflexes are quite normal.

The light reflex is mediated by afferent (optic nerve) and efferent (parasympathetic) fibres. The anatomy of these is also discussed in Chapter 2.

Pupillary abnormalities in neurological practice are best considered in two categories:

- 1 Disorders of the light reflex
- 2 Disorders of the sympathetic innervation to the eye.

### Disorders of the light reflex

These can be divided into afferent, central and efferent disorders. The afferent limb of the light reflex is via the optic nerve where fibres pass to the pretectal region and thence to the Edinger–Westphal nucleus bilaterally. The parasympathetic efferent outflow, firing of which causes constriction of the pupil, originates in the Edinger–Westphal nucleus. The preganglionic fibres follow the course of the IIIrd nerve to the ciliary ganglion and then synapse with the post-ganglionic fibres which travel to the iris sphincter muscle in the short posterior ciliary nerves.

### Complete afferent pupillary defect

When there is complete blindness in one eye because of pathology in the retina or optic nerve then a light shone in the blind eye produces no reaction in either pupil, whereas a light shone in the normally sighted fellow eye constricts both pupils. This situation is

encountered in any complete optic nerve lesion, and the most common causes are tumour or trauma.

The light reflex tests the integrity of the anterior visual pathways. A preserved light reflex, in the presence of apparent total blindness in the eye, indicates either that the blindness is non-organic or that it arises from the posterior visual pathways.

### Relative afferent pupillary defect

A pupil with a relative afferent defect (sometimes known as the Marcus Gunn pupil) is identified by the swinging light test. When light is directed into the affected eye this will cause only mild constriction of both pupils (because the afferent defect reduces the amount of light stimulus reaching the pretectum), and when directed into the unaffected eye it will cause a larger constriction of both pupils (because more of the light stimulus is reaching the pretectum to drive the pupils). When the light is rapidly alternated between the two eyes, the pretectum 'sees' the light stimulus as brighter when the stimulus is presented to the good eye and dimmer when the stimulus is presented to the affected eye; as a result, the pupils constrict when stimulating the good eye and dilate when stimulating the affected eye. This sign is called a relative afferent pupil defect (RAPD).

The presence of an RAPD indicates that there is unilateral (or markedly asymmetric) disease of the optic nerve (most commonly) or retina (less commonly). It is extremely rare for preretinal diseases (e.g. corneal pathology, cataract or vitreous haemorrhage) to cause this sign provided the torch light is bright enough, nor should an RAPD be attributed to a 'lazy eye' or maculopathy.

The most common optic nerve disorder causing an RAPD is optic neuritis associated with MS. Other causes include an ischaemic optic neuropathy, optic nerve tumour (optic nerve meningioma, glioma), orbital disease causing compression of the optic nerve (including thyroid orbitopathy), infection and inflammation (including sarcoidosis and Lyme disease), radiation damage or trauma. Other unilateral optic neuropathies including Leber's hereditary optic neuropathy will also result in this sign.

Extensive retinal disease will sometimes cause a 'Marcus Gunn' effect. This may be seen with retinal infarction, infection, tumours and detachment, but in these patients additional optic nerve disease must be excluded. Disease confined to the macula rarely gives rise to an RAPD.

### Central (midbrain) lesions of the light reflex

When the pupil is affected by a midbrain lesion, there are two common patterns: the Argyll Robertson and Parinaud syndromes.

*Argyll Robertson's syndrome* This venerable sign is rarely encountered in clinical practice now. However, it used to be a common finding, characteristically in tertiary syphilis. The pupils typically are small and irregular and do not react to light but do react to accommodation (light near dissociation). The features are caused by damage of the central inhibitory fibres ventral to the aqueduct. Similar pupillary abnormalities are occasionally encountered in diabetes, MS or myotonic dystrophy. Occasionally, the 'inverse Argyll Robertson pupil' (no accommodation reflex but a preserved light reflex) is observed in cases of tertiary syphilis and was common in encephalitis lethargica.

*Parinaud's syndrome* Parinaud's syndrome (synonym: dorsal midbrain syndrome) is a term used to describe a cluster of five clinical signs:

- Dilated (or mid-dilated) pupils that do not react to light, but which do react to accommodation.

- Paralysis of voluntary up-gaze with preservation of down-gaze (a supranuclear gaze palsy where up-gaze can still be demonstrated using the doll's head manoeuvre, i.e. using the oculocephalic reflex).
- Convergence retraction nystagmus on attempted up-gaze. The eyes pull inward on up-gaze and the eyeballs retract.
- Eyelid retraction (Collier's sign).
- Convergence paralysis.

The syndrome is caused by damage to fibres in the dorsal midbrain, specifically to the posterior commissure. The syndrome can result from many pathologies in this anatomical location. It is a characteristic sign of a pineal gland tumour (usually a pinealoma) but is also commonly encountered with any extrinsic space-occupying lesions in this region including other brain tumours and hydrocephalus. Intrinsic mesencephalic pathologies such as MS, angiomas, infection (e.g. toxoplasmosis) and ischaemic or haemorrhagic stroke are uncommon causes. Transient Parinaud's syndrome may rarely result from a tonic-clonic seizure.

Treatment is primarily directed towards the aetiology of the dorsal midbrain damage. MRI is the common first choice investigation and will usually reveal the cause.

If the cause is alleviated, the eye findings of Parinaud's syndrome generally improve, either rapidly or over a period of months. If symptomatic therapy is needed (which is rare) up-gaze palsy and the retraction nystagmus can be improved by bilateral inferior rectus recession.

### Efferent parasympathetic defects of the light reflex

Anatomically these can be divided into preganglionic and post-ganglionic parasympathetic lesions. In acute preganglionic block, there is a large unreactive pupil with absent light and accommodation reflexes. If in isolation, it is usually pharmacologic rather than neurogenic and caused by exposure of the eye to drugs or eye drops. Preganglionic lesions are usually associated with a IIIrd nerve palsy and may be caused by an acute compressive (neurosurgical) cause or basal meningitis. Other causes, and the clinical features, of IIIrd nerve palsy are considered above.

### Holmes–Adie syndrome

The Holmes–Adie syndrome (HAS; named after William John Adie, 1886–1935, and Gordon Morgan Holmes, 1876–1965, both from the National Hospital, Queen Square) is characterised by two key clinical signs: a tonic pupil and tendon areflexia. The tonic pupil shows little or no reaction to light, and when examined under magnification it is often observed that some meridians of the pupil margin respond to light whereas others do not ('sector palsy') causing the pupil to appear misshapen. In contrast, the pupil shows an exaggerated response to near but the constriction is markedly slowed (hence 'tonic'). The other cardinal feature of this syndrome is the absence of deep tendon reflexes (especially knee jerks), a clinical sign that is never associated with symptoms. HAS typically occurs in young adults (third to fifth decade), with a female preponderance. It often affects one pupil initially but the other eye usually becomes affected years or even decades later. Once present, the condition persists and the pupil changes are irreversible. Some individuals with HAS also develop sweating abnormalities, with patches of hyperhidrosis and hypohidrosis (Ross's syndrome).

HAS is most commonly noticed by chance, when the affected individual looks in a mirror and sees the pupil abnormality.

Sometimes there is blurring of vision and photophobia (intolerance to bright light) because of the pupillary dilatation, or difficulty with near vision because of failure of accommodation of the lens. The clinical features of HAS are thought to be caused by damage to the ciliary ganglion and the dorsal root spinal ganglia, although the cause is unknown and the syndrome remains idiopathic. The diagnosis is made on clinical grounds. Treatment is not usually needed, but pilocarpine drops can be used, three times a day, to constrict the pupil if necessary. Thoracic sympathectomy or botulinum toxin injection is a definitive treatment for excessive sweating.

Tonic pupils are not always a result of HAS and may also be seen in a number of other ophthalmic (e.g. following eye or orbital surgery) and neurological conditions (e.g. in generalised dysautonomias and peripheral neuropathies), in which case there will always be other symptoms and signs indicating the underlying aetiology.

### Disorders of the sympathetic nervous supply to the pupil

The sympathetic pathway originates in the posterior hypothalamus, travels through the brainstem (including the lateral medulla) and then descends in the cervical cord to the C8–T1 level. There the first order neurones synapse with the second order neurones which leave the cord and enter the paravertebral sympathetic chain to the superior cervical ganglion. They subsequently synapse with the third order (post-ganglionic fibres) which ascend around the internal carotid artery to the base of the skull. In the cavernous sinus they form a peri-arterial plexus in the adventitia of the artery. The oculosympathetic fibres pass through the superior orbital fissure in the long ciliary nerves while sudomotor and vasomotor fibres to the face travel with branches of the external carotid artery. Excitatory fibres supply the dilator pupillae, Müller's muscle and the blood vessels of the eye. Inhibitory fibres supply the ciliary muscle and the sphincter pupillae.

### Horner's syndrome

Horner's syndrome is caused by dysfunction of the sympathetic nervous supply to the eye. It can be caused by damage anywhere along the lengthy three-neurone sympathetic pathway – and can be divided into 'central' (first-order), 'preganglionic' (second order) and 'post-ganglionic' (third order) lesions. It is an important syndrome, not because it affects vision itself (this is unusual) but because some of the common causes of the syndrome require urgent attention.

**Clinical features** The cardinal signs are ptosis (from loss of sympathetic tone in Müller muscle) and miosis (constricted pupil). Other signs include 'upside-down' ptosis (slight elevation of the lower lid) giving rise to narrowing of the palpebral aperture and apparent enophthalmos, conjunctival injection and anhidrosis (decreased sweating). If the syndrome develops around birth or in very early childhood, the iris on the affected side may become less pigmented (heterochromia iridis) because melanisation of the ocular tissues in early life requires an intact sympathetic nerve supply. An important clinical point is that the ptosis caused by Horner's syndrome occurs with a constricted pupil and the ptosis caused by a IIIrd nerve palsy is usually more severe and associated with a dilated pupil (from a loss of innervation to the sphincter pupillae).

**Causes** Horner's syndrome can be congenital but is usually acquired. A list of causes is shown in Table 14.24. Traumatic birth injury is one cause of a congenital Horner's (Klumpke paralysis) and the diagnosis is usually obvious. Most cases are isolated and idiopathic. Rare genetic causes also result in a congenital Horner's syndrome. Congenital cases show heterochromia (the affected iris is less pigmented).

The acquired causes are almost all unilateral if caused by a focal lesion, and can be caused by interference with the sympathetic nervous supply at any point in its long anatomical course (Chapter 2). Bilateral Horner's syndrome is characteristic of

autonomic neuropathies (e.g. diabetes or amyloid). In children, the development of a Horner's syndrome requires urgent imaging to exclude a neuroblastoma. In adults, a characteristic presentation of dissection of the carotid artery is the development of a Horner's syndrome with ipsilateral neck or face pain. The Raeder syndrome (paratrigeminal syndrome) comprises oculo-sympathetic palsy and ipsilateral facial pain, often with some involvement of the trigeminal and oculomotor nerves. Pancoast tumour, carcinoma at the apex of the lung, also may present with a Horner's syndrome. Cluster headaches cause a transient Horner's syndrome, which is useful in diagnosis.

**Table 14.24** Acquired causes of unilateral Horner's syndrome.

Type of lesion	Anatomical position	Common pathologies
<b>Preganglionic</b>		
First order neurone	Hypothalamus, midbrain, pons, medulla, cervical cord	Multiple sclerosis Tumour Vascular lesion (in medulla, as part of the lateral medullary syndrome; Wallenberg's syndrome) Syringomyelia
Second order neurone	T1 level of spinal cord/column, sympathetic chain, the superior cervical ganglion	Thoracic cord lesions Neck trauma Spinal column lesions and disc prolapse Cervical rib Aneurysm/dissection of aorta or subclavian artery Central venous catheterisation Abscess or infection, lymphadenopathy Thyroid neoplasm Lesions in the apex of the lung (especially Pancoast's tumour)
<b>Post-ganglionic</b>		
Third order neurone	Internal carotid artery, base of the skull, ophthalmic nerve, cavernous sinus, superior orbital fissure, orbit	Aneurysms or dissection of the internal carotid artery Cavernous sinus lesion (fistula, aneurysm, granuloma) Skull base or orbital tumour Skull base malformation (e.g. Arnold–Chiari malformation) Infection Meningioma Trauma Nasopharyngeal carcinoma Orbital pathology (including trauma, tumour, granuloma, infection) Neuroblastoma (in children) Herpes zoster

**Table 14.25** Summary of responses to topical agents in Horner's syndrome.

	0.5% apraclonidine	4% cocaine	1% hydroxyamphetamine
Normal	No response	Dilates	Dilates
Preganglionic Horner's syndrome (recent)	Dilates	No response	Dilates impressively
Preganglionic Horner's syndrome (long-standing)	Dilates	No response	May dilate if no transsynaptic degeneration of third order neurones
Post-ganglionic Horner's syndrome	Dilates	No response	No response

**Diagnosis** The clinical features are so characteristic that no diagnostic tests are usually needed. However, the diagnosis of the underlying cause depends on the clinical situation and will often involve MRI and MR angiography.

Pharmacological tests can be used to confirm the diagnosis and to differentiate a preganglionic from a post-ganglionic Horner's syndrome. The most reliable test for confirmation of the diagnosis is instillation of topical 4% cocaine eye drops; this prevents re-uptake of noradrenaline in the sympathetic nerves to the iris dilator muscles and causes dilatation of the pupil in a normal eye but not in an eye with Horner's syndrome. Nowadays cocaine eye drops are often unavailable so an effective alternative drug to use is topical apraclonidine; this is a weak adrenergic agonist that has little or no effect on a normal pupil but causes dilation (and reversal of the anisocoria) in Horner's syndrome because of the denervation supersensitivity present in the dilator muscle fibres. Neither of these drugs can localise the lesion; for this it is necessary to use 1% hydroxyamphetamine, a drug that releases noradrenaline from intact sympathetic nerve endings – this drug dilates a normal pupil, has no effect on a patient with a post-ganglionic Horner and produces an exaggerated mydriasis in patients with a pre-ganglionic Horner (Table 14.25).

# Neuro-Otology: Problems of Dizziness, Balance and Hearing

Rosalyn Davies, Linda M. Luxon, Doris-Eva Bamiou and Adolfo Bronstein

National Hospital for Neurology & Neurosurgery

## Dizziness and vertigo: introduction

Dizziness is an umbrella term describing symptoms varying from vague light-headedness and disorientation to imbalance and vertigo. Vertigo means the illusion of movement of either the body or the surroundings, typically spinning or sometimes tilting or rocking to and fro.

Vertigo is either of internal origin – a mismatch between sensory inputs – or it may be linked to retinal slip during the slow phase of nystagmus (i.e. the image moves across the retina); in each case the surroundings or the head seem to move. Much information can be gleaned from detailed descriptions of dizziness and especially vertigo, sometimes pointing to the specific semicircular canal involved.

Any vestibular dysfunction can be accompanied by:

- Vertigo – rotary, swaying, tilting or postural imbalance
- Blurring of vision or slippage of the visual field with head movement, and
- Autonomic symptoms – nausea, vomiting, sweating, distress and anxiety.

Acute, severe vertigo causes prostration.

## Epidemiology

Dizziness and vertigo are common. One UK community survey showed that one in four adults have had significant dizziness. Dizziness is a substantial cause of morbidity, loss of time from work, repeated medical attendances and costly investigation – one study showed that on average more than four physicians were visited before precise diagnosis of a vestibular problem. Dizziness is a frequent reason for consultation by those over 65 years and, like headache, is common worldwide.

## Basic concepts

### Three-dimensional spatial orientation

Balance is achieved and maintained by a complex sensorimotor system. Orienting sensory information is derived from the paired vestibular labyrinths, visual input and somato-sensory afferents (joint, tendon and muscle position sense, and superficial sensation). This information converges on the brainstem vestibular nuclei and is integrated with modulating influences from the reticular activating system and higher centres: cortex, cerebellum and

extrapyramidal system. Effector pathways from the vestibular nuclei project to the oculomotor nuclei generating compensatory eye movements (i.e. the efferent limb of the vestibulo-ocular reflex, a three neurone reflex arc). Other efferents pass to the neck, trunk and limb muscles, the vestibulo-spinal tracts, which modulate spinal reflex arcs. Efferents also project to the vestibular cortex from the brainstem (Figure 15.1).

The vestibular system has three primary functions:

- 1 To stabilise gaze in space during head movement (e.g. reading a sign while walking)
- 2 To control posture when the head and body are static (e.g. while standing and during passive motion), and
- 3 To facilitate perception of orientation and motion.

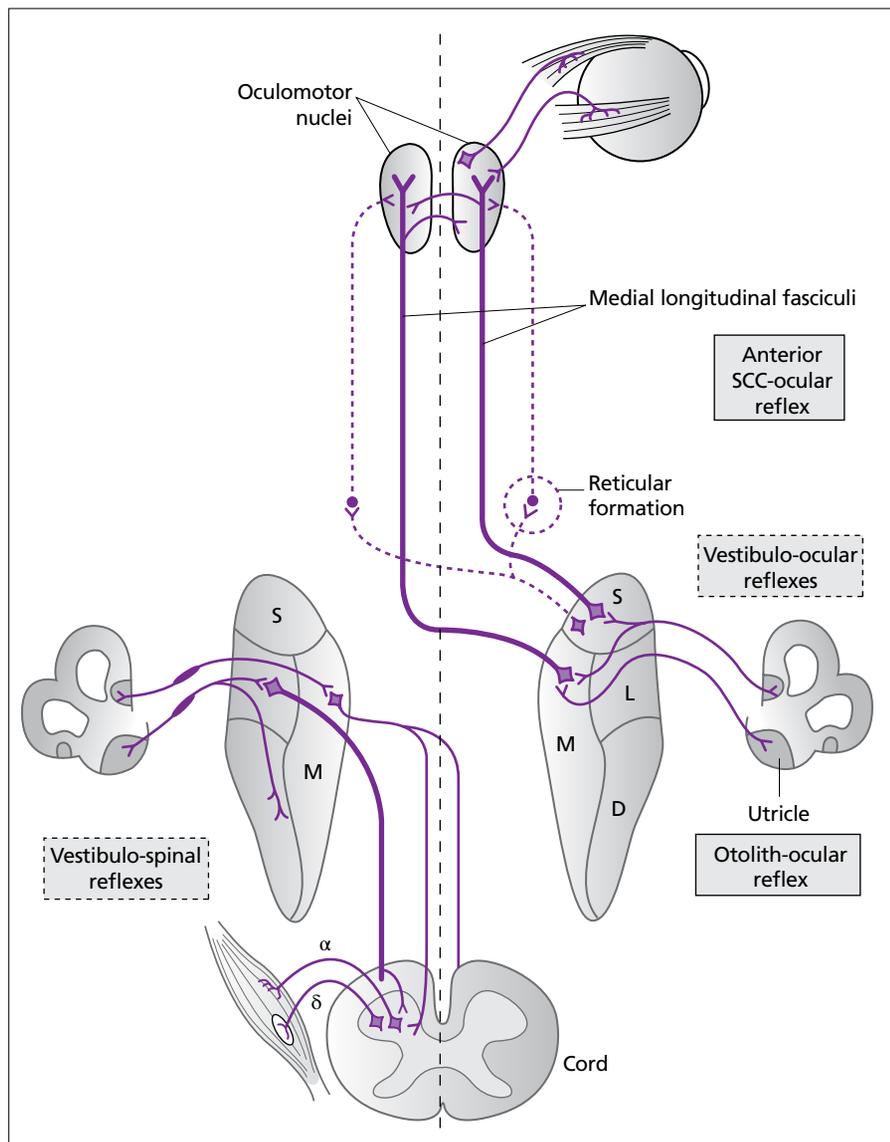

### Vestibulo-ocular reflexes

The parallel vestibular and oculomotor systems have evolved in such a way that they function in three similar planes. These planes of head movement are:

- 1 *Yaw*: head rotation about the vertical  $z$ -axis
- 2 *Pitch*: head flexion/extension about the horizontal  $y$ -axis, and
- 3 *Roll*: lateral head tilt about the horizontal  $x$ -axis.

This alignment, between spatial planes of the three semicircular canals and the planes of the three sets of extraocular muscles is such that when the two, paired labyrinths are excited, the two eyes move conjugately (i.e. they are yoked), producing an appropriately directed compensatory eye movement. This is the vestibulo-ocular reflex. For example, the paired horizontal semicircular canals function as a gauge of rotational acceleration in the yaw plane and are connected via the brainstem nuclei to the set of extraocular muscles whose primary direction of pull is also in the horizontal plane – the lateral and medial recti. The action of these muscles is to produce a compensatory eye movement in the horizontal plane in an equal and opposite direction to that of head movement, thus maintaining stable gaze.

The neuronal circuitry is similar for the vertical planes of pitch and roll: the anterior and posterior semicircular canals, sited diagonally to the sagittal plane (Figure 15.2) are connected to the paired extraocular muscles whose primary action is aligned to the spatial planes of each canal. Thus, the superior and inferior recti move the eye up or down when that eye is adducted; the inferior and superior oblique muscles move the eye up and down when it is adducted.

**Figure 15.1** Vestibulo-ocular and vestibulo-spinal reflexes. S, L, M, D: superior, lateral, medial and descending vestibular nuclei.

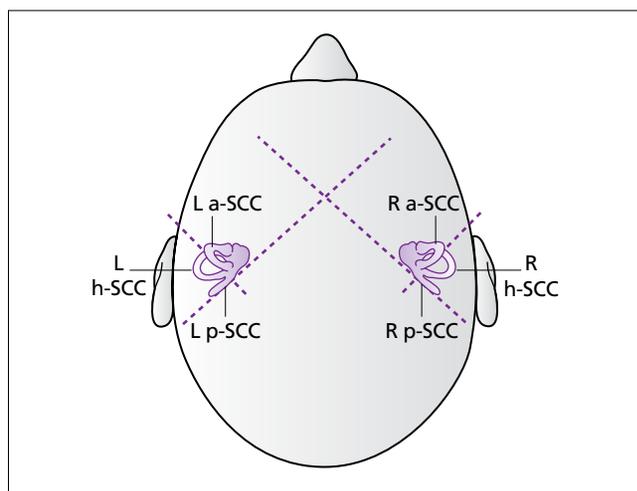

The system is driven by the relationship between endolymph and cristae (Chapter 2). The relevant principles were described by Ewald in 1892:

- 1 Head and eye movements always take place in the plane of the canal that is stimulated and in the direction of endolymph flow.
- 2 In the horizontal canal, endolymph flow towards the ampulla (ampullo-petal) causes a greater response than endolymph flow away from the ampulla (ampullo-fugal).
- 3 In the vertical canals, endolymph flow away from the ampulla (ampullo-fugal) causes a greater response than endolymph flow towards the ampulla (ampullo-petal).

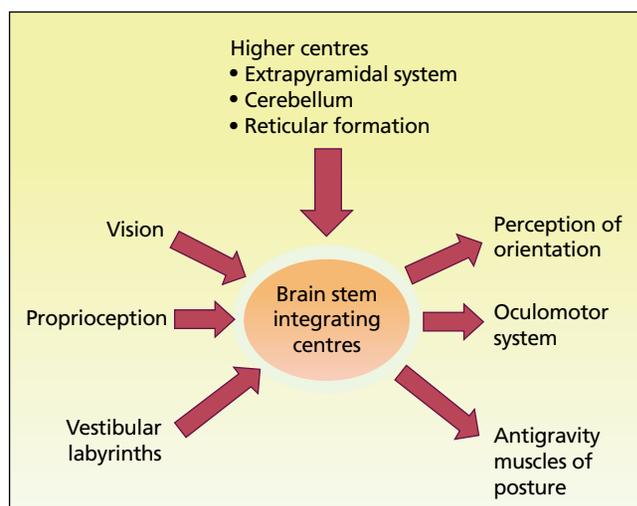

### Encoding of head movements in space

Sensory epithelium of each vestibular end organ includes the maculae found in the utricle and saccule, and the cristae, found in the ampulla in each of the three semicircular canals. Both maculae and cristae contain sensory hair cells with projecting kinocilia. Linear

acceleration and gravitational forces are transduced by the otolith organs of the utricle and saccule; angular acceleration is transduced by the cristae. As a result of the orientation of the semicircular canals and arrangement of hair cells, head movements in any plane are encoded by the pattern of deflection of kinocilia. Stabilising sensory information thus derived is relayed to the vestibular nuclei, integrated and stored in a data centre probably within the reticular formation. New sensory data are constantly compared with this data bank; under normal circumstances, there is a match between visual, proprioceptive and vestibular inputs, thus maintaining equilibrium (Figure 15.3). This matching up of sensory inputs is essential for spatial orientation and perception of motion. Vertigo results from a mismatch between sensory information from these inputs, leading to impaired perception of a stationary environment. Vestibular sensations can also occur as a response to a moving environment (e.g. motion sickness), or with pathology of any of the three sensory stabilising systems. Examples of the latter include

**Figure 15.2** Topographical orientation of the anterior, horizontal and posterior semicircular canals. a-SCC, anterior semicircular canal; h-SCC: horizontal semicircular canal; p-SCC: posterior semicircular canal. Source: Rudge 1983. Reproduced with permission of Elsevier.

disturbed labyrinthine input during an attack of Ménière's disease; altered visual input with the first use of varifocal lenses; or with impaired proprioception following a knee joint replacement. The unpleasant autonomic sensations of nausea, vomiting and anxiety that often accompany vertigo are mediated by vestibulo-autonomic pathways.

## Neuro-otological assessment

### Clinical examination

#### What to examine

- Brief neurological examination
- Gait and posture

- Nystagmus, eye movements, positional testing
- Orthostatic blood pressure.

#### When to examine what – the clinical presentation of balance disorders

- Acute vertigo
- Recurrent vertigo and dizziness
- Chronic dizziness and imbalance.

As in any other clinical examination in medical practice, the physician is guided by the symptoms reported by the patient. A good physician would not spend too much time examining the vestibular-ocular reflex if his/her patient's dizzy spells are always preceded by chest pain and palpitations. If we focus on peripheral and central vestibular disorders, these can usually be diagnosed with a good history and examination. A summary of the clinical examination is first presented, followed by a strategy to apply the various components of the examination to the specific clinical presentations.

#### What to examine

##### Brief neurological examination

Neurological disease affecting the sensory input, strength, tone, coordination or praxis of the lower limbs will cause a degree of unsteadiness and sense of imbalance. As these sensations can be described by patients as 'dizziness', the clinician must be sure that the cause of his patient's dizziness or imbalance is not a lower limb neurological problem. Neuro-otologists of any background (ENT, audiovestibular medicine, audiology or neurology) should examine the patient neurologically, particularly the gait and postural reflexes, if explaining the patient's symptoms on the basis of a vestibular disorder prove elusive. Of note, patients may, during the early stages of a neurological gait disorder (small vessel white matter disease in particular) describe imbalance and yet formal examination of the lower limbs is normal. Slight unsteadiness during turning while walking or hypokinetic postural responses during pulls to the trunk may be the only objective abnormality during the examination, as is discussed later.

##### Gait and posture

Examination of gait with eyes open is very useful for detecting neurological disorders that compromise balance and gait and can therefore predispose to falls. It is indeed an important part of the general neurological examination and there are many specific gait types (e.g. parkinsonian, cerebellar, polyneuropathic, tabetic and spastic gait). The clinician should observe the general speed of gait, size of the base of support, regularity of step production and turning. Difficulties in initiating gait can be seen in gait apraxias, small vessel disease and parkinsonism.

Increasing the base of support is an automatic reaction adopted when healthy people (walking on a boat, drunkenness) or patients perceive that their balance capabilities are reduced. Broad based gait is observed in any condition limiting balance, including acute vertigo (both peripheral and central), polyneuropathies, cerebellar disease and many pyramidal and extrapyramidal disorders. The relatively narrow gait present in patients with idiopathic Parkinson's disease may indicate reduced adaptability (to their objective imbalance) in their motor system. Unilateral vestibular disorders, except in the acute vertigo phase, do not cause significant abnormalities.

- *Gait test*: this is a 5 m walk, first with the eyes open and then with the eyes closed, with the examiner close alongside for

safety. The patient should walk at normal speed towards a fixed target. As with Unterberger's test, patients with recent unilateral vestibular hypofunction tend to deviate towards the side of the lesion.

- **Tandem gait test:** this is useful for assessing vestibulo-spinal function. When performed with the eyes open, tandem walking is primarily a test of cerebellar function because vision compensates for chronic vestibular and proprioceptive deficits. Tandem walking with eyes closed is a good test of vestibular function as long as cerebellar and proprioceptive functions remain intact: ask the patient to take 10 heel-toe steps at a comfortable speed, starting with feet in the tandem (heel to toe) position and arms folded against the chest. Most normal subjects can manage 10 accurate tandem steps in three trials.
- **Romberg's test:** described in 1846 in patients with dorsal column loss following tabes dorsalis; the test is positive if there is increased body sway when the eyes are closed and the patient stands with feet close together. The principle behind the test is that balance is maintained with minimal physiological sway when all three sensory inputs are functioning (i.e. vision, vestibular input and proprioceptive input). With the loss of one or more of these inputs, there is increased physiological sway.
- **Unterberger's test:** In the 1930s, Unterberger described the tendency for vestibular imbalance to cause patients to turn when walking. The test identifies that the direction of turning in patients with unilateral vestibular deficits coincides with the direction of past-pointing and falling (i.e. in the direction of the slow component of nystagmus). The test is performed by asking the patient to stand with arms extended and thumbs raised, to close their eyes and asked to march on the spot for about 50 steps. However, there is often marked variability in the rotation angle in the same subject on repeated testing and non-organic problems frequently produce apparent abnormalities, thus Unterberger's test should be interpreted with care.

### Nystagmus, eye movements, positional testing

**Clinical examination of eye movements** The vestibular system provides a powerful input to the oculomotor system so eye movements must be examined in detail. In a patient suspected to have a peripheral vestibular disorder (labyrinth and VIIIth nerve) one can consider that the examination has two broad aims:

- 1 To search for direct ocular signs indicative of a peripheral vestibular disorder, typically nystagmus, benign paroxysmal positional vertigo (BPPV) or a positive head thrust test (see Head impulse test)
- 2 To exclude a central nervous system (CNS) lesion by making sure that non-vestibularly mediated eye movements are normal. The oculomotor examination should include:
  - Cover test
  - Search for spontaneous and gaze-evoked nystagmus
  - Convergence
  - Smooth pursuit
  - Saccades
  - Vestibular-ocular reflexes
  - Positional manoeuvres.

If the patient reports diplopia, or if at any point during the examination the two eyes appear dysconjugate, examination of the individual cranial nerves III, IV and VI and a cover test is mandatory (Chapter 14). Beware of infantile strabismus as oculomotor findings become less reliable.

### Cover test

Misalignment of the visual axes needs to be identified (i.e. manifest or latent strabismus). Either can lead to eye movement abnormalities as fixation switches from one eye to the other. If one eye has become amblyopic, the better eye should be assessed, both by clinical tests and oculography. Commonly, a patient with acquired strabismus will turn or tilt their head to minimise diplopia. Turning is seen typically with paresis of a horizontal extraocular muscle (e.g. following VIth nerve palsy), when the head is turned towards the weak lateral rectus. Following a IVth nerve palsy, the head tends to tilt, if slightly, towards the side of the weak superior oblique.

To perform the cover test, the patient is asked to fixate a distant target, with refractive correction in place. Each eye is covered in turn; this prevents foveal fixation by the covered eye. The cover test relies on the fact that foveation occurs in the eye forced to fixate; movement redress occurs if the retinal image was not directed to the fovea before the eye took up fixation. The patient is asked to fixate with the uncovered eye on a target; the covered eye is then observed as the cover is removed.

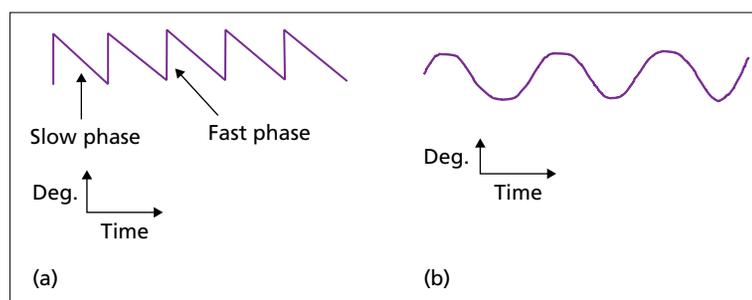

**Horizontal misalignment** A squint (manifest strabismus) is seen when the visual axes of the two eyes deviate with the eyes uncovered: an exotropion (divergent squint) means that the affected eye is turned outward in primary gaze; an esotropion (convergent squint) describes the eye turned inward in primary gaze. Latent strabismus describes the situation when misalignment is corrected spontaneously by fusional mechanisms when both eyes are uncovered (i.e. the problem becomes apparent only on cover testing). Exophoria is identified when the eye moves inward as the cover is removed; esophoria is identified when the eye moves outwards with refixation.

**Vertical misalignment** Skew deviation is a vertical misalignment of the visual axes (i.e. it is a vertical tropia), and may be either a hypotropia (uncovered eye moves up as the other is covered) or a hypertropia (the uncovered eye moves down as the other is covered). By convention, the higher of the eyes is referred to as hypertrophic/hyperphoric, regardless of which is at fault. The hypertropia may be the same in nearly all positions of gaze (concomitant) or vary with right or left gaze (non-concomitant) and is usually associated with the ocular tilt reaction (OTR). When non-concomitant, skew deviation can be distinguished from a superior oblique palsy by the direction of any torsion of the elevated eye (intorsion with a skew, extorsion with a IVth nerve palsy). Skew deviation can be either sustained or paroxysmal. Skew deviation is caused typically by brainstem or cerebellar lesions.

**Latent nystagmus** Nystagmus is seen in the uncovered eye during cover testing. Typically, the nystagmus beats away from the covered eye and is conjugate. Latent nystagmus can be unilateral or bilateral. Some cases are associated with congenital nystagmus (see Congenital nystagmus).

### Spontaneous nystagmus

The search for spontaneous nystagmus begins in the primary (straight ahead position) of the eyes. In the presence of nystagmus, ascertain: (i) the waveform (e.g. saw-tooth, jerk or 'beating nystagmus'); or pendular nystagmus, and (ii) the direction of the beat (Figure 15.4a). As spontaneous nystagmus is often enhanced by convergence, it is convenient to examine convergence at the same time, by slowly moving an object in and out along the visual axis.

**Figures 15.4** Oculographic recordings of types of nystagmus: (a) saw-tooth or 'beating' nystagmus (the direction of beat is defined as the direction of the fast phase with upwards deflection of the recording indicating movement to the right); (b) pendular nystagmus.

Absence of convergence occurs in midbrain lesions, but it must be remembered that reduced/absent convergence is very common in normal people above the age of 60 years.

Patients have to be clearly instructed to look at a pre-determined fixation object and the eyes should be well-illuminated. The presence of spontaneous nystagmus in primary gaze immediately raises the question, is this caused by a peripheral or central lesion? If the patient is in the midst of an acute vertigo attack, with severe unsteadiness and nausea, the nystagmus can be either peripheral or central, but if the patient comes as a routine ambulatory patient and does not look acutely ill, the nystagmus is more likely to be of central origin. A clinically visible nystagmus of peripheral vestibular origin can only be seen in the acute phase of the disorder (e.g. vestibular neuritis, Ménière's disorder). The nystagmus is essentially horizontal with a minor torsional (rotary) component. The fast phase beats contra-lesionally, but in the acute irritative phase of Ménière's attack, it can beat ipsi-lesionally.

Can a nystagmus like this result from a central lesion? Yes, in particular, lesions in the VIIIth nerve root entry zone or vestibular nuclei, but, almost invariably, there are additional brainstem symptoms and signs. Any other nystagmus is almost certainly of central origin. These differ from a peripheral vestibular nystagmus in waveform (e.g. pendular, a quasi-sinusoidal oscillation of the eye without distinction between the slow and fast phases; Figure 15.4b) or beat plane (e.g. vertical up or downbeat, or torsional nystagmus). A large horizontal nystagmus in a patient with no significant vestibular or neurological symptoms should always raise the possibility of congenital nystagmus.

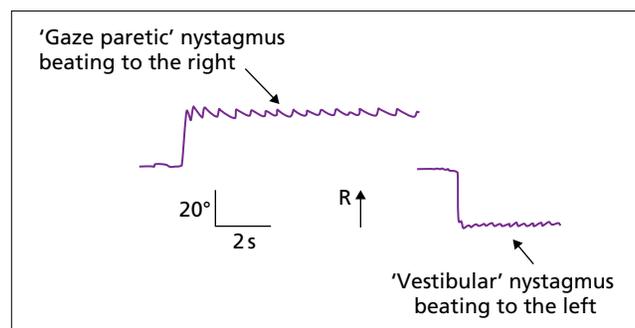

### Gaze evoked nystagmus

Soon after the acute stage of a peripheral vestibular lesion, the nystagmus is not visible in primary gaze but only on gaze deviation in the direction of the fast phase. A useful classification for the severity of nystagmus is Alexander's law:

- *First degree nystagmus*: only visible on gaze deviation in the direction of the fast phase
- *Second degree nystagmus*: when present in primary gaze as well as the direction of the fast phase, and
- *Third degree*: when it is also visible when the eyes are deviated in the opposite direction to that of the fast phase.

Alexander's law applies to most peripheral vestibular nystagmus. Downbeat nystagmus in primary gaze, which is always of central origin, often does not enhance on looking down but on looking sideways.

Nystagmus on gaze deviation can also indicate a central lesion. This is what is frequently called gaze paretic nystagmus, not to be

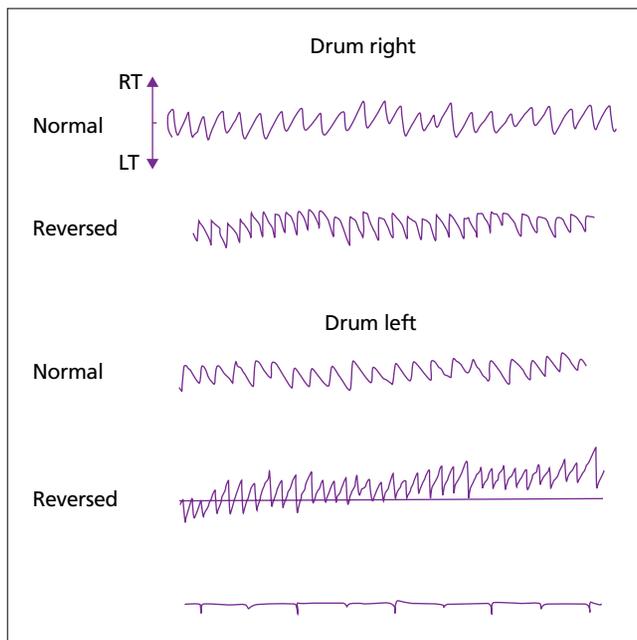

**Figure 15.5** Oculographic recordings of Brun's nystagmus. Horizontal electro-oculography (EOG) in a patient with Brun's nystagmus caused by a large right-sided cerebello-pontine angle lesion. Note the larger amplitude 'gaze paretic' nystagmus beating to the right (top trace) and the smaller amplitude 'vestibular' nystagmus beating to the left (lower trace).

confused with the broader term gaze evoked nystagmus. The term gaze paretic implies that the patient has difficulty in holding gaze in an eccentric position in the orbit. The eyes drift in centripetally with a slow phase which progressively decreases in velocity, until a new saccade re-fixates the eccentric target. This nystagmus, usually of larger amplitude than peripheral vestibular nystagmus, is caused by damage to the gaze holding mechanisms mediated by ipsilateral brainstem and cerebellar structures. An example of vestibular and gaze paretic nystagmus present in the same patient is Brun's nystagmus caused by a large, extracanalicular, acoustic neuroma. The vestibular nystagmus, as expected in any destructive vestibular lesion is in the opposite direction to the side of the tumour. The coarser nystagmus, evoked by looking in the same direction as the tumour, is gaze paretic because of brainstem-cerebellar compression (Figure 15.5). Gaze paretic nystagmus can be present in all directions of gaze in the same patient, typically in symmetrical processes such as cerebellar degenerations.

### Congenital nystagmus

The patient with congenital nystagmus rarely complains of oscillopsia, but does have a central eye movement abnormality. The nystagmus is in the horizontal plane and may change direction. There is a null point, which is often the eye position the patient adopts for reading; the slow phase is dysmorphic with non-linear slow phases and may be exponential as can be demonstrated on the

**Figure 15.6** Congenital nystagmus. EOG showing the optokinetic response in a patient with congenital nystagmus (i.e. reversal of optokinetic nystagmus [OKN] direction with the slow phase of the patient's eyes in the opposite direction to the direction of the OKN drum). Source: Hood 1984. Reproduced with permission of John Wiley & Sons.

electro-nystagmogram (ENG). Characteristically, there is reversal of optokinetic nystagmus (OKN; i.e. the slow phase of OKN does not match the direction of drum rotation; Figure 15.6).

### Smooth pursuit eye movements

When tracking an object with our eyes we use a combination of fast (saccadic) and slow phase eye movements. Strictly speaking, only the latter should be considered smooth pursuit. When the target moves slowly ( $<10\text{--}15^\circ/\text{s}$ ) the eye is capable of following it almost exclusively with smooth pursuit movements (i.e. with a gain of 1.0). When targets move at velocities  $>40^\circ/\text{s}$ , the proportion of tracking carried out by saccades increases progressively and the gain decreases. Clinically speaking, smooth pursuit looks abnormal or 'broken up' when the observer detects too much saccadic tracking; this gives a cogwheel, jerky appearance to the pursuit movements.

In principle, the presence of normal pursuit rules out a central vestibular disorder. Similarly, a patient with balance symptoms and unequivocally broken pursuit movements almost certainly has a neurological rather than a labyrinthine disorder. In order for the clinician to reach these conclusions confidently, the examination has to be technically correct. To start with the patient should be able to see the target correctly. Any object can be a target, not only the examiner's finger or pen. In patients too young, too old or with attentional problems, a substantial, solid target such as a key, a toy, a mobile phone or a credit card can increase performance. Make sure that in elderly subjects, with presbyopia and age-related convergence insufficiency, the object is presented at comfortable viewing distance. Sometimes the examination must be conducted with the patient wearing his/her own glasses.

Also the target has to be moved slowly, taking 3–4 seconds to travel from right to left, and vice versa. One cycle is not usually enough because patients may not understand the task and jump their eyes ahead of target; the patient should be encouraged to 'glue' their eyes to the target. Pursuit should be assessed in both the horizontal and vertical planes.

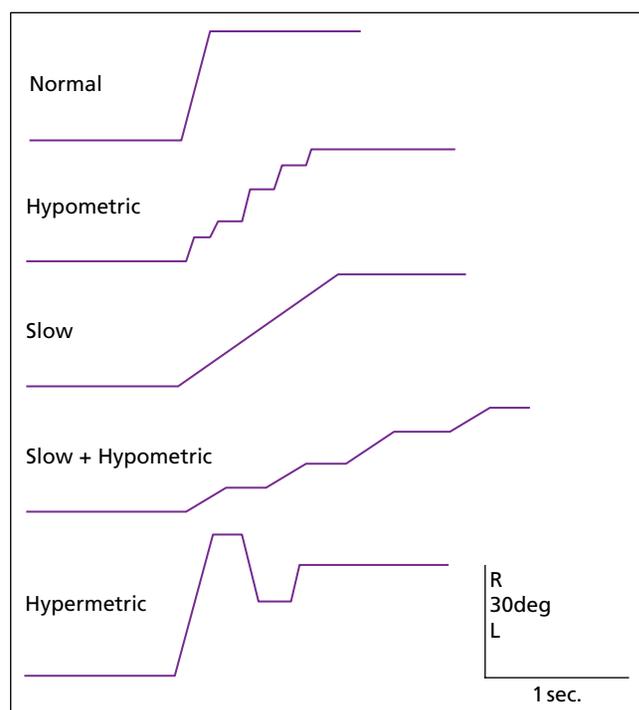

It is easy to identify asymmetric pursuit with excessive 'catch up' saccades in one direction only. When pursuit is broken, say to the right, the lesion may be in the (right) cerebellum or (left) parietal lobe. Brainstem lesions can have more complex effects (e.g. if they involve the vestibular nuclei which can generate nystagmus), but often are ipsilateral too. Small asymmetries in the horizontal plane, if consistent, are significant whereas asymmetries in the vertical plane can occur in many normal subjects. Global or pan-directional abnormalities of smooth pursuit are more difficult to interpret because pursuit pathways are polysynaptic, including visual pathways, parietal and frontal cortices, vestibular nuclei and cerebellar flocculus. This makes them vulnerable to trivial sources of mild diffuse CNS dysfunction, including ageing, psychotropic drugs and alcohol. The influence of age on pursuit is considerable so one must be careful in diagnosing bilaterally abnormal smooth pursuit in an elderly patient.

### Saccadic eye movements

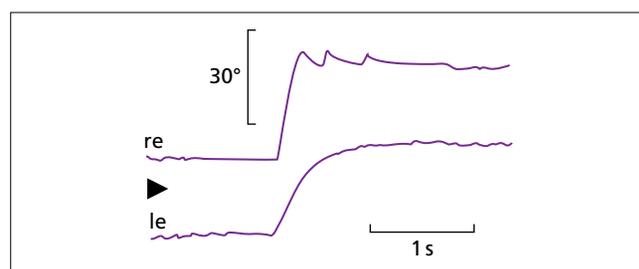

Saccades are fast movements of the eyes ( $200\text{--}500^\circ/\text{s}$ ) which allow us to shift gaze from one object of interest to another. These re-fixations occur incessantly so that gross saccadic defects are often detected when simply speaking to the patient. It should be said at the outset that just saying that a patient has abnormal saccades is not sufficient to make a topographic diagnosis. There are at least three independent properties of saccades: (i) velocity (normal, slow or absent saccades, e.g. a gaze palsy); (ii) accuracy (normo-, hypo- or hypermetric) and (iii) binocular conjugacy (conjugate or dysconjugate, e.g. internuclear ophthalmoplegia). All these three aspects can be assessed clinically.

**Saccadic velocity** It is possible to gain some insight into saccadic velocity by simply asking the patient to look fully to the right, left, up and down. However, it is better to assess accuracy at the same time, in which a visible target should be provided, usually the examiner's finger placed at  $20\text{--}30^\circ$  to the right–left up–down of primary gaze. The patient is instructed to look at the target when, for instance, the right or left finger flick, or when the hand opens up. It is customary to reinforce the visual stimulus with a simultaneous verbal command such as 'right', 'left' (from the patient's point of view!) or 'pen', 'finger'. Subtypes of saccades (e.g. self-paced saccades, anti-saccades) can be elicited with more complex instructions and these can be selectively abnormal in fronto-basal ganglia disorders.

**Saccadic accuracy** Saccadic amplitude is normally smaller than target amplitude and the subject makes 1–2 additional, smaller, corrective saccades towards the target. The presence of 2–3 corrective saccades consistently is considered saccadic hypometria, and severely hypometric saccades look fragmented, often called 'multiple step' saccades. If the initial saccade is too large and travels past the target, the patient makes corrective saccades in the opposite direction of the initial saccade. This is saccadic hypermetria, a reliable cerebellar sign (Figure 15.7). The appearance is similar to abnormal past-pointing during a 'finger–nose' test in an ataxic patient. By contrast, saccadic hypometria is less specific and can be caused by lesions in the cortex, basal ganglia, brainstem, cerebellum and oculomotor nucleus, nerve and muscle. Combined slow and

**Figure 15.7** Examples of normal and abnormal saccades. Idealised examples of normal and abnormal saccades; apart from a small degree of symmetric hypometria, which can be normal, abnormalities of saccades suggest CNS (or neuromuscular) disorder.

**Figure 15.8** Left internuclear ophthalmoplegia (INO). Right (re) and left eye (le) horizontal EOG in a patient with a left internuclear ophthalmoplegia (INO). Note the slower adduction velocity (slope) of the left eye, with respect to that of the right eye abduction velocity. The unocular or 'ataxic' nystagmus of the abducting eye, as shown here in 're', is a frequent component of the INO.

hypometric saccades are not uncommon, an extreme case is progressive supranuclear palsy (PSP; Chapter 6).

**Saccadic conjugacy** When examining saccadic conjugacy (the two eyes should travel at the same speed) it is important to ensure there is no individual IIIrd, IVth or VIth nerve palsy. A common source of dysconjugacy in the horizontal plane is the internuclear ophthalmoplegia (INO) in which the abducting eye saccades are fast and large, whereas saccades in the adducting eye are slow and small. INOs are caused by lesions of the medial longitudinal fasciculus (MLF) which connects abducens interneurons of the VI nucleus with medial rectus motor neurones in the contralateral VI nucleus.

Abducens interneurons cross the midline immediately to form the ascending MLF on the other side of the brainstem. Thus, a right INO means that right eye adduction during gaze to the left is slow, hypometric or incomplete because of a small right MLF lesion. As innervation to the eyes is yoked, the attempt of the CNS to overcome the limitation in adduction makes saccades in the abducting eye larger (hypermetric). This sequence of overshoots in the abducting eye leads to the characteristic monocular 'ataxic' nystagmus (Figure 15.8).

### Optokinetic nystagmus

The OKN system in humans is not a truly separate oculomotor system. When OKN is elicited with a small hand-held drum or by moving a newspaper in front of a patient's eyes, the slow phase movement comes from the smooth pursuit system and the re-setting eye movements (fast phases of OKN) are saccades. For these reasons, if smooth pursuit and saccades have been properly examined what can be learnt additionally from observation of OKN is very little. Peripheral vestibular lesions, unless acute and massive with clinically visible spontaneous nystagmus, leave OKN unaffected. A slight directional preponderance, concordant with the peripheral vestibular nystagmus, may be observed in a peripheral vestibular disorder, but gross asymmetries indicate CNS lesions.

### Vestibulo-ocular reflexes

The vestibulo-ocular reflex (VOR) stabilises gaze in space during head movements, thus allowing us to see clearly when for instance we walk, run or turn our head. It does so by generating slow phase eye movements of an almost equal velocity, but opposite in direction, to head movement. This is achieved by a three-neurone, short latency reflex: a Scarpa ganglion neurone, a vestibular nucleus neurone and an oculomotor neurone (III, IV or VI).

Thanks to our increased understanding of the physiological basis of the VOR and our improved skills in observing eye movements, we can assess the VOR in the clinic. Unilateral and bilateral loss of vestibular function can, in many cases, be identified clinically, but will be easier the more severe and the more acute the lesion is. In contrast, a unilateral, partial, long-standing, peripheral vestibular disorder cannot be detected clinically and a caloric test is required. The clinical manoeuvres available rely either on a slow doll's head manoeuvre assessed either by (i) direct observation of the eyes or ophthalmoscopy and (ii) measurement of visual acuity; or a fast version of the doll's head, the 'head impulse' or 'head thrust' test.

### Doll's head eye manoeuvre

This manoeuvre requires the patient sitting in front of the examiner, close enough to be able to observe the patient's eyes carefully. The patient is instructed to fixate a feature of the examiner's face (nose or bridge of nose). The examiner then turns the patient's head from side to side, at a frequency of 0.5 to 1 Hz. In the complete absence of VOR, the patient's eye movements will not be smooth but will be interrupted by 'catch-up' saccades towards the fixation target. This occurs because at frequencies of 0.5–1 Hz, a head oscillation of  $+30^\circ/s$ , will generate peak head velocities above  $100^\circ/s$  which are too high for the pursuit or cervico-ocular reflex to compensate. As slow phase eye movements are unable to keep up with the target, catch-up saccades are put in, and these can be easily observed if close enough. In patients with bilateral severe loss of vestibular function (e.g. gentamycin ototoxicity, meningitis or

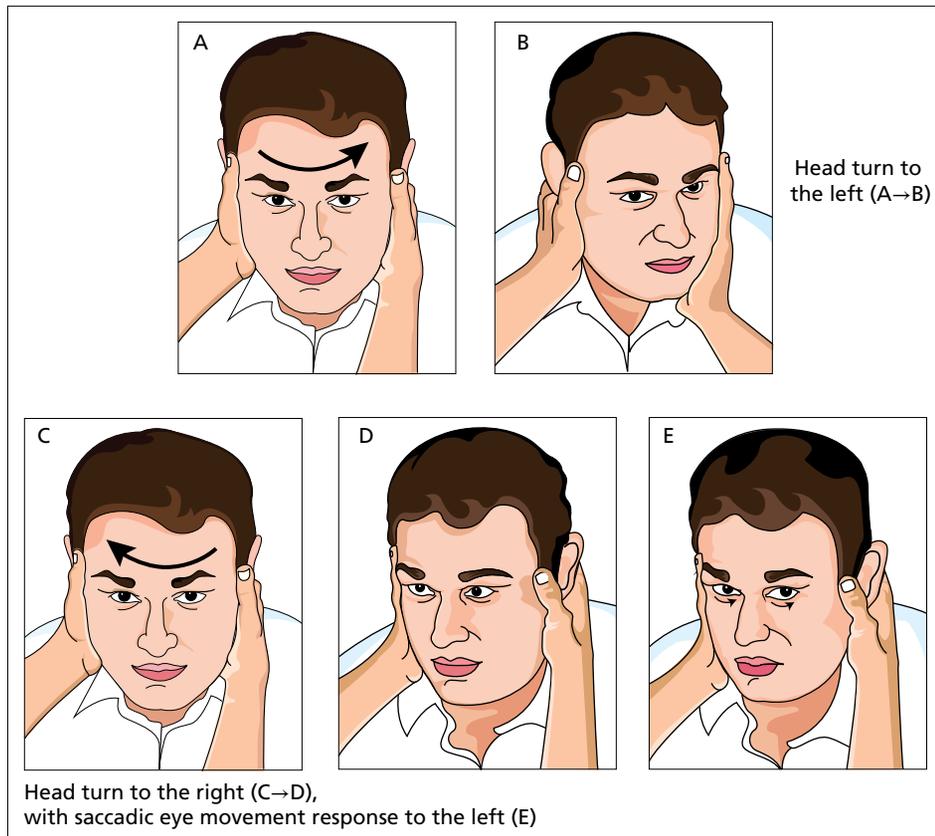

idiopathically), the manoeuvre is positive. A further procedure uses ophthalmoscopy for the assessment of vestibular disorders. The ophthalmoscope is a powerful magnifying glass and nystagmus of small amplitude or catch up saccades during head turns as described above can be detected easily.

### Dynamic visual acuity

A similar movement of the head can be used to investigate the VOR while reading a visual acuity chart. A baseline, binocular visual acuity measurement is noted, say 6/6. Standing behind the patient, the examiner oscillates the patient's head at about 1 Hz while a new visual acuity measurement is taken. A normal subject's visual acuity does not change with respect to the baseline reading or it can deteriorate by one line, say 6/9. A loss of two lines in visual acuity must be treated as suspicious and when three lines or more are lost, the results are frankly abnormal, suggesting the patient's VOR is grossly reduced. False positives may occur if the patient has a spontaneous nystagmus (e.g. a down-beating nystagmus), which is exacerbated by head movement and/or lateral gaze. False negatives occur if the patients themselves oscillate the head, because they briefly stop the head motion and get a snapshot of the visual acuity chart. Although the examination of a patient's eyes during the doll's head manoeuvre can in some instances detect a unilateral lesion, this is detected more efficiently with the head impulse test.

### Head impulse test

The value of VOR examination as described is limited by the fact that they are all carried out with relatively low head velocities. The VOR is only irreplaceable during high accelerations of the head. Neither pursuit, optokinetic nor cervical mechanisms can fully take over from the VOR during brisk head movements. For this reason, Halmagyi and Curthoys (1988) (Figure 15.9) have popularised the examination of the doll's head manoeuvre with discrete, brisk and unpredictable head turns. In essence, the patient is seated with the examiner at close range to observe the eyes carefully or with a video-camera if it is wished to document the findings. The patient is instructed to fixate a target such as the examiner's nose and the head is turned briskly in discrete steps of  $+10$ – $15^\circ$  across the midline by the examiner, thus producing head velocities of several hundred degrees per second. A fast right head (nose) turn will make a patient with a right-sided vestibular loss introduce one or more catch-up saccades towards the target (i.e. towards the left), in order to refixate. These catch-up saccades can easily be identified by a trained observer. The test is clearly useful for identifying an acute, unilateral, peripheral vestibular deficit, for instance in a patient with vestibular neuritis. In patients with chronic uncompensated, incomplete unilateral lesions, the test is often negative or inconclusive. A study comparing caloric testing with the head impulse test shows that the overall sensitivity

**Figure 15.9** Halmagyi head thrust test. A fast right head turn will make a patient with a right-sided vestibular loss introduce one or more catch-up saccades towards the target (i.e. towards the left), in order to refixate.

(a)

(b)

**Figure 15.10** Two ways of examining vestibulo-ocular reflex suppression (VORS). (a) The patient fixating an object carried in his bite and (b) his outstretched thumbs. The examiner helps the subject oscillate his head (a) or trunk (b) while carefully observing the patient's eyes, to see if vestibular nystagmus is suppressed (good VORS) or breaks through (poor VORS).

of the head impulse test is 34%. However, specificity is high (100%) and all patients with a canal paresis of >87% had a positive head impulse test.

### Vestibulo-ocular reflex suppression

When a subject rotates the head in the environment, the eyes adopt a pattern of alternating slow and fast phases, a physiological vestibular nystagmus. In a normally lit room, this is aided by OKN. The human brain can also suppress the vestibulo-ocular reflex suppression (VORS) with mechanisms closely related to pursuit mechanisms and pathways. Abnormalities in VOR are indicative of central dysfunction, as discussed already for smooth pursuit.

Clinical examination of VORS is easy, both clinically and during oculography (Figure 15.10). The general principle is to oscillate the patient while s/he fixates a head-fixed target. Any obvious break-through nystagmus indicates poor suppression. In the clinic this can be achieved by asking the patient to clasp the hands together in front and put the thumbs up as a target; the patient can then oscillate side to side 'en bloc', by himself/herself if standing up, or the examiner can oscillate the patient's swivel chair if sitting down. Alternatively, the patient can bite and carry a ruler with his/her teeth and fixate on an object attached to the opposite end, while moving the head side to side. As with pursuit, the oscillation should be slow, say 2–5 s from left to right, and vice versa (0.1–0.25 Hz) and the examiner should have a good view of the patient's eyes.

Patients with peripheral vestibular lesions have a normal VORS (or even 'supra-normal' as they are trained to suppress their own nystagmus). In central lesions, the abnormality of pursuit and VORS go hand in hand (i.e. a patient with a right cerebellar lesion

will have abnormal rightwards pursuit and abnormal VORS, with visible nystagmus breaking through, when turning the head rightwards).

### Positional manoeuvres, Dix–Hallpike and roll manoeuvres

One of the most common causes of vertigo is BPPV. This accounts for one-quarter of all patients presenting with dizziness and vertigo. Positional manoeuvres are a vital component of the examination of the balance disordered patient, particularly in the light of effective treatments available for BPPV. This condition is usually diagnosed from the history and confirmed using the Dix–Hallpike and supine roll manoeuvres. With the pathological ear undermost, the Dix–Hallpike manoeuvre and roll manoeuvre produces characteristic nystagmus (Table 15.1).

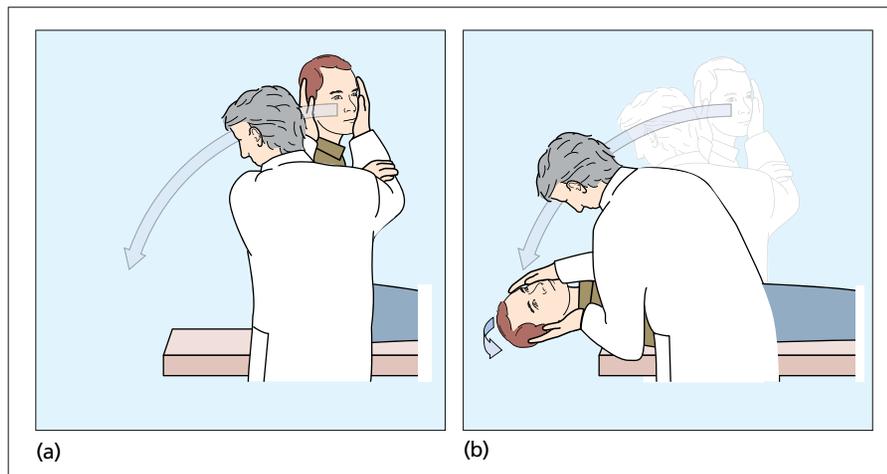

The Dix–Hallpike manoeuvre is a valuable test in such patients and can distinguish between the peripheral nystagmus of BPPV, central positional nystagmus and atypical positional nystagmus (Figure 15.11):

- Seat the patient on a couch so that when supine, his/her head extends over the end of the couch.
- Ask the patient to remove spectacles (warn them they may feel intensely dizzy with the test) and to keep the eyes open and maintain gaze on the examiner's forehead (remove your stethoscope – it can fly around.)
- The patient's head is turned 30–45° towards the examiner and moved rapidly into the lying position with the head hanging 30° over the head of the couch. In this way the posterior semicircular canal of the undermost ear is moved directly through its plane of orientation. The patient's eyes are observed for nystagmus for up to 1 minute.
- The manoeuvre is carried out with one and then the other ear undermost.

**Table 15.1** Characteristic features of different types of positional nystagmus.

	p-BPPV	h-BPPV geotropic	h-BPPV apogeotropic	a-BPPV	Central
History	Vertigo on turning over in bed, getting in or out of bed, looking up or down	Vertigo on rolling from side to side in bed	Same as for geotropic h-BPPV	Same as for p-BPPV	Often little in the way of positional vertigo
Diagnostic positional test	Hallpike or side-lying (on affected side)	Supine roll test	Supine roll test	Hallpike, or side-lying (on opposite side)	Hallpike
Latency	2–20 s	5 s	Nil	2–20 s	Nil
Nystagmus	Torsional (geotropic)/vertical (upward) with head tilt in the plane of the posterior canal	Horizontal (geotropic) more marked towards affected ear	Horizontal (apogeotropic) more marked towards affected ear	Vertical (downbeat)/small torsional component towards affected ear	Pure vertical or torsional not direction changing
Duration	40 s	<60 s	60 s	40 s	60 s
Reversibility	On sitting	On rolling to other side	On rolling to other side	On sitting	No
Fatiguability	Yes	Yes	No	Variable	No

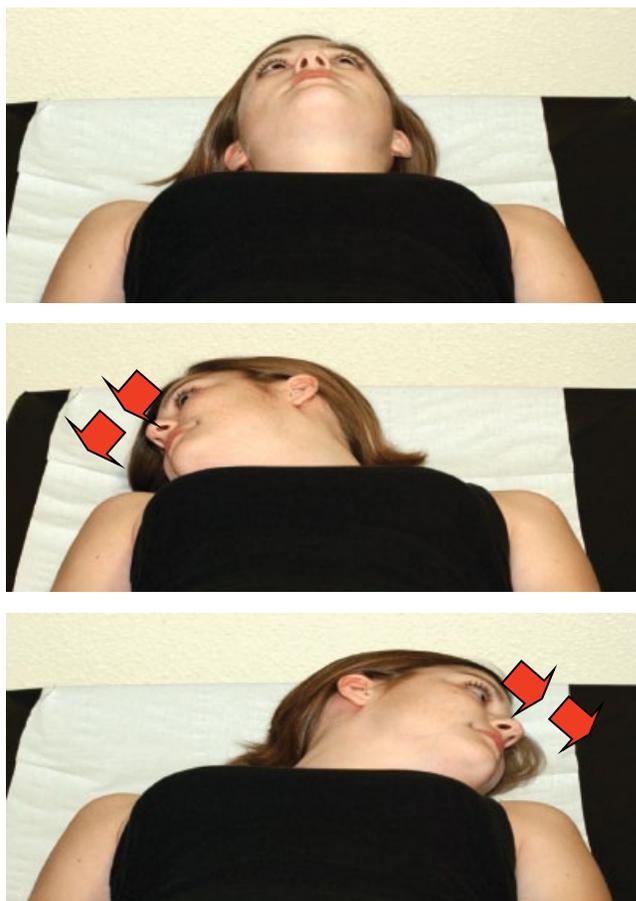

a-BPPV, anterior canal benign paroxysmal positional vertigo; h-BPPV, horizontal canal benign paroxysmal positional vertigo; p-BPPV, posterior canal benign paroxysmal positional vertigo.

**Figure 15.11** The Dix–Hallpike manoeuvre (see text).

In central positional nystagmus, sometimes seen in multiple sclerosis, Arnold–Chiari malformations, posterior fossa lesions or cerebellar vascular disease, typically there is no latency to the onset of nystagmus, frequently little vertigo and no adaptation or fatigability. The direction of nystagmus may be towards the uppermost ear, torsional or may be vertical. Positional nystagmus may be the only sign of posterior fossa pathology.

The supine roll manoeuvre is carried out by seating the patient on the couch with their legs outstretched (Figure 15.12). Holding

their head, the examiner lays the patient straight back on the couch looking for horizontal nystagmus. Once supine, the patient's head is turned towards the right side through 90° around the longitudinal z-axis. Typically, the induced nystagmus of canalolithiasis of horizontal canal BPPV (h-BPPV) beats towards the undermost ear (geotropic), and is more prolonged than that of posterior canal BPPV (p-BPPV). The nystagmus and associated vertigo is allowed to settle. The patient's head is then turned 180° to the left around the same longitudinal z-axis. Any nystagmus

**Figure 15.12** The roll test (see text). Source: Bertholon 2006. Reproduced with permission of Sage.

caused by horizontal canalolithiasis reverses (e.g. right-beating nystagmus becomes left-beating), in that it remains geotropic and is direction changing.

To check for h-BPPV in the opposite ear, repeat the manoeuvre, starting by moving the patient's head from the straight back position through 90° to the left side, waiting for the nystagmus to appear and disappear, and then rolling the head through 180° to the right. Laterality of h-BPPV is assigned to the side to which the more marked horizontal nystagmus occurs. Occasionally when the head is rolled there is apogeotropic horizontal nystagmus (i.e. beating away from the ground). This similarly reverses when the head is turned to the other ear and is a result of h-BPPV cupulolithiasis. In this instance the side of head turn resulting in weaker nystagmus indicates the affected ear.

### Orthostatic blood pressure

Even in specialised neuro-otological clinics, many patient's symptoms turn out to be caused by orthostatic drop in blood pressure. The incidence is higher in non-specialised setting, often associated with old age, diabetes, antihypertensive medication and vaso-active medication (e.g. prostate alpha blocking drugs). In patients whose symptoms develop while standing or walking, the blood pressure should be measured when supine after 10 minutes lying, immediately on standing and again after a further 3 minutes standing. Heart rate should also be recorded as

it can identify the postural orthostatic tachycardia syndrome (POTS; Chapter 24).

## When to examine what – the clinical presentation of balance disorders

### Acute vertigo

Here you need to establish if the vertigo is just bothersome but otherwise trivial, and if it is likely to be caused by a peripheral vestibular disorder or a CNS lesion, most commonly a stroke. Enquire directly about central symptoms and also about acute hearing loss or tinnitus. Look for general neurological signs (including oculomotor signs such as skew deviation, abnormal pursuit or saccades) and unilateral deafness. Establish if the nystagmus is compatible with a peripheral disorder (unilateral, mostly horizontal beating). If the above examination does not indicate CNS disease, a positive (abnormal) head impulse test in the opposite direction to that of the nystagmus would confirm the peripheral origin of the vertigo. Note that patients with BPPV present to A&E departments so be ready to do a positional manoeuvre. If you are in doubt organise a CT angiogram and/or MRI. Investigation suite audio-vestibular tests are rarely necessary in the acute situation and, except in specialised centres, not available as emergency investigations.

### Recurrent vertigo

The common aetiologies in this group are BPPV and migraine. Thus, eliciting positional triggers and migrainous features in the history is paramount. Positional manoeuvres are essential for the diagnosis of BPPV but examination in patients with vestibular migraine is by and large normal. Diagnostic criteria for Ménière's disease require the presence of a sensori-neural hearing loss, so otoscopy plus clinical and instrumental hearing tests are mandatory. Postural blood pressure measurements are useful, particularly in the elderly. Audiological investigations can be helpful: normal in migraine and abnormal in Ménière's disease. Most patients with recurrent (and chronic) symptoms end up having MRI, but this is not strictly necessary if clinical and laboratory audio-vestibular examination is normal.

### Chronic dizziness and/or unsteadiness

Most patients in this group will have a previous history of vestibular symptoms, followed by poor central vestibular compensation or secondary psychological symptoms. The examination is usually normal. Audio-vestibular investigations (if not performed already) may help to understand the underlying condition and quantify the overall level of residual vestibular function. The risk in the 'chronic dizzy patients' category is that a neurological gait disorder is missed – early or circumscribed (vestibulo-cerebellar) disorders are the most common. Patients need a general neurological examination, paying attention to sensory-motor function of the lower limbs and gait, and a detailed eye movement examination looking for CNS signs or bilaterally abnormal head impulse test (indicating bilateral vestibular failure). Eye movement recordings showing central-type nystagmus and abnormalities of saccades and/or pursuit will reinforce the diagnosis of a CNS disorder. MRI head scans are useful to document cerebellar disorder or white matter small vessel disease.

Table 15.2 lists the main causes of dizziness according to the generally recognised site of lesion, and Table 15.3 identifies the main medical causes of dizziness.

## Commonly used vestibular investigations

The three approaches to physiological investigation of the vestibular system are:

- Recording eye movements
- Measurements of postural changes, and
- Measurements of the caloric responses (to hot and cold thermal irrigations) of the semicircular canals.

Eye movements are well-suited to measurement. Ocular motility is restricted to the rotations of the globe, the eye muscles moving the globe against an unchanging resistance. Different types of eye movement can be distinguished by their physiological properties. Direct observation of eye movements is useful, while recording techniques such as electronystagmography, video-oculography (VOG) and spiral coil recordings allow detailed evaluation and provide a permanent record for comparative purposes.

### Electronystagmograph

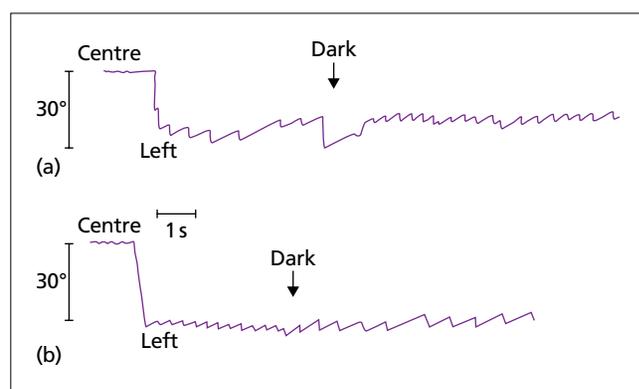

Electro-nystagmography (ENG; also known as electro-oculography, EOG) has traditionally been the simplest and most readily available system for recording eye movements. A recording electrode placed laterally to the eye becomes increasingly positive as the eye turns towards it and negative when the eye turns away. The voltage change represents the change in eye position. Only small angular movements are involved in nystagmus and thus the relationship between voltage change and eye movement is virtually linear within small degrees of arc. The polarity of the recording is arranged so that a deflection of the eye to the left causes a downward deflection of the pen and vice versa. The sensitivity of ENG is such that it can record consistently eye rotations of 0.5°. This sensitivity is actually less than that of direct visual inspection – approximately 0.1°.

The plane of the recording electrodes is in the plane of recorded eye movement; electrodes attached medially and laterally to the eye record horizontal components of eye movement, whereas those attached above and below record vertical components. A single-channel ENG machine summates horizontal movements of both eyes from bi-temporal recordings on to the same trace. A two-channel ENG records movement of each eye separately; four-channel ENG can record simultaneously vertical and horizontal movements. Paper speed at 10 mm/s is used, although when saccadic accuracy and velocity are measured, 100 mm/s or even faster speeds may be necessary. Calibration is such that a standard angle of eye deviation produces a defined amplitude of pen deflection – commonly 10 mm of pen deflection for each 10° of eye movement. A detailed standardised protocol is essential.

### Clinical relevance of ENG

The main value of ENG recordings is that some patients have demonstrable nystagmus only when optic fixation is removed.

- *Peripheral vestibular disorders*: unless acute, these are unlikely to be associated with nystagmus in the presence of optic fixation but nystagmus can be revealed if fixation is removed, i.e. with the use of the Frenzel's glasses or video- or electro-nystagmoscopy, and is of increased amplitude in darkness (Figure 15.13). Nystagmus is uni-directional with the largest amplitude on horizontal gaze towards the direction of the fast component (see Gaze evoked nystagmus).
- *Vestibular nuclei lesions*: in darkness the amplitude of nystagmus may hardly alter but the velocity of the slow phase may be decreased. Often the nystagmus is bi-directional.
- *Cerebellar lesions*: these may be associated with pathological square waves with duration <200 ms. With direct current ENG recordings a characteristic abnormality of cerebellar pathology is the failure to maintain lateral gaze, with a slow drifting movement of the eyes towards the midline. Rebound nystagmus can also be seen, but when cerebellar, it is transient and persists for a maximum of 20 s. Patients with cerebellar disease may have difficulties in executing commands for saccadic movement. When asked to turn their gaze laterally quickly, they overshoot the target.

**Figure 15.13** Electro-nystagmogram (ENG): effect of removing optical fixation. (a) The effects of gaze testing in a patient with a peripheral vestibular deficit: the spontaneous nystagmus enhances in the absence of optic fixation; (b) a central, gaze-evoked nystagmus: the nystagmus decreases in frequency and slow component velocity in the absence of optic fixation. ### Rotary chair testing

Rotary chair testing allows measurement and recording of eye movement responses to precise vestibular stimuli. This can be of immense clinical value. The VOR provides a simple example of a reflex arc comprising the vestibular sense organ, the primary, secondary and tertiary vestibular neurones and the effector organs, the oculomotor muscles. Angular acceleration in the plane of the semicircular canal leads to endolymph displacement in a direction opposite to that of rotation. As a consequence, the cupula of that canal deviates in the same direction as the endolymph, resulting in a change of vestibular tonus, an excitatory stimulus being matched by an inhibitory stimulus from the opposite side. As a result there is an impact on the pair of muscles producing the compensatory eye movement (i.e. excitation of the antagonist muscle and disinhibition of the agonist muscle). An acceleration to the right in the plane of the horizontal canal will produce deviation of the eyes to the left.

### Types of rotary chair stimuli

*Impulsive (step velocity) stimuli* Constant velocities such as 40, 60, 80 or 120°/s are attained with an abrupt acceleration of the chair, brought to constant velocity within 1 s. This constant velocity is maintained for up to 2 min while the nystagmic response dies away. The chair is suddenly brought to rest with the same deceleration and the normal limits of nystagmus intensity are established with normal subjects. This provides a rapid assessment of gain (peak slow component velocity ÷ change in chair velocity) and the time constant (time for the slow component velocity to fall to 37% of its initial value) of the canal reflex.

*Sinusoidal stimuli* To and fro swinging movements of the chair around its vertical axis are programmed with variable stimulus parameters (e.g. frequency and amplitude). The threshold for recordable nystagmus, defined as the angular acceleration maintained for 20 s that will produce nystagmus is 0.15°/s<sup>2</sup> in the absence of optic fixation. With optic fixation the nystagmus threshold is raised and is normally about 1°/s<sup>2</sup>. Rotational testing is normally performed in darkness but sinusoidal rotation can also be performed with the eyes focused on a target that revolves with the patient, around the vertical axis. This has the purpose of allowing VOR suppression to be assessed. This is an important test of central vestibular function, as visual suppression of the VOR is mediated by central vestibular pathways.

### Clinical relevance of rotary chair testing

Rotational stimuli can be used to demonstrate a directional preponderance as determined by the ratio of the duration of nystagmus following the onset of acceleration to that following deceleration. A disadvantage is that both labyrinths are tested simultaneously; unilateral dysfunction may be difficult to identify if the lesion is old and the patient is well-compensated. Rotary chair testing is of particular value in the following situations:

- A negative caloric test, where high frequency oscillation/high intensity acceleration may give evidence of some residual vestibular function.
- Investigation of visuo-vestibular interactions – when failure to suppress the vestibulo-ocular reflex with fixation is evidence of central vestibular dysfunction.

With computerised analysis of responses to rotary chair testing, results can be depicted in a quadrantic fashion following the sequence of start–stop stimuli in a clockwise then anticlockwise direction.

These displays include a mathematical computation of directional preponderance using slow phase velocity and/or durational criteria. Multivariate analysis of sinusoidal harmonic accelerations, asymptotic gain and the time constant have demonstrated a minimal misclassification rate when comparing normal people with patients with total canal paresis.

### Video-oculography

Video-oculography is a technique for observing and recording eye movements. An infra-red camera is mounted within goggles and connected to a video monitor. Observation and recordings of the eye movements in the absence of optic fixation can be made in response to a variety of stimuli. This technique is now a standard investigative tool in many departments. A test protocol can be performed which allows video recording of the following:

- Spontaneous nystagmus
- Head-shaking nystagmus
- Passive head tilt
- Head rotation through 180°.

VOG is valuable for identifying and classifying peripheral vestibular lesions and is commonly used in audio-vestibular investigation suites nationally.

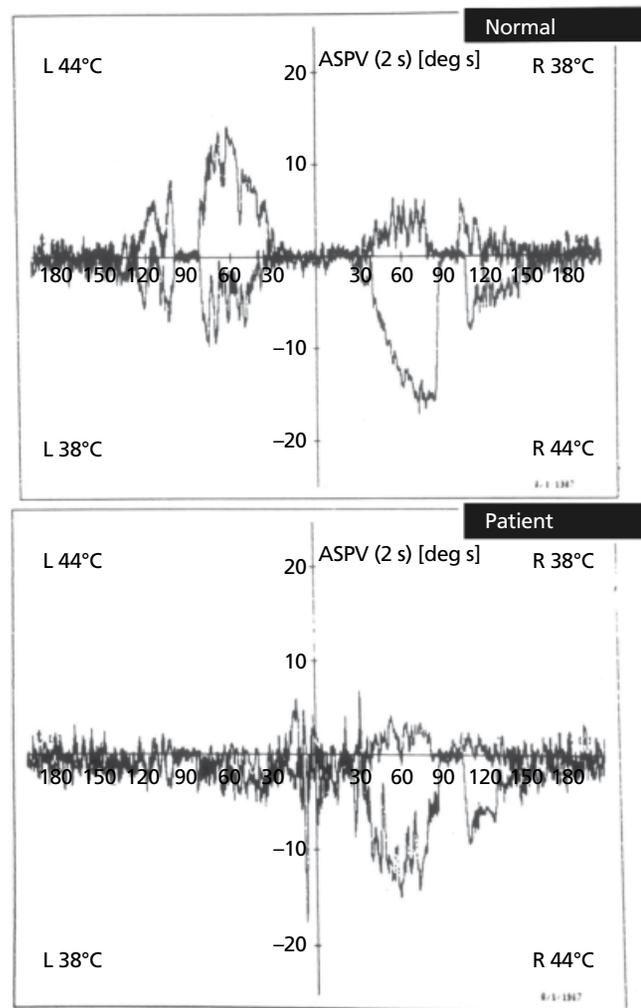

### Caloric testing

This is the most widely available of all vestibular tests and for many otologists is the cornerstone of vestibular diagnosis. Its great value is that it allows each labyrinth to be tested separately and is a method of demonstrating a peripheral vestibular deficit. The stimulus is easy to apply and involves inexpensive methodology.

#### Principles of caloric testing

After irrigation of the ear with water 7°C below (30°), and then 7°C above (44°) body temperature, a gradient is set up between the external auditory meatus (EAM) and the two limbs of the horizontal canal. This is by virtue of the position of the patient, whose head is at 30° to the horizontal on the couch. This means that the horizontal semicircular canal becomes vertical and the temperature gradient crosses from one limb of the canal to the other. It is commonly believed that the endolymph circulates because of the difference in the specific gravity on the two sides of the canal. With warm water, there is ampullo-petal flow, with cupular deflection towards the utricle, resulting in activation of the VOR, a sensation of vertigo and horizontal nystagmus directed towards the stimulated ear. However, there remains some doubt about this convection theory, because caloric nystagmus under micro-gravity conditions still occurs (e.g. in space).

The Hallpike–Fitzgerald bithermal caloric test has been available to clinicians for more than 60 years. Each ear is irrigated in turn for 40 s first with water at 30°C and then at 44°C. Inspection of the tympanic membrane after warm irrigation confirms an adequate stimulus if a red flush is seen on the membrane. Direct observation of the eyes allows the endpoint of the nystagmic reaction to be measured. During the procedure, the patient is asked to direct gaze on a fixation point on the ceiling, making the endpoint easier to determine. At this point the lights are switched off and the eyes observed with Frenzel's glasses or infra-red gun. Under normal situations the vestibular nystagmus would be expected to reappear. The endpoints of each test are graphically recorded. More commonly used now is the VNG caloric where an infra-red camera is mounted within goggles and connected to a

**Figure 15.14** Four-quadrant display of caloric irrigations: (a) the four-quadrant display of a set of normal responses to caloric irrigations in a normal subject; (b) the four-quadrant display of responses in a patient demonstrating a left canal paresis. Source: Davies 2004. Reproduced with permission of BMJ.

video monitor to record and analyse responses to thermal irrigations (Figure 15.14).

#### Quantitative analysis

Normally, nystagmus ceases 90–140 s after onset of irrigation and returns for up to a further 60 s after removal of optic fixation. Two abnormal patterns may appear, either separately or in combination, and are of diagnostic importance.

- 1 **Total canal paresis:** this is the complete loss of labyrinthine function in one ear, seen when there is a total absence of nystagmus following both 30° and 44° irrigations, even in the absence of optic fixation. Ideally, the test should be repeated using cold water at 20° for 60 seconds to confirm the result. It may reflect an ipsilateral lesion of the labyrinth, VIIIth nerve or brainstem vestibular nuclei, and confirms unilateral vestibular hypofunction.
- 2 **Directional preponderance:** this occurs when the responses to thermal irrigations produce an excess of nystagmus in one direction (i.e. towards either the right or the left). This indicates

imbalance of vestibular tone arriving at the oculomotor nuclei, a result of either a peripheral vestibular lesion (labyrinth, VIIIth nerve or nuclei) or from a central vestibular lesion, within the cerebellum or brainstem. With more pronounced degrees of vestibular tone imbalance, spontaneous nystagmus makes its appearance.

Figures for duration of nystagmic responses in seconds can be entered into the Jongkees formula, which calculates a percentage figure expressing either the degree of canal paresis or directional preponderance.

Another measurement, the optic fixation index (OFI) is calculated by dividing the summed durations in the light by the summed durations in the dark. If there is no enhancement in the absence of optic fixation (i.e. the OFI is 1.0), the cause may be central – within the cerebellum or vestibulo-cerebellar tracts. Bilateral decreased caloric responses indicate either bilateral vestibular impairment, or vestibular habituation. The latter is seen in acrobats, ice skaters and ballet dancers (OFI <0.5).

There are some disadvantages of VNG calorics when compared with the Fitzgerald–Hallpike technique: it is difficult to detect the endpoint of nystagmus as accurately as with direct vision, but hard copy data are recorded. Other nystagmic components in the vertical direction (e.g. torsional nystagmus) can be seen with VOG calorics. A direct comparison has been made between the maximum slow component velocity and the durations of the four caloric responses in normal subjects. The durations were relatively stable as a parameter, whereas the slow component velocities showed considerable variations in some subjects. Further analysis showed that the test–retest unreliability of the slow component velocity was unacceptably high. Direct visual observation has the advantage that the endpoint of the nystagmus can be estimated more reliably both with and without optic fixation, but does rely on an experienced observer.

### Closed-circuit and air caloric testing

Some commercial caloric testing kits use closed irrigation systems to warm and cool the EAM or use air instead of water. The problem with the former is that the tube in which the water flows does not fully occupy the EAM, thus reducing the effectiveness of the stimulus. With the latter, the specific heat of air is much lower than that of water; this means a greater temperature differential is required to effect the same temperature gradient across the labyrinth (i.e. a hot air stimulus of 50°C which needs to be delivered for 60 s will give an equivalent to the 44°C water stimulus). This may be unpleasant and tolerated poorly. Air calorics are generally regarded as less reliable than traditional hot and cold water calorics.

### Clinical value of caloric testing

Caloric testing is an essential part of the evaluation of the vestibular system. It tests each labyrinth individually and does not require any sophisticated instruments if water irrigation is used. The quantification and normal values of the measured parameters of the caloric induced nystagmus have been well established. The Jongkees formula is a validated measure, to calculate both canal paresis and directional preponderance. However, caloric test results do not correlate with the degree of dizziness or vertigo and are thus not a measure of discomfort or distress caused by these physiological abnormalities. Also, if a patient has a degree of directional preponderance or canal paresis, this may reflect a vestibular insult at some time even in the distant past, and one from which clinical recovery would be usual. This can have particular relevance in legal claims.

### Posturography

It is well known that alterations in vestibular function can profoundly affect posture. Postural control is a vital physiological function if we are to continue any daily activity and is determined by a complex sensorimotor feedback system dependent on a variety of coordinated reflexes. Only in the last three decades have objective measures of vestibulo-spinal postural reflexes been possible. Clinically, the Romberg test has been used to assess postural stability. During normal standing, the body is in continuous motion (i.e. physiological sway), even when attempting to remain still. This is an active process, whereby any loss of balance is compensated by movement of the body's centre of gravity (CoG). These movements result in visually detectable sway movements that maintain the CoG vertically over the base of support.

Static force-plate posturography was an early method of measuring body sway. A typical force-plate consists of a flat rigid surface supported on three or more points by independent force-measuring devices. As the patient stands on the plate, the vertical forces recorded by the measuring devices are used to calculate the position of the centre of the vertical forces exerted on the force-plate over time. With the height and weight of the patient, a computer model of body dynamics can be used to derive the CoG sway angle over time.

Moving platform posturography has been designed to overcome the limitations of the static force platform by controlling the relative contributions of visual, somato sensory and vestibular input. Commercially available platforms calculate body sway based on changes in horizontally (sheer) and vertically oriented (torque) strain gauges mounted under the support surface. The Equitest platform (Figure 15.15) utilises the concept of sway-referencing (i.e. both the support surface and the visual surround can be modulated in phase with the patient's own body sway).

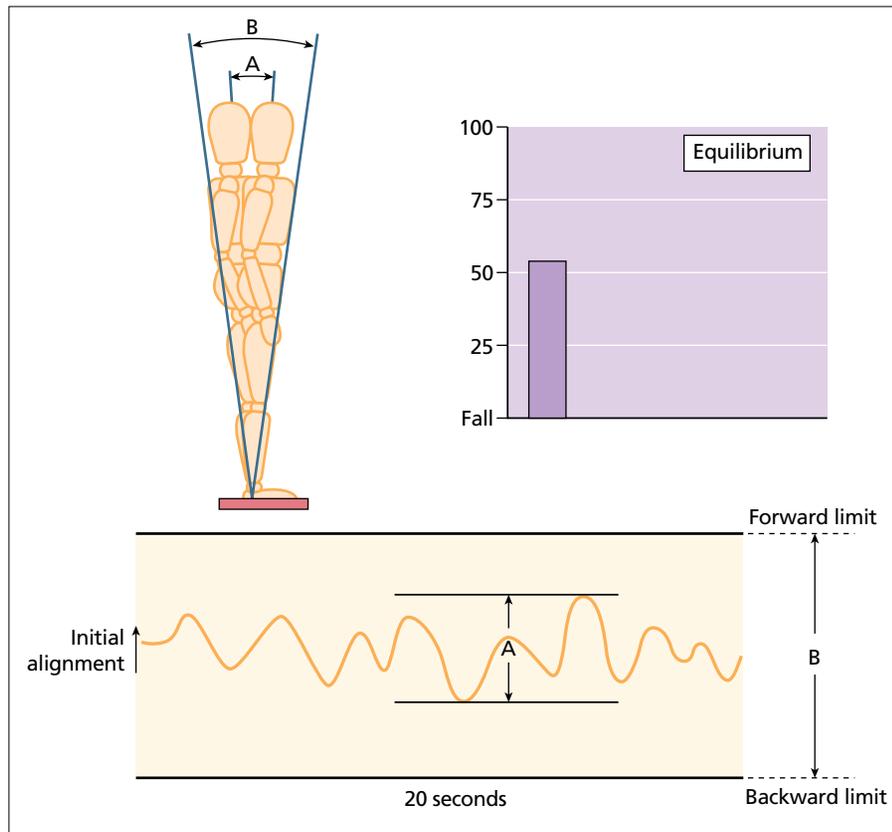

This coupling of either the platform or visual surround to the sway of the subject allows the angle between the foot and the lower leg to be maintained at a constant value, thus minimising somatosensory input with visual input remaining constant despite the subject's sway, respectively.

Six conditions are used in the sensory organisation testing and analysis of the sway scores allowing each of the three principal balance sensors to be isolated and comparisons made to assess sensory preference. The sensory organisation test battery identifies abnormal patterns of postural control, not adequately assessed by studies of the vestibulo-ocular reflex alone and examines the utilisation and integration of visual and somatosensory input with vestibular information, especially under conditions of sensory conflict.

The moving platform has been shown to be of great benefit with individual serial measurement in rehabilitation but of limited value as a diagnostic test.

### Vestibular evoked myogenic potentials

Cervical vestibular evoked myogenic potentials (cVEMP) is a neural-event related potential. The cVEMP is an ipsilateral vestibulo-colic reflex with a short latency (<10 ms) which has a regulatory role (i.e. fine tuning of the voluntary motor commands directed to the neck muscles). Its origin is a loud acoustic stimulus which provokes a saccular response via the inferior vestibular nerve, lateral vestibular nucleus, lateral/medial vestibulo-spinal tract and motor neurones of the sternocleidomastoid (SCM) muscle. The clinical relevance is still being fully evaluated but an absent cVEMP is pathologic, if the patient is below the age of 60 years and the appropriate stimulus has been used. It tests the integrity of the

**Figure 15.15** The Equitest balance platform – derivation of equilibrium score. The equilibrium score compares patient sway (a) with the theoretical limits of stability for normal subjects (b). Patient sway is calculated from the maximum peak-to-peak anterior to posterior sway occurring over the 20-second trial period.

vestibulo-colic reflex (i.e. saccule, inferior vestibular nerve) and can be abnormal in cases of acoustic neuroma, vestibular neuritis, Tullio and dehiscence of the superior semicircular canal (characterised by an abnormally lowered cVEMP threshold) and Ménière's disease.

Ocular VEMP (oVEMP) has emerged as a useful test in the clinical arena and is a manifestation of the utricular–ocular reflex which stabilises the eyes in response to linear head movements. The potential is recorded from surface electrodes beneath the eyes (placed on the belly of the superior oblique muscle) in response to bone conducted vibration and has a short latency negative (excitatory) component with a latency of 10 ms to peak, identified as n10. Again, this is a relatively new tool and its test sensitivity and specificity in different vestibular disorders is still to be fully evaluated.

**Limitations of vestibular tests** A major disadvantage of all types of vestibular test is that normative data have to be established for each laboratory before they can be used, as they depend on equipment and exact methodology. The equipment for the rotary chair and posturography is expensive and requires space and in the former case complete blackout of the room. There is no gold standard for vestibular testing and the results of all the tests in the battery must be collated alongside the clinical picture. A further limitation is that while vestibular testing may show an abnormality, not infrequently the site of the lesion cannot be indicated with certainty.

## Clinical disorders

The major peripheral vestibular syndromes are described here.

### Vestibular neuritis

Vestibular neuritis is one of the three most common causes of acute vertigo. It can be thought of as an acute unilateral vestibular paresis and has variously been known as vestibular neuronitis, vestibular neuro-labyrinthitis or acute vestibulopathy. The syndrome is also often referred to as labyrinthitis, considered a misnomer as there is neither hearing loss nor tinnitus. Vestibular neuritis is a well-recognised syndrome rather than a clearly defined clinicopathological entity, and is characterised by:

- Acute rotary vertigo (sense of movement away from the side of the lesion)
- Blurred vision/oscillopsia (fast phase of nystagmus directed contralaterally)
- Postural imbalance (positive Romberg and falling towards the side of lesion), and
- Nausea and vomiting.

The onset of vestibular neuritis is typically sudden, without prelude and the degree of real distress out of proportion to the seriousness of the condition. Resolution is usual within a matter of weeks. The clinical picture may be sufficiently clear for further investigation to be unnecessary. For confirmation of diagnosis, unilateral peripheral vestibular hypofunction needs to be identified either at the bedside (Halmagyi head impulse test) or in the balance clinic (using a caloric test). The caloric test shows ipsilateral

hypo-responsiveness or non-responsiveness, a sign of horizontal semicircular canal dysfunction.

### Aetiology

The possible aetiologies of vestibular neuritis include viral and vascular insults, although in practice a cause is rarely established. Pointers toward a viral aetiology or viral re-activation are:

- Frequency of preceding upper respiratory tract infection
- Postmortem studies – cell degeneration of one or more vestibular nerve trunks, and
- Demonstration of latent herpes simplex virus type I in human vestibular ganglia.

Vestibular neuritis is thought to have a predilection for the superior division of the vestibular nerve, but the dysfunction may equally involve the sensory hair cells of the vestibular end organ and hence the term 'neuritis' is used. Similar presentations can be caused by:

- Multiple sclerosis when a plaque is within the VIIIth nerve root entry zone, and
- Cerebellar vascular disease.

### Clinical assessment

Nystagmus is caused by an imbalance between afferent vestibular tone from the two labyrinths. Decrease in afferent activity from the affected ear is integrated with unaltered activity from the normal ear to produce the vestibular, or slow, phase of the nystagmus which is directed towards the affected ear. The fast or saccadic phase, which re-fixes the target on the fovea is towards the unaffected labyrinth. The acute nystagmus is predominantly horizontal-torsional. The reason for this is considered to be the net effect of the three unopposed semicircular canals (i.e. horizontal, posterior and anterior canals). Activity of the two vertical canals cancels out the vertical effect – the posterior canal tending to drive the eyes upwards and the anterior canal tending to drive the eyes downward. The patient senses movement across the retina only during the slow phase of nystagmus and because of the inverting effect of the lens, the sense of movement appears to be in the same direction as the fast phase of the nystagmus.

The postural reactions initiated by the vestibulo-spinal reflexes are usually opposite to the direction of vertigo. This results in Romberg's and Unterberger's tests being directed towards the side of the lesion. The patient's subjective sense of straight ahead and perceived visual vertical represents perceptual consequences of vestibular tone imbalance in yaw and roll planes.

### Neuro-otological investigations

If investigation is necessary, VNG confirms a spontaneous vestibular nystagmus directed towards the unaffected ear that increases with removal of optic fixation. With gaze towards the unaffected side (i.e. in the direction of the fast phase), the nystagmus increases in frequency and amplitude. On gaze towards the affected ear, the nystagmus decreases in amplitude and frequency. This effect on the nystagmus by direction of gaze (Alexander's law; see Gaze evoked nystagmus) may be first degree, second degree or third degree.

### Course

Throughout the acute phase (1–3 days), patients feel intensely unwell and tend to stay in bed. All head movements exacerbate vertigo, nausea and imbalance. After some 3 days, the spontaneous nystagmus is usually suppressed by optic fixation in the primary position but can still be detected with gaze towards the unaffected

ear, and in the absence of optic fixation (e.g. with Frenzel's glasses). After 1–6 weeks, most patients become asymptomatic, experiencing dizziness only with rapid head movements. Some 50–70% show complete recovery as assessed by caloric testing.

### Differential diagnosis of vestibular neuritis

When a patient presents acutely with symptoms of severe persistent isolated vertigo with imbalance, the distinct likelihood is that vestibular neuritis is the cause. However, the possibility of cerebellar infarction must also be considered. Symptoms typical of vestibular neuritis can be the sole manifestation of the cerebellar infarction but a three-step bedside oculomotor examination with the acronym 'HINTS' (head impulse–nystagmus–test of skew) appears to be sensitive for detecting stroke. The term pseudovestibular neuritis (PVN) for isolated vertigo of cerebellar origin has also been coined (Table 15.4). The territory most commonly involved is supplied by the medial branch of the posterior inferior cerebellar artery (mPICA). MRI of the brain may be necessary to distinguish between the two conditions and with the tendency towards defensive practice, imaging is becoming hard to avoid.

### Benign paroxysmal positional vertigo

Barany first described benign positional vertigo in 1921, recognising it as a lesion of the vestibular end organ involving the otolith, but not until 1952 was it redefined and renamed as benign paroxysmal positional vertigo (BPPV). BPPV, when it affects the posterior semicircular canal (p-BPPV) is characterised by brief attacks of rotary vertigo and concomitant, positioning (aka positional), rotary-vertical/geotropic nystagmus, elicited by changes in head position in the plane of the posterior semicircular canal.

### Incidence of BPPV

BPPV is probably the most common cause of vertigo, particularly in the elderly. One survey reported that by the age of 70 years, 30% of the population had experienced BPPV at least once. However,

**Table 15.4** Features of cerebellar infarction presenting as apparent vestibular neuritis.

Findings in 24 patients with mPICA cerebellar infarction and PVN	
Halmagyi headthrust test	Normal
<sup>1</sup> Spontaneous nystagmus*	15
<sup>1</sup> Gaze-evoked nystagmus	24
Unidirectional <sup>†</sup>	7
Bidirectional:	
direction changing <sup>‡</sup>	13
direction unchanging	4
<sup>1</sup> Asymmetric smooth pursuit	6
<sup>1</sup> Asymmetric OKN	4
<sup>1</sup> Canal paresis	None

mPICA, medial branch of the posterior inferior cerebellar artery; OKN, optokinetic nystagmus; PVN, pseudovestibular neuritis.

<sup>1</sup> Performed using electro-nystagmography (ENG) 1 week after onset of vertigo.

patients of any age can be affected, the overall mean age of onset being in the fifth decade, with a peak incidence around the mid-sixties, women outnumbering men by nearly 2 : 1. There is a slight female predominance in a presumed post-viral group, a higher female : male ratio in an idiopathic group and no sex predominance in a post-traumatic group. The peak age of onset is the fourth decade for the presumed post-viral group, the sixth decade for the idiopathic and an even distribution through the second to sixth decades in the post-traumatic group.

### Posterior semicircular canal BPPV

The diagnosis of p-BPPV is made by a typical history of severe vertigo lasting less than 1 minute, triggered by specific head movements (e.g. lying back or rolling over in bed, extending the neck to change a light bulb or pick a book from a high shelf, or bending forwards to wash the hair). It is thought to be caused by an accumulation of otolith debris which has become displaced from the otolith membrane of the utricle and has settled as a bolus of crystals in the most gravity-dependent part of the inner ear, the posterior semicircular canal. The bolus is heavier than the surrounding endolymph and gravitates to the most dependent part of the canal during changes in head position (canalolithiasis; Figure 15.16).

Acting like a plunger, the bolus exerts an ampullo-fugal pull on the cupula, triggering the BPPV attack. The diagnosis is confirmed by characteristic nystagmus on Dix–Hallpike manoeuvre (i.e. ampullo-fugal stimulation of the cupula of the posterior semicircular canal causes excitation of the ipsilateral superior oblique and the contralateral inferior rectus muscle, causing both eyes to move downward). The re-fixating fast phase of the nystagmus is upbeat and is combined with a torsional component because of the different angles of insertion of the oblique and rectus muscles.

The diagnostic criteria for nystagmus typical of p-BPPV are:

- *Latency*: vertigo and nystagmus commence between several and 20 s after the head-hanging position is reached
- *Duration*: nystagmus gradually reduces after 10–40 s, before it disappears
- *Rotary-vertical (upbeat) nystagmus* is present with the fast phase beating toward the undermost ear (geotropic)

- *Reversal*: on returning to the upright position the vertigo and nystagmus may reoccur less violently in the opposite direction
- *Fatiguability*: on repeating the manoeuvre, the vertigo and nystagmus lessen.

The initial Dix–Hallpike test should be directed toward the ear assumed to be affected, as the nystagmus will become less evident on subsequent manoeuvres, demonstrating fatiguability.

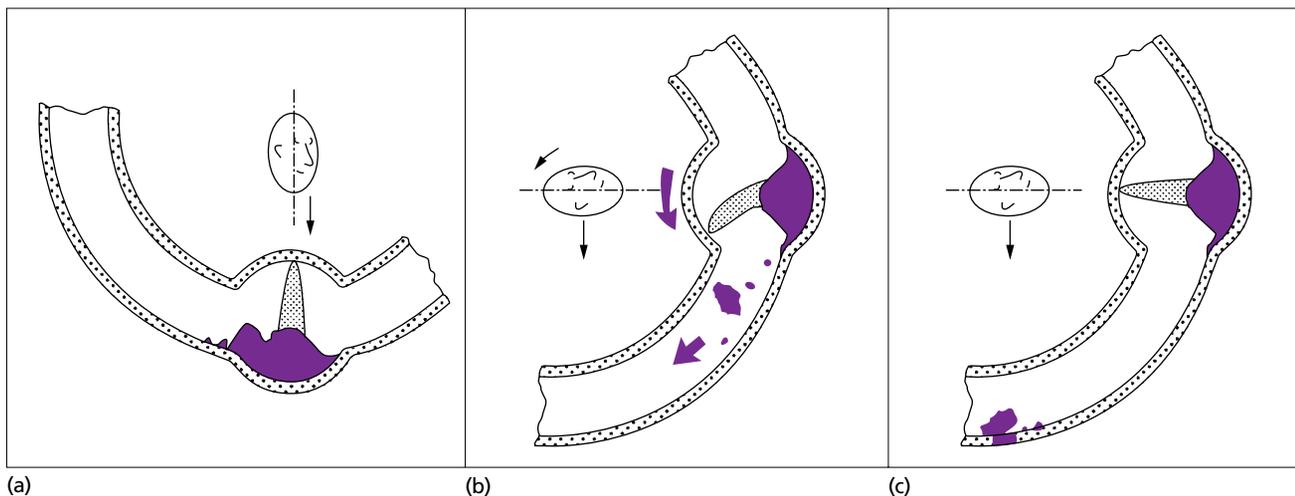

### Horizontal canal BPPV – geometric type

Between 5% and 20% of patients with BPPV are thought to suffer from horizontal canalolithiasis (h-BPPV). It may be combined with p-BPPV of the same ear or represent a transition from p-BPPV to h-BPPV as a result of a therapeutic manoeuvre. These two varieties of BPPV are thought to have similar aetiological bases. Symptomatically patients experience episodic vertigo when turning the head from side to side or on lying back in bed. When the Dix–Hallpike manoeuvre provokes a purely horizontal nystagmus, h-BPPV should be suspected. However, the Dix–Hallpike test is positive for horizontal nystagmus in only 80% of h-BPPV cases. The supine roll test is diagnostic of h-BPPV. When h-BPPV occurs as the result of loose otolith crystals in the canal itself (i.e. canalolithiasis), the nystagmus is geotropic – it beats towards the undermost ear.

### Apogeotropic horizontal canal BPPV

Atypical h-BPPV is caused by cupulolithiasis (i.e. otolith crystals are adherent to the cupula rather than remaining free-floating in the horizontal canal endolymph). This causes apogeotropic positional nystagmus – nystagmus in the direction opposite to rotation.

The diagnostic manoeuvres are the same for h-BPPV cupulolithiasis and h-BPPV canalolithiasis. The difference is that in cupulolithiasis the nystagmus is apogeotropic: with right h-BPPV caused by cupulolithiasis, when the head is rolled to the right this will elicit left-beating nystagmus. In both types, the nystagmus is direction changing (i.e. when the direction of the head roll is reversed, so is the direction of the nystagmus). The nystagmus of horizontal canalolithiasis is often quite prolonged, distressing and may take some 2 minutes to settle. The nystagmus depends on the assumed head position and not on the net angle of rotation.

**Figure 15.16** Canalolithiasis. Schematic representation of a free-floating ‘heavy clot’ of otoconial debris acting like a plunger on the endolymph and cupula of the posterior semicircular canal with a head movement in the plane of the canal. Source: Brandt and Steddin 1993.

### Anterior canal BPPV

BPPV of the anterior canal (a-BPPV) is a rare variant, and poorly characterised. It sometimes occurs as an unwanted effect of a particle repositioning manoeuvre (see Head Impulse Test further on) for p-BPPV (i.e. when the otolith debris is inadvertently redirected into the anterior canal from the common crus at the final stage of an Epley manoeuvre). One proposed model is that positional downbeating nystagmus can be caused by anterior semicircular canalithiasis, assuming central causes are excluded. This is because of the ampullo-fugal effects of anterior canal stimulation. Extrapolating to nystagmus induced by the Dix-Hallpike manoeuvre, any downbeating nystagmus could be explained by anterior canalithiasis in the uppermost ear. However, the differential diagnosis of positional downbeating nystagmus must always include central involvement and hence brain imaging.

The frequency of the different varieties of BPPV is shown in Table 15.5.

### Migraine-related dizziness

Migraine and vertigo are both common disorders and the possibility of a causal link between the two has been postulated for well over a century, but patho-mechanisms have been difficult to elucidate. The lifetime prevalence of vertigo, both vestibular and non-vestibular, is around 25%. Prevalence studies show that migraine affects at least 16% of the adult population at some time in their lives, with women having a higher prevalence than men. In a dizziness clinic, the prevalence of migraine is over 30%. Of note is that the co-occurrence of migraine and vertigo is three times higher than would be expected by a merely statistical interaction of common disorders.

Several studies have characterised the clinical features and temporal association of dizziness and headache in patients with both. One study found that in more than 150 dizzy patients, over 35% had a verifiable diagnosis of migraine; 88% of these had dizziness both with and between migraine attacks; dizziness and/or vertigo could occur at any time during a migraine attack (i.e. as part of an aura or with the headache); often it was head movement or visual motion related. The initial dizziness coincided with the first migraine in 23%; and vestibular testing showed a directional preponderance in 50% and a canal paresis in 25%.

### Definitions

Dizziness is a symptom in the following migraine syndromes basilar migraine; benign paroxysmal vertigo of childhood; benign recurrent vertigo. More recently, a plethora of names has been introduced to better characterise the link and hence migraine-associated dizziness,

migraine-related vestibulopathy, vestibular migraine and migrainous vertigo have all been used. Questionnaires exist to simplify classification of migraine-related dizziness, but the cornerstones are to make an accurate diagnosis of migraine using established criteria (International Headache Society; Chapter 12) and, in the absence of an alternative explanation, to diagnose migraine linked temporally with dizziness as vestibular migraine using the Neuhauser *et al.* (2001) (and subsequently Lempert *et al.* 2009) criterion.

This link between migraine and dizziness has now formally incorporated into International Headache Society (IHS) terminology, and there is acceptance that dizziness can be related to migraine in other ways than exclusively as one of the aura symptoms of basilar migraine. Less than 10% of the patients with dizziness and migraine meet basilar type migraine criteria.

### Basilar migraine

It is common experience that many patients with migrainous headaches describe dizziness, and occasionally vertigo, prior to the onset of headache. If two or more aura symptoms as defined in Table 15.6 are present prior to a typical migraine headache, basilar migraine may be diagnosed.

### Vestibular migraine

Vestibular migraine is described as recurrent episodes of vestibular symptoms which are associated with migraine or migrainous features when other vestibular and headache disorders have been ruled out (Table 15.7). The diagnosis of 'possible vestibular migraine' is as for definite, but requires that only one of the criteria B or C for vestibular migraine is fulfilled.

### Benign recurrent vertigo

Benign recurrent vertigo was first described in patients who had attacks of sudden intense vertigo, postural imbalance with or without nausea, spontaneous or positional nystagmus lasting several hours, but without headache. Because it is agreed that migraine is not exclusively a headache syndrome, such stereotyped attacks of vertigo with a timescale equivalent to migraine could be regarded as a migraine equivalent.

### Ménière's disease

Ménière's disease, also known as endolymphatic hydrops, is an inner ear disorder characterised by prolonged attacks of vertigo, fluctuating hearing loss, tinnitus and aural fullness. To make a definite diagnosis American Academy of Otolaryngology

**Table 15.6** Diagnostic criteria for basilar migraine as defined by the International Headache Society (IHS).

---

Diagnostic criteria for basilar migraine:

A At least two attacks fulfilling criteria B–D

B Aura consisting of at least two of the following fully reversible symptoms, but no motor weakness:

- Dysarthria
- Vertigo
- Tinnitus
- Hypacusia
- Diplopia
- Visual symptoms simultaneously in both temporal and nasal fields of both eyes
- Ataxia
- Decreased level of consciousness
- Simultaneously bilateral paraesthesias

C At least one of the following:

- 1 At least one aura symptom develops gradually over  $\geq 5$  minutes and/or different aura symptoms occur in succession over  $\geq 5$  minutes
- 2 Each aura symptom lasts  $\geq 5$  and  $\leq 60$  minutes

D Headache fulfilling criteria B–D for IHS diagnostic criteria of migraine without aura (Chapter 12) begins during the aura or follows aura within 60 minutes

---

**Table 15.7** Diagnostic criteria for definite vestibular migraine (International Headache Society and Bárány Society 2012).

---

A At least five episodes of vestibular symptoms, of moderate or severe intensity, lasting 5 min to 72 hours, e.g.

- Rotational vertigo
- Illusory self or object motion
- Positional vertigo
- Head motion intolerance

B Current or previous history of migraine with or without aura according to the International Classification of Headache Disorders (ICHD)

C One or more migraine features with at least 50% of the vestibular episodes:

- Headache with at least two of the following characteristics: one-sided location, pulsating quality, moderate or severe pain intensity, aggravation by routine physical activity
- Photophobia and phonophobia
- Visual aura

D Not better accounted for by another vestibular or ICHD diagnosis

---

1995 criteria are commonly used. Nonetheless, monosymptomatic cochlear or vestibular variants are possible depending on whether the endolymphatic hydrops affects predominantly the auditory or vestibular part of the labyrinth, and with time these patients may develop the full disorder. This is a reminder to keep a watching brief on those patients whose initial symptoms do not match the full criteria.

The mechanism underlying the disorder is thought to be a failure of resorption of endolymph by the endolymphatic sac. This view is supported by electromyographic studies, by the finding of peri-saccular fibrosis of the endolymphatic duct and by high resolution MRI. With Ménière's cases, the endolymphatic duct can

be visualised on MRI less often than in control subjects. This over-accumulation of endolymph leads to distortion of the membranous labyrinth (i.e. endolymphatic hydrops).

Ménière's disease can rarely be congenital, for example associated with Mondini dysplasia. It is usually acquired (e.g. after an evident inflammatory or traumatic insult to the labyrinth, when it is sometimes known as delayed endolymphatic hydrops), or idiopathic, when it occurs in about 21/100 000 of the population, presenting at 40–60 years of age. The endolymphatic hydrops starts in the helicotrema leading to ruptures of Reissner's membrane separating perilymph from the endolymph and accounting for the symptoms of fullness of the ear during an attack. With these periodic ruptures of Reissner's membrane there is endolymph discharge with a flux of potassium ions across the breached membrane (from 150 mmol/L in endolymph to 8 mmol/L in perilymph). This causes a temporary palsy of the vestibulo-cochlear nerve fibres located in the perilymph space. There is an initial excitation of the nerves leading to severe vertigo and an irritative nystagmus (i.e. beating towards the affected ear). Later, there is blockade of action potentials leading to inactivation of the axonal sodium channels and nystagmus (known as destructive nystagmus) beating toward the unaffected ear. Initially, the ruptures heal, but with disease progression, there are permanent alterations in the morphological features of the membranous labyrinth with loss of cochlear and vestibular neurones. Eventually there is atrophy of the organ of Corti and the vestibular end organ.

Typically, the major loss of hearing occurs in the first few years. In the early stages the hearing loss tends to be reversible, affecting the low frequencies only, but with advancing cochlear involvement, a peaked audiogram can be seen (best threshold at 2000 Hz) and eventually a flat loss is found in a majority of patients. The hearing loss is typically recruiting as identified by stapedius reflex thresholds within 60 dBHL of the pure tone audiometric thresholds at the same frequencies. In general, the longer the patients are followed, the greater the percentage of those who develop bilateral disease. A total of 15% have bilateral disease by 2 years, and by 20 years 30–60% are bilateral. At autopsy, 30% of the temporal bones in patients with Ménière's disease have bilateral involvement.

The early attacks of vertigo are severe, often associated with vomiting. These prostrate the patient for between 2 and 24 hours. About 6% of patients develop drop attacks (Tumarkin's crises) and occasionally there is a loss of consciousness from secondary syncope. The differential diagnosis of the attacks of vertigo can be difficult and includes vestibular migraine, benign recurrent vertigo and other causes of acute vertigo. With disease progression a canal paresis of the affected ear can be seen on caloric testing.

### Bilateral vestibular failure

Bilateral vestibular failure (BVF) in adults is a rare clinical entity characterised by unsteadiness, particularly in the dark, and oscillopsia. BVF is defined by the absence of a nystagmic response to both caloric and rotary stimuli.

There are many causes. Some cases have associated neurological disease, such as a progressive cerebellar syndrome, or other cranial neuropathies. Gentamicin ototoxicity, vasculitis and malignant meningitis are also causes. Some cases follow bacterial meningitis.

Clinical presentation depends on whether BVF is very long-standing or recently acquired, and if acquired whether this has been a sequential process or had a sudden onset simultaneously affecting both ears. When the loss is sequential, there are episodes of vertigo lasting from minutes to days. These preceding symptoms may be

entirely absent in patients with sudden bilateral BVF. Oscillopsia is a common feature, particularly when walking or travelling in a car. It is a result of the loss of the vestibulo-ocular reflex, particularly at high frequencies (i.e. 1 Hz) associated with physiological head movements. Unsteadiness in the dark or on rough ground is also typical and patients feel most stable when walking in good lighting conditions and on firm ground. When BVF has been present from infancy (e.g. following neonatal meningitis), the absence of peripheral vestibular function is surprisingly well tolerated. There may be some delay in developmental milestones; eventually, young children may learn to ride a bike. Caution is advised for patients with BVF in certain situations (e.g. swimming underwater).

The diagnosis is suspected when the Halmagyi headthrust test is positive to both right and left. In patients with BVF, gaze shifts with the head (doll's eye movement) and only after the head movement is there a corrective saccade to bring the object of interest back on to the fovea. The diagnosis is confirmed with caloric and rotary chair testing: no nystagmic response is elicited with ice cold water and chair accelerations of  $120^\circ/s^2$ , respectively.

### Vestibular paroxysmia

The very existence of this clinical entity has been questioned but it is supported strongly by the prompt response to treatment with carbamazepine. There is paroxysmal hyperactivity to vestibular stimulation combined with a functional defect between attacks. The neuro-pathophysiology is attributed to neurovascular compression, much in the same way as trigeminal neuralgia; ephaptic transmission has also been proposed as a mechanism. The following features define the syndrome:

- Short intense attacks of rotational or to-and-fro vertigo lasting seconds to minutes
- Attacks frequently provoked by particular head positions
- Impaired hearing permanently or during an attack
- Audio-vestibular deficits on testing, and
- Exclusion of a central cause.

### Motion sickness

This common problem is caused by repetitive stimulation of the vestibular system. Motion sickness occurs frequently at sea and in cars (especially in children), but also with less usual forms of travel such as on a camel or an elephant. Motion sickness is now rare during commercial flights, but it is a problem during space travel, and one reason why the airship industry did not flourish.

Nausea, sweating, dizziness, vertigo and profuse vomiting develop over several hours or less, accompanied by an irresistible desire either to stop moving or return to land. Prostration and intense incapacitating malaise frequently follow, seen typically in seasickness. The distress, incapacity and dehydration caused by severe seasickness should not be underestimated.

Early symptoms at sea are sometimes helped by maintaining visual contact with the horizon, eating and avoiding the stuffy atmosphere of a cabin. Alcohol tends to make matters worse. However, the motion of a vessel is less dramatic close to its centre of gravity, and hence many sufferers, once symptoms have become established, are averse to remaining on deck, and prefer to 'go below'.

Prophylactic antihistamines, vestibular sedatives (hyoscine, cyclizine or cinnarizine) and stem ginger are of some value. Recovery and habituation with no further attacks usually take place between several hours and several days. However, some individuals remain especially prone to recurrent bouts of seasickness, and prefer to remain on dry land.

The precise pathogenesis and neuronal circuitry of motion sickness remains relatively little studied – but there is no doubt that its origin is within the semicircular canals, when they are subjected to particular combinations of pitch, roll and yaw.

## Management of vestibular disorders

Management of vestibular pathology requires a clear understanding of normal physiology, the mechanisms of dysfunction and compensation, together with the autonomic and psychological sequelae of vestibular pathology. This leads to accurate diagnosis in the majority, therapy for systemic disorders with vestibular features, prompt intervention for emergencies and rehabilitation for chronic vestibular symptoms, both peripheral and central.

The treatment of vestibular pathology involves:

- Specific therapy for systemic disorders with vestibular manifestations
- Specific pharmacological therapies for labyrinthine disorders
- Vestibular rehabilitation physiotherapy, including canalith repositioning procedures (CRPs)
- Psychological support, and
- Surgical interventions.

A plan should be established for each patient, to include an explanation of the symptoms. These are often bizarre and not easily understood in the context of ear disease (e.g. visual vertigo in a supermarket). The importance of the patient understanding the rationale of the management programme cannot be overemphasised; this ensures compliance.

Concurrent drug regimens should be evaluated during the general medical assessment. This will allow appropriate management of conditions exacerbating or preventing recovery of vestibular symptoms (e.g. hypertension, diabetes, hyperlipidaemia, arthritis or ophthalmological conditions and drug effects). Treatment for specific vestibular disorders (e.g. Ménière's disease and BPPV) should be undertaken. Persistent vertiginous symptoms are managed by intensive vestibular rehabilitation physiotherapy. A regular exercise programme compatible with the patient's age and physical abilities should be commenced. Psychological factors will be addressed by psychotherapy or drugs.

Monitoring of recovery following treatment can prove difficult, as there is a marked discrepancy between vestibular symptoms and signs and vestibular test results. Therefore, outcome measures of recovery have been developed including validated questionnaires documenting vestibular symptomatology, disability and handicap (e.g. the Dizziness Handicap Inventory and the Vertigo Symptom Scale). In addition, validated psychological questionnaires such as the Beck Anxiety and Depression Scales and quality of life evaluations such as the Short Form 36, are commonly used. Functional measurements such as the Dynamic Gait Index, the Functional Gait Index and the Timed Get-Up-and-Go Test may also provide valuable evidence of improvement. In addition, objective resolution of positional nystagmus in BPPV may be of value. Posturographic results can demonstrate improving CoG measurements and more appropriate balance strategies as symptomatic recovery occurs in both peripheral and central vestibular pathology. The ultimate aim is to discharge the patient with full integration into occupational and personal activities.

### Drug treatment

Recent developments in neurochemistry have begun to clarify the role of neurotransmitters within the vestibular system, but despite these developments, few of the recent advances have led to the

development of new antivertiginous drugs. The treatment of vestibular disorders remains primarily empirical, because of the paucity of high quality clinical drug trials and an evidence-based approach. There are four arms to the pharmacological treatment of vertigo:

- 1 Vestibular suppressant drugs for acute vertigo
- 2 Specific treatment of vestibular disorders (e.g. Ménière's disease, migrainous vertigo and central vestibular disorders)
- 3 Drugs used to treat systemic diseases that cause vertigo
- 4 Experimental drugs (e.g. drugs that may accelerate compensation).

### Symptomatic treatment of acute vestibular symptoms

Acute unilateral loss of vestibular function gives rise to symptoms of vertigo, nausea, vomiting, sweating, pallor and diarrhoea. Patients find such symptoms alarming and commonly fear a serious neurological condition such as a brain tumour or a stroke. Simple reassurance is highly effective, but should be followed by an explanation of the underlying pathology giving rise to such symptoms, and appropriate treatment with antiemetics such as hyoscine, prochlorperazine, promethazine, cyclizine or metoclopramide. Buccal administration of prochlorperazine is effective, but intramuscular therapy can be administered if oral preparations cannot be tolerated because of vomiting. Hyoscine may be administered transdermally. In general, antiemetic drugs act by blocking the afferent pathways from the chemoreceptor zone in the area postrema, the gastrointestinal tract and the labyrinth to the medullary vomiting centre.

Secondly, vestibular sedative drugs should be administered acutely. However, there is good evidence that such medication should be prescribed for the minimum period as the drugs interfere with vestibular compensation. Such drugs include anticholinergics (hyoscine, scopolamine), antihistamines (promethazine, prochlorperazine, cyclizine and metoclopramide) and the calcium-channel antagonists (cinnarizine, flunarizine). These latter two drugs, together with prochlorperazine, may give rise to extrapyramidal side effects, and their dosage should be carefully titrated against symptomatic response, especially in the elderly. In addition, flunarizine has been associated with depression.

Diazepam has been widely used, particularly in North America, in the management of acute unilateral vestibular deafferentation and has been reported to be effective as a consequence of the reduction of neural activity, and inhibition throughout the CNS, including the vestibular nerve and nuclei. Benzodiazepines may be of value in the treatment of vertigo, to counter the anxiety commonly associated with acute vestibular crises. Recent work would suggest the value of steroids in promoting recovery of labyrinthine function in the initial phases of an acute vestibular episode.

### Specific treatment of vestibular disorders

Ménière's disease is a commonly misdiagnosed vestibular syndrome, and appropriate treatment requires accurate diagnosis. There are few double-blind randomised studies assessing treatment efficacy in this condition, and it is important to recall the 80% placebo response rate. Medical treatment is either symptomatic, or aimed at influencing the presumed underlying pathological process of endolymphatic hydrops, or sometimes at the hypothesised immunological pathogenesis; surgical treatment aims first to decompress the hydrops (e.g. saccus decompression). Other, destructive procedures in intractable cases include intratympanic gentamicin (so-called medical labyrinthectomy), surgical labyrinthectomy or vestibular neurectomy.

No evidence-based standard treatment protocols exist, and general measures may include lifestyle adaptations such as stress reduction, food elimination and even allergy immunotherapy. Medical therapy commonly includes a low-salt diet and diuretics, although to date there is no clinical trial of sufficient quality to confirm the efficacy of diuretic treatment. Bendroflumethiazide is the thiazide diuretic of choice, although chlorthalidone has been reported to be beneficial in early uncontrolled studies; both diazide and acetazolamide have also been advocated.

Betahistine is a histamine analogue that has been reported to bring about a reduction of the asymmetric functioning of the vestibular end-organs, improve microvascular circulation in the stria vascularis of the cochlea and inhibit the activity of the vestibular nuclei. A systematic review identified major flaws in the clinical trials of betahistine and Ménière's disease. With these limitations, the review noted that betahistine may bring about a reduction in vertigo and tinnitus, but no specific therapeutic effect could be confirmed.

Steroids have been used in the treatment of Ménière's disease on the assumption that they may ameliorate an autoimmune diathesis, but there are no double-blind controlled trials to prove their efficacy. Treatment may be taken orally, or topical application via tympanostomy tubes into the middle ear, which may achieve better drug penetration with less side effects than systemic administration. The outcome of steroid treatment and methotrexate remains controversial.

In patients with intractable vertigo, but preserved auditory function, the instillation of intratympanic gentamicin was popularised in the 1990s and has become a common treatment particularly in North America. Gentamicin is predominantly vestibulo-toxic, but no standard treatment protocol or dose has been defined. High rates of therapeutic success in the control of vertigo have been reported, but sensorineural hearing loss has been reported in up to 30% of cases. Moreover, recurrence of vertiginous symptoms may develop in up to one-third of treated cases within 24 months. Careful consideration of this form of management is required, in view of the significant percentage of patients who develop bilateral involvement with Ménière's disease.

Hyperbaric oxygen therapy with continuous variations in pressure has been reported to be of benefit, as has treatment with the Meniett device, which delivers intermittent micropressure pulse waves to the inner ear through a tympanostomy tube. In a prospective randomised placebo-controlled multicentre clinical trial, the Meniett device was reported to show significant improvement in terms of frequency and intensity of vertigo, dizziness, aural pressure and tinnitus, but further scientific evaluation is required.

Surgical management of Ménière's disease includes prophylactic measures such as endolymphatic sac decompression, for which there is no firm evidence of efficacy and destructive surgical procedures. These latter techniques are primarily reserved for patients with intractable vertigo and profound hearing loss, with clear evidence of the side of lesion giving rise to symptoms. Surgical options include vestibular nerve section and labyrinthectomy. However, such procedures should be undertaken with extreme caution, not only because of the possibility of bilateral pathology in Ménière's disease, but also because of the possible failure of compensation for a total unilateral vestibular loss.

### Migraine

The treatment of migrainous vertigo parallels that of migrainous headache (Chapter 12). Dietary measures, lifestyle adaptation and stress reduction techniques are important first measures, together

with psychological management and intensive vestibular rehabilitation physiotherapy, for the 25–30% of patients with migrainous vertigo who demonstrate peripheral vestibular dysfunction.

The pharmacological treatment of migraine includes both prophylactic and acute symptomatic management. Prophylactic treatment should be considered in recurrent acute episodes of vertigo in which symptomatic treatment is inadequate. Beta-blockers such as propranolol, calcium-channel blockers such as cinnarazine, serotonin antagonists such as pizotifen, in addition to tricyclic antidepressants such as amitriptyline, have all been shown to be effective in some cases. Symptomatic treatment may include antivertiginous and antiemetic drugs as well as specific treatment for headache. Triptans have been shown to be highly effective in ameliorating both dizziness and headache and may also relieve nausea, vomiting and phonophobia. Sublingual, subcutaneous or rectal zolmitriptan have been recommended as the duration of migrainous vertigo may be too short to warrant treatment with oral triptans. Ergot drugs and acetazolamide have also been reported to be effective in controlling migrainous vertigo.

### Episodic ataxia

Episodic ataxia type 2 (Chapter 17) can present with acute vertigo and ataxia, with or without interval symptoms. Both acetazolamide and 4-amino-pyridine have been reported to help.

### Central vestibular dysfunction

Central vestibular dysfunction associated with neurological disease is exceedingly difficult to help. It commonly presents with ataxia and disordered oculomotor function, including bi-directional, dysconjugate, rotatory, vertical, periodic, alternating, see-saw or pendular nystagmus. No single treatment is of benefit to all patients, but an understanding of ocular physiology and the neurochemistry of the vestibular system have enabled a rational approach to specific treatments.

Both clonazepam and 3,4-diaminopyridine have been reported to help downbeat nystagmus, while acquired pendular nystagmus may respond to gabapentin. Baclofen has some effect in periodic alternating nystagmus. No specific treatment regimes have been defined; frequently, drugs are used empirically and doses titrated against response and side effects.

For patients with chronic instability and ataxia of central vestibular origin there is some evidence that intensive vestibular rehabilitation physiotherapy and gait retraining strategies may help both stability and confidence.

### Treatment of chronic peripheral vertigo

#### Vestibular rehabilitation physiotherapy

The majority of patients with persistent chronic vestibular symptoms demonstrate uncompensated unilateral peripheral vestibular dysfunction. Less commonly, patients may present with chronic symptoms caused by bilateral vestibular hypofunction, and for both unilateral and bilateral dysfunction, intensive vestibular rehabilitation physiotherapy is the mainstay of treatment. Every effort should be made to ensure optimal sensory input for balance: correction of visual/ophthalmological disorders such as cataracts, aggressive management of joint/orthopaedic problems (e.g. arthritis) and medical management of fluctuating vestibular conditions such as Ménière's disease or BPPV.

Compensation cannot be effective in the face of inadequate sensory input or fluctuating vestibular activity. Importantly, antiemetics and/or vestibular sedative drugs should not be used for chronic symptoms – there is evidence that they impair vestibular

compensation. Notwithstanding this fact, there is widespread and inappropriate prescription of these drugs for chronic vestibular symptoms both in primary and tertiary care.

CNS plasticity underpins vestibular rehabilitation and symptomatic vestibular compensation. The Cawthorne–Cooksey exercises are systematic exercises aimed at stimulating visual, vestibular and proprioceptive input on a repetitive basis to enhance compensation. They were initially introduced empirically in the 1940s. In the 1970s and 1980s, animal experimentation provided a scientific basis for their value, providing evidence to support the rationale for specific physiotherapy for chronic vestibular symptoms. Subsequently, a range of vestibular rehabilitation programmes has been devised, containing a number of key elements:

- A detailed explanation of the rationale of exercises, and the aim of therapy to ensure patient motivation and compliance
- A graded approach, with increasing sensory input and speed of task, to expedite compensation
- Emphasis upon exercises that are functionally relevant and that actually provoke dizziness in individual patients, and
- Repeated short but frequent repetitions of individual exercises to promote habituation.

Many studies have shown the efficacy of these regimes. Recent research has highlighted that customised exercises with a programme devised specifically for each patient, based on individual vestibular limitations, is most effective. Mechanical exercise programmes including optokinetic stimulation, visual flow stimuli and rotational stimuli have been shown to be especially helpful and to optimise vestibular compensation. Other strategies shown to enhance compensation include virtual reality tai chi and support surface translations.

Traditionally, vestibular rehabilitation physiotherapy has been used in the treatment of unilateral peripheral vestibular disorders that have failed to compensate. Many factors are associated with failure of compensation (Figure 15.17) and most can be targeted with physiotherapy, by specific evaluations including standardised health report questionnaires, scored balance assessment tests and dynamic posturography. These measures also document recovery, support patient motivation and cooperation and direct ongoing physiotherapy.

It cannot be overemphasised that a detailed explanation of the underlying pathological processes, with a basic understanding of vestibular compensation, is crucial if the patient is to accept that

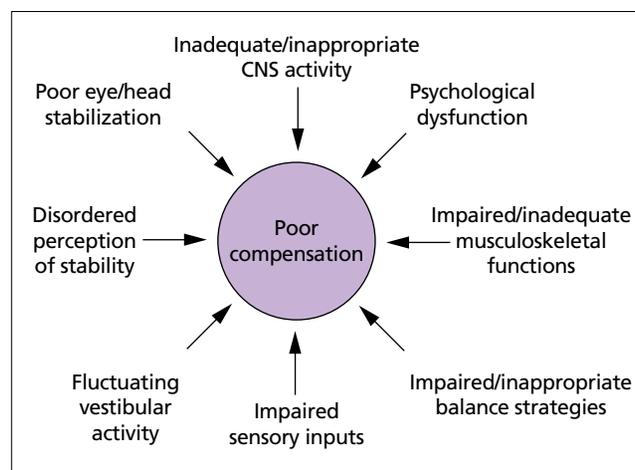

Figure 15.17 Factors predisposing to decompensation.

physiotherapy rather than some alternative, technically sophisticated option is more appropriate. Early intervention may be beneficial, but neither long-standing symptoms nor old age are negative prognostic factors – enthusiastic treatment is always worth trying.

Recent work has also confirmed the value of vestibular rehabilitation physiotherapy in the management of migraine, bilateral vestibular failure and central vestibular pathologies including brainstem and cerebellar disease. An important group of patients, whose symptoms are frequently found to be intractable to standard rehabilitation techniques, are those with visual dependence and visual vertigo. In this group, optokinetic training and mechanical rehabilitative interventions have been shown to be of value. Virtual reality stimulation may be of specific value in this group. A further subset of patients with persistent dizziness are those with vestibular pathology associated with psychological symptoms. This group undoubtedly benefit from vestibular rehabilitation physiotherapy, although a range of psychological support measures should be provided in parallel.

### Particle repositioning procedures

BPPV is the most common vestibular syndrome and requires specific particle repositioning procedures aimed at addressing the underlying mechanism of cupulo- or canalithiasis. Accurate diagnosis is crucial for three reasons:

- 1 Central positional nystagmus, although rare, may indicate serious life-threatening neurological pathology.

- 2 Management of cupulolithiasis and/or canalithiasis of each of the three semicircular canals requires specific different interventions.

- 3 The correct specific particle-repositioning procedure is highly successful for these debilitating conditions.

The symptoms associated with BPPV commonly abate over several weeks, but in some 30% symptoms persist, with significant disability and distress. Many different procedures for BPPV have been described, but the two established techniques are the Semont liberatory manoeuvre and the Epley particle-repositioning procedure.

The Brandt–Daroff exercises were devised for the treatment of cupulolithiasis, and consist of rapid movements of the body and head from one lateral position to the other. However, the movement is not tightly aligned to the plane of posterior canal and is repetitive, displacing repositioned crystals and is less used than formerly to manage p-BPPV.

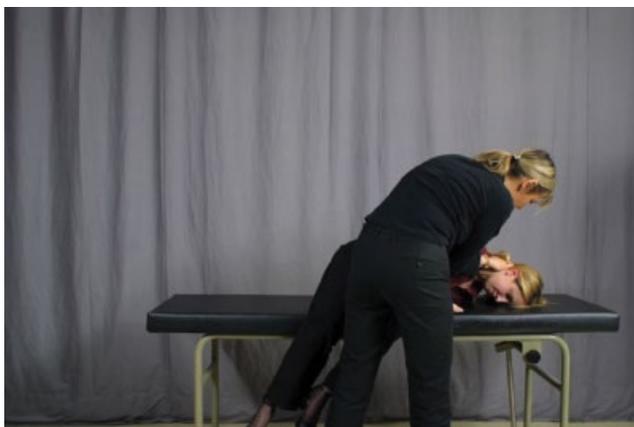

The Semont manoeuvre, developed to liberate otolithic deposits from the cupula of the posterior semicircular canal, is conducted by lying the patient on the affected side with the face turned 45° towards the ceiling. The patient is then rapidly swung in an arc through the sitting position, to lie on the opposite side with the face turned downwards by 45°. This latter position should be maintained for 5 minutes prior to the patient being brought slowly up to the sitting position (Figure 15.18).

(a)

(b)

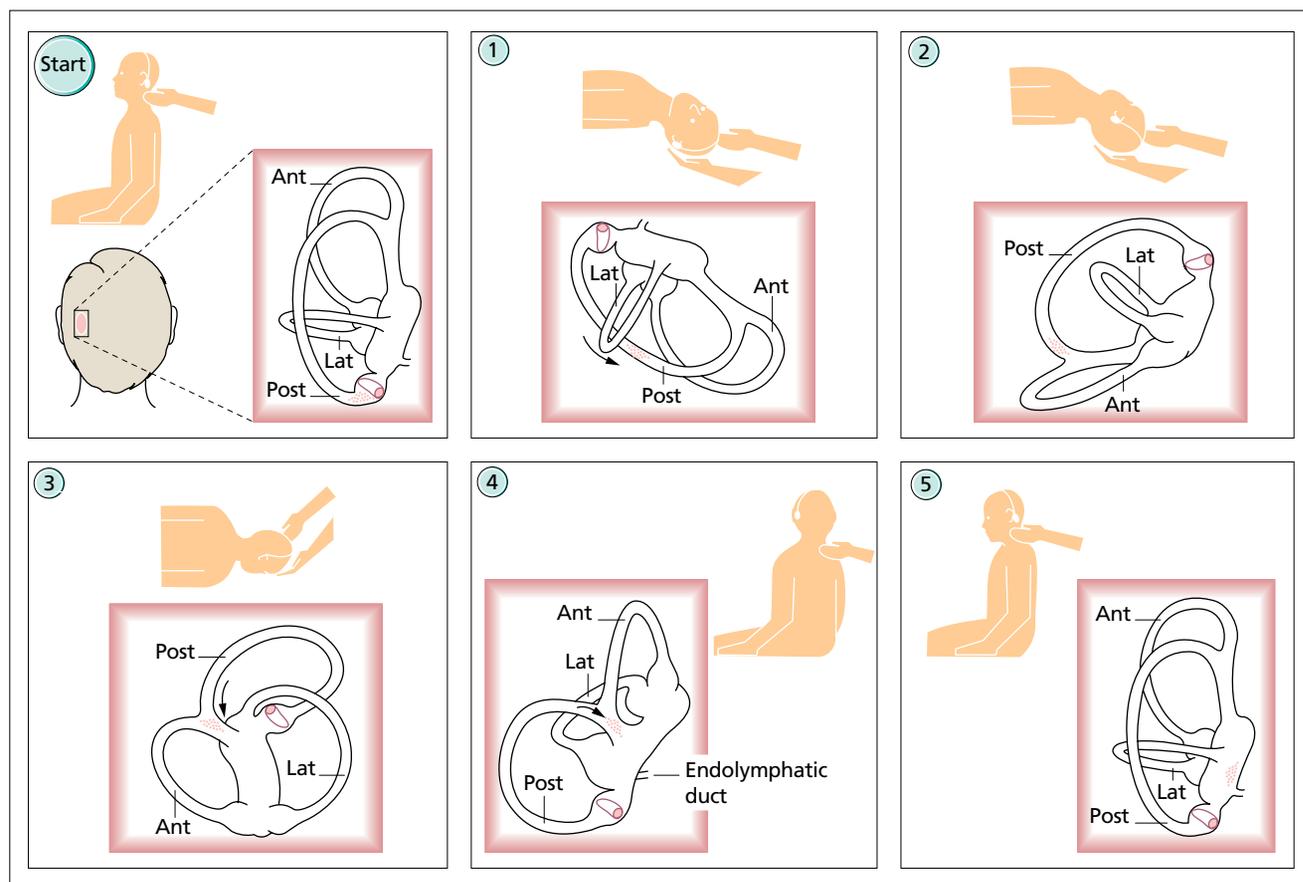

(c)

(d)

**Figure 15.18** Semont manoeuvre (see text).

**Figure 15.19** Epley manoeuvre (see text).

The Epley particle repositioning procedure (1992) was introduced as a successful technique for treating p-BPPV (Figure 15.19). Subsequently, the technique has been adapted for the treatment of a-BPPV. The manoeuvre is comprised of five separate positions, the first being the Dix–Hallpike manoeuvre for the identification of p-BPPV. The various positions that are then assumed result in the otoconial debris moving to the most dependent part of the posterior canal, and from there to the common crus and then out of the canal into the vestibule where, upon assuming the critical head position, debris does not fall on to the cupula of the posterior canal.

Both the Epley and Semont manoeuvres have been widely evaluated, for both subjective outcome and objective absence of positional nystagmus. They are highly effective, with around 90% of patients becoming symptom-free after repeated manoeuvres. Some evidence suggests the best recovery rate is in cases where vertigo has been caused by vestibular neuritis, while those cases caused by trauma have a poorer outcome, with a recurrence rate of some 50% at 5 years. Importantly, it is well recognised that p-BPPV can convert to a-BPPV or hBPPV after a particle repositioning procedure; careful observation of nystagmus is required to ensure that an appropriate second procedure is conducted where the first appears to have failed.

Specific treatments for h-BPPV and a-BPPV have been described. Horizontal dysfunction resulting from canalolithiasis may be treated with a 12-hour prolonged positioning on the healthy side (Vannuchi manoeuvre) while the barbeque roll (Lempert roll

manoeuvre) with 270° rotation in the direction opposite to the affected ear, around the longitudinal axis, have both been reported to be effective. a-BPPV can be treated with a reverse Epley particle repositioning procedure (i.e. a right a-BPPV can be treated with a left posterior canal repositioning procedure). Physical treatments for BPPV are highly effective, and <1% require surgical intervention. Historically, vestibular nerve section has been carried out, but the surgical treatment of choice in intractable cases is now considered to be occlusion of the posterior semicircular canal.

### Psychological treatment

Psychological symptoms in association with vestibular pathology are well recognised and frequently result in intense and protracted symptoms when there has been failure to compensate from a vestibular deficit. Many studies have highlighted the association of agoraphobia, anxiety states, panic attacks, depression and avoidance behaviour, together with phobias such as space and motion phobia in patients with vestibular symptoms. Recent work has outlined a possible underlying neurological basis for the relationship between anxiety and vestibular symptoms. Psychological support is a key factor in rehabilitation of many patients with vestibular symptoms and should always be considered when there is no satisfactory explanation either for failure to recover, or decompensation following earlier improvement.

Importantly, the clinician should understand the interaction of psychological and vestibular factors, in order to provide a satisfactory and understandable explanation of the way in which the patient's

symptoms are compounded by the interaction of these two aspects of the illness. The specific mode of treatment will depend on the primary underlying psychological disorder: avoidance behaviour, panic attacks, phobias, anxiety states and/or depression. Cognitive-behavioural therapy in parallel with physiotherapy is invaluable in patients who have developed avoidance behaviour and/or panic attacks, while formal psychiatric intervention is required in patients with anxiety states and depression. The index of suspicion of an underlying psychological problem should be high in patients with vestibular dysfunction.

### Surgical management of vertigo

Surgical intervention for the treatment of isolated vertigo is rarely needed. The conditions most usually requiring surgical intervention are the life-threatening complications of otitis media, cerebellopontine angle tumours and perilymph fistulae. Surgical procedures may be divided into those aimed at alleviating underlying pathophysiology (e.g. canal-plugging procedures in BPPV and endolymphatic sac decompression for Ménière's disease), although there is little evidence to support the value of the latter intervention. Intractable vertigo with good hearing in Ménière's may be treated by destructive procedures such as vestibular neurectomy or chemical labyrinthectomy (gentamicin), while intractable vertigo with profound hearing loss may be treated with surgical labyrinthectomy. It should be reiterated that destructive procedures should be undertaken with great caution, for two reasons:

- 1 The possibility of the development of bilateral vestibular dysfunction (e.g. in the case of Ménière's disease or head trauma), and
- 2 The possibility of persistent vertigo from poor vestibular compensation: there is scant evidence to suggest that total vestibular loss will compensate more effectively than partial vestibular failure.

In conclusion, simple treatment strategies are highly effective for the majority with these distressing and incapacitating symptoms. This is particularly important for the neurologist, who is frequently

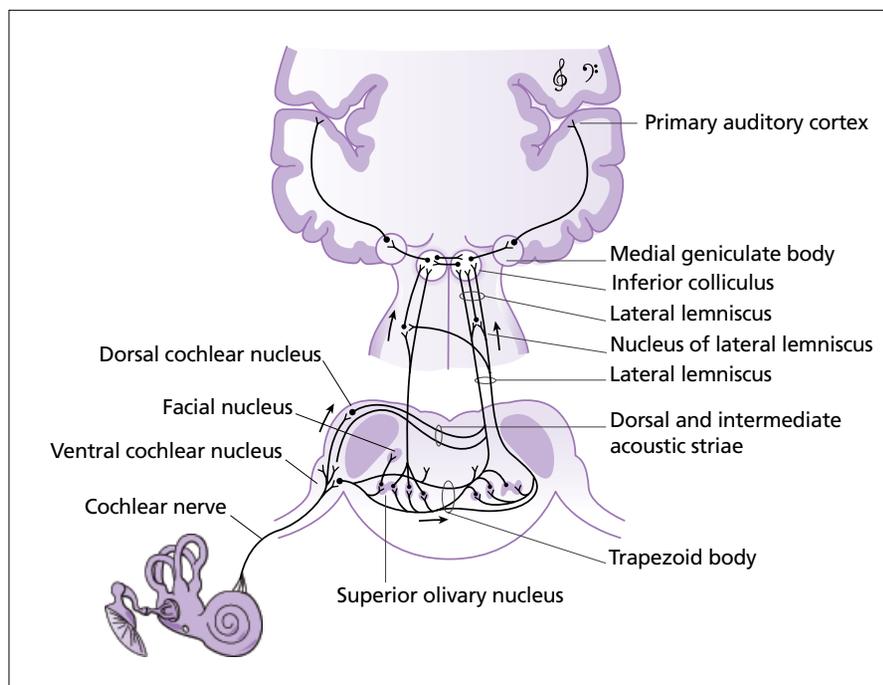

referred a patient whose symptoms have defied diagnosis and management by an otological colleague. A rational approach to the diagnosis and management of vestibular symptoms is cost-effective for the health care system and has significant personal and occupational benefits for the patient.

## Hearing disorders

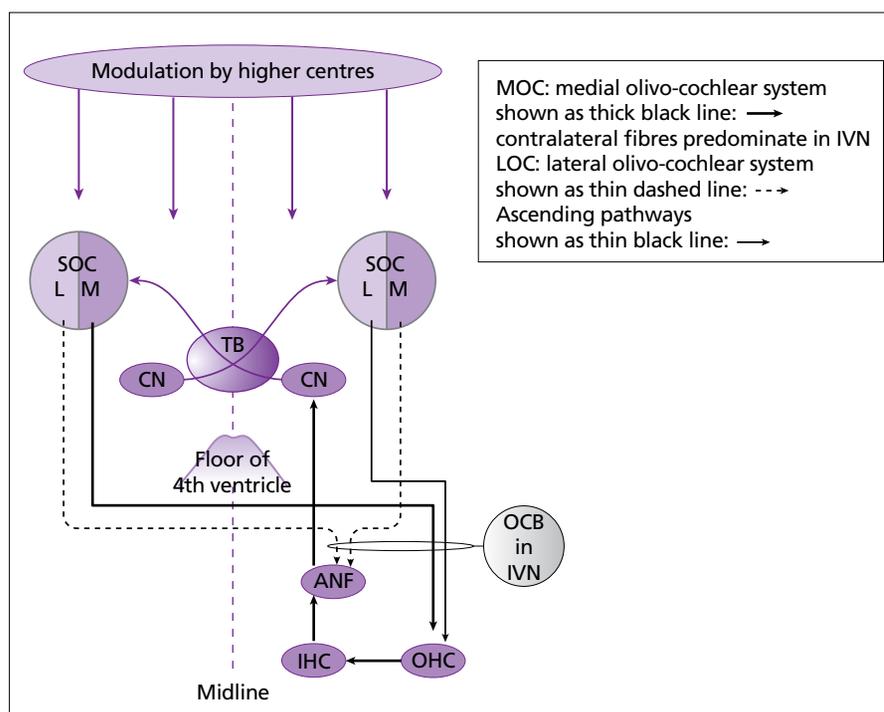

### Anatomy and physiology

Anatomically, the ear is divided into the external, the middle and the internal ears (Chapter 2). Physiologically, the external and middle ears collect, enhance and amplify sound, while the inner hair cells of the organ of Corti transduce mechanical energy into electrical activity. The outer hair cells of the organ of Corti act as both modulators and amplifiers, capable of fine tuning the receptor function of the cochlea. Auditory signals from the organ of Corti are transmitted along the afferent auditory pathway (Figure 15.20): auditory nerve to the ipsilateral cochlear nucleus, from where the majority of afferent auditory fibres project to the contralateral superior olivary complex, lateral lemniscus, inferior colliculus, medial geniculate body and onwards to the auditory cortex.

The auditory efferent pathway (Figure 15.21) arises in the auditory cortex and descends in parallel to the afferent pathway. The anatomy of the higher efferent auditory system remains ill-defined, but within the brainstem the olivo-cochlear bundle projects from the superior olivary complex to the cochlea via the medial and lateral olivo-cochlear system to the contralateral outer hair cells and the ipsilateral inner hair cells of the organ of Corti, respectively. Efferent fibres leave the brainstem in the inferior division of the vestibular nerve. The precise functions of the efferent auditory system remain poorly understood, but amongst the suggested hypotheses are shifts of the dynamic range of hearing to enhance signal detection and frequency selectivity, protection from excessive noise and facilitation of selective attention.

### Definitions and introduction

Disorders of the ear represent 24% of all disabilities in the adult UK population.

Hearing loss is the most common sensory disability worldwide and in the UK population over 50 years, 35% have at least mild loss of hearing. This may be the result of pathology in the external, middle or internal ear or eighth nerve or central auditory pathways. In the United Kingdom, 1.1/1000 babies are born with permanent bilateral hearing impairment; but this figure doubles by the age of 16. Hearing impairment and deafness have profound socio-economic and psychological consequences. Without appropriate care, children may fail to develop normal speech, language and cognitive skills which limit educational and occupational choices, while adults are less likely to be in skilled employment and suffer social stigmatisation, isolation and a high incidence of psychiatric illness.

Tinnitus is a perception of a sound that originates from within the body rather than the external world. It affects about 10% of most populations studied; about half find tinnitus sufficiently intrusive to seek help. If perceived solely by the patient tinnitus is called subjective and is commonly related to hearing impairment. Objective tinnitus refers to sound audible externally – it has a physical source, such as palatal myoclonus, an arteriovenous fistula or turbulent flow through a stenotic artery. Occasional tinnitus is an almost universal perception, but the prevalence of persistent tinnitus is positively correlated with age and female gender and its intrusiveness is correlated with psychological factors.

Hyperacusis, reduced tolerance to noise or an increased sensitivity to sounds at levels that would not cause discomfort in a normal

individual, is the most common dysacusis, occurring in some 6–7% of the population. It is generally associated with normal hearing, but it is reported in 40–80% of people with tinnitus. Hyperacusis differs from loudness recruitment, which refers to oversensitivity to loud sounds.

Impaired structure and/or function of the eighth nerve and auditory brain may have little or no effect on hearing thresholds, but may cause deficits in other aspects of hearing such as distortion of hearing and auditory localisation deficits.

### Basic concepts

Hearing loss and tinnitus most commonly indicate middle ear or cochlear dysfunction, but may reflect VIIIth nerve or central auditory pathology as part of a neurological disorder. These latter pathologies characteristically present with difficulties with sound localisation or hearing in conditions of poor signal to noise ratio (e.g. in the presence of background noise).

### Conductive hearing loss

Pathology affecting the external and middle ear causes abnormalities of mechanical transmission of sound waves from the environment to the cochlea, known as conductive hearing loss. Typically, there is middle ear enhancement of the auditory signal, but pure conductive hearing losses do not exceed 60 dBHL across the speech frequencies on audiometry.

### Sensorineural hearing loss

Cochlear and VIIIth nerve pathology results in sensorineural hearing loss with an inability to transduce the mechanical energy of sound waves into electrical activity within the cochlea or transmit the

signals along the VIIIth nerve (Figure 15.20). The precise site may be distinguished on the basis of two pathophysiological phenomena:

- 1 **Loudness recruitment:** an abnormally rapid increase in loudness with an increase of intensity of stimulus, characteristic of cochlear dysfunction.
- 2 **Abnormal auditory adaptation:** a decline in discharge frequency with time, observed following an initial burst of neural activity in response to an adequate continuing auditory stimulus, characteristic of VIIIth nerve or brainstem dysfunction.

### Auditory neuropathy

Auditory neuropathy or dyssynchrony describes patients in whom hearing impairment is characterised by disordered processing of sound, commonly the result of retro-cochlear pathology from the inner hair cells of the cochlea distally, through to the auditory brainstem pathways centrally. Characteristically, pure tone audiometric thresholds are relatively well preserved, but speech perception is markedly impaired, and acoustic brainstem evoked responses (ABR) are found to be delayed or absent. Cases are not uncommon – some 5–12% of those previously considered to have severe hearing disorder in paediatric populations. The importance of recognising these patients is well established as they have specific management requirements.

### Brainstem auditory dysfunction

The auditory nuclei in the brainstem extract signals from background noise and allow binaural integration of auditory information. Electrophysiological and behavioural tests of auditory separation and binaural interaction are of particular value in assessment and include: masked speech, the synthetic sentence identification with ipsilateral computing message test, the masking level difference test and the binaural fusion test.

### Auditory processing disorder

Auditory processing disorder (APD) is recognised as a distinct entity, but diagnosis remains a challenge, not only because of the complexity of the auditory brain, but also because of the lack of accepted diagnostic criteria, and a systematic diagnostic test battery. The British Society of Audiology has proposed that APD ‘results from impaired neural function and is characterised by poor recognition, discrimination, separation, grouping, localisation, or ordering of non-speech sounds. APD does not result solely from a deficit in general attention, language or other cognitive processes.’ Similarly, the American Speech-Language-Hearing Association (ASHA, 1996) proposed that the term ‘central’ should precede the term APD, because ‘most definitions of the disorder focus on the central auditory nervous system’ and thus defined (C)APD as ‘a deficit in neural processing of auditory stimuli that is not due to higher order language, cognitive, or related factors’.

Patients with APD may demonstrate normal audiograms but show deficits in sound localisation, auditory pattern recognition and sound discrimination, temporal processing, processing of degraded auditory signals or processing of the auditory signal when embedded in competing acoustic signals.

## Clinical examination of the ear and hearing

### Otосcopy

Pathology of the auricle, the external auditory meatus and the tympanic membrane (TM) may be identified by direct examination with an otoscope or using a head-worn light source, leaving the

**Table 15.8** Fistula sign.

<p>This comprises the following:</p> <ul style="list-style-type: none"> <li>• Raised pressure causes a conjugate deviation of the eyes towards the opposite ear</li> <li>• With maintenance of pressure, a corrective fast eye movement (nystagmus) will be introduced towards the affected ear</li> </ul> <p>Depending on where the fistula has developed, the nystagmus will be:</p> <ul style="list-style-type: none"> <li>• Horizontal (horizontal semicircular canal)</li> <li>• Torsional (anterior canal)</li> <li>• Vertical (posterior canal)</li> </ul> <p>External auditory meatus pressure can be raised by pressure on the tragus, but more accurately by tympanometry. Hennebert’s sign is a positive fistula sign in the presence of an intact tympanic membrane</p>
---

hands free. Importantly, cholesteatoma should be excluded. A Siegel speculum can be fitted to vary intra-meatal pressure and provide evidence of a labyrinthine fistula (Table 15.8). A stiff TM secondary to a middle ear effusion results or a flaccid TM, secondary to a healed perforation.

### Auricle (pinna)

Congenital abnormalities of the auricle may be associated with findings of middle and inner ear abnormalities.

### External auditory meatus

Wax can be removed using a head-light by probe or syringing, after softening if necessary with ceruminolytics (e.g. olive oil).

Congenital conditions include a stenosed or atretic EAM. Acquired abnormalities include foreign body obstruction; otitis externa – caused by *Staphylococcus*, *Pseudomonas* and diphtheroids, fungal infections such *Aspergillus* and *Candida*, and viral infections such as zoster (Ramsay-Hunt syndrome). Exostoses are small rounded bony outgrowths, common in those who swim or dive frequently.

### Tympanic membrane and middle ear

The normal eardrum has the appearance of mother-of-pearl with a light reflex, seen antero-inferiorly, but this may be lost if the membrane is thickened. White patches of tympanosclerosis are a result of hyaline secondary to old middle ear disease. Blood may be seen behind the TM, and manifestations of infection may be visible. Retraction of the membrane occurs when there is chronic lowering of pressure within the middle ear (i.e. with chronic obstruction of the Eustachian tube). A fluid level may be visible if secretory otitis media has resulted from reduction of pressure. A bulging drum may occur with raised middle ear pressure (normal colour) or with acute suppurative otitis media (cherry red). Perforations may be marginal (unsafe) or central (safe) perforations in the pars tensa, and attic perforations, which may indicate the presence of cholesteatoma.

### Tuning fork tests

Tuning fork tests using 256 and 512 Hz forks (Tables 15.9 and 15.10; Chapter 4) were traditionally used to distinguish conductive from sensorineural hearing loss, and also to identify functional hearing loss. The principles of tuning fork tests are:

- The inner ear is more sensitive to sound conducted by air than bone;
- In pure conductive hearing loss, the affected ear is subject to less environmental noise and is more sensitive to bone-conducted sound.

**Table 15.9** Rinne tuning fork test.

---

Heinrich Rinne described his tuning fork test in 1855:

- 1 The fork is struck and held with the tines perpendicular to the long axis of the external auditory meatus with the closest tine 1 cm from the entrance to the meatus
- 2 The patient is asked to report if they can hear the sound (AC)
- 3 The fork is immediately transferred behind the ear with the base firmly pressed to the bone overlying the mastoid (BC)
- 4 The patient is asked which sound is louder: that in front of the ear, or that behind the ear?

The Rinne test is positive if  $AC > BC$  (i.e. the sound in front of the ear is reported as the louder). This indicates:

- Normal hearing, or
- An ear with a sensorineural hearing loss

The Rinne test is negative if  $BC > AC$  (i.e. the sound in front of the ear is reported as the quieter). This identifies:

- A significant conductive component of hearing loss of  $>15$  db
- But, a false negative Rinne test can occur if there is severe sensorineural hearing loss in the tested ear; the BC stimulus is heard in the non-tested ear because of transcranial transmission, and thus will be louder than AC sound. This can be overcome by masking the non-affected ear with a Barany noise box

The Rinne test has a high specificity for conductive hearing loss, but a low sensitivity, this not reaching 90% until the air–bone gap  $>30$  db

---

**Table 15.10** Weber tuning fork test.

---

The aim of Ernst Weber's test (1934) is to identify the better hearing cochlea. It is used in conjunction with the Rinne test and is of most use in patients with unilateral hearing loss:

- 1 The 512-Hz tuning fork is struck and placed to the head in the midline, either at the vertex or on the forehead
- 2 The patient is asked to say whether the sound is heard better in one ear, or equally in both ears

A central Weber is described if the tone is heard centrally:

- This identifies a patient with normal hearing

A lateralising Weber is when the tone is heard to one side:

- This identifies the side of the better hearing cochlea
- But, if there is a conductive component to the hearing loss, the tone may be heard in the poorer-hearing ear (Table 15.9)

Results need interpretation with care and only in conjunction with further hearing tests

---

## Audiological investigations

Auditory tests aim to define pathology within the auditory system, and to site the level of the lesion. A battery of audiological tests is required to:

- Quantify the audiometric threshold at each frequency
- Differentiate conductive from sensorineural hearing loss
- Differentiate cochlear from retro-cochlear abnormality
- Identify central auditory dysfunction in the brainstem, mid-brain or auditory cortex, and
- Identify any non-organic hearing impairment.

### Baseline audiometric tests

#### Pure-tone audiometry

The cornerstone of audiological testing is the pure-tone audiogram (PTA) which measures subjective hearing thresholds and demonstrates the severity, configuration and type of hearing loss, provided

there is good patient cooperation. If the patient is unable or unwilling to cooperate, additional audiological investigation, such as oto-acoustic emissions and auditory evoked responses are essential to provide objective measures of hearing.

Pure tone audiometry is performed in a sound-proofed room with a standardised protocol across auditory frequencies of 125–8000 Hz in each ear. Electrically generated pure tones are delivered through headphones or a bone conductor applied to the mastoid process, and the subject is required to respond to the quietest tone, this being recorded as the air or bone conducted hearing threshold for that frequency. For bone conduction, because the intra-aural attenuation for bone conducted sound is negligible, the ear not being tested is masked with narrow-band noise centred on the test frequency. For clinical purposes, air conduction threshold values better than 20 dBHL are considered to be normal. Bone conduction thresholds significantly better than air conduction thresholds indicate a disorder affecting transmission of sound through the middle ear into the inner ear (i.e. conductive hearing loss), whereas bone conduction and air conduction thresholds that are similar imply sensorineural hearing loss.

#### Acoustic impedance measurements

Tympanometric measurements provide information about pressure within the middle ear and TM compliance. Passive measurements are made of the change in acoustic impedance or immittance of the TM as a function of the pressure in the sealed external acoustic meatus. High impedance abnormalities include middle ear effusion, retracted TM or ossicular fixation. Low impedance abnormalities include thin atrophic TMs and ossicular disruption following head trauma.

Stapedius reflex measurements provide information about the inner ear, in addition to the VIIIth nerve and brainstem function. Dynamic changes are measured, resulting from contraction of stapedius, and stapedial reflex thresholds, in response to stimuli of 500, 1000, 2000 and 4000 Hz, at intensities of 70–100 dB sound pressure level. These provide evidence of recruitment and abnormal auditory adaptation.

#### Speech audiometry

Speech audiometry assesses auditory discrimination as opposed to auditory acuity, requiring the subject to repeat standard word lists delivered through headphones at varying intensities. The responses are scored to provide an assessment of auditory discrimination which, together with other tests, is valuable in distinguishing conductive and sensorineural hearing impairment. This is of particular value in assessing efficacy of hearing aids. Speech recognition tests are also an essential item of the test battery for identification of auditory neuropathy, as speech intelligibility scores are poorer than can be explained by pure tone thresholds.

#### Electro-acoustic and electrophysiological tests

Event-related potentials provide the most objective technique of assessing auditory function and the functional integrity of their generators, and help to site pathology within the auditory system and include:

- Oto-acoustic emissions (OAE)
- Electro-cochleography (ECoChG)
- Acoustic brainstem evoked responses (ABR)
- Middle latency responses, and
- Cortical evoked responses.

### Oto-acoustic emissions

OAEs, first characterised in 1978, are low-intensity sounds generated by the contractile elements of the outer hair cells in the cochlea in response to acoustic stimuli (Figure 15.22). Typically, 260 transients (clicks) at 80–86 dB SPL are presented to evoke a response captured over a time frame of 20 ms after stimulus application and known as transient evoked OAE (TEOAE).

A defining feature of patients with auditory neuropathy is the clearly recognisable waveforms of the TEOAE in the absence of ABR, indicating normal cochlear outer hair cell function. Various studies have reported the lack of contralateral suppression of TEOAE in patients with auditory neuropathy, consistent with VIIIth nerve pathology occurring in the contralateral afferent pathway.

### Cochlear microphonics and electro-cochleography

Cochlear microphonics are the early components of the ABR generated in the cochlea. They occur in the 0.7–1 ms window post-stimulus and show similar waveform characteristics to the stimulus itself. Typically, this response is cancelled out when performing ABR by using alternate polarity clicks, thereby generating a 'microphonic-free' ABR. Trans-tympanic ECoChG indicate that the phase reversal to the click stimulus occurs at the level of the cochlea itself, and therefore the presence of cochlear microphonics is indicative of a preneural response to sound. ECoChG is used to measure the summing and action potentials and is most commonly used in the diagnosis of Ménière's disease, when the summing potential to action potential ratio is greater than 30% (in the normal population it is significantly smaller).

### Acoustic brainstem evoked responses

ABR are detected by surface electrodes, and represent electrical activity transmitted by the VIIIth nerve and brainstem auditory relay centres in the 10 s immediately after an acoustic stimulus. Waves I and II are thought to arise from the VIIIth nerve, while waves III, IV and V from generator sites within the brainstem auditory pathways (Figure 15.23). Prolongation of the I–III interval can be seen in auditory nerve and cochlear nucleus pathology. Prolongation of the III–V is usually indicated when pathology is

sited above the level of the cochlear nucleus, while absent IV and/or V waves are found in cases with involvement of the mid-upper pons. Inter-aural latency comparisons of wave V are of value in diagnosis of acoustic neurinoma, but may not be useful in detecting brainstem involvement. An absent ABR of the patient with auditory neuropathy may be explained by the altered temporal synchrony of the auditory brainstem pathway.

### Middle latency response

The middle latency response generator sites are presumed to be within thalamo-cortical pathways to the auditory cortex. Sensitivity and specificity of middle latency responses for central auditory pathology is reasonably good, and the test is therefore valid and objective in assessment of central auditory dysfunction, but sleep and sedation may affect responses.

### Cortical-evoked auditory responses

Cortical- or late-evoked auditory responses are the most effective method of defining auditory thresholds at each frequency in a patient who is unable or unwilling to cooperate; they are essential in legal cases, in which non-organic loss should always be considered.

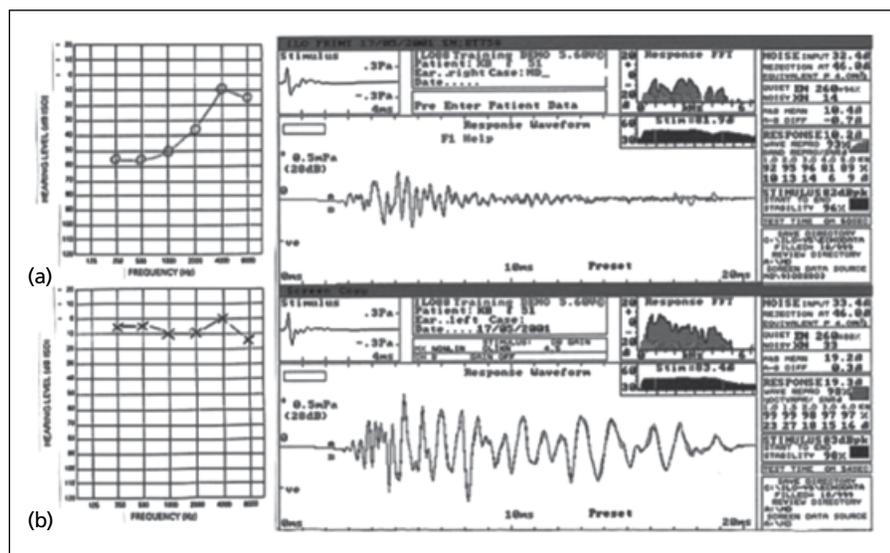

## Aetiology of hearing loss

### Conductive hearing loss

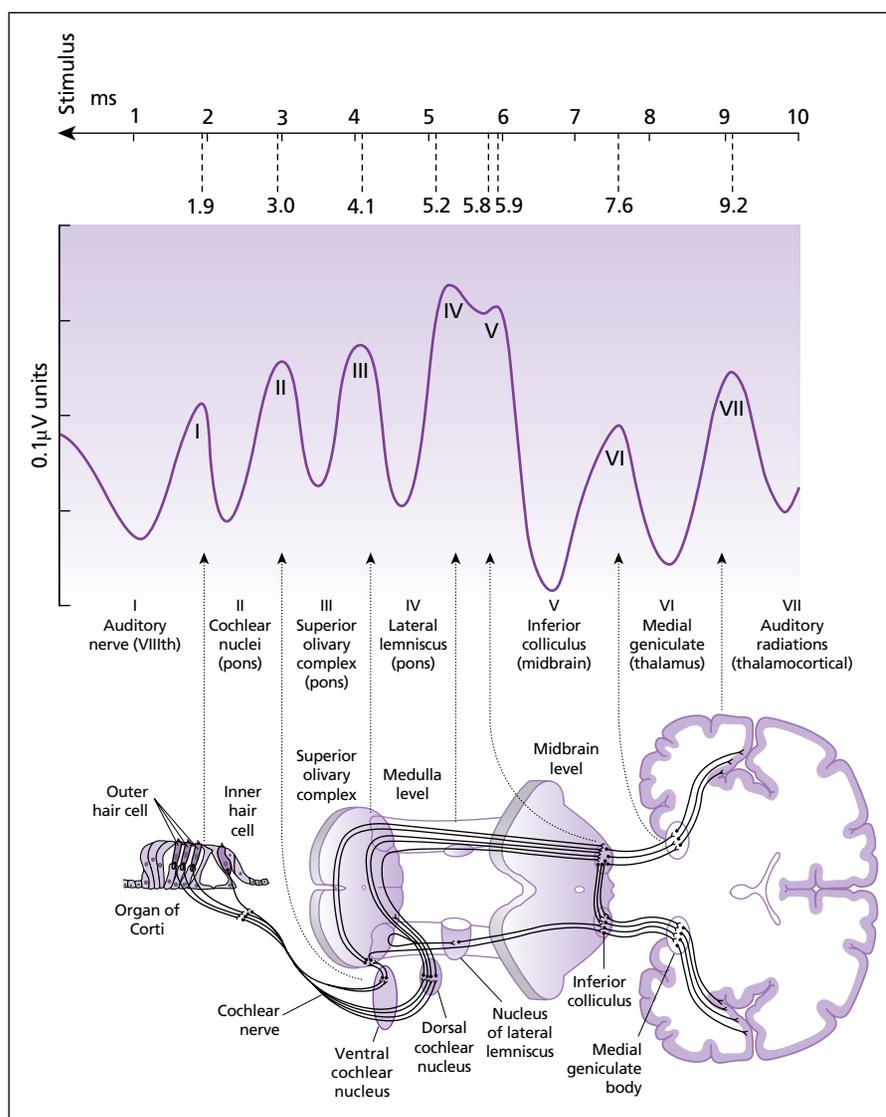

#### Disorders of the tympanic membrane and middle ear

Acquired disorders include acute otitis media, chronic otitis media, serous otitis media, cholesteatoma and ossicular abnormalities.

*Acute otitis media* is most prevalent in children. Chronic acute otitis media unassociated with cholesteatoma is characterised by recurrent infections rather than persistent infections and by odourless, rather than offensive discharge. A central TM perforation and a break in the ossicular chain or malleus fixation are regarded as safe, and unlikely to be associated with cholesteatoma. Serous otitis media is recognised by an air–fluid level in the middle ear, or a bluish discoloration of the drum. Other effusions into the middle ear include blood (e.g. haemo-tympanum after head trauma) or cerebrospinal fluid (CSF) within the middle ear space.

**Figure 15.22** Oto-acoustic emissions in a patient with Ménière's disease. (a) Right ear of patient: pure-tone audiogram (PTA) showing typical low frequency hearing loss; transient evoked oto-acoustic emissions (TEOAE) showing reduced response. (b) Left ear of patient: PTA showing normal hearing; TEOAE showing normal response.

**Figure 15.23** Acoustic brainstem evoked responses. Showing the series of neurogenic potentials in the 10-second post click stimulus and the putative generator sites in the VIIIth nerve, brainstem and thalamus. Source: Duane 1977.

*Cholesteatoma* commonly arises in ears undergoing long periods of negative middle ear pressure and persisting middle ear infection (i.e. following chronic suppurative otitis media). They are potentially serious and requires surgical removal, as they slowly increase in size and may erode the surrounding bone producing intracranial complications. Diagnosis is made from a history of perforation, chronic foul-smelling discharge and keratin debris in the pars flaccida area on otoscopic examination.

*Otosclerosis* is an inherited autosomal dominant hearing disorder, developing in later childhood or adulthood, associated with the *TGFB1* gene. Deposition of bone leads to fixation of the stapes footplate and a conductive hearing loss. The otosclerotic process can extend to involve the otic capsule, to cause additional sensorineural hearing loss and vertigo.

*Glomus tumours* are jugulo-tympanic paraganglionomas that tend to expand within the petrous temporal bone and may also extend into the labyrinth, or present as cranial nerve abnormalities. A glomus tumour can present with pulsatile tinnitus and a vascular mass lying behind the TM can sometimes be seen (Chapter 12).

### Sensorineural hearing loss

Interest in sensorineural hearing loss has flourished in recent years, because of both the earlier detection of infants with profound hearing loss through newborn hearing screening programmes and because of effective prosthetic, pharmacological and genetic developments.

### Genetic hearing loss

There have been significant strides in the understanding of genetic and environmental causes of both cochlear and retrocochlear hearing loss. A plethora of genes with autosomal dominant, recessive and mitochondrial inheritance have been reported, in addition to genetic aberrations giving rise to X-linked hearing loss (Hereditary Hearing Loss Homepage <http://hereditaryhearingloss.org>). Many of these forms of genetic hearing impairment present either in a non-syndromal or syndromal pattern.

Age-related hearing loss, characterised by progressive deterioration of auditory sensitivity with age, is the leading cause of adult auditory impairment. Until recently it had been attributed to a variety of factors including genetic, nutritional, socio-economic and

environmental variables but recent research has suggested that specific genes predispose individuals to environmental triggers affecting various molecular mechanisms underlying changes in auditory function. Specifically, a mitochondrial mutation associated with aminoglycoside-induced hearing loss has been reported.

*Autosomal recessive hearing loss* accounts for approximately 40% of all cases of childhood hearing loss and manifests as stable, profound, congenital/prelingual impairment. There may be marked intra-familial variation in the severity of the loss and audiology is generally normal.

*Autosomal dominant sensorineural hearing loss* is uncommon in prelingual profound hearing impairment, but is well recognised in families with hearing loss of various configurations, differing ages of onset and differing rates of progression.

*Syndromic hearing loss*: more than 100 syndromes have been reported with associated hearing impairment; the more common, with their predominant features, are summarised in Table 15.11. Many of these present in childhood, but hearing loss associated with certain syndromes can progress or indeed become apparent in adult life.

### Metabolic disease

*Diabetes mellitus*: there is no clear evidence indicating whether or not patients with diabetes mellitus have auditory and/or vestibular abnormalities as a consequence of neuropathy, angiopathy or both pathologies. Genetic studies have defined the relationship of diabetes and hearing loss in mitochondrial mutations and in mutations of the *WFS1* gene in the Wolfram syndrome of hearing impairment, diabetes mellitus and optic atrophy.

*Renal failure* is commonly associated with hearing loss. Ototoxicity from disease, drugs and axonal uraemic neuropathy have all been implicated as possible aetiologies, while both dialysis and renal transplantation have been reported to be associated with recovery of hearing impairment.

### Drugs

Many drugs produce ototoxicity, including chloroquine, loop diuretics, aminoglycosides and salicylates. Platinum-based chemotherapeutic agents, in addition to the aminoglycosides, have been shown to damage the hair cells of the inner ear, while vincristine sulfate has been shown to produce bilateral cochlear nerve damage. Thalidomide has been demonstrated to produce aplasia of the VIIIth nerve in association with a Michel aplasia of the inner ear. In neurological practice, intrathecal streptomycin used for the treatment of meningitis, is a cause of deafness. Regular blood level estimations are helpful in preventing ototoxicity.

### Acoustic trauma

*Noise-induced permanent threshold shift* is a common and preventable cause of sensorineural hearing loss, associated with hazardous occupational and/or recreational exposure to noise or acoustic trauma (e.g. gunfire and explosions). Characteristically, the maximal loss is at 4000 Hz, with a notched configuration to the audiogram. With time, the adjacent frequencies gradually deteriorate, but it is rare for a hearing loss greater than 70 dB to be the result of occupational noise exposure.

*Acute barotrauma* associated with diving, depressurisation in aircraft and explosions may give rise to tympanic membrane haemorrhage into the middle ear, with conductive hearing loss or perilymph fistula which is commonly associated with auditory and vestibular symptoms.

*Physical trauma* (head injury) may lead to middle ear, inner ear, VIIIth nerve and/or central auditory loss. In mild and moderate head injuries auditory abnormalities, commonly high frequency sensorineural loss, is found in 50% of cases. Labyrinthine concussion and both longitudinal and transverse fractures of the petrous temporal bone may result in sensorineural and/or conductive hearing loss.

### Autoimmune disorders (Table 15.12)

*Autoimmune inner ear disease (AIED)* refers to a presumed autoimmune condition in which there is sudden or rapidly progressive hearing loss in the absence of any other neurological or systemic immunological abnormalities. Although AIED seems to be caused by autoimmune attack on inner ear proteins, no specific antigen has yet been identified. Typically, the hearing loss is bilateral, rapidly progressive and associated with vestibular symptoms. Treatment with steroids (both intra-tympanic and orally administered), methotrexate, plasmapheresis, cyclophosphamide or azathioprine may be effective.

*Cogan's syndrome* is a rare, presumed autoimmune disorder, affecting the eye and the ear that develops usually in children and young adults in the aftermath of an upper respiratory tract infection. No infectious agent has been conclusively identified as a cause. Inflammatory ocular symptoms, together with vestibular symptoms and hearing loss with rapid progression to total bilateral deafness, are common. Systemic manifestations include lymphadenopathy, night sweats and cardiorespiratory involvement including aortitis, aortic valve insufficiency, pericardial effusion and coronary arteritis, pleuritis and myocardial infarction.

*Vogt-Koyanagi-Harada syndrome (VKH) syndrome* is a rare condition characterised by bilateral uveitis with cutaneous lesions (vitiligo, alopecia and poliosis), neurological features (CSF pleocytosis) and auditory abnormalities. It is essentially a disorder of melanocyte-containing organs, and occurs more frequently in individuals with darker skins. It is more common in females and usually presents in children or young adults.

*Behçet's syndrome* commonly presents with oro-genital ulceration, arthritis and headache (Chapter 26) but about one-third of cases have predominantly high-frequency cochlear hearing loss and vestibular involvement.

*Susac's syndrome* is a rare micro-angiopathy resulting in encephalopathy, retinopathy and hearing loss, and is assumed to have an autoimmune basis (Chapters 5 and 26). It occurs mainly in young adult women and has an acute or subacute presentation. Low frequency, unilateral or bilateral sensorineural hearing loss is often the presenting feature, associated usually with tinnitus and vestibular disturbance. The encephalopathy causes prominent headache, personality change, paranoia, confusion and cognitive impairment.

*Other autoimmune conditions associated with deafness* include systemic lupus erythematosus (SLE), ulcerative colitis, scleroderma, polyarteritis nodosa, Sjögren's syndrome, giant cell arteritis and Wegener's granulomatosis. Treatment is of the underlying condition.

### Retro-cochlear hearing disorders

Retro-cochlear hearing loss is either genetic, acquired congenitally or postnatally (Tables 15.13 and 15.14). In addition to genetic cochlear dysfunction, a small number of children have isolated autosomal recessive auditory neuropathy related to mutations of the otoferlin gene. Mutations in *12SrRna* gene are also associated with auditory neuropathy.

**Table 15.11** Inheritance, predominant features, auditory and vestibular abnormalities and CNS findings in syndromes associated with hearing loss.

Syndrome	Mode of inheritance	Predominant features	Auditory and vestibular features	CNS status
Treacher–Collins	AD	Mandibulofacial dysostosis	Severe dysplasia middle and internal ear (A + V)	N
Branchio-otorenal	AD	Branchial cysts/fistulae Structural ± functional renal abnormalities	Anomalies of external ear CHL 20%, SNHL 30%, mixed 50%	N
CHARGE	Occasional AD Rare AR Most sporadic	Coloboma, <b>heart defect</b> , <b>atresia of choanae</b> , <b>retarded growth and development</b> , <b>genital hypoplasia</b> , <b>ear anomalies</b>	Structural labyrinth (A + V) dysplasia VIII nerve involvement Absent semicircular canals SNHL ± CHL	Impaired IQ and development
Usher's	AR	Retinitis pigmentosa	Type I: A + V failure Type II: A failure Type III: Variable	N
Alstrom's	AR	Pigmentary retinopathy Diabetes mellitus Obesity	SNHL	N
Apert's	Mainly sporadic. Some AD	Craniosynostosis + oral manifestations Brachydactyly	CHL ME anomalies	Frequent low IQ CNS manifestations
Crouzon's	AD	Craniosynostosis Shallow orbits Ocular proptosis	CHL ME anomalies	Generally N
Osteogenesis imperfecta	AD	Blue sclera Opalescent teeth Deformities of long bone and spine, Hyperextensibility	Type 1 Mild CHL >10 years of age Progressive mixed hearing loss	Generally N
Stickler's	AD	Flat midface and cleft palate High myopia and retinal detachment and cataracts Arthropathy Spondylo-epiphyseal dysplasia	Progressive SNHL	N
Wildervanck's	Sporadic	Fused cervical vertebrae Abducens palsy and retracted globe	SNHL, CHL or mixed in ~30%. Vestibular failure common	Usually N

(continued)

**Table 15.11** (continued)

Syndrome	Mode of inheritance	Predominant features	Auditory and vestibular features	CNS status
Alport's	Usually X-linked dominant, rarely AR	Progressive glomerulonephritis Bilateral anterior lenticonus and macular flecks or peripheral coalescing flecks	Progressive SNHL in >10 years in approximately 50% of cases	Usually N
Jervell-Lange-Nielsen	AR	Prolonged Q-T interval Fainting spells/sudden death	Profound SNHL Scheibe anomaly	N
Pendred's	AR	Goitre	Mondini defect Dilated vestibular aqueduct Severe-profound SNHL Vestibular failure 30%	N
Mucopolysaccharidoses: Hurler's Hunter's	AR except Hunter's syndrome which is X-linked	Growth failure. Death <10 years Craniofacial dysmorphism Lysosomal storage Excess excretion of dermatomes and heparin sulphates Severe form <ARR>→ death at 4–14 years Mild form <ARR>→ less severe than Hurler's syndrome	Progressive CHL Central auditory dysfunction Mixed HL in ~50%	Impaired IQ and development
Refsum's	AR	Retinitis pigmentosa HMSN (Cardiac enlargement/dysrhythmias Ichthyosis)	Progressive SNHL Vestibular function: normal	Anosmia Progressive weakness + sensory neuropathy, cerebellar signs
Down's	Trisomy 21	Short stature Dysmorphic facial features Hypotonia Single palmar crease Cardiac anomalies Delayed mental development	Abnormal external ear morphology CHL and/or SNHL in majority	Impaired IQ and development

A, auditory; AD, autosomal dominant; AR, autosomal recessive; CHL, conductive hearing loss; HL, hearing loss; ME, middle ear; SNHL, sensorineural hearing loss; V, vestibular. Source: Luxon 2007. Reproduced with permission of Oxford University Press.

**Table 15.12** Autoimmune syndromes associated with hearing loss.

Condition/ syndrome	Neuro-otologic syndrome	Associated findings	Epidemiology	Laboratory markers/diagnostic tests
Cogan's syndrome	'Ménière-like': attacks of vertigo, nausea, tinnitus, and hearing loss	Eye inflammation (keratitis, scleritis, conjunctivitis, uveitis, retinal vasculitis); systemic vasculitis in 10%	Young adults and older children (median 25 years)	Neutrophilia, raised ESR/CRP, MRI enhancement of vestibulocochlear structures
Wegener's granulomatosis	Usually conductive hearing loss; often have otitis media; SNHL reported, but usually as part of mixed picture	Rhinorrhoea and sinusitis; pulmonary, renal, joint manifestations; peripheral nervous system involvement	40–50 years; males and females equally affected	Raised ESR/CRP, raised ANCA (proteinase 3), granulomatous infiltration on MRI, biopsy
Polyarteritis nodosa	Rapid SNHL	Systemic vasculitis (kidney, gut); constitutional symptoms; mononeuritis multiplex	Male > female; older age of onset	Leukocytosis, raised ESR, visceral angiography, organ/nerve/muscle biopsy
Systemic lupus erythematosus	Subacute SNHL, often subclinical (NSAIDs and antimalarials may complicate picture – both may cause SNHL)	Skin, joint, renal, neuropsychiatric; constitutional symptoms	Female > male (5 : 1); age 15–40 years	Raised ESR, ANA, dsDNA antibodies, antiphospholipid antibodies, complement consumption
Sjögren's syndrome	Often subclinical	Dry eyes, dry mouth; Raynaud's and joint symptoms; neuropathies (axonal, sensory-ataxic, trigeminal)	Female > male	ANA, Ro, La, Schirmer's test, lip biopsy

ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; MRI, magnetic resonance imaging; NSAIDs, non-steroidal anti-inflammatory drugs; SNHL, sensorineural hearing loss.

**Table 15.13** Genetic/congenitally acquired retro-cochlear hearing disorders.

Genetic	Non-syndromal	Non-syndromal recessive auditory neuropathy due to mutations in the otoferlin gene Delayed maturation of auditory pathways in neonates	
Genetic	Syndromal	With peripheral neuropathy	Hereditary sensorimotor neuropathy, e.g. Roma (gypsy) families Friedreich's ataxia Neurofibromatosis type 2 Refsum's disease
Genetic	Syndromal	Without peripheral neuropathy	Arnold–Chiari Usher's syndrome Mitochondrial myopathies: MELAS Chronic progressive external ophthalmoplegia Mohr–Tranebjaerg's syndrome (deafness/ dystonia peptide) Skeletal syndromes: Branchio-otorenal Wildervanck's Bone dysplasias: Osteopetroses Hyperostosis cranialis Cammurati–Engelmann's disease Gaucher's
Congenital/toxic/metabolic			Perinatal risk factors: Asphyxia Respiratory distress syndrome Low birth weight Cerebral palsy Hyperbilirubinaemia Thalidomide

MELAS, mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes.

### Charcot–Marie–Tooth disease

Domed-shaped sensorineural hearing loss occurs in Charcot–Marie–Tooth disease (Chapter 10) type 1a and hereditary neuropathy with liability to pressure palsies (HNPP). In the latter, half are thought to have the common PMP22 deletion, and half a PMP22 frameshift mutation. In HNPP cases, data suggest excessive presbycusis.

### Neurofibromatosis type 2

This autosomal dominant genetic disorder, associated with acoustic neuromas, commonly causes retro-cochlear hearing loss, as the presenting symptom. Neurofibromatosis type 2 (NF2) is 10 times less common than NF1 and occurs in 1/30 000–40 000 people. Mutations are found in the NF2 gene (neurofibromin 2; merlin), a tumour suppressor gene located on chromosome 22. Over 50% of NF2 cases are a result of new mutations. The clinical manifestations include peripheral neurocutaneous manifestations (café-au-lait spots and peripheral nerve neurofibromas), ocular abnormalities (juvenile posterior subcapsular lens opacity, retinal hamartomas and optic nerve sheath meningiomas) and both CNS and spinal tumours. CNS tumours include meningiomas (often multiple), vestibular schwannomas (acoustic neuromas), schwannomas in other locations, optic nerve gliomas, ependymomas and neurofibromas. Ninety per cent of NF2 patients have vestibular schwannomas, often bilateral; 50% develop meningiomas or other cranial nerve tumours, 40% develop spinal ependymomas or astrocytomas and 90% ocular manifestations, when examined in detail.

The type of genetic defect influences prognosis: nonsense or frameshift mutations generally cause severe disease, and missense mutations, in-frame deletions or large deletions cause milder disease. Severity varies in those with splice site mutations. The growth rate of VIIIth nerve tumours in NF2 is variable; for very slow growing tumours there is a case for non-operative management. However, the majority of patients with NF2 will develop severe deafness, and some will also become blind. Mean survival after diagnosis is some 15 years and the mean age of death in NF2 around 40 years.

### Friedreich's ataxia

Friedreich's is the most common inherited ataxia (Chapter 17), and is frequently caused by a large expansion of an intronic GAA repeat, resulting in decreased expression of the gene product frataxin. The condition is usually inherited in an autosomal recessive pattern, and as frataxin is a mitochondrial protein, it suggests that dysfunction in Friedreich's ataxia is caused by a mitochondrial abnormality. Hearing impairment is an associated but unusual feature.

### Refsum's disease

Refsum's disease (Chapter 19) is characterised by defective peroxisomal alpha oxidation of phytanic acid, with clinical features of retinitis pigmentosa, polyneuropathy, anosmia and hearing loss. Adult Refsum's disease is a recessive disorder of the phytanoyl CoA hydroxylase, *PAHX* gene on chromosome 10p30. Although hearing loss in Refsum's disease is common, only a few detailed assessments

**Table 15.14** Acquired retro-cochlear hearing disorders.

Acquired infection	Viral	Herpes zoster/herpes simplex: Ramsay-Hunt syndrome Bell's palsy CMV, varicella, mumps HIV/AIDS
	Bacterial Fungal/protozoan Spirochaetal	Basal meningitis Pneumococcal Meningococcal Haemophilus Tuberculosis Cryptococcosis Coccidiomycosis Toxoplasmosis Syphilis, borrelia
Immune-mediated	Post-infective Vasculitic/granulomatous	Guillain-Barré SLE, rheumatoid, sarcoid, Behçet's syndrome
Demyelination	Multiple sclerosis VIIIth nerve Brainstem	
Neoplasia/neoplasia related	Vestibular schwannoma Meningioma Cerebellopontine angle lesions Carcinomatosis Malignant meningitis Radiotherapy	
Metabolic/toxic	Uraemia Paget's disease Organic mercury Cisplatin Superficial siderosis	
Vascular	?Migraine Posterior inferior cerebellar artery syndrome Posterior fossa aneurysms AVM Vascular loops	

AVM, arteriovenous malformations; CMV, cytomegalovirus; SLE, systemic lupus erythematosus.

exist. One report demonstrates that seven of nine adults with Refsum's had a mild to moderate sensorineural hearing loss, predominantly of high-frequency type, and subtle auditory nerve involvement was identified in seven on the basis of ABR.

### Mitochondrial disorders

Mitochondrial conditions have a propensity to cause sensorineural hearing loss (Table 15.15). Kearns-Sayre syndrome and MELAS (mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes) cases tend to have progressive hearing loss of both cochlear and retro-cochlear origin. No correlation between the type and severity of hearing loss and number or severity of other clinical neurological findings is found. In one study of adult patients with 3243A < G mutation, 13 of 16 had a sensorineural hearing loss that was progressive, and both this feature and the severity were correlated with the mutation heteroplasmy in muscle at entry and at end of follow-up. Sensorineural deafness is also a feature of MERRF (myoclonic epilepsy with ragged red fibres) as well as the other less common syndromes (Chapter 10).

### Inherited muscle disorders

Inherited muscle disorders can be associated with hearing loss, including facioscapulohumeral dystrophy and myotonic dystrophy. In this latter condition, the hearing loss is reported to resemble 'precocious presbycusis', or an excessive high-frequency hearing loss characteristic of presbycusis, and genetic anticipation.

### Acquired retro-cochlear hearing disorders (Table 15.14)

**Infections** Bacterial, viral and mycotic infections may give rise to hearing impairment by direct invasion, blood-borne transmission or via CSF.

**Viral infections** Sudden sensorineural hearing loss in adults is often presumed to be viral in origin. The Ramsay-Hunt syndrome is characterised by facial palsy, hearing loss, and characteristic herpetic vesicles around the pinna and in the external auditory meatus. Sensorineural hearing loss occurs in half to two-thirds of cases and is the result of cochlear or retro-cochlear involvement.

**Table 15.15** Clinical features of mitochondrial syndromes associated with deafness.

Condition/syndrome	Neuro-otological syndrome	Main clinical features	Additional features	Epidemiology	Laboratory markers
MELAS	Cochlear origin; symmetric gradual onset SNHL	Encephalopathy (seizures $\pm$ dementia); stroke-like episodes; mitochondrial myopathy	Short stature; normal early psychomotor development; recurrent headache and vomiting	Usually first decade; sometimes 10–40 years	Ragged red fibres on muscle biopsy; increased lactate
MERRF	Symmetric gradual onset SNHL	Myoclonus; epilepsy; cerebellar syndrome; myopathy	Short stature; dementia; optic atrophy; cardiomyopathy; Wolff–Parkinson–White syndrome; peripheral neuropathy	Usually childhood onset, but may be adults	Ragged red fibres on muscle biopsy; increased lactate
KSS	Symmetric gradual onset SNHL	Retinitis pigmentosa; ophthalmoplegia	Cardiac conduction block; cerebellar syndrome; short stature; impaired intellect	Onset <20 years; majority are sporadic	Ragged red fibres on muscle biopsy; increased lactate, raised CSF protein

CSF, cerebrospinal fluid; KSS, Kearns–Sayre syndrome; MELAS, mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes; MERRF, myoclonic epilepsy with ragged red fibres; SNHL, sensorineural hearing loss.

Source: Overell 2004. Reproduced with permission of the BMJ.

**HIV/AIDS and syphilis** A variety of auditory abnormalities have been reported in HIV infection, ranging from conductive to sensorineural hearing loss, with mild audiometric changes, abnormalities in ABR and central auditory dysfunction. A study of HIV revealed a prevalence of hearing impairment of 23%, which may have been associated with opportunistic infections such as otosyphilis, cytomegalovirus or streptococcal meningitis, or treatment.

In otosyphilis, various presentations are seen, including sudden sensorineural hearing loss and a pattern suggestive of Ménière's disease. Importantly, this is one form of treatable hearing loss and this diagnosis should be sought in any unexplained case of sensorineural hearing loss, particularly in HIV-positive patients. Treatment of otosyphilis with penicillin and corticosteroids may improve tinnitus and vertigo in some cases.

**Bacterial meningitis** Sensorineural hearing loss in children during or following bacterial meningitis, including TB, is well known, with prevalence of 5–30%. There is little evidence that any single bacterial infection causes greater loss of hearing, either in frequency or degree. Treatment with antibiotics and adjuvant corticosteroids reduces fatalities and also lowers rates of severe hearing loss and other long-term neurological sequelae.

**Lyme disease** Lyme disease (*Borrelia burgdorferi* infection) causes a spreading erythematous rash on the trunk followed by meningo-radicularitis and hearing loss. Elevated antibodies to *Borrelia* antigen have been found in 17% of 98 subjects with a unilateral sudden or fluctuating sensorineural hearing loss. Treatment with intravenous penicillin results in improvement of high-frequency hearing loss in some cases.

#### Extrinsic and intrinsic tumours of the cerebellopontine angle

Cerebellopontine angle (CPA) tumours (cerebellar medulloblastoma, vestibular schwannoma, meningioma, cholesteatoma, ependymoma, glomus jugulare tumour and metastasis) present commonly with retro-cochlear hearing loss and are diagnosed by MRI. Malignant meningitis and paraneoplastic syndromes can also present with hearing loss (Chapter 21).

**Vestibular schwannoma** The prevalence of vestibular schwannoma is about 1/100 000 persons, with a peak incidence in the fifth and sixth decades. Vestibular schwannomas account for 10% of intracranial tumours, and more than 75% of CPA lesions. Ninety per cent of cases appear to develop spontaneously and tend to be unilateral, arising from the vestibular portion of the VIIIth cranial nerve just within the internal auditory canal. The earliest features are sensorineural hearing loss (50%), tinnitus (21%), dizziness (9%) and rotary vertigo (5%). Later symptoms resulting from compression of adjacent structures include ipsilateral facial weakness, ipsilateral facial sensory loss, ataxia, headache, vomiting and signs of raised intracranial pressure (Chapters 13 and 21).

Although most of these tumours arise on the superior division of the vestibular nerve, the most common presenting features are deafness and tinnitus. In all patients with unilateral sensorineural hearing impairment, asymmetric bilateral sensorineural loss or unilateral tinnitus, it is essential to exclude a small vestibular schwannoma by detailed MRI.

#### Multiple sclerosis

About 5–10% of patients with MS experience significant hearing loss, but subtle hearing loss is more common. MS plaques have been identified in the VIIIth nerve root entry zone, cochlear nucleus and in the pons. Sudden hearing loss in MS is rare but typically improves. An ABR abnormality provides clinical evidence of a brainstem lesion in over 75% of cases of MS, but in over half of those there is an absence of clinical brainstem signs.

#### Sarcoidosis

Bilateral deafness is a feature of neurosarcoidosis (Chapter 26), which can present with cranial nerve dysfunction, typically bilateral facial nerve lesions, including the auditory nerve in about 5% of cases. The deafness is usually of VIIIth nerve origin, although cases are described of granulomatous processes causing necrosis of the incus and encasing the chorda tympani. Treatment of the deafness is with conventional immunosuppressive agents; there is one case report of effectiveness of infliximab.

### Vascular disease

Stroke, both haemorrhagic and ischaemic, can cause hearing disorders at many levels within the brain, although these are rare. Cavemomas in the brainstem can sometimes cause deafness, either by small haemorrhages or increase in size. Aneurysms of the anterior inferior cerebellar artery (AICA) constitute less than 1% of all intracranial aneurysms with those of the distal portion (d-AICA) accounting for less than 0.1%. Because of the proximity of the d-AICA to the CPA and the VII–VIIIth nerve complex, aneurysms can mimic vestibular schwannoma, with auditory symptoms – tinnitus and hearing loss. Neuro-otological features related to AICA aneurysms depend on the arterial segment involved, and the relation to the CPA and IAM. Mechanisms include brainstem compression, rupture and post-embolisation infarction.

**Posterior circulation ischaemia** Sudden deafness occurs following inferior collicular infarction, vertebral artery dissection, infarction of the anterior–inferior cerebellar artery and, rarely, migraine. In one study, 8% of 364 cases of vertebro-basilar insufficiency demonstrated sensorineural hearing loss, the majority being unilateral. Vertigo was associated with hearing loss in most cases. Approximately 50% showed a cochlear type of hearing loss, with approximately half improving over 1 year.

Pontine vascular lesions typically have the greatest effect on hearing. Two overlapping syndromes are recognised: inferior pontine and lateral pontine. Both comprise ipsilateral facial palsy, hearing loss, loss of taste in the anterior two-thirds of the tongue with loss of lateral conjugate gaze. In the lateral pontine syndrome there is also facial sensory loss.

**Vascular loops** There is no definitive evidence to conclude that vascular loops compress the VIIIth nerve, to produce vestibular or auditory symptoms.

### Superficial siderosis

Superficial siderosis is an insidious, progressive, rare disorder (Chapter 17). Symptoms include sensorineural deafness (95%), cerebellar ataxia (88%) and pyramidal signs (76%), dementia (24%), bladder disturbance (24%), anosmia (in >17%), anisocoria (>10%) and sensory signs (13%). Clinical features appear to be caused by chronic subarachnoid haemorrhage from a dural arteriovenous malformation or fistula, dural cyst, other dural pathology, vascular tumour or unknown source. If untreated, the condition results in severe disability and premature death. Diagnosis is confirmed by CSF examination, which shows various breakdown products of haemoglobin, and by MRI, which shows a prominent black rim around posterior fossa structures and sulci on T2 imaging. Treatment is identification and ablation of the source of bleeding, if this is possible.

### Auditory processing disorders

Auditory processing disorders (APD) can manifest in both children and adults with difficulties with word recognition, environmental sounds or music and with uncertainty about what an individual hears, despite the presence of normal hearing thresholds. Patients may experience difficulties listening in a background of noise or with people conversing, difficulties in understanding degraded or rapid speech, following oral instructions, localising sounds or with the perception of music. They may also have language and other disorders, professional and academic problems and behavioural, emotional, social and other difficulties.

A detailed history of the auditory complaints is vital. First, this is so because patients may deny the presence of hearing complaints, unless questioned in detail – they do not always attribute difficulties to hearing problems. Secondly, features of auditory complaints may help define the diagnosis (e.g. in cases of cortical deafness), in which the patient has abnormal hearing thresholds because of bilateral auditory cortex lesions, and in auditory agnosias, of speech, music and environmental sounds, which may be isolated or in combination. Thirdly, identification of specific auditory complaints (e.g. specific pitch difficulties or music-related problems) guides the choice of tests and provides some clues to the site of the lesion.

### Aetiology of APD

There are no robust epidemiological data. However, APD is believed to affect 7% of children and prevalence may be even higher in adults. Disordered auditory processing may occur in the presence of the following:

- Genetic causes. These include syndromes that affect brain structure or make the brain more susceptible to damage. The genetic basis of these auditory processing deficits observed with other developmental disorders remains unclear.
- Neurological conditions such as tumours, stroke and MS.
- Auditory deprivation (e.g. following otitis media with effusion or other type of peripheral hearing loss).
- In the presence of other higher order disorders such as attention deficit disorder, dyslexia, specific language impairment – although in these cases no causal link has been established.
- Age-related changes of the central auditory system, distinct from age-related cochlear hearing loss or cognitive decline.
- Some forms of tinnitus and musical hallucinations, attributed to abnormal activity of the auditory brain may be examples of ‘positive’ disorders of auditory processing.

The following examples illustrate well-recognised presentations of these pathologies. Recent work with insular stroke cases has demonstrated more subtle defects of central processing.

### Cortical hearing impairment

Cortical hearing loss is rare, but is most commonly associated with vascular disease or trauma affecting both temporal lobes. Additional and more dramatic neurological sequelae, including hemiparesis and dysphasia, are the rule. The primary auditory cortex lies in the anterior–posterior transverse temporal gyrus of Heschl. Each ear has bilateral representation in the auditory cortex, and thus it is possible to remove the non-dominant hemisphere in humans without significant effect on either the pure-tone audiogram or the discrimination of distorted speech.

In some cases, the primary auditory deficit predominates, and these cases are described as true cortical deafness. In this situation, a patient may present with no subjective experience of hearing, and demonstrate profound hearing loss on pure-tone audiometry. This may be misdiagnosed as peripheral if electroacoustic and electrophysiological testing are not conducted. For example, oto-acoustic emissions and ABR will demonstrate normal peripheral auditory function. However, abnormal central auditory function will be identified by the later auditory evoked potentials, specifically the middle latency response N1 and P2 waves.

### Auditory agnosia

Auditory agnosia was defined originally as a selective disorder of sound recognition: ‘I can hear you talking, but I cannot translate it.’ This group can be further subdivided into several different clinical presentations: those who are unable to recognise a particular type of

sound (e.g. speech, music or particular environmental noises, such as a dog barking), and those who are unable to discriminate at all between verbal and non-verbal sounds. Most cases correspond to the wider definition with impairment of all modalities of auditory function. Nonetheless, there are also cases of verbal auditory agnosia ('word deafness') in which speech perception is severely impaired, while recognition of non-verbal material such as musical tunes embedded within environmental noise remains intact.

### Interhemispheric lesions

Patients with surgical section of the posterior corpus callosum demonstrate a typical pattern of auditory processing test results termed the Auditory Disconnection Profile. Characteristically, they have normal performance on monaural low-redundancy speech tests, left ear deficits on dichotic speech tests and bilateral deficits on temporal pattern testing.

## Management of auditory disorders

Management of hearing impairment includes:

- Prevention to ensure protection from noise hazards, and avoidance of ototoxic drugs
- Medical management of systemic medical conditions that may be causing or exacerbating auditory dysfunction
- Auditory rehabilitation – a problem-solving exercise centred on each individual patient
- Hearing aids.

Many cases of cochlear hearing impairment are helped by hearing aids, but additional impairments such as arthritis or cerebellar dysfunction confound the fitting process. Importantly, provision of a hearing aid is only effective when the patient wishes to pursue this line of management, rather than it being the suggestion of well-meaning family members or others. The value of environmental aids and instruction in communication skills also helps long-term rehabilitation.

### Hearing aids

Hearing aids have a pivotal role in audiological rehabilitation; precise details of their prescription is outside the scope of this chapter. Conventional aids may be body-worn, head-worn by mounting in spectacles, or mounted in or around the ear. The major advantage of body-worn aids is the very high gain and maximum output achieved, whereas the disadvantage is the obvious and unsightly nature of the device, and the poor microphone placement. Post-aural, in-the-ear or in-the-canal hearing aids are often highly effective, but some patients will require additional environmental aids (e.g. amplification systems attached to TVs or telephones, alerting warning devices, such as flashing lights connected to a door bell or an alarm clock).

The need for counselling of hearing-impaired people and their relatives or carers cannot be overemphasised. Simple tactics such as ensuring that light is always on the speaker's face, with the better ear tilted towards the speaker, and minimising background noise can really help communication. Psychological support should always be considered, and social and occupational support offered.

### Conductive hearing loss

Any obstruction to the transmission of sound through the external ear by a foreign body, wax, polyp, tumour or infection must be corrected. Acute otitis externa requires suction clearance under microscopy, culture and sensitivity of the organism, and appropriate medication, with or without steroids. Acute otitis media requires pain relief, re-establishment of Eustachian tube function using

nasal drops, inhalations or decongestants, mucolytics and systemic antibiotics: amoxicillin is the usual drug of choice. Vaccines have been introduced against *Streptococcus pneumoniae*, *Neisseria catarrhalis*, respiratory syncytial virus, adenovirus, influenza A and parainfluenza viruses. Chronic suppurative otitis media requires antibiotics to eliminate infection, followed by surgical repair of a perforated ear drum or damage to the ossicles; this helps prevent reinfection and improve sound transmission.

Conductive hearing loss caused by otosclerosis or hereditary osseous dysplasias may be managed conservatively using hearing aids, or surgically by stapedectomy. The procedure carries a small risk of complication of late sudden sensorineural hearing loss, and for this reason stapedectomy is not generally undertaken on both ears. Congenital malformations of the auditory canal and the middle ear may be treated conservatively with bone conduction or bone-anchored hearing aids or may be surgically remediable.

### Sensorineural hearing loss

The management of sudden sensorineural hearing loss is a medical emergency requiring hospital admission, bed rest and investigation of possible causes. In the case of bilateral hearing loss, psychological and aggressive auditory rehabilitation are required. There is no universally evidence-based treatment, and a spontaneous recovery rate of approximately 65% is usual. Proposed therapies include inhalation of carbogen (CO<sub>2</sub>-oxygen mixtures), hyperbaric oxygen, antiviral treatment, immunosuppression, calcium-channel blockers, steroids, blood volume expanders and various combinations of these different treatment strategies. Randomised controlled studies have demonstrated the efficacy of systemic steroids, but follow-up has questioned their benefit. Steroid therapy is often contraindicated in the presence of bacterial infection, recent surgery, peptic ulceration, a history of TB, poorly controlled hypertension or diabetes.

The management of progressive hearing impairment depends on the underlying aetiology. Syphilitic labyrinthitis is treated with steroids and penicillin, while rapidly expanding CPA tumours are surgically removed or treated with laser therapy. In the majority of cases of small tumours, however, a 'watch, wait and monitor' policy is effective. Immune-mediated sensorineural hearing loss requires urgent management with steroids and/or immunosuppressives following diagnosis. The treatment of Ménière's disease remains empirical. Therapies can be divided into medical regimes, including dietary modifications, drugs (diuretics, vestibular sedatives, drugs aimed at improving the circulation of the inner ear and immunosuppressives), psychological support, physiotherapy and auditory rehabilitation. A recent low-pressure pulse generator (Meniett device) has been advocated as a non-invasive effective treatment for Ménière's disease, but there is no definite evidence of efficacy. Conventional surgical treatment is considered when medical management has failed to control vertigo. Chemical labyrinthectomy using intra-tympanic gentamicin has superseded surgical interventions as a method of controlling severe vestibular symptoms, although no clear treatment protocol has been established and cochleo-toxicity is a significant risk. Chronic symptoms of dizziness resulting from vestibular dysfunction and hearing impairment may be treated with auditory and vestibular rehabilitation.

Chronic sensorineural hearing impairment is managed by appropriate treatment of any relevant medical condition and audiological rehabilitation of residual hearing. The selection and fitting of hearing aids is the key element of rehabilitation for the majority of patients with hearing impairment, but in the last two decades implantable devices have revolutionised auditory rehabilitation. Middle ear implants (vibrators on one of the ossicles or on the

tympenic membrane) may be used with all types of hearing loss, although their value is not yet clearly defined. Cochlear implants, in one or both ears, are widely used in profound hearing impairment (e.g. congenital loss or secondary to meningitis, superficial siderosis, mitochondrial disease and head trauma). As with all hearing aid provision, the patient requires long-term auditory training within a specialised multi-disciplinary team following implantation.

### VIIIth nerve disorders

Patients whose test results fulfil the criteria for auditory neuropathy represent a heterogeneous group in whom degraded speech perception inconsistent with pure tone sensitivity remains the common feature. Management strategies will be determined by the age of the patient.

### Amplification and rehabilitation strategies

**Early language intervention** For children with auditory neural dys-synchrony (AN), the onsets of plosive consonants and transitions – which make speech intelligible – are lost, preventing these children from categorising or sequencing sounds. A phoneme-based language therapy known as cued speech is used. This is a method whereby cues to vowel and consonant sounds that are difficult to perceive from lip-reading, can be given by synchronous hand-shapes presented alongside either the mouth or pharynx of the speaker. These cues will give syntax and phonological structure to language and are more easily learned by parents.

**Hearing aids** Various studies have examined the benefits of hearing aids, and shown variable results. The main concern regarding the use of hearing aids in patients with AN is that they can cause significant noise exposure and permanent threshold shift (up to as much as 20 dBHL). The use of an algorithmic approach to hearing aid fitting and real ear measures to verify parameters of the hearing aid needs to be calculated in much the same way as for the risk-benefit analysis for children with sensorineural hearing loss.

Gap detection and modulation transfer function are abnormal in patients with AN, and a speech-processing type of hearing aid with a high-frequency emphasis to enhance high-frequency transient speech sounds (i.e. consonants) has been recommended. Also, the use of directional microphones and personal FM systems to improve the signal : noise ratio in those patients with pronounced difficulties with speech in background noise has been proposed.

**Use of cochlear implants** Studies are now being published as to the benefit of cochlear implantation. Studies report small numbers only in children, all of whom had undergone a trial period of powerful behind-the-ear aid use. Neural response telemetry (NRT) is used to assess neural synchrony and temporal coding post-cochlear implant. The presence of the electrically evoked compound action potential (ECAP) is interpreted as indicating that electrical stimulation has restored some degree of synchrony and temporal encoding at the level of the cochlear nerve. Generally, authors conclude that cochlear implantation should be performed only after a trial of conventional amplification and that each decision to implant must be based on the individual circumstances. Auditory brainstem implants have been used in profoundly deaf patients in whom there is complete dysfunction of the VIIIth nerve (e.g. in NF2).

### Auditory processing disorders

Intervention for APD is multidisciplinary. Test results help to determine appropriate strategies for each patient. Intervention strategies include environmental modifications, signal enhancement, speaker adaptations, auditory training and compensatory strategies. While

there is some evidence to suggest that these manoeuvres help, there are no robust trials to support them. Management is currently based on clinical judgement, and there is much individual variation between units. APD is an expanding field, and there is need for systematic, validated tests, and for studies to assess efficacy of interventions.

### Environmental modifications

Noise and sound reflections from surfaces within a room distort and degrade acoustic signals. A noise survey of the acoustic environment (e.g. the classroom) may help determine first whether it adheres to UK building regulations that define the upper limit of noise and, secondly, identify potential corrective measures, such as carpets, curtains, acoustic panelling and sealing of doors and windows.

### Signal enhancement strategies

Personal or soundfield FM systems are devices that receive and amplify speech, via a microphone/transmitter, both worn by the speaker. The amplified signal is then transmitted via FM wireless waves to loudspeakers (soundfield) or a special receiver (personal system) that the listener wears in or over the ears. These systems help counteract background noise, sound reflections and loss of acoustic energy over distance.

### Relatives and carers: speaker-based adaptations

Speakers (i.e. those in contact with the patient) should be taught how to deliver speech at a slightly slower pace than normal, segment speech and stress different speech segments in order to enhance a message. In addition, rephrasing rather than repetition, and use of visual or other cues may be of help.

### Auditory training programmes and compensatory strategies

Auditory training can help in both auditory and non-auditory performance, such as language and reading, and may actually modify cortical neural representation. Informal auditory training does not require technical resources; activities are chosen from the patient's complaints and test results. Patients can perform these programmes unaided or with help of a therapist. Auditory training tasks can be in computer game format, with adaptive procedures (i.e. tasks become more difficult as the listener improves). Examples of computer-based auditory programmes include:

- Earobics ([www.earobics.com](http://www.earobics.com))
- FastForWord ([www.scilearn.com](http://www.scilearn.com))
- Phonomena ([www.mindweavers.co.uk](http://www.mindweavers.co.uk))
- Brain Fitness for older adults ([www.positscience.com](http://www.positscience.com)).

The Brain Fitness programme consists of six adaptive exercises that aim to enhance fidelity in auditory sensory input and language representations during hour-long sessions, 5 days/week over 8 weeks. One study of patients >60 years showed that those who completed the programme improved significantly in trained tasks and in auditory memory and that improvement was maintained for 3 months. Compensatory strategies include active listening, auditory vigilance training, auditory memory enhancement, metacognitive, linguistic, metalinguistic and other strategies.

# Spinal Column and Spinal Cord Disorders

Simon Farmer and David Choi

National Hospital for Neurology & Neurosurgery

Clinicians involved in the diagnosis and management of spinal disease face formidable challenges. While advances in neuroimaging have provided great insight into the disordered anatomy that underlies many conditions especially those of interest to spinal surgeons there is still much to be learnt about the basic mechanisms of disordered development, the physiology and pathophysiology of spinal cord function along with the mechanisms of spinal repair and the most effective management strategies. In this chapter there is much of common interest with the sub-specialities of neuro-rehabilitation, neuro-inflammation, neuro-infection, neuro-genetics and neuro-muscular disorders.

Spinal surgery from the neurosurgical and orthopaedic perspectives is a rapidly developing field. Spinal disease is a multi-disciplinary subject with important contributions from neurologists, neurosurgeons, orthopaedic surgeons, rheumatologists, neuroradiologists, neurophysiologists, pain specialists, rehabilitationists and the multi-disciplinary team.

This chapter is broadly divided into four sections: (i) spinal embryology anatomy and physiology; (ii) diagnosis of spinal column and cord disorders; and (iii) specific diseases of the spinal column and spinal cord and (iv) their clinical management including medical and surgical approaches.

## Spinal embryology, anatomy and physiology

### Embryology of the spine

The adult spine is divided anatomically into the cranio-cervical junction, and the cervical, thoracic, lumbar and sacro-coccygeal spine. Developmental abnormalities may arise at each level. Interpretation of congenital and acquired anomalies of the vertebral column is aided by an understanding of normal development. In early fetal life the ectodermal germ layer gives rise to the primitive neural tube which, in turn, gives rise to the entire nervous system during primary neurulation. This normally closes by the end of the fourth intrauterine week; failure of this primary neurulation results in fusion defects such as anencephaly or spina bifida. By this time the primary brain vesicles are present, representing forebrain, midbrain and hindbrain. Mesoderm lies around the neural tube and by the end of the fifth intrauterine week will have completed segmentation into recognisable somite pairs (occipital to coccygeal).

Once established, the epithelioid cells of these somites rapidly transform and migrate towards the notochord where they differentiate into three distinct cell lines: sclerotomes (from which connective tissue, cartilage and bone are derived), myotomes (providing segmental muscle) and dermatomes (providing segmental skin). Chondrification of the sclerotomes leads to the development of ossification centres, with an anterior and posterior centre for each vertebral body and a pair for each arch. The process is largely complete by the end of the third month of fetal development.

Disruption during these early stages accounts for many of the vertebral and cranio-cervical anomalies. After the third month of gestation the vertebral column and dura lengthen more rapidly than the spinal cord resulting in regression of the cord tip, leaving the filum terminale below. By term, the cord tip typically lies at the L2–3 interspace. Failure of distension of the brain vesicle results in abnormal brain cavities (including the ventricles) and may result from a failure of the central canal of the spinal cord to obliterate. Secondary neurulation arises in the distal sacral and coccygeal segments but does not produce functioning neural elements. Problems with secondary neurulation may give rise to lipomas of the filum terminale and tethering which prevents the normal ascent of the spinal cord during vertebral growth. Therefore, the conus medullaris continues to lie below its normal position at the L1–2 border.

The fetal spine can be reliably identified on ultrasound at 12 weeks and an accurate assessment of its integrity can be determined by 20 weeks.

### Genetic control of spinal development

The notochord provides the template for spinal development although only remnants of it persist in the nucleus pulposus of the cartilaginous discs. The notochord orchestrates the production of numerous signalling molecules between it and the neural tube and somites, initiated by the production of the protein product of a notochord gene called 'Sonic Hedgehog'. Sonic Hedgehog induces differentiation in the ventral and lateral neural tube as well as sclerotome differentiation in the somites. Mesoderm around the neural tube segments into 44 somite pairs (4 occipital, 8 cervical, 12 thoracic, 5 lumbar, 5 sacral and 10 coccygeal) by the end of the fifth week. The segmentation process itself is complex. In the chick, mouse and human embryos segments are formed sequentially. The driver for presomitic mesoderm segmentation may involve an intrinsic

molecular oscillator: 'the segmentation clock'. There is rhythmic production of mRNA from several genes related to the NOTCH gene-signalling pathway. In chick embryos, the periodicity is approximately 90 minutes with new somites being formed sequentially. The NOTCH-related genes include 'Lunatic Fringe (LFNG)', Delta-like (DLL), Presenilin and Mesoderm Posterior 2 (MESP2; Figure 16.1). Failure of oscillatory signalling may lead to failure of segmentation in a rostral-caudal direction where the first most caudal somites (whose ultimate fate is to be at vertebral level) are formed normally but then there is progressive loss of segmentation because of degradation of the molecular rhythmicity leading to anomalies of the most rostral vertebra. So far, mutations causing skeletal and spinal abnormality have been identified in the human homologues of three genes associated to the mouse segmentation clock: MESP2 and LFNG – associated with AR spondylocostal

dysostosis II and DLL3 AR spondylocostal dysostosis 1 – also known as Jarcho-Levin syndrome.

While the NOTCH genes specify longitudinal segmentation of the developing spinal cord, another group of genes, the Hox (homeobox) family, specifies axial development including vertebral shape. In humans there are four families of Hox genes (Hox A-D) which are also expressed caudally to rostrally, but with differing rostral extents. A rostro-caudal signal is therefore created in the developing embryo, which specifies positional values to each spinal level. Abnormal expression can be demonstrated in transgenic mice, for example mutation of Hox-b4 results in duplication of the atlas, such that a second atlas replaces the axis vertebra. Hox genes have been associated with human congenital anomaly (e.g. the hand-foot-genital syndrome). Often, large Hox mutations produce a severely disrupted body habitus incompatible with intrauterine life.

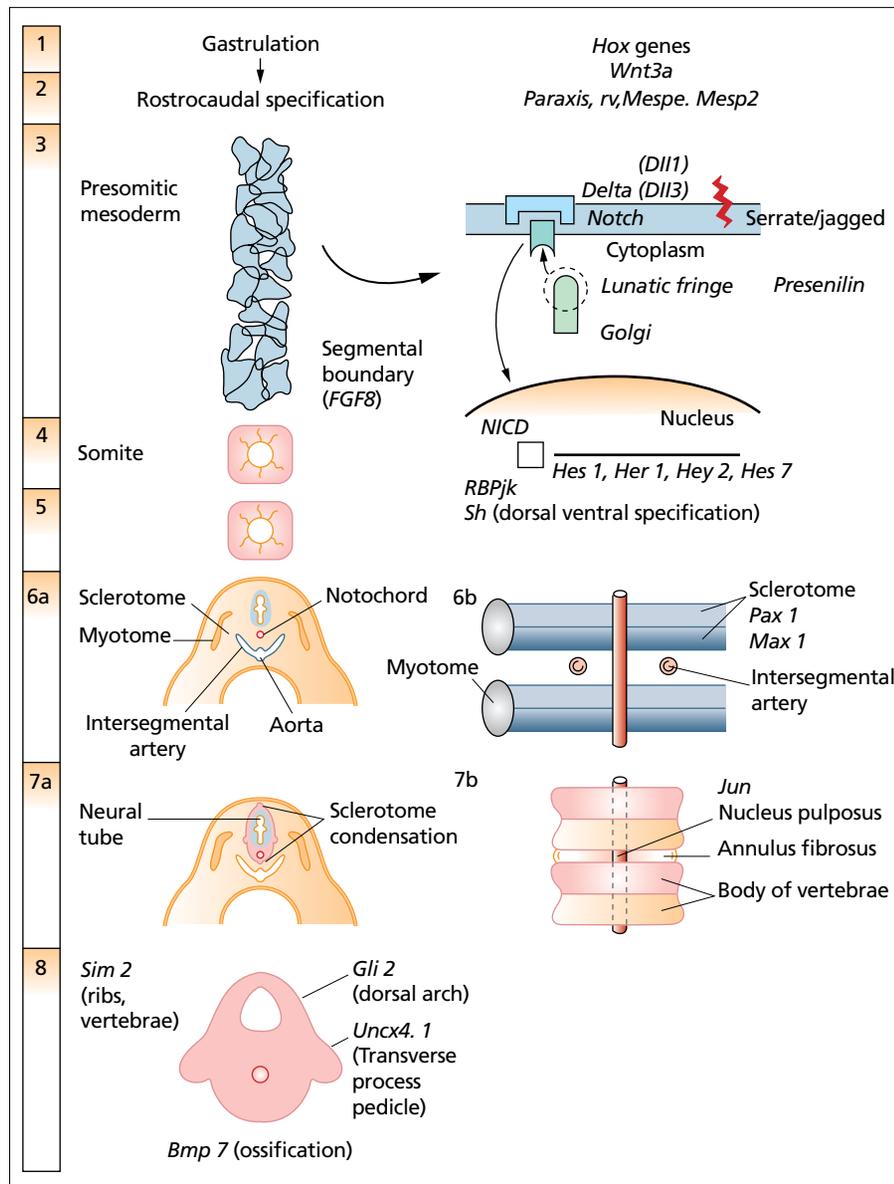

Figure 16.1 Possible steps in mouse spinal development with relevant genes (in text).

## Identifying genetic mutations involved in spinal anomaly

Much of the research effort into understanding the genetics of spinal developmental anomaly involves the study of conservation of genes during evolution. Possibly only 200 chromosomal rearrangements have occurred in total because the mouse and human lineages diverged. This means that detailed study of the mouse genome may yield important homologues of human genetically determined spinal maldevelopment. Syntegy conservation may be used to identify fruitful areas of the mouse and human genome in which mutations may produce phenotypes recognisable in human developmental disorders. This allows the search for causative genetic mutations in human malformations to be narrowed. From analysis of mouse developmental abnormalities and comparison with homologous human malformations which include spinal malformation, the following genes have been identified: *Hox*, *Notch*, *Pax1*, *Mox1*, *Gli*, *Unex4.1*, *BMP-7* and *Jun*. Mutations in the *Pax1* gene have been associated with vertebral anomalies in humans.

A new technique of Cre-recombinase-mediated transgenesis mapping has been used to map the destinations of embryonic neural crest and mesodermal stem cells. This mapping has been resolved at the single cell level and it reveals that the boundaries traverse homogeneous skeleton of neck and shoulders. From this mapping it has been discovered that in vertebrates the neural crest anchors the head to the anterior shoulder girdle. Mesoderm, which is controlled by expression of a *Hox* gene, links trunk muscles to the posterior neck and shoulder skeleton. It has been suggested that muscle attachments may be a new way of defining homologous pieces of skeleton. The skeleton identified using the Cre-recombinase technique is abnormal in Klippel–Feil and Chiari malformations. This genetic mapping technique may greatly increase our understanding of head, neck and shoulder morphology; furthermore, it situates human, head, neck and shoulder anomalies in a context that reflects the known complexity of neck and shoulder evolution in vertebrate lineages (Figure 16.1). The genetics of complex skeletal and spinal deformity is beyond the scope of this chapter but is broad terms the syndromes are divided into those that affect bone and those that affect cartilage.

## Anatomy and physiology of spinal maldevelopment

### Disorders of axonal guidance

In this section of the chapter we discuss conditions that have yielded insight into spinal cord maldevelopment. Consideration of the details of Klippel–Feil syndrome, X-linked Kallmann syndrome and congenital hemiplegia pathophysiology has led to a wider appreciation of corticospinal tract development. While there are many tracts within the spinal cord, the normal development of which is crucial to function, much is known about the development and maldevelopment of the pyramidal tract and thus work in this area has led to an understanding of developmental anomalies.

The pyramidal tract develops late in humans: in the embryo the fibres have reached the pyramidal decussation by the eighth week post-fertilisation; however, the subsequent development is slow, with tract myelination continuing into the child's third year of life. Our understanding of human pyramidal tract development is highly dependent on data from rodents and subhuman primates. In rat, the corticospinal growth cone must navigate through the internal capsule, cerebral peduncle, pons and medulla to reach the spinal grey matter. At a number of points in the journey there are 'choice

points' at which chemo-attractants and repellents can influence the journey. Mutations in genes coding for these molecules lead to gross developmental anomalies. The corticospinal tract reaches the cervical cord shortly after birth and then gradually extends to the lumbosacral regions. Initially, there are exuberant collaterals such that most parts of the cortex, including the occipital cortex, innervate the spinal cord. There is then a rapid withdrawal of collaterals and loss of fibres from the corticospinal tract. Whether this process is activity dependant is not fully known. Failure of pyramidal decussation occurs in a number of conditions including Klippel–Feil and X-linked Kallmann syndromes. In animal models, mutations in oligodendrite membrane-bound neurite growth inhibitors appear to lead to a loss of the normal channelling of myelinated fibres leading to abnormalities of growth; furthermore, a midline anchored repellent (ephrin-B3) prevents the cortico-spinal tract from recrossing into the ipsilateral spine.

In humans, malformations of the corticospinal tract may be caused by:

- 1 Induction failure, disruption during early spinal development (see Klippel–Feil syndrome)
- 2 Abnormal cell proliferation
- 3 Abnormal neural migration
- 4 Abnormal guidance mechanisms
- 5 Acquired injury.

In all of these cases there are abnormalities of the pyramidal tract, the pyramids and the pyramidal decussation with abnormal ipsilateral corticospinal pathways. Mirror movements are a common feature of a number of these conditions and have been described in all the categories of pyramidal tract malformation set out later. The characteristic neurophysiology described in detail for Klippel–Feil syndrome has been discovered also for X-linked Kallmann's syndrome, disorders of neural migration and prenatally acquired hemiplegia. In addition, ipsilateral transcranial magnetic brain stimulation (TMS) responses indicating an abnormal ipsilateral cortico-spinal tract have been described in patients with familial horizontal gaze palsy with progressive scoliosis (HGPPS). In these subjects, deletions in the *ROBO3* gene cause failure of pyramidal decussation. *LICAM* disorders, which are associated with a variety of phenotypes including X-linked hydrocephalus, have also been studied using TMS and, surprisingly, given that in animal models a misdirected pyramidal tract is usually the result of *LICAM* mutations, no TMS evidence of an abnormal ipsilateral pathway was detected in humans. However, in the only neurophysiological study to have been performed, subjects with *LICAM* mutations were not studied in the ways set out above, instead the focus of the investigation was on proximal rather than distal upper limb muscles. Recently, congenital mirror movements have been found to be caused by mutations in the *DCC* gene.

### Congenital mirror movements

These are intense involuntary movements, primarily of distal upper limb muscles, that mirror the voluntary unilateral movement. They cannot be suppressed and typically do not occur during passive movement. Mirror movements occur normally during a child's motor development; however, they are rarely intense and disappear by the age of 6 years. Pathological mirror movements are rarely disabling and patients learn adaptive proximal movements so as to avoid inappropriate finger movements (e.g. wrong key strikes while typing). Neurophysiological study of mirror movements has provided striking insights into central motor control and aberrant neural pathways.

In the first study of its kind, a single subject with Klippel–Feil syndrome and mirror movements was found to have abnormal simultaneous bilateral short-latency responses to focal electrical stimulation of unilateral focal electrical stimulation or right primary motor cortex indicating that in the presence of an aberrant fast conducting ipsilateral corticospinal tract. In this subject the spinal (short) latency cutaneomuscular (CMR) and stretch reflexes are confined, as in normal subjects, to the stimulated side but the long-latency components of the CMR and stretch reflexes were found at equal latency in both the stimulated and non-stimulated limbs. Cross-correlation analysis of electromyographic (EMG) activity recorded simultaneously from homologous muscles of left and right hands reveals, in contrast to healthy subjects, the presence of a short duration peak at time zero indicating that during normal muscle contraction both hands receive abnormal common presynaptic drive. This abnormal drive can be shown to be highly muscle specific, indicating that abnormal bilateral corticospinal axons innervate the equivalent motor neurone. This result suggested that the abnormality is at the level of the pyramidal decussation with normal neuronal guidance mechanisms to the spinal motor neurone pools thereafter. Recent studies using EMG–EMG coherence analysis and EEG–EMG coherence analysis in subjects with X-linked Kallmann's syndrome with mirror movements have shown that aberrant corticospinal pathways provide abnormal oscillatory drive from cortex to muscle. Taken together, these findings indicate that voluntary and long-loop reflex activity in abnormal central motor pathways produces the mirror movements seen in Klippel–Feil syndrome and other neurodevelopmental conditions. Similar findings have been reported in a number of other patient groups in which intense mirror movements are a feature (e.g. congenital hemiplegic cerebral palsy, X-linked Kallmann's syndrome, RBO3-HGPPS).

The findings in hemiplegic cerebral palsy are of particular interest for they indicate that the corticospinal axons reach both sides of the spinal cord from the undamaged motor cortex. The presence of mirror movements with characteristic neurophysiological findings is associated with MRI scans in which there is no gliosis in response to the cerebral injury, suggesting that antenatal insults before gestational age of 28 weeks causing hemiplegia are associated with very significant pyramidal tract reorganisation and mirror movements. This remarkable central nervous reorganisation may help to sustain function of the child's hemiplegic hand, albeit at the expense of mirror movements. Studies in the cat have shown that lesioning or even functional inactivation of one corticospinal tract at a time in development when there are naturally bilateral innervations of both sides of the spinal cord from both hemispheres induces abnormal persistence of ipsilateral corticospinal pathways suggesting that activity dependence is important for corticospinal function. These neurophysiological findings draw attention to early life syndromes of disordered axonal guidance and abnormal lesion induced corticospinal persistence.

### Human vertebral segmentation defects

Numerous congenital defects of the spinal column have been identified that result from segmental disruption, for example Klippel–Feil syndrome, Alagille's syndrome, spondylocostal dysostosis (Jarcho–Levin syndrome), congenital scoliosis and kyphosis, Goldenhar's syndrome and the VATER (vertebro–anal–tracheo–esophageal–renal) and VACTERL (vertebral–anal–cardiac–tracheo–esophageal–renal–limb) syndromes. In many of these syndromes there are severe abnormalities affecting a number of body parts. The vertebral segmentation abnormalities may be generalised, regionalised or localised.

The vertebral abnormalities (including wedge, hemi or butterfly vertebrae) that give rise to congenital scoliosis and kyphosis are likely to involve problems of somitogenesis. Two mutations in the Notch signalling pathway have been identified these are *Delta-like 3* in spondylocostal dysostosis and *Jag1* in Alagille's syndrome. Spondylocostal dysostosis is dominantly and recessively inherited with multiple segmentation abnormalities of vertebra, axial skeleton and ribs leading to a non-progressive kyphoscoliosis. Alagille's syndrome is a severe multi-organ disorder affecting the liver, heart, eyes, facial bones associated with vertebral segmentation defects. It is likely that Klippel–Feil syndrome results from a disorder either in *Notch* gene signalling or the *PAX* gene but as yet the genetic aetiology is unknown. Furthermore, the syndrome may also be caused by non-genetic errors of development (e.g. resulting from teratogens) and the long narrow shape of the unsegmented vertebral bodies might suggest a problem around the time of chondrification.

Split-cord malformations may occur during development, either anteriorly resulting from a split notochord, or posteriorly because of incomplete closure of the neural tube. A split notochord is likely to induce the development of split vertebral bodies, separated by invaginating gut endoderm or an accessory neuroenteric canal.

Abnormalities of the atlas and axis vertebrae probably also occur because of intrauterine trauma rather than abnormalities of genetic expression. Anterior and posterior spina bifida of the atlas occur in mucopolysaccharidoses and Down's syndrome where excessive movement at the stage of chondrification of the atlas probably results in an incomplete bony ring.

## Diagnosis of spinal column and spinal cord disorders

### Clinical assessment of spinal disorders

In this section the primary focus is on those symptoms and physical signs that are of particular value in helping the experienced clinician achieve an accurate and timely diagnosis and an assessment that allows a coherent plan of management to be formulated.

### Cranio-cervical junction

Symptoms and signs may be insidious or rapid in onset. Clinical presentation is diverse depending on the level affected.

The lower brainstem, cranial nerves, cervical roots and upper cervical cord may be compromised by pressure from bone or soft tissue, there also may be indirect compromise of the blood supply. Congenital anomalies of the cranio-cervical junction are often associated with dysmorphic features and obvious skeletal anomalies. Patients most commonly complain of headache and neck pain worsened by movement and coughing. Pain characteristically originates in the suboccipital region and radiates to the vertex in a C2 distribution. Head tilt and 'torticollis' are more common in children, but may sometimes occur in adults. In children with cranio-cervical junction anomalies, hearing loss is the most common cranial nerve symptom. In adults, trigeminal distribution pain and neuralgia can result from direct compression of the Vth nerve or compression of the Vth nerve nuclei in the upper cervical cord. Lesions of other cranial nerves, particularly IX, X, XI and XII, are also seen. Spinal cord compression produces a myelopathic picture with upper motor neurone features, which may progress to involve bladder and bowel control. Occasionally, the myelopathy is confined to the upper limbs. There can be a predilection for the dorsal columns, producing marked joint position sense loss. Brainstem involvement produces dysphagia, dysarthria, internuclear ophthalmoplegia and nystagmus

(most commonly horizontal but more classically down-beating). Central apnoea, vivid nightmares associated with sleep apnoea, drop attacks and syncope are important additional features. The intimate relationship of the vertebral arteries to the upper cervical spine and foramen magnum can increase the risk of vertebrobasilar ischaemia. Sequential 'clock-face' involvement of limbs may occur with neural compression at the foramen magnum: spastic weakness of the extremities with progression of motor symptoms, which may begin in the ipsilateral upper limb, followed by weakness of the ipsilateral lower limb, contralateral lower limb and progressing to the contralateral upper limb, caused by compression of the pyramidal decussations. Cruciate paralysis (bilateral upper limb weakness with relative sparing of the lower limbs) and dissociated sensory loss are often associated with pressure on the upper portion of the pyramidal tracts and an intramedullary process, respectively.

### Syringobulbia and syringomyelia

Cavitation of the spinal cord sometimes extending into the brainstem is an association of crani-cervical junction anomalies. The symptoms and physical signs reflect a pathology that starts centrally and expands outwards. The patient complains of painless injuries, muscle wasting and weakness and, more rarely, limb weakness. More unusual presentations, for instance central apnoea, also occur. The classic onion skin sensory loss of syringobulbia is caused by involvement of the spinal nucleus or the tract of the trigeminal nerve and may be associated with tongue wasting, trigeminal pain, palatal and laryngeal weakness and symptoms of medullary involvement. The cavity in syringomyelia affects crossing spinothalamic fibres producing a half-cape or cape loss of pain and temperature sensation; posterior column function is relatively preserved but abnormalities can occasionally be found. There is amyotrophy at the level of the cavity with tendon reflex loss. In advanced stages, neuropathic Charcot joints develop. Below the cavity there can be upper motor neurone symptoms and signs with disturbances of sphincter function, which contrast with the lower motor neurone symptoms and signs at the level of the syrinx.

### Cervical spine

The presenting symptoms of cervical spine disease reflect the aetiology. As degenerative disease is the most common condition affecting the cervical spine, pain is the most frequent presenting symptom. The nature and distribution of the pain is a useful pointer to the site and nature of the pathology. In spondylotic disease, typically there is a dull ache in the neck worsened by movement. Spurling's sign is a reliable test of mechanical root compression (the examiner turns and flexes the patient's head to the affected side while applying downward pressure to the top of the patient's head). The sign is considered positive when the pain arising in the neck radiates in the direction of the corresponding dermatome ipsilaterally. The radicular component of the pain is often a dull ache with sharper exacerbations. Cough impulse pain may frequently accompany disc protrusion or prolapse. The symptoms and signs of weakness and numbness may localise a particular radicular level, but the spinal level of traditional dermatomes and myotomes may vary by a level up or down. Below the pathological level there may be upper motor neurone symptoms, signs and a spinal sensory level reflecting cord compression. The patient's complaints can often suggest cervical instability: 'My head feels loose' or 'I have to hold my head' and should not be discounted as an anxiety disorder. Lhermitte's symptoms resulting from posterior column compressions may also occur as a result of cervical instability. Hand weakness in high

cervical cord compression may be caused by a combination of pyramidal tract compression and de-afferentation from dorsal column involvement. It can be difficult to describe by a patient. When asked to explain their symptoms, the patient with chronic cervical myelopathy looks at their hands while trying to articulate what is wrong: 'They just don't work'.

### Thoracic spine

Degenerative thoracic spine disease typically presents with local or radicular pain but few other symptoms or signs until spinal cord compromise develops, at which point there is usually a combination of upper motor neurone weakness, a spinal sensory level and sphincter disturbance. Thoracic arteriovenous malformations (AVMs) and fistulas may initially present with chronic subtle or intermittent symptoms which progress with time.

### Lumbar and sacrococcygeal spine

Degenerative disease is the most common pathology at this site, therefore pain, which may be localised and radicular, is the most common presenting complaint. This pain is usually a dull ache with exacerbations which are often movement sensitive. The anatomical distribution of the radicular component of the pain and the physical signs demonstrate the site of the pathology. In nerve root lesions, lower motor neurone signs reflect the myotomes innervated by the root. For example, wasting of extensor digitorum brevis over the dorsum of the foot indicates an L5 innervated muscle. Tendon reflex loss is a further important indicator of the nerve roots involvement. Sensory loss reflects the dermatomal distribution of the affected root.

Degenerative lumbar canal stenosis presents with low back pain, leg pain, heaviness or weakness often worsened by exercise and standing straight. Patients with spinal claudication prefer to adopt a slightly flexed posture and may find it easier to walk leaning on a shopping trolley, or frequently squat down as if to tie a shoelace. They may be able to ride a bicycle for a longer period of time than they can walk, again because of the flexed riding position. Leg weakness and tendon reflex loss may be exercise-dependent and therefore patients should be examined after they have walked. These findings are important in distinguishing spinal claudication from vascular claudication, which is worse with increased muscular activity, affecting more often the calf muscles, does not vary with posture and is associated with trophic skin changes. Cauda equina syndromes are an acute neurological emergence presenting with low back pain, sciatic-type pain, saddle sensory loss, leg weakness, sphincter and sexual dysfunction. The most important physical signs are those of lower motor neurone weakness in the affected myotomes, sensory loss (especially S3-S5), pain on straight leg raising, tendon reflex loss (ankle jerks) and poor anal tone/voluntary sphincter contraction. Cauda equina symptoms also present insidiously and the clinician needs to be alert for gradual onset sphincteric involvement, disturbances of sexual function and saddle sensory loss, either resulting from degenerative lumbar stenosis or sometimes intrinsic spinal cord pathology affecting the conus.

### Other clinical features of spinal disease

It is important to examine for spinal deformity especially scoliosis and kyphosis. If a spinal deformity is evident then the examination should, as well as seeking evidence for local spinal disease, also consider generalised neuromuscular conditions and neurocutaneous conditions. Neurofibromatosis type 1 (Chapters 14 and 26) in particular can be readily diagnosed by the presence of café-au-lait

spots, Lisch nodules of the iris, axillary freckling and cutaneous neurofibromas. Papilloedema is an uncommon but recognised sign of spinal pathology and is associated with high cerebrospinal fluid (CSF) protein. Autonomic symptoms and signs are of limited localising value but are seen in severe spinal lesions in which there is loss of temperature control and disturbances of sweating.

### Diagnosis of spinal tumours

Clinical presentation is typically with pain and neurological dysfunction. Night pain or pain at rest is characteristic. Nocturnal pain is related to disturbances in CSF venous outflow causing engorgement and swelling of the spinal cord. Axial spinal pain not located in the lumbosacral region should be regarded as a red flag and warrants further investigation, particularly if it is associated with weight loss, decreased appetite or previous medical history of malignancy.

Investigations include blood tests, urine analysis for Bence-Jones protein, and other tumour markers. Radiologically plain X-rays, computed tomography (CT), magnetic resonance imaging (MRI), isotope bone scan, positron emission tomography (PET) scan are all potential imaging technologies. For primary bone tumours it is desirable to have maximal information prior to treatment. A biopsy (hollow needle core biopsy or fine needle aspiration under CT scan guidance) can be very helpful in treatment decisions. For example, the prognosis from Ewing's tumour is better if chemotherapy is given pre-operatively. Similar treatment protocols should be for treatment of osteosarcoma. Other tumours are best dealt with by an en bloc dissection. Identification of tumour type at an early stage is of vital importance in planning definitive treatment.

Pre-operative MRI in many cases allows a diagnosis to be made. It is now an essential part of tumour localisation and characterisation necessary for pre-operative planning. MRI features helpful for diagnosis are shown in Table 16.1.

**Table 16.1** Magnetic resonance imaging (MRI) characteristics of intradural spinal tumours.

#### Ependymoma

T1-weighted images – isointense signal with spinal cord

T2-weighted images – hyperintense signal

Strong homogeneous enhancement with contrast

#### Astrocytoma

T1-weighted images – isointense or hypointense signal with spinal cord

T2-weighted images – hyperintense signal

Cyst formation

Heterogeneous enhancement with contrast

#### Haemangioblastoma

T1-weighted images – isointense signal to spinal cord

T2-weighted images – hyperintense signal

Cystic with tumour nodule (50–70%)

Enhances strongly with contrast

Extramedullary extension in 15%

### Clinical features of vascular disorders of the spine

Spinal cord infarction usually presents acutely, often with pain followed by paralysis and sensory loss. The most common arterial territory involved is the anterior spinal artery. In anterior spinal artery occlusion the anterior two-thirds of the spinal cord is affected. The spinal level is determined by where in its course the supply from the anterior spinal artery is interrupted. The patient presents with an acute flaccid paraparesis with loss of sphincter control and anaesthesia to temperature and pain but classically with preservation of posterior column functions of joint position and vibration sense. The most typical level is the upper thoracic cord but involvement of the cervical spine and even the caudal brainstem can occur. Anterior spinal artery infarction can be partial. The syndromes of posterior spinal artery infarction, watershed infarction, venous infection, transverse infarction, central cord infarction and lacunar infarction are far more rare. Watershed infarcts and spinal artery hypoperfusion causing spinal transient ischaemic attack (TIA) and 'claudication' may occur because of atheromatous disease of the aorta and its branches. The most common site of hypoperfusion syndromes is the mid thoracic area T4–9 where perfusion is relatively poor. Common causes of spinal cord infarction are listed in Table 16.2.

Haemorrhage in the spine is classified according to the spinal level and anatomical site. Haemorrhages may be intramedullary, subarachnoid, epidural and subdural. The presentation is usually acute with severe spinal pain and myelopathy with a motor and

**Table 16.2** Causes of spinal cord infarction.

Artherosclerosis	Diabetes, hypertension, hyperlipidaemia
Inflammatory	Sarcoidosis, arachnoiditis
Infective	Syphilis, TB, herpes zoster, HIV, bacterial meningitis
Vasculitis	SLE, giant cell polyarteritis
Aortic disease	Dissecting abdominal aortic aneurysm, aortic occlusion, trauma, Takayasu syndrome
Arteriopathy	Connective tissue disease, Marfan's syndrome, fibromuscular dysplasia
Embollic disease	Cardiac embolism, decompression sickness
Hypoperfusion states	Cardiac arrest, hypovolemia, cardiopulmonary bypass
Vertebral artery disease	Dissection, trauma
Hypercoagulable states	Clotting factor disorders, antiphospholipid antibodies, blood transfusion
Drug abuse	Cocaine, heroin, ecstasy
Miscellaneous medical	Anaemia, sickle cell, Moyamoya, CADASIL, Paget's disease
Iatrogenic	Vascular surgery, cardiac surgery, spinal surgery, diagnostic catheter radiology, interventional radiology, spinal/epidural anaesthesia; intrathecal drugs

CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; SLE, systemic lupus erythematosus; TB, tuberculosis.

sensory level and sphincter loss. Spinal subarachnoid haemorrhage presents with severe back pain, radicular pain followed by the classic signs and symptoms of subarachnoid bleeding (i.e. obtundation, neck stiffness and photophobia). Myelopathy may be present but, unlike other causes of spinal haemorrhage, is not necessarily severe.

### Diagnosis of spinal vascular disease

The differential diagnosis of spinal cord vascular diseases is influenced primarily by the rapidity of symptom presentation. Severe infectious, para-infectious and inflammatory myelitis including Devic's disease may present acutely. However, hyperacute presentations are more suggestive of vascular disease. Subacute and chronic presentations, either without haemorrhage as in dural AVMs or with small venous haemorrhage as with cavernomas, need to be differentiated from the causes of progressive myelopathy, particularly structural causes and spinal demyelination.

MRI is the primary diagnostic investigation. Spinal MRI will detect over 90% of acute spinal cord ischaemic lesions. Diffusion-weighted and contrast-enhanced MRI may increase the yield further. MRI usually excludes compressive lesions and often will find evidence of demyelination especially if cranial MRI is also performed. Imaging of the aorta with abdominal CT, CT and MR angiography is very important. Subdural and epidural haematomas are detectable but need to be distinguished from abscesses and other causes of fluid collection. AVMs and dural fistulae are usually detectable with expert neuroradiological interpretation of T1.5 MRI. The vessels of the malformation are seen as serpiginous flow voids. In addition, there is usually T2-weighted signal change within the spinal cord substance. However, AVMs and dural fistulae can be missed on MRI. Spinal myelography has detected the vessels of AVMs and dural fistulae that are not visible on MRI. Finally, spinal angiography may be required both for definitive diagnosis and to plan treatment with interventional radiological occlusion either through embolisation or gluing techniques.

In suspected spinal subarachnoid haemorrhage cranial CT often detects subarachnoid blood and a lumbar puncture will provide definitive evidence of subarachnoid haemorrhage. Other investigations are directed towards detection of the cause or contributing factors of the infarct or haemorrhage (e.g. looking for infections such as syphilis, hypercoagulant and hypocoagulant states and vasculitis).

### Radiological assessment of spinal disorders

The mainstay of radiological investigation involves X-rays, CT and MRI. Plain and dynamic X-rays are useful for assessing spinal stability, range of movements, and reducibility if deformity is present. CT scans are very useful to assess bone integrity, degenerative changes, bone fracture, and provide a good assessment of mechanical stability. MRI is better at visualising the spinal cord and nerve roots, soft tissues (including discs and interspinous muscles and ligaments), facet joint effusions, spinal tumours and vascular abnormalities.

## Specific diseases of the spinal column and spinal cord and their management

### Skeletal disorders affecting the spine

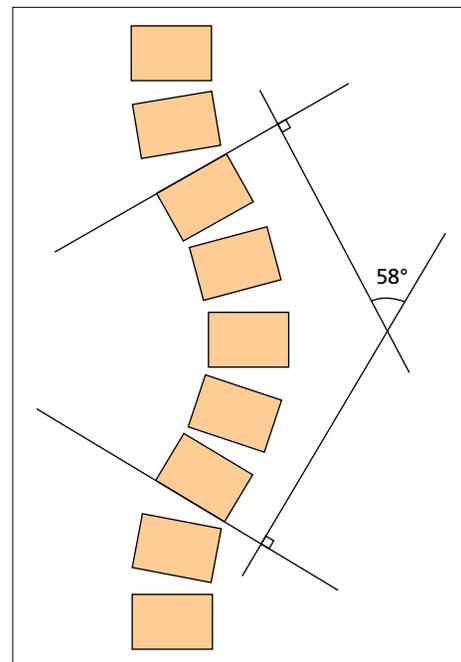

#### Idiopathic scoliosis

Scoliosis refers to a lateral deviation of the spine in the coronal plane and is always abnormal. Idiopathic scoliosis is a disorder unique to humans and is therefore felt to relate to fully erect

bipedalism. Only secondary forms of scoliosis are seen in even our nearest primate cousins. It may be classified on the basis of clinical examination into structural and non-structural forms. In a structural scoliosis there is a rotational component to the curve, which is best seen on forward flexion when prominence of rib or loin musculature becomes apparent. This is not the case in non-structural scoliosis, where there is no rotational element. Non-structural scoliosis may be a marker of other pathology such as leg length discrepancy or muscle spasm but is rarely of clinical significance in itself. However, if associated with underlying neurological disease it may progress to a structural deformity.

Once a structural scoliosis is diagnosed, the severity and potential for progression must be assessed. Erect posterior-anterior and lateral X-rays should be taken in a standardised manner so that serial films can be compared. The severity of the curve is given by the Cobb angle, which describes the angle created by the intersection of lines drawn across the end-plates of the upper and lowermost vertebrae delineating the curve (i.e. those with the greatest opposing tilt as illustrated in Figure 16.2). Angles  $>20^\circ$  in skeletally immature children demand particular vigilance for it is during periods of rapid growth that scoliosis may progress significantly. Scoliosis presenting in younger children thus has a greater risk of progression. Progression of scoliosis in adults is less common, although underlying neuromuscular disease, pregnancy and osteoporosis pose increased risks. In general, 25% of scolioses do not progress, 25% progress slowly and 25% progress rapidly.

The major causes of structural scoliosis are given in Table 16.3. The most common type is idiopathic scoliosis, accounting for around 70% of all cases. The child is otherwise healthy and no underlying pathology is found. The prevalence of adolescent scoliosis, the most common form, is approximately 4% of the population if mild cases are included. The majority of idiopathic scoliosis are right-sided, thoracic and painless.

**Figure 16.2** Cobb angle. Diagram illustrating method of calculating the Cobb angle to guide treatment of scoliosis.

**Table 16.3** Causes of structural scoliosis.

<b>Idiopathic scoliosis</b>
Infantile <3 years
Juvenile 3–10 years
Adolescent >10 years
<b>Congenital scoliosis</b>
Failure of vertebral segmentation and/or formation
<b>Neuromuscular scoliosis</b>
<b>Neuropathic</b>
Upper motor neurone
Cerebral palsy
Lower motor neurone
Spinal muscular atrophy, poliomyelitis, hereditary neuropathies and dysautonomias
Mixed
Myelomeningocele, spinal dysraphism, tethered cord, syrinx
Myopathic
Congenital myopathies
Muscular dystrophies (e.g. Duchenne's)
<b>Miscellaneous causes</b>
Skeletal dysplasias
Marfan's syndrome
Neurofibromatosis
Spinocerebellar degenerations including Friedreich's ataxia
Arthrogryposis
Rett's syndrome
Metabolic bone disease
Dystonia
Parkinson's disease and parkinsonian syndromes
Cranio-cervical junction anomalies especially if associated with syringomyelia
Spinal tumours/trauma/irradiation

The cause of idiopathic scoliosis is multi-factorial and the development and progression of the scoliosis may have different mechanisms. There is often a positive family history of scoliosis, with girls eight times more likely than boys to require treatment. The pattern of inheritance is consistent with a dominant major gene diallele model (the gene is as yet unidentified) with incomplete penetrance. Progression of the curve is more common in thoracic or large curves (>35°) with skeletal maturity another important consideration. The consequences of severe idiopathic scoliosis are cosmetic deformity, cardiopulmonary compromise and back pain.

In adolescents with suspected idiopathic scoliosis, standing lateral and posterior–anterior X-rays should be performed and those patients with curves greater than 20° should be followed by repeat X-rays every 4–6 months. Curves progressing more than 5° in 4–6 months, or exceeding 30°, should be treated with a brace which may delay or arrest scoliosis progression in the

skeletally immature child. A thoracolumbar spinal orthosis is generally used, with an added cervical extension (as in the Milwaukee brace) if the apex of the curve is above T8. Bracing is rarely effective once the curve exceeds 45° and it is in these patients that surgery is recommended. Surgery may also be advised if there is a significant thoracic lordosis or rotational deformity that impairs pulmonary function.

### Congenital scoliosis

In congenital scoliosis the vertebrae are anomalous either because of a failure of natural segmentation, leading to asymmetric fusion, or to failure of formation, in which only part of the vertebra is formed (see Human vertebral segmentation defects). Often there is a combination of both pathologies. Failure of segmentation may lead to a unilateral fused bar with scoliosis away from the fused side, or a block vertebra. Abnormalities in mesenchymal formation may lead to mild wedging or absence of half a vertebra producing a hemivertebra with a single pedicle and lamina with subsequent scoliosis. In congenital scoliosis there is a high incidence of associated anomalies: neuraxis anomalies in up to 40% of patients, renal and gastrointestinal tract abnormalities in 20% and congenital heart defects in approximately 10%. Sometimes the scoliosis is part of a syndromic diagnosis such as in the Klippel–Feil and Noonan syndromes. Clinically, the scoliosis may vary from a mild non-progressive deformity to a severe and rapidly progressive curve that compromises the spinal cord.

Neuropathic scoliosis is often associated with rapidly progressing curves in juveniles (3- to 10-year-olds) with pain and neurological findings that reflect the underlying disease, such as a tethered cord, diastematomyelia or lipoma. It is important to look for signs of a skin dimple, sinus, haemangioma or hairy patch in all children with a scoliosis, and to perform an MRI scan. Early treatment of the underlying disorder can arrest the progression of the scoliosis, but if treatment is delayed then the curve may reach the point where altered biomechanical forces take effect and the curve continues to progress despite treatment.

If a neurogenic cause for scoliosis is overlooked and the curve is incorrectly believed to be idiopathic, then neurological damage may occur during surgical correction. For example, a tethered cord can be stretched further during instrumentation and straightening of the spine.

### Neuromuscular scoliosis

Spinal deformity is common in many of the neuromuscular disorders. In the developed world cerebral palsy, spina bifida and Duchenne muscular dystrophy are the most common causes of neuromuscular scoliosis, although poliomyelitis is still an important cause in developing countries. Because of the underlying condition, the spinal curvature, in contrast to idiopathic scoliosis, generally presents earlier, is more extensive and is more likely to deteriorate through childhood and into adult life, particularly during the 'growth spurt'. Other systems are often already compromised, for example there may be muscle imbalance, cardiopulmonary insufficiency, poor nutrition, insensate skin and osteoporosis. The physical and functional effects of the scoliosis often exacerbate these problems. In addition, the scoliosis may adversely affect walking and seating and cause pain as the ribs abut the iliac crest. This is often compounded by coexisting pelvic obliquity, particularly in the non-ambulant patient.

In congenital or neuromuscular scoliosis there may be a role for bracing but, given the relentless progression of the scoliosis in many

of these conditions, early surgery is often indicated. In non-ambulant patients the spinal fusion should involve the pelvis. Surgical risk, particularly of haemostasis and postoperative chest infection, is high in this patient group.

### Kyphosis and lordosis

The spine naturally shows some curvature in the anteroposterior plane, seen as a kyphosis in the thoracic region and lordosis at the lumbar spine. A normal lumbar lordosis shows full correction on forward flexion. A kyphosis greater than 40° is abnormal. It may be congenital, caused by a lack of fusion of the vertebral bodies anteriorly or a lack of formation of one or more anterior bodies. Although less common than congenital scoliosis it carries a more severe prognosis, as a higher proportion of patients will develop progressive deformity and myelopathy, particularly during the adolescent growth spurt. Patients with anterior failure of vertebral body formation who present with a sharp angle kyphosis are at particular risk of rapid progression and spinal cord compression. Early arthrodesis is indicated in these cases. Other causes of abnormal kyphosis include Scheuermann's kyphosis, post-trauma, osteomalacia, osteoporosis and tumour infiltration. Scheuermann's kyphosis is the most common form of acquired kyphosis. Presenting in adolescents, it is generally benign and may be corrected with a brace if applied during the adolescent growth spurt. Kyphosis only occasionally progresses once skeletal maturity is reached.

In kyphosis, bracing is advocated for skeletally immature patients with progressive curves less than 60° (normal range 25–40°). Surgery is often required if the curve exceeds 60°. Correction of a kyphosis should be performed at the lowest level possible to minimise risk, and the presence of any fixed flexion deformity at the hips should be noted and corrected first, because this will affect the overall sagittal balance of the spine.

### Miscellaneous causes of spinal deformity

A number of primary diseases of bone and connective tissue produce pathology of the spine and cranio-cervical junction. Those that present neurological problems are classified into four broad categories.

**Osteopenic disorders** In osteopenic disorders bone mineralisation is reduced. These include endocrine diseases such as hypoparathyroidism, Cushing's disease, osteomalacia, primary osteoporosis and osteogenesis imperfecta.

Osteogenesis imperfecta (OI) is a heritable disorder of collagen that results in osteopenia and increased bone fragility. In 95% of patients mutations are found in the genes (*COL1A1* and *COL1A2*) encoding the  $\alpha 1$  and  $\alpha 2$  collagen chains. This results in reduced amounts of collagen which is often structurally abnormal. To date, over 200 mutations have been found; however, there is no close correlation between the molecular abnormalities and the clinical manifestations which are highly variable.

Prenatal diagnosis is available for some forms of the disease. The Sillence classification delineates four major phenotypes on the basis of bone fragility, growth and the presence or absence of additional features such as blue sclerae, dentinogenesis imperfecta and pre-natal hearing loss. Progressive skeletal deformity is a particular feature of OI type 111 and often requires orthopaedic intervention. Basilar invagination is a rare but important complication of OI in which the skull base develops abnormally and appears to 'fold in' like the undersurface of a closed-cup mushroom, and the C2 odontoid peg translocates upwards. This may be associated with ventral

brainstem compression, hydromyelia and hydrocephalus. It generally presents in early adult life with progressive neurological symptoms and signs, the most common being headache and lower cranial nerve dysfunction, particularly atypical trigeminal neuralgia. A range of other features occur from nystagmus to ataxia and quadriplegia. Trigeminal pain, if intractable, may require stereotactic surgery. The treatment of myelopathy involves ventral decompression and occipito-cervical fusion, with or without decompression of the foramen magnum.

Currently, there is much interest in the role of bisphosphonates in the management of OI. They reduce bone pain, improve both bone density and vertebral height, and may improve mobility through reducing spinal deformity. They are recommended in children but very long-term benefits on disease progression, function and quality of life have yet to be fully demonstrated and there are concerns about long-term adverse consequences of the treatment. Bisphosphonate treatment of mild OI is not indicated because of the potential long-term risks of therapy.

Osteoporosis is a progressive decrease in bone mass and density that can predispose to vertebral body fracture. The most common spinal manifestation is a compression or wedge fracture presenting with back pain or radicular pain, and very occasionally cauda equina or spinal cord compression. Multiple wedge fractures can lead to chronic pain and kyphotic deformity. Management includes conservative options (pain control, bracing, steroid injections), minimally invasive techniques (vertebroplasty) or surgery (pedicle screw fixation).

**Skeletal dysplasias** The two largest categories of these disease are the osteochondrodysplasias and the dysostoses. Osteochondrodysplasias are defined as abnormalities of cartilage or bone growth and development. They generally present as short-limbed dwarfism, with autosomal dominant achondroplasia resulting from mutations in fibroblast growth factor pathways with two mutations in the *FGFR3* gene causing around 99% of cases. Approximately 50% of children with achondroplasia have a thoracolumbar kyphosis in infancy and there is a risk of spinal cord stenosis. Patients characteristically have macrocephaly but a small mid face and small foramen magnum. These abnormalities place them at risk of symptomatic stenosis and hydrocephalus. Sleep apnoea is seen in the majority of patients, which may have a central or respiratory cause. Cervicomedullary decompression with resection of the foramen magnum may be necessary. Atlanto-axial instability has been increasingly recognised in the skeletal dysplasias.

The dysostoses are defined as malformations of individual bones singly or in combination. These include the craniosynostoses (Crouzon and Apert syndromes) in which vertebral anomalies are commonly recognised and Klippel-Feil syndrome (see Klippel-Feil syndrome).

**Metabolic storage disorders** Metabolic storage diseases include the mucopolysaccharidoses, the glycoprotein storage disorders, the gangliosidoses and the mucopolipidoses. These neurodegenerative diseases vary in their severity but show characteristic skeletal dysplasias, such as 'hooked' vertebrae, broad ribs and flared pelvis. Thoracolumbar kyphosis is common, with a risk of spinal cord compression. Other neurological complications include cognitive deterioration, carpal tunnel syndrome and deafness. In Morquio's syndrome (mucopolysaccharidosis IV) the os odontoideum is dysplastic or absent. These patients also have striking ligamentous laxity which gives a particularly high risk of atlanto-axial instability and spinal cord compression.

**Mesenchymal and connective tissue disorders** Around 30% of patients with neurofibromatosis will develop scoliosis, of which 40% will have associated cervical spine abnormalities. The scoliosis often manifests as an acute-angled short segment kyphoscoliosis, which will inevitably progress unless fusion is performed. Approximately 50% of patients with Marfan's syndrome develop significant scoliosis.

### Management of spinal deformity

Patient management varies from case to case and will be influenced by the underlying diagnosis, current levels of function, especially ambulatory abilities, life expectancy and concomitant medical problems. In broad terms, surgery may be performed for progressive deformity, neurological symptoms or pain, but is associated with risks, including infection (2–5%) and neurological damage (1–2%). The primary goal of corrective surgery is to produce a balanced spine in the coronal and sagittal planes when non-operative measures have been unsuccessful. However, it should be remembered that a deformity in one part of the spine will often be coupled with a compensatory scoliosis or kyphosis in another, and correction of the primary deformity should be performed in the context of the overall balance of the spine. A lumbar scoliosis, for example, should not be corrected in isolation if it would lead to overall coronal imbalance as a result of persisting 'compensatory' scoliosis elsewhere.

**Degenerative scoliosis** In adults, scoliosis may occur in later years because of asymmetric degeneration in discs, facet joints or osteoporotic wedging of vertebral bodies. Surgical fixation might be considered in the presence of pain or progressive deformity.

### Surgical correction of spinal deformity

Good results are dependent on meticulous patient selection at all stages, with multi-disciplinary pre-operative assessment, experienced specialised spinal surgeons, intraoperative neurophysiological spinal cord monitoring and intensive care support postoperatively. Complications in the immediate peri-operative period include haemorrhage, respiratory and cardiovascular problems. Infection occurs in 2–5% of patients. Paraplegia occurs in 1% of patients and nerve root damage in 1–2%. Up to 5% of patients experience failure of fusion.

In the past, Harrington rods were used to correct deformity by a posterior approach to the spine: these are steel rods with laminar hooks used to open out the concave side of the scoliosis. This technique of unilateral distraction was useful in correcting coronal balance, but not kyphotic deformity. Now the most common surgical technique for correction of deformity is the insertion of pedicle screws, which can be manipulated to good alignment and secured to titanium rods, supplemented with sublaminar and transverse process hooks if required (Figure 16.3). These newer systems of instrumentation allow simultaneous correction of imbalances in the sagittal, coronal and axial planes. Iliac crest bone graft is placed over the construct and between transverse processes to produce a solid fusion.

Standing posterior–anterior and lateral X-rays are required for surgical planning, and primary curves may be identified. Specific categories of primary deformities and compensatory curves have been described. The endpoints for the fusion and the positions of the pedicle screw and hook anchor points can be planned depending on the curve type and degree of flexibility.

Thoracolumbar kyphosis may be corrected by a similar posterior approach, but requires a wedge excision of vertebral body or a subtraction osteotomy of pedicles, to allow sufficient movement for reduction of the deformity. An anterior release operation (e.g. via a

**Figure 16.3** Lateral spine X-ray showing pedicle screw fixation for correction of spinal deformity resulting from tumour.

thoracotomy) may need to be performed to allow sufficient movement to reduce the kyphosis.

Other approaches include thoracotomy and thoracoscopy for antero-lateral correction of a thoracic deformity, and the retroperitoneal approach to the antero-lateral lumbar spine. Indications for these approaches include congenital malformation of vertebrae, rigid deformities requiring release, pseudoarthrosis after posterior fixation and in children less than 10 years old. Posterior fixation in the skeletally immature patient causes growth arrest of the posterior elements, but growth may continue at the vertebral endplates resulting in progression of the primary curve. For antero-lateral approaches, the convex side of the spine is exposed and screws placed into the vertebral bodies. The screw-heads are attached to a rod, and compression of the screws then reduces the deformity.

### Cranio-cervical junction anomalies

The pathophysiology of the cranio-cervical junction anomalies is complex. An important classification has been proposed by Menezes (1999), reproduced in Table 16.4. This subdivides the anomalies into congenital, developmental and acquired causes.

**Clinical features of cranio-cervical junction anomaly** There are three principal mechanisms by which the cranio-cervical junction anomalies lead to neurological signs. Frequently, more than one mechanism coexists.

**Direct compression** This may result from developmental abnormalities of the odontoid process. Of particular importance is the condition of odontoid fusion where the odontoid and the body of the axis are not fused. Atlas assimilation, where there is failure of segmentation

**Table 16.4** Causes of craniocervical anomalies.

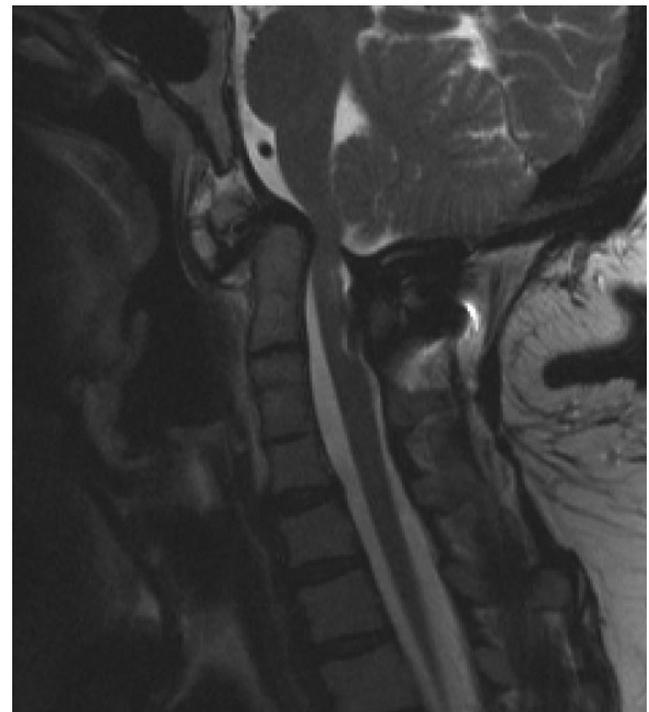

<b>Congenital anomalies and malformations</b>
Occipital sclerotome malformations – atlas assimilation, pro-atlas remnants
Atlas malformations – bifid atlas, assimilation, fusion, absent arches
Axis malformations – segmentation defects, odontoid dysplasias
<b>Developmental and acquired anomalies</b>
<b>Foramen magnum abnormalities</b>
Foramen stenosis, e.g. achondroplasia (AD <i>FGFR3</i> gene)
Secondary invagination (e.g. osteogenesis imperfecta, Paget's disease)
<b>Atlantoaxial instability</b>
Down's syndrome
Metabolic disorders (e.g. Morquio's, Hurler's syndromes)
Infections (e.g. Grisel's syndrome, tuberculosis)
Trauma
Inflammation (e.g. rheumatoid arthritis, Reiter's syndrome)
Tumour (e.g. osteoblastoma, neurofibromatosis, chordoma, meningioma)
Miscellaneous (e.g. syringomyelia)

AD, autosomal dominant.

between the fourth occipital and first spinal sclerotomes, is relatively common and is particularly associated with the Chiari malformations. Direct compression may also result from abnormal articulation around cervical vertebral blocks as is seen in the Klippel–Feil syndrome.

**Structural** Basilar invagination describes deformity of the osseous structures of the skull base that leads to upward displacement of the edge of the foramen magnum. In its primary congenital form it is often associated with platybasia where the clivus and anterior skull base are abnormally flattened. It can be associated with more subtle developmental bony anomalies and associated neurodysgeneses such as hindbrain herniation (particularly Chiari malformations) and syringohydromyelia. The foramen magnum itself may be narrow, usually as a feature of underlying skeletal dysplasia, as in achondroplasia. Acquired forms of basilar invagination are more common and result from any bone softening condition. The most important causes are osteogenesis imperfecta and Paget's disease. Diagnosis of basilar invagination on cervical spine X-ray historically involved measuring the position of the odontoid tip with respect to either the foramen magnum itself (McRae line) or from lines drawn between the roof of the hard palate and either the posterior lip of the foramen magnum (Chamberlin line) or the caudal part of the occipital bone (McGregor line), although now the diagnosis is more commonly made by CT or MRI scan (Figure 16.4).

**Atlanto-axial instability** Atlanto-axial dislocation results from incompetence of the transverse ligaments or abnormalities of the dens itself. Instability is defined by an atlanto-dens interval >4 mm, and is demonstrated by flexion/extension X-rays of cervical spine or sagittal CT reconstruction. Three-dimensional CT allows assessment of any rotational component. Instability may occur spontaneously or develop secondarily to inflammation or trauma.

**Figure 16.4** Congenital basal impression. T2-weighted sagittal MRI showing odontoid peg compression of cranio-cervical junction.

It is a recognised feature of the complex developmental cranio-facial and cranio-vertebral anomalies, particularly if there is atlas assimilation and segmentation failure as in the Klippel–Feil syndrome. Syndromes that are also associated with ligamentous laxity carry a particular risk of dislocation (e.g. the mucopolysaccharidoses and Down's syndrome).

### Down's syndrome

Trisomy 21 occurs in around 1/650 live births and is the single most common cause of severe learning difficulties. Patients initially present with characteristic dysmorphic features and hypotonia, often with associated cardiac and gastrointestinal anomalies. It is estimated that up to 25% of patients with Down's syndrome have asymptomatic atlanto-axial instability. Only around 1% are symptomatic. Recognised presentations include mild pyramidal tract signs with gait disturbance or the precipitous onset of cord compression. In the absence of signs or symptoms, screening of the atlanto-dens interval is no longer routine.

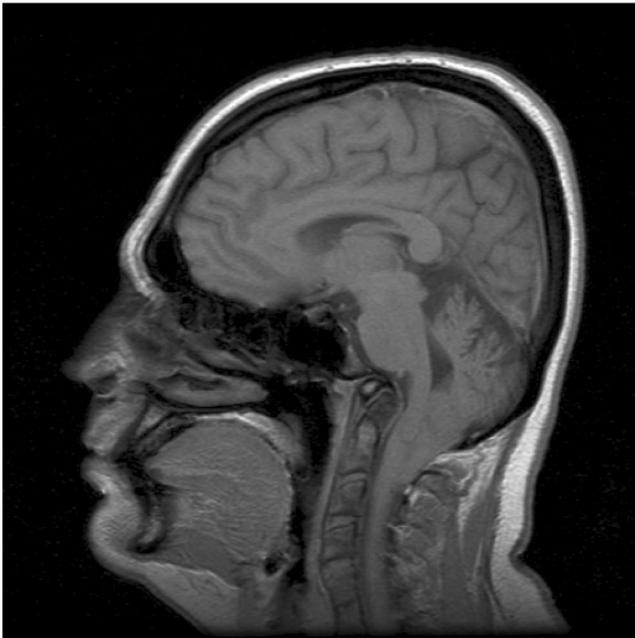

### Chiari malformations

There are four types of hindbrain malformation.

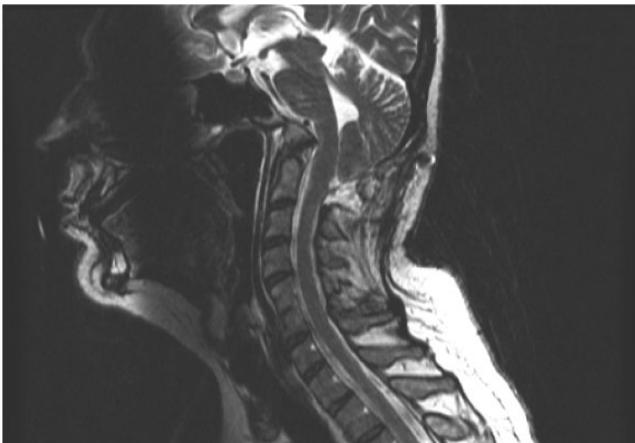

The Chiari I malformation is demonstrated on neuroimaging by the dorsal extension of the cerebellar tonsils below the level of the foramen magnum. The prevalence of Chiari I in asymptomatic individuals is probably less than 1%, but higher if tonsillar descent on sagittal MRI is associated with appropriate symptoms or other hind-brain anomalies and in around 50% of cases of true cerebellar ectopia there is elongation of the medulla. Approximately 50% of Chiari I malformations are associated with cranio-cervical anomalies and syringomyelia. The development of Chiari I is likely to be multifactorial. It has been postulated on the basis of familial aggregation that Chiari I is a disorder of para-axial mesoderm. Chiari I is present in renal-coloboma syndrome in which mutations in the *PAX-2* gene

have been identified. However, unlike Chiari II–IV there are clear examples of acquired Chiari I in which serial MRI has demonstrated postnatal development of the anomaly. Furthermore, lowering of CSF pressure following lumbar puncture or lumbar peritoneal shunting may be a risk factor for cerebellar tonsil descent. Chiari I has occurred during baclofen-pump insertion. There are well-documented examples of ‘Chiari’ or ‘pseudo-Chiari’ malformations improving following treatment of abnormally low CSF pressure caused by CSF leakage (Figure 16.5 and Figure 16.6).

The symptoms and signs resulting from Chiari I overlap with those associated with other cranio-cervical anomalies. These include headache, especially cough headache, nystagmus

**Figure 16.5** Chiari I malformation. MRI showing pre-operative appearances.

**Figure 16.6** Chiari I malformation. Post foramen magnum decompression MRI of patient whose scan is shown in Figure 16.5.

and quadriplegia. Additional symptoms and signs may result from associated hydrocephalus or syringomyelia. The condition is rarely symptomatic in childhood. Unusual presentations of Chiari I have been described: sudden death, syncope, ventricular fibrillation resulting from head movement, lingual myoclonus, pulsatile tinnitus, Ménière-type symptoms, acquired esotropia, central apnoea and paroxysmal rage.

Chiari II malformation is a congenital anomaly that is associated with myelomeningocele and hydrocephalus in >90% of cases and generally manifests in the neonatal period. It consists of caudal displacement of the medulla and cerebellum (particularly vermis) into the cervical canal overriding the spinal cord often accompanied by partial herniation of the fourth ventricle and distortion of midbrain tectum. Associated abnormalities of supratentorial and midbrain structures are common.

Chiari III is analogous to type II but describes downward displacement of the cerebellum into a posterior encephalocele, again with elongation and herniation of the fourth ventricle. Clinical features are severe and often life-threatening, particularly where there is cranial nerve dysfunction.

The Chiari IV malformation describes cerebellar hypoplasia and on current understanding is not part of the Chiari spectrum.

Asymptomatic Chiari I malformations can be treated conservatively. There have been case reports of sudden death in some patients with untreated malformations, but majority of these were not truly asymptomatic. Pregnancy in patients with significant Chiari I needs to be monitored and managed with care. Pushing during the second stage of labour causing further tonsillar descent and inadvertent dural puncture during epidural anaesthesia producing coning are two risks that need to be carefully considered. Some neurologists and neurosurgeons recommend that the baby be delivered by caesarean section and under general anaesthetic. Planned pregnancy is not an indication for prophylactic foramen magnum decompression.

Surgical treatment involves decompression of the foramen magnum and should be offered on the basis of significant and relevant symptoms (e.g. severe cough headache), or the presence of physical signs indicating neurological compromise. Posterior suboccipital decompression is the standard surgical management for symptomatic malformations, although there is much debate over how much bone to remove, whether the dura should be opened, scored or left intact, whether to use a dural patch graft or leave the dura widely open, and whether to resect the cerebellar tonsils to encourage good CSF flow. Surgery aims to prevent progression of symptoms, and improvement is seen in more than 80% of patients. Coexistent hydrocephalus usually improves after decompression of the foramen magnum, but if persistent, ventriculo-peritoneal shunting can be performed. Persistent syringomyelia may be treated by syringostomy, or by syringo-subarachnoid, syringopleural or syringo-peritoneal shunting. After foramen magnum decompression it can take several weeks for a patient to become accustomed to their altered CSF dynamics, and the patient may feel unsteady or experience low-pressure headaches. Aseptic meningitis occurs in a minority, and usually responds to a tapered course of steroids over a few weeks.

### **Congenital basilar invagination**

Congenital basilar invagination results from a defect in the development of the cartilaginous skull base, producing elevation of the foramen magnum in relation to the occipital bone, with invagination of the lip of the foramen, along with flattening of the angle

between the clivus and anterior fossa floor. This may be associated with other anomalies including occipitalisation of the atlas, Klippel-Feil segmentation defects, Chiari malformation and syringomyelia. Basilar invagination should be distinguished from basilar impression, which is an acquired vertical translocation of the odontoid process into the foramen magnum occurring in conditions such as rheumatoid disease. Basilar impression is not usually associated with moulding of the skull base.

### Os odontoideum

Congenital atlanto-axial instability is sometimes caused by aplasia or hypoplasia of the odontoid process, but is more commonly the result of an os odontoideum. This is an independent ossicle located above the centrum of the axis vertebra in the position of the odontoid process, which may be associated with a hypoplastic or completely absent dens. The abnormality is more common in Down's syndrome, spondylo-epiphyseal dysplasias and Morquio's syndrome. The cause is thought to be *in utero*, neonatal or childhood fracture of the odontoid process with subsequent non-union and remodelling. If there is significant instability in a physically active patient, surgical fusion of C1 and C2 is recommended to minimise the risk of damage to the spinal cord in the future. Radiological instability is seen in 15–30% of people with Down's syndrome, but the instability is symptomatic in only 1–2% of patients, often because of learning difficulties. The current recommendation for patients with Down's syndrome and atlanto-axial instability is to restrict sporting activities if asymptomatic and to fuse patients who develop symptoms.

### Management of craniocervical junction anomalies

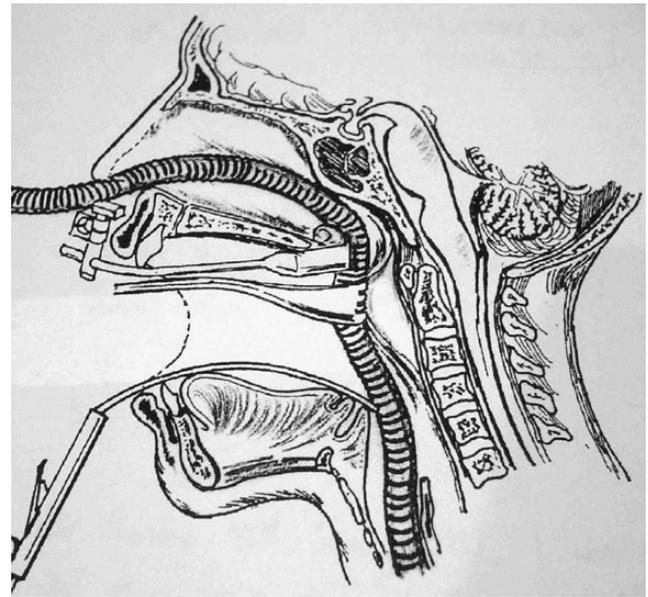

The surgical treatment of cranio-cervical junction anomaly is complex and complete description is beyond the scope of this chapter. If neurological symptoms and signs of brainstem compression occur, or abnormal movement at C1–2 generates significant pain, then surgery is usually indicated. The aim of surgery is twofold: first to decompress and secondly to stabilise the cranio-cervical junction when necessary. Anterior decompressive surgery is commonly performed by the transoral approach, for example for tumours, rheumatoid pannus, os odontoideum and non-united odontoid fractures (Figure 16.7). Posterior decompression may be performed for Chiari malformations.

Horizontal atlantoaxial instability is commonly treated by posterior C1–2 fixation and bone graft, whereas vertical instability or 'cranial settling', analogous to a toffee apple on a stick, requires posterior occipito-cervical fusion.

### Syringomyelia

A syrinx is a cystic cavity in the spinal cord (syringomyelia) or brainstem (syringobulbia) that is lined by spinal cord parenchyma, as distinct from a cystic cavity which is in continuity with the central canal and lined by ependymal cells (hydromyelia). It is caused by abnormal transmission of raised CSF pressure through the spinal cord parenchyma during coughing and raised intra-abdominal or thoracic pressure, as a result of pathologically altered CSF dynamics. Syringomyelia can be caused by several conditions:

- 1 Trauma, with or without spinal cord injury, often with spinal deformity. Around 2–8% of patients with spinal cord injury develop a syrinx over time, usually several years after the injury.
- 2 Congenital conditions such as Chiari malformations, basilar invagination and Dandy-Walker syndrome.

**Figure 16.7** The transoral approach to the anterior craniocervical junction.

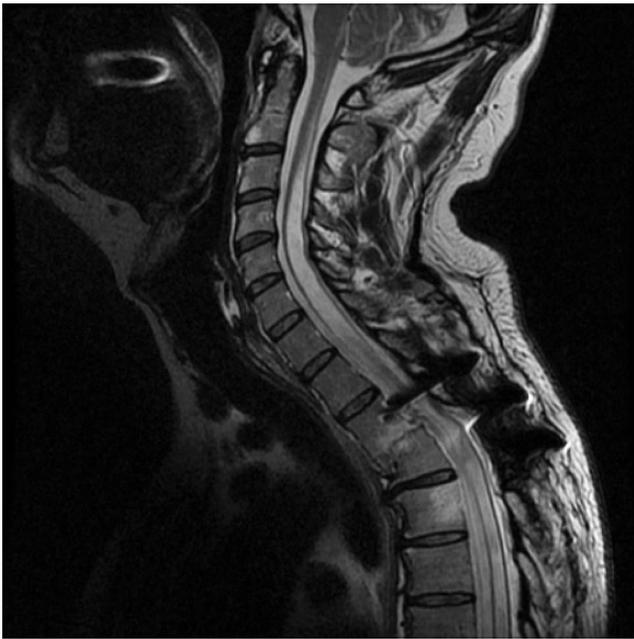

- 3 Tumours, especially intramedullary tumours such as astrocytomas and ependymomas. Investigation of syringomyelia should always include a gadolinium-enhanced MRI scan to exclude a tumour as the cause.
- 4 Arachnoiditis, particularly when affecting thoracic and cervical spine.
- 5 Spinal infections such as pyogenic meningitis and tuberculosis.

The symptoms and signs of syringomyelia typically progress gradually over time, and are discussed in the section above. Diagnosis is usually made from the clinical features and typical appearance on MRI of the spine (Figure 16.8). A cause for the syrinx (e.g. Chiari malformation, spinal tumour or arachnoiditis) should be actively sought.

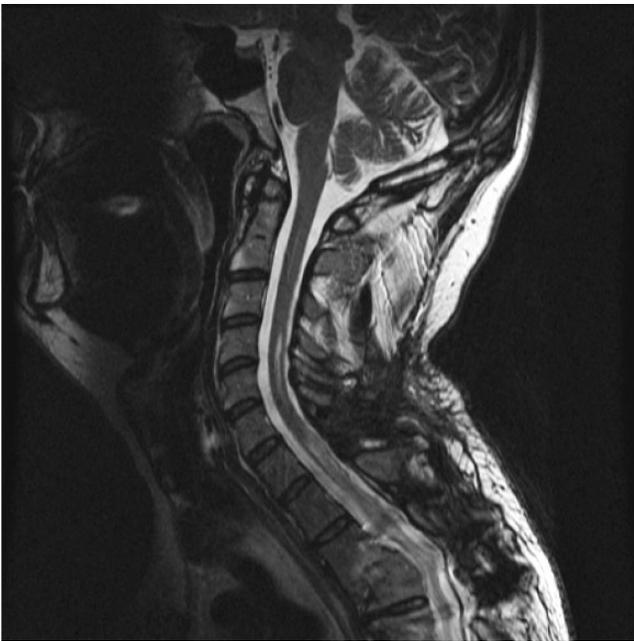

**Treatment of syringomyelia** Non-progressive post-traumatic syringomyelia or hydromyelia causing mild clinical features is best managed conservatively. Progressive symptoms of syringomyelia need to be treated. As far as possible, the cause of the syrinx should be treated first (e.g. posterior fossa decompression for Chiari malformation). If the syrinx progresses and is symptomatic, treatment includes percutaneous drainage or open syringotomy. However, these techniques are associated with a high rate of syrinx recurrence, and a more permanent measure is to inset a shunt between the syrinx and the subarachnoid space, pleural or peritoneal cavities (Figure 16.9). Seventy-five per cent of patients were stabilised or improved in one surgical series by shunting, but because of the rarity of the condition and the variability in the surgical techniques available it is difficult to compare the outcomes of specific surgical options.

### Spinal dysraphism

Spinal dysraphic states are caused by localised failure of neural tube closure during fetal development. Myelomeningocele is the most common form, with an incidence of 0.8/1000 live births. Neural tube defects are caused by a variety of mechanisms: chromosomal abnormalities, single gene defects and teratogens (including valproate and carbamazepine). There are marked regional

**Figure 16.8** Syringomyelia. MRI showing post-traumatic cervico-thoracic syrinx (note T2–3 trauma and artefact resulting from pedicle screws).

**Figure 16.9** Syringomyelia. MRI of patient whose scan is shown in Figure 16.8 following insertion of syringopleural shunt resulting in successful syrinx decompression.

variations in its incidence and the condition is heterogeneous. There are strong genetic components and recurrence risks rise from 1–2% after one affected child to 10% with two affected children. Certain polymorphisms in genes involved in gene repair and folic acid metabolic pathways are associated with an increased risk of neural tube defect. The process of neurulation may be disrupted

by teratogenic agents and in particular by maternal and/or fetal folate deficiency. Early folic acid supplementation reduces the incidence of neural tube defects, so that all women are recommended to take supplemental folate prior to conception and during the first trimester. It is estimated that approximately 70% of neural tube defects are preventable through maternal folic acid supplementation (400 µg/day). This advice is especially important for women with a previously affected pregnancy or those taking anticonvulsants in whom the incidence of neural tube defects is around 1% of pregnancies; larger amounts of folic acid are recommended for these women (5 mg/day). Folic acid supplementation should be started pre-conception. Routine antenatal screening provides a prenatal diagnosis in many cases; raised maternal serum alpha-fetoprotein is associated with open neural tube defects and fetal ultrasonography allows cranial and vertebral structures to be visualised directly. Prenatal counselling and pregnancy termination can then be offered.

Myelomeningocele and myelosclerosis account for 95% of cases of spinal dysraphism, with exposed neural tissue a common feature. In a meningocele and in spina bifida occulta neural elements are covered by skin. The clinical features are determined by the extent of the myelocoele and the presence of associated abnormalities, which may include both neural and extraneural anomalies. Progressive hydrocephalus requiring surgical treatment is present in 90% of cases and around 70% have a Chiari II malformation. Learning difficulties are common, one-third have an IQ <80. Syringomyelia is present in up to 75% of cases and is often associated with severe scoliosis. Approximately one-third of patients have diastematomyelia.

Approximately 80% of open spina bifida defects are located in the lumbosacral area. The sensory level indicates the upper level of the lesion. Lesions above L3 result in complete paraplegia, but motor deficits may otherwise be patchy with a mixed pattern of upper and lower motor neurone signs. Sphincter and detrusor function is always compromised and careful urological assessment is required. Surgical closure is undertaken within 48–72 hours of delivery to reduce the risk of ascending infection and protect viable neural tissue within the placode. Following closure delayed hydrocephalus is likely. Patients generally require ongoing medical care by a multi-disciplinary team.

Spina bifida occulta is a term used for occult dysraphism, where neural structures have not herniated through the mesenchymal defect. It includes diastematomyelia, terminal myelocystocele and tight filum terminale. Lipomyelomeningocele and dermal sinuses are often included in this category as they also result from abnormal secondary neurulation. Spina bifida occulta is usually neurologically asymptomatic. The majority of patients have associated cutaneous abnormalities such as a tuft of hair or a dimple over the region, and plain X-rays show underlying vertebral anomalies. MRI scan then confirms the diagnosis. Two neurological presentations are recognised. First, a congenital asymmetric weakness and atrophy of the lower limbs and second the ‘tethered cord syndrome’ with progressive and sometimes precipitous onset of weakness and spasticity. The latter often presents in childhood or during the adolescent growth spurt and is an important cause of toe walking in childhood. Both presentations may be associated with sphincter disturbance. Treatment is primarily neurosurgical, with release of the spinal cord from the tethering lesion, with full preoperative neurological and urological assessment. Orthopaedic, orthotic and physiotherapy management of lower limb deformity is also important.

**Klippel–Feil syndrome**

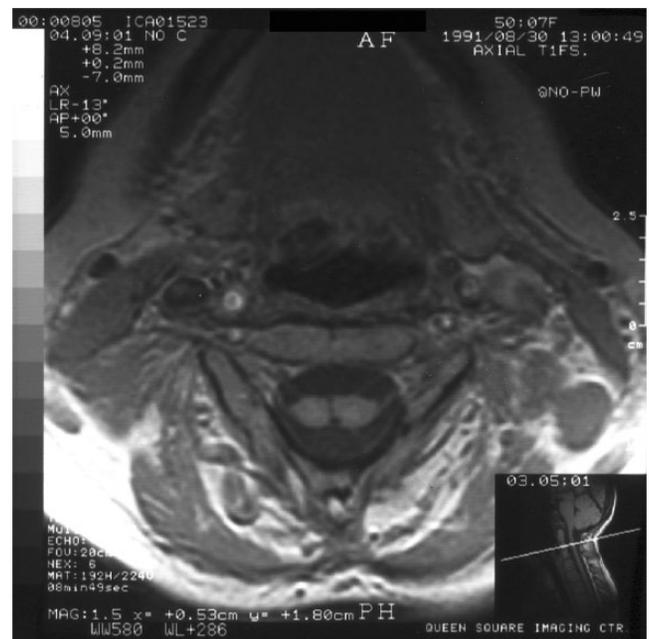

Described in 1912, the disorder is characterised by a short neck, impaired neck mobility and a low hairline. The incidence is approximately 1/42 000 births. Three types of Klippel–Feil syndrome are described. The skeletal abnormalities include fusion of two or more cervical or cervico-thoracic vertebrae (Figure 16.10). The syndrome is heterogeneous; differing numbers and positions of fused vertebrae are described and the associated anomalies are highly variable. The condition may be familial: dominant, recessive and X-linked inheritance patterns have been proposed and mutations in the *PAX1* gene may be associated with the condition. Despite the sometimes dramatic

spinal abnormalities, a follow-up study over a 10-year period has indicated that only 20% of patients experienced significant cervical spine symptoms and only 6% required surgical intervention.

Extravertebral anomalies associated with Klippel–Feil syndrome affect multiple systems. Skeletal and systemic abnormalities include scoliosis, scapula elevation, rib anomalies, cranio-facial dysmorphism, pulmonary, cardiac, gastrointestinal and urogenital anomalies. Neurological problems include syringomyelia, cranial nerve abnormalities, Duane retraction syndrome, deafness, acquired myelopathy resulting from the spinal abnormality, thin corpus callosum, split cervical spinal cord (Figure 16.11) and failure of pyramidal tract decussation. The latter anomaly is particularly interesting as it may underlie the intense congenital mirror movements that affect a number of these patients. Table 16.5 gives examples of pyramidal tract malformation and misdirection.

**Figure 16.10** Lateral X-ray of patient with Klippel–Feil syndrome showing vertebral segmentation anomaly.

## Rheumatological disorders affecting the spine and spinal cord

**Page's disease** The disorder is rare before the age of 40 but becomes increasingly common with time, affecting 10% of 90-year-olds. The clinical features are those of bone pain, local deformity, bone enlargement, pathological fracture and a predisposition to sarcomatous change. The disorder often affects the skull and spine and as a result neurological involvement is common. Typical radiological appearances and the finding of an elevated serum alkaline phosphatase confirm a diagnosis of Page's disease. The disease is one of excessive bone desorption with excessive osteoblastic and osteolytic activity. A genetic predisposition is described and some familial cases have been linked to chromosome 18q. A syndrome of Page's disease with inclusion body myositis and dementia has been described. Pagetic osteoclasts contain nuclear inclusions and osteoclastic infection is one proposed mechanism although firm evidence for a causative paramyxovirus infection is lacking.

There are numerous potential neurological sequelae of Page's disease. Direct compression by pagetic bone may lead to headache, dementia, brainstem and cerebellar dysfunction, cranial neuropathies, myelopathy, cauda equina syndrome and radiculopathies. The most common cranial neuropathy is sensori-neural deafness. Optic atrophy, trigeminal neuralgia and hemifacial spasm may occur also. Pagetic softening of the skull may lead to basilar invagination resulting in brainstem and high cervical compression syndromes and occasionally hydrocephalus. The brain and spinal cord can become acutely compressed from epidural haematoma. The vascularity of pagetic bone may lead to cerebral ischaemia as part of a steal syndrome (compared with normal bone, blood flow in pagetic bone is increased threefold). Neurological syndromes may also develop because of compression of blood vessels.

Page's disease generally responds to treatment with bisphosphonates although a relative resistance to these drugs is described. First line treatment is with potent oral bisphosphonates. Second line treatment regimes include calcitonin, etidronate and intravenous bisphosphonates. Bone pain in particular can resolve within 1–2 weeks of commencement of treatment. Treatment efficacy may be monitored by serum alkaline phosphatase levels and a therapeutic response is expected in approximately 80% of patients treated. Neurological syndromes often improve with medical treatment. Rapidly progressive neurological syndromes require high-dose intravenous bisphosphonate therapy and/or treatment with calcitonin. However, hydrocephalus generally requires shunting. Surgical decompression for basilar invagination, cranial nerve lesions, spinal cord and root compression is indicated if neurological symptoms and signs progress rapidly or despite best medical treatment. Medical treatment prior to surgical intervention may reduce bone vascularity and thus the risk of peri-operative haemorrhage.

**Rheumatoid arthritis** Rheumatoid arthritis is a chronic inflammatory immune-mediated symmetrical polyarthritis with a predilection for the distal joints. Females are affected twice as commonly as males and the prevalence ranges between 0.2% and 2% of the population in Europe and North America. The inflamed synovium is termed the pannus; it is characterised by T- and B-cell activation, cytokine release, immune complex deposition, angiogenesis and cellular proliferation. This inflammatory process leads to damage and destruction of bone, cartilage and ligaments. Aggressive immunosuppressive therapy with disease-modifying drugs (in particular sulfasalazine and methotrexate) improves the prognosis of rheumatoid arthritis. The newer immune-modifying drugs, such

as antitumour necrosis factor and anti-interleukin 1 agents, have further improved prognosis, and compared with past decades, fewer rheumatoid patients are now presenting for surgery to the cervical spine and large joints.

Neurological manifestations of rheumatoid arthritis include entrapment neuropathy, vasculitic neuropathy, myopathy and ischaemic syndromes caused by vasculitis; these are discussed further in Chapter 26. The spinal cord manifestations result from ligamentous disruption, bone destruction and secondary osteoporosis. A rare syndrome of diffuse dural infiltration with inflammatory cells producing a pachymeningitis has been described.

Patients with rheumatoid arthritis of the cervical spine frequently experience headache and neck pain; however, the most feared neurological complication of rheumatoid arthritis is upper cervical cord and brainstem compression. Neurological symptoms usually result from one of three processes: atlanto-axial subluxation, basilar impression (vertical translocation) or subaxial subluxation.

Involvement of the atlanto-axial ligament often combined with local pannus formation and bone destruction produces subluxation. Atlanto-axial subluxation affects 25% of rheumatoid patients of whom 25% have neurological signs. Atlanto-axial subluxation may occur in lateral, rotational, anterior, posterior and vertical directions; the latter three directions being the most neurologically significant. Rheumatoid arthritis may affect the spinal cord caudal to the C1–2 level independently or in association with a high cord lesion. Postmortem studies of myelopathy show necrosis, gliosis and Wallerian degeneration within ascending and descending white matter. Cervical myelopathy is caused by repetitive minor trauma to the spinal cord because of excessive movement of the unstable level. The degree of atlanto-axial subluxation is well characterised by plain flexion–extension radiography; however, because a large part of the compression is caused by inflammatory soft tissue proper assessment requires MRI (Figure 16.12).

**Natural history** In a series of 235 rheumatoid patients referred for neurosurgical assessment of cranio-cervical junction instability, 60% had myelopathy, the majority of these either had motor or mixed motor and sensory long-tract signs; in approximately 10% the predominant deficits were loss of joint position and Rombergism, indicating a mainly posterior compression. Cranial nerve signs and nystagmus were rare and in this series were associated with other pathologies, especially Chiari malformation.

Rheumatoid arthritis initially involves the hands and feet, and large joints usually require surgery before the neck. Casey *et al.* (1996) discovered that cervical disease requiring surgical treatment tended to occur in patients who had had between two and four previous large joint arthroplasties. This implies that the greater degrees of mobility in rheumatoid joints leads to accelerated degeneration and instability. Hence, the cervical spine is affected commonly, particularly the atlanto-axial joint and the cranio-cervical junction, and the lower spine is usually spared. The percentage of rheumatoid patients who develop atlanto-axial subluxation varies between series, and reported frequencies are biased by the source of data collection. There are few large population-based cohort studies in the literature. Non-surgical studies over the past few decades report that 14–73% of patients with rheumatoid develop atlanto-axial subluxation, with a mean incidence of 35% (21% horizontal and 14% vertical subluxation). More than 30% will have symptomatic atlanto-axial subluxation 5–7 years after the onset of the disease. Five per cent then become myelopathic a decade later, 14–17 years after onset. Once myelopathy has developed the outlook is poor, with up to 50% mortality within a year.

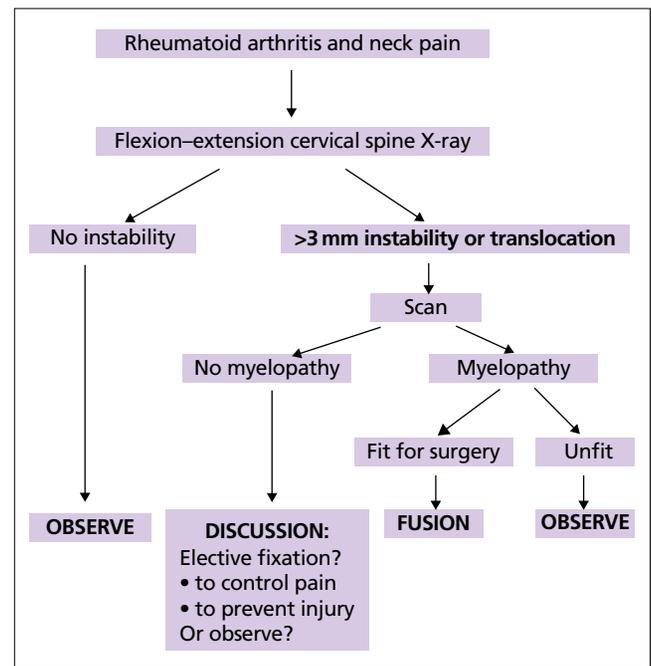

**Figure 16.12** Sagittal T2-weighted MRI scan of cervical spine in rheumatoid disease, showing odontoid pseudo-tumour causing cord compression, and kyphotic subluxation of the sub-axial spine.

### Indications for surgical management of the rheumatoid spine

A study of surgical outcome comparing the 1970s with the 1990s found an improvement in surgical mortality from 9% to 0%, a decrease in complication rate from 50% to 22%, and improvement of symptoms in 89% of patients who had surgery. Improved outcomes have been a result of better instrumentation and the trend towards earlier surgery; it is now accepted that operations for non-ambulant myelopathic patients are associated with an unacceptably high complication rate, and poor functional improvement. Atlanto-axial fusion is now more commonly performed for instability causing pain, early neurological symptoms and signs, occipital neuralgia or progressive radiological appearances (Figure 16.13).

Selection of appropriate patients for surgical intervention is difficult. The policy of waiting until rheumatoid patients with atlanto-axial subluxation develop signs of serious myelopathy has been strongly challenged on the basis that once spinal cord damage has been sustained it is rarely reversible. In a prospective trial it has been shown that following surgical stabilisation, with or without transoral anterior decompression, approximately 60% of ambulant patients will show stabilisation or improvement of their functional status; in contrast only 20% of non-ambulant patients will show any recovery. Furthermore, surgical morbidity and mortality was found to be significantly higher in the non-ambulant (12.7%) than the ambulant group (8.9%). In the past, major surgery was often performed for patients with end-stage myelopathy, often with poor results. Now surgical stabilisation is generally performed at an

**Figure 16.13** Algorithm for assessment and treatment of rheumatoid atlanto-axial disease (in text).

earlier stage once instability has been demonstrated. Early surgery is associated with a better outcome, lower risk and prevents further deterioration in the diseased joint.

It should be noted that the combination of mild neurological impairment and rheumatological/orthopaedic problems puts rheumatoid patients at increased risk of falls and even minor cervical injury can produce catastrophic neurological deterioration. Atlanto-axial subluxation increases the anaesthetic risk because of neck extension during artificial ventilation (Table 16.6).

### Spondyloarthropathies

The inflammatory spondyloarthropathies include ankylosing spondylitis, psoriatic arthritis; arthritis associated with inflammatory bowel disease and reactive arthritis (for instance in Reiter disease). Low back pain is common to all conditions. The primary neurological manifestations are best described by a consideration of ankylosing spondylitis, and similar features occur in the other spondyloarthritides.

Ankylosing spondylitis is the most common of the seronegative spondyloarthritides, affecting up to 2% of the population in the West. It usually presents with gradual onset low back pain and stiffness of the large joints. The condition can affect other organ systems. Men are affected more than women. Disease onset is typically before age 40. HLA B27 is strongly associated with >90% of patients expressing the antigen. Unlike rheumatoid disease, it commonly affects the spine and sacroiliac joints, rather than the peripheral joints, and the disease progresses in a caudal-rostal direction, resulting in flexion deformities in posture. The pathological hallmark is the development of enthesopathy, that is inflammation around sites of tendonous insertion. Syndesmophytes form in the spinal column points where spinal ligaments attach to the vertebral bodies.

**Table 16.6** Indications for different types of surgical stabilization in rheumatoid disease.**C1–2 fixation should be considered for**

Instability and intractable pain  
 Clinical myelopathy  
 Occipital neuralgia  
 Progressive radiological subluxation  
 Anteroposterior spinal cord diameter less than 6 mm on flexion MRI  
 PADI less than 10 mm on CT  
 Patients with instability who are unable to wear a hard collar or brace

**Fixation of the occiput to cervical spine should be considered for**

Vertical translocation  
 Excessive degeneration or instability of the occipito-atlantal joints  
 When C1 or C2 bone quality does not allow adequate screw purchase or fixation of a short segment  
 Disruption of the ring of C1 by fracture or after transoral odontoidectomy  
 When there is a significant 'staircase' deformity or instability in the subaxial spine, requiring a longer construct to simultaneously fuse lower levels

**Transoral decompression and posterior fixation should be considered**

When there is irreducible atlanto-axial subluxation causing ventral compression of the neuraxis  
 When there is marked vertical translocation (>5 mm) causing brainstem compression  
 When an anterior soft tissue mass causes compression around the cranio-cervical junction

MRI, magnetic resonance imaging; PADI, posterior atlantodental interval.

The neurological manifestations of ankylosing spondylitis are usually a late stage complication. Loss of spinal movement is associated with vertebral body squaring and extensive loss of ligamentous laxity because of syndesmophyte formation. This process produces a rigid spine with kyphosis. Spinal involvement may produce atlanto-axial subluxation, pathological vertebral fracture, disco-vertebral destruction, spinal canal especially lumbar canal stenosis and a cauda equina syndrome (Figure 16.14). Atlanto-axial subluxation occurs more rarely than in rheumatoid arthritis; however, the management issues are similar. Spinal rigidity and disco-vertebral problems predispose to cord compression. Acute spinal cord compression resulting from epidural haematoma is a recognised problem. Spinal fractures are more common because of the rigidity of the spine, and the use of a rigid collar in the emergency department is often prevented by the degree of kyphotic deformity. Forcing the neck into a collar can itself result in a cervical fracture. Despite the tendency to ankylosis in these patients, conservative management often results in a pseudoarthrosis, and anterior or posterior fusion with surgical fixation is required.

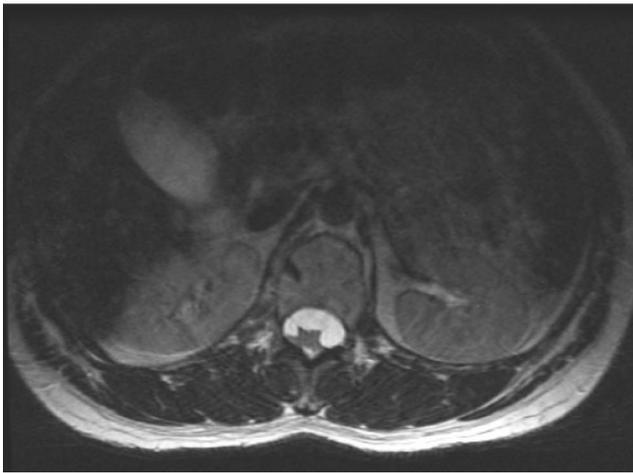

**Figure 16.14** Lateral X-ray of thoro-columbar spine in a patient with ankylosing spondylitis.

The cauda equina syndrome is a rare late stage complication of ankylosing spondylitis. It presents gradually with leg pain, leg weakness, sensory disturbance and sphincteric dysfunction. On imaging studies posterior lumbar-sacral diverticulae are present. An arachnoiditis may also contribute to the development of the cauda equina syndrome; however, the presence of the diverticulae indicates that ankylosing spondylitis is the likely cause rather than some other form of arachnoiditis (Figure 16.15). It is important to remember that spinal irradiation was used to treat ankylosing spondylitis and late radiation neurological damage and bone sarcoma may result.

**Spinal trauma**

The most common cause for spinal injury is vehicle accidents, followed by violent assault, falls and sports injury, especially high board diving. Severity of injury may be classified using the American Spinal Injury Association (ASIA) Score for quantitative assessment of motor and sensory function, or the ASIA/Frankel grading system, A–E for clinical grading:

- A** The most severe with no motor or sensory function below the level of the lesion, and with no preservation of sensation in sacral dermatomes S4–S5.
- B** 'Incomplete' in which there is no motor function below the lesion but there is preservation of sensory function (in this group sacral preservation of pinprick sensation indicates a better prognosis for functional recovery).

**Figure 16.15** Axial MRI of thoracic spine showing deformation of thoracic cord caused by arachnoiditis.

- C** 'Incomplete' motor function is preserved below level of lesion (MRC <3).
- D** 'Incomplete' motor function is preserved below level of the lesion with 50% muscles MRC grade 3 or above.
- E** Normal motor and sensory function.

The majority of grade A patients will show some recovery of motor function (increase in one level) especially in the first 6 months, although later improvement does occur. Between 20% and 30% of grade B patients recover to grade D or E, 50–70% of grade C patients recover to grade D or E. Ambulation is normally achieved in patients who recover to grade D. In severe spinal cord lesions the level of the lesion critically determines the functional outcome with preservation of arm function (lesion below C6) being important for maintenance of transfers and activities of daily living. Assisted ventilation is required for patients with severe spinal cord lesions above C3. Independence of bowel and bladder function, albeit with intermittent self-catheterisation, may be expected if upper limb function is preserved.

### Acute management of spinal injury

Resuscitation of the patient and treatment of life-threatening injuries are the initial priorities. Immobilisation of the spine at the scene of the trauma, especially the neck, should be performed until the neurological and mechanical integrity of the spine can be established. A cervical injury should be assumed until proven otherwise in all patients with a significant force of injury or those who are unconscious.

The investigators of the National Acute Spinal Cord Injury Studies (NASCIS) advocated the use of methylprednisolone within 8 hours of the injury, a bolus of 30 mg/kg followed by 23 hours of IV methylprednisolone 5.4 mg/kg/hour. Its effects are not completely understood but as well as reducing oedema steroids may prevent lipid peroxidation, which disrupts myelin. Other drugs that prevent lipid peroxidation are also under trial. However, there is a body of evidence that the side effects of steroids outweigh the benefits in head injuries. The CRASH trial (Corticosteroid Randomisation After Significant Head Injury) looked at the 6-month outcomes of over 10 000 randomised patients and found that mortality in those given high-dose steroids was greater than in those receiving placebo. The majority of data for the use of steroids

in spinal cord injury do not show a beneficial effect, and questions have been raised about the handling of data in the NASCIS 2 subgroup analysis. A systematic review of 157 studies of methylprednisolone infusion in spinal cord injuries concluded that there is insufficient evidence to support the use of steroids as a treatment standard. Opinions differ but most surgeons and physicians feel that there is no clinical evidence to support use of high-dose intravenous methylprednisolone during the acute phase of traumatic spinal cord injury.

Surgery should be performed for incomplete lesions with cord compression and progressive neurological signs, mechanical instability preventing mobilisation, and if internal reduction of dislocation is required. Wound débridement may be necessary for dirty penetrating injuries. However, surgery will not improve a fixed neurological deficit that has been present from the time of injury.

The optimal surgical management of spinal fractures and cord injury remains controversial. Traditionally, patients were treated with 6–12 weeks of bed rest, traction and then mobilisation with external orthotic stabilisation. Proponents of conservative management argue that bed rest improves perfusion of the spinal cord at this very vulnerable stage following injury. Neurological outcome was studied in 63 consecutive patients with incomplete cervical cord injuries and was found to be dependent on the initial presenting neurological level of function. The neurological deficit at presentation and also the extent of recovery were not associated with the degree of spinal canal compromise. However, prolonged bed rest is associated with deep venous thrombosis, pulmonary embolism, chest infections, pressure sores and muscle atrophy. The development of titanium constructs and instrumentation over the past few decades have allowed surgeons to produce robust fixation and fusion at an early stage, facilitating early mobilisation, vigorous physiotherapy and avoidance of these complications. A review of the evidence for surgical management of spinal injuries concluded that many animal studies and class II and III human studies supported early intervention in improving neurological outcome. However, there is no class I evidence to support conservative or surgical management of acute spinal injuries, and most clinicians seem to base their judgement on belief, logic and individual experience.

There is a significant trend towards early surgical intervention to minimise the risks of immobilisation and maximise spinal stability for the future, as well as for reasons of health economics. Surgery should be performed in the controlled environment of the next available daytime list. The risks of surgery itself have decreased with the widespread use of modern technology and operating microscopes and, broadly speaking, there is a 1% chance of irreversible cord damage and a 5% chance of other problems including infection, failure of fusion and anaesthetic risks.

Central cord contusion of the cervical spine without instability may occur, especially if there is a background of spondylosis spinal canal stenosis. Some surgeons recommend non-operative management of these patients because of the theoretical risk of worsening their function if surgery is performed within 4–6 weeks of the injury. The evidence for this traditional approach is weak, and originates from a small series of eight patients, two of whom deteriorated after surgery to decompress the cord and section the dentate ligaments. The authors recommend early surgery in this group of patients if there is no spontaneous improvement and the spinal cord is compressed, or if a patient improves but then deteriorates. If there is no active cord compression or instability, then early decompression is not warranted. Of patients with a central cord contusion

and tetraplegia or severe paresis, 50% eventually walk again and sphincter control usually recovers but manual dexterity tends to recover less satisfactorily.

**Experimental therapy for spinal cord injuries** In the last three decades there has been much research interest, searching for a cure for paralysis after spinal cord injury. Animal models have demonstrated positive effects of many strategies, but clinical studies have so far failed to produce a significant benefit. Several strategies are presently being studied:

- 1 Neuroprotection and anti-inflammatory agents (e.g. riluzole, minocycline)
- 2 Neuroregeneration and the use of nerve growth factors (e.g. Cethrin)
- 3 Inactivating inhibitory cues in the glial scar, myelin or extracellular matrix (e.g. anti-Nogo-A antibodies, chondroitin sulfate proteoglycan inhibition)
- 4 Stem cell or regenerative cell techniques (various stem cells, olfactory ensheathing cells, cultured Schwann cells, peripheral nerve grafts)
- 5 Enhancing local plasticity (monoamine agonists, cellular therapies)
- 6 Rehabilitation and training, functional electrical stimulation (rehabilitation techniques, method, amount, timing, and epidural spinal cord stimulation)
- 7 Surgical stabilisation and decompression (method of surgery, timing of decompression).

**The olfactory system as a model for nerve repair** Until the 1970s it had been thought that no new nerve cells are formed in the adult brain, but with the new labelling technique it was found that in one part of the nervous system – the olfactory system – new nerve cells are being continually generated by division of an adult stem cell located in the nasal mucosa. Throughout normal life, and also at a much accelerated rate after injury to the olfactory nerves, the adult olfactory nerve cells die and are completely replaced by the progeny of adult stem cells lying in the olfactory mucosa. The nerve fibres belonging to the new nerve cells grow through the cribriform plate of the base of the skull and enter the brain. Olfactory ensheathing cells (OECs) are responsible for promoting this regeneration, and have been shown to improve the outcome when transplanted into experimental spinal cord and nerve root injuries in rodent and canine models.

**Clinical application of olfactory ensheathing cell transplantation** The encouraging reparative results in animal experiments have led to a clinical safety trial in Brisbane, Australia, which has shown no adverse side effects following transplantation of OECs cultured from biopsy samples from the patient's own olfactory mucosa and injected as a suspension at multiple sites in spinal cord injuries. But even with autografts of OECs cultured from biopsy samples of the patient's own nasal mucosa, there remains a need to characterise the human cells and establish a standard culture technology. Although typically located posteriorly on the superior turbinate and adjacent lining of the sphenoidal recess and nasal septum, considerable variability has been reported in the distribution of the human olfactory area and its histology, probably as a result of the inevitable accumulation throughout life of the effects of periodic infectious and allergenic insults, as well as continuous exposure to damaging agents in the air we breathe. At Queen Square, a project is underway to characterise the OECs that are cultured from human olfactory mucosa, grow the

cells under standardised conditions and perform autologous cell transplantation for patients with acute brachial plexus avulsion.

**Surgical management of spinal fractures** The authors advocate early internal stabilisation once the patient is well enough, with reduction or decompression if required. Specific management is tailored to the patient, neurological and radiological findings.

**Cervical fractures** Fractures of C1 may be caused by a vertical blow to the vertex of the head, resulting in at least two fractures of the ring of the C1 vertebra (Jefferson fracture). The fragments tend to displace outwards, and usually there is no neurological deficit. Jefferson fractures are usually managed by immobilisation in a halo brace or rigid collar, depending on the degree of instability. Fusion is usually achieved by immobilisation alone, and surgical fixation is rarely required.

Occasionally, rotation of a C1 facet may occur beyond the articular surface of the C2 facet below, resulting in rotatory subluxation and locking of the facet. This may occur because of trauma, in rheumatoid disease or may occur spontaneously, especially in children. Patients present with a characteristic 'cock robin' posture: rotation away from the dislocated side, slight flexion and lateral tilt towards the dislocated side, with contralateral spasm of the sternocleidomastoid muscle.

Reduction may be achieved by gentle traction and manipulation under anaesthetic, or if it is more long-standing, open reduction may be required, using the far lateral approach to the cranio-cervical junction.

Atlanto-occipital dislocation may occur with extreme longitudinal distraction, with or without horizontal dislocation of the cranio-cervical junction. This often results in cardiopulmonary arrest and death. Traction will worsen the situation. Treatment involves internal fixation

Fractures of C2 include the 'hangman's fracture' through the pars interarticularis of the C2 pedicles. The resulting spondylolisthesis is more commonly caused by hyperextension and axial loading during a road traffic accident. These fractures rarely cause a neurological deficit provided there is no significant dislocation, because the diameter of the spinal canal at C2 is effectively increased by the fracture. Instability is indicated by excessive subluxation or angulation of C2 on C3, which is exaggerated on flexion and extension X-rays. Reduction may be achieved by skull traction. Most of these fractures heal with immobilisation using a halo brace or rigid orthosis. Surgery is indicated if the fracture will not reduce adequately, if there is cord compression, or if fusion is not achieved by non-operative measures. The most common operation involves an anterior approach, C2–3 discectomy, fusion and insertion of an anterior plate.

Road traffic accidents and falls from a height are a common cause of odontoid fractures in young people. However, they may occur in older people by seemingly minor falls, hitting the forehead on the ground. Acute symptoms are usually pain and occipital neuralgia, but cervical myelopathy may occur with long-standing fractures and instability. They may be classified into three types:

- 1 Type I fractures are through the tip of the peg, are rare, and usually stable.
- 2 Type II fractures are through the base of the peg, and are unstable. These are the most common peg fractures, and the least likely to fuse with immobilisation alone.
- 3 Type III fractures involve the body of C2, are usually stable and heal with immobilisation alone.

Surgery is usually indicated in type II fractures with excessive displacement of the peg (>4–6 mm in any direction), in older age groups when spontaneous fusion is less likely, or with chronic non-union of the fracture. Within 6 weeks of the accident, a type II peg fracture may be fixed with anterior odontoid peg screws (Figure 16.16), but after longer intervals soft tissue becomes interposed between the bone fragments and posterior C1–2 fixation and bone grafting is required (Figure 16.17). This latter operation will limit cervical rotation by 30%.

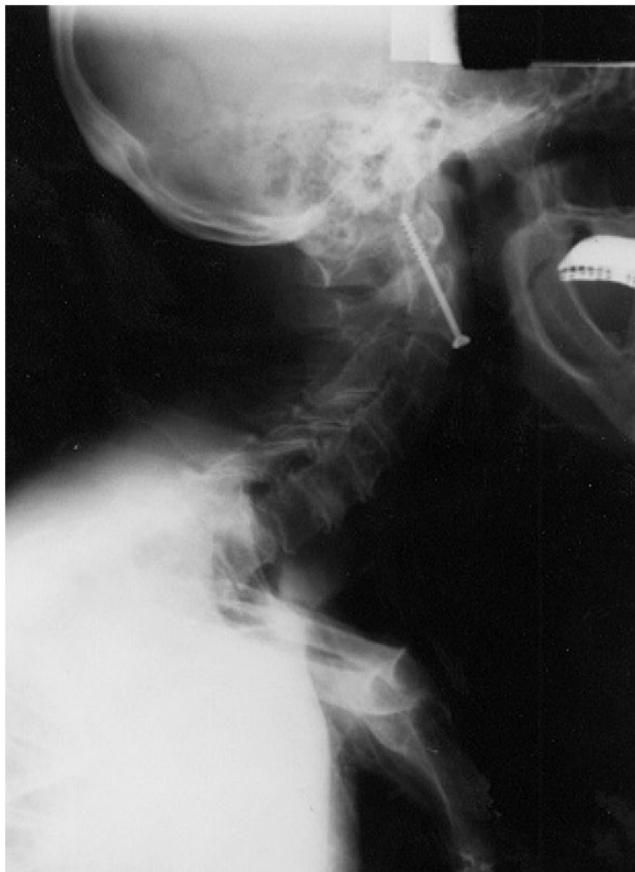

Injuries associated with hyperflexion and rotation of the neck can result in a unilateral facet joint dislocation in the subaxial cervical spine. This does not usually cause neurological deficits, nor is instability seen on flexion–extension X-rays. However, extreme hyperflexion injuries may result in bilateral dislocation of the facet joints, usually associated with more extensive disruption of joint capsules, discs and posterior ligaments. CT scanning should be performed to inspect the integrity of the facets, and traction is used to reduce bilateral dislocations. If traction is unsuccessful, then open reduction is required, either by an anterior or posterior approach, followed by fixation and bone graft fusion.

**Thoracolumbar fractures** The stability of thoracolumbar fractures is well described by the Denis three-column model. The spine is considered as three columns of stability: the anterior, middle and posterior columns. The anterior column consists of the anterior half of the vertebral bodies, discs and the anterior

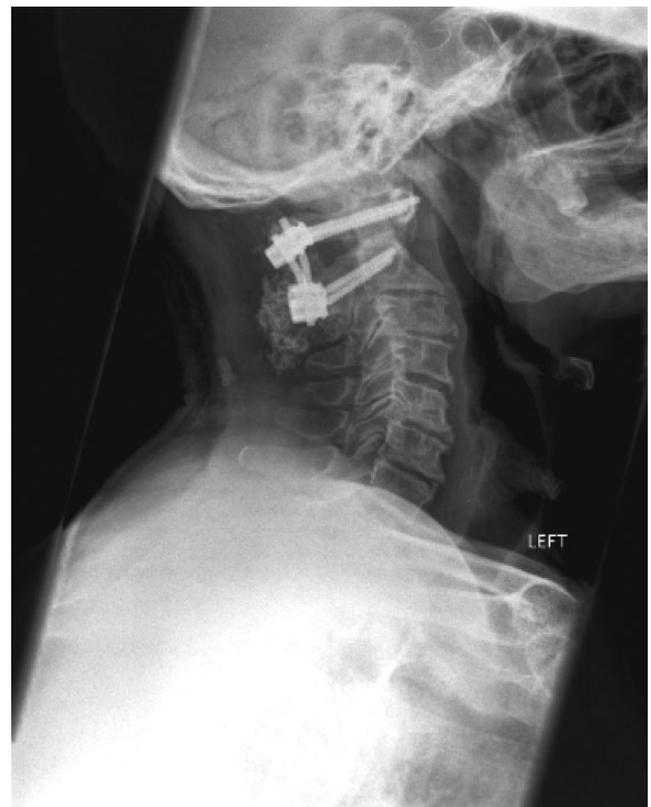

longitudinal ligament. The middle column includes the posterior half of the vertebral bodies, discs and the posterior longitudinal ligament. The posterior column is made up of the facet joints, joint capsules, laminae, spinous processes and adjoining ligaments. Disruption of two of the three columns is considered to be mechanically unstable and probably requires operative fixation, whereas disruption of a single column is likely to be stable and can be treated with bed rest. If surgery is required, posterior instrumentation with pedicle screws is the most common fixation technique, although thoracotomy or retroperitoneal approaches are sometimes required for stabilisation of the thoracic and lumbar spines, respectively.

#### *Non-surgical management of spinal trauma*

**Whiplash injury** Whiplash is a traumatic injury to the cervical soft tissues (including joint capsules, ligaments and muscles) resulting from hyperflexion or hyperextension, in the absence of fractures or instability. Symptoms of pain usually start several hours after the injury, and may be associated with tension headache and poor concentration. Diagnosis is by exclusion of instability, disc herniation or spinal cord injury. The extent to which the symptoms have an organic basis is controversial and medico-legal practice is swamped with claims of disabling symptoms caused by whiplash many of which probably have no justification. It is interesting to note the findings of a Lithuanian study, where few drivers have insurance and disability compensation is unlikely. In this survey there was no significant difference in the incidence of chronic neck pain in people who were involved in a road traffic accident and the general population.

**Figure 16.16** Lateral cervical X-ray showing a screw inserted to stabilise an acutely fractured odontoid peg.

**Figure 16.17** Lateral cervical X-ray showing C1–2 fixation for chronic odontoid peg fracture.

**Rehabilitation** Rehabilitation is covered in detail in Chapter 18. The primary goal of rehabilitation should be to increase functional capability, especially in walking and standing. Weight-supported treadmill training has shown promise in partial spinal cord lesions. In contrast to studies in the cat, at present there is little evidence in humans for a spinal central pattern generator that in the absence of descending control will drive limb movements and posture capable of supporting functional gait. Spinal pattern generators are favourably influenced by afferent feedback from the limbs and centrally by neurotransmitters, especially adrenergic transmitters. This raises the possibility that functional gains in spinal cord injured humans can be achieved through use of treadmill training supplemented by afferent stimulation and adrenergic drugs.

**Long-term care of spinal cord injured patients** This is considered in more detail in Chapter 18. Complications of long-term management include pressure sores, autonomic dysreflexia, spasticity, syringomyelia, deep vein thrombosis and respiratory problems. Regular turning and good standards of nursing care, physiotherapy, compression stockings, subcutaneous low molecular weight heparin and antispasmodic medications minimise these risks. Autonomic dysreflexia is an exaggerated response to normally innocuous stimuli, occurring in patients with spinal cord injury above T6, and resulting in tachycardia, hypertensive surges, sweating, anxiety and headache. The most common causes are bladder distension, faecal impaction, urinary tract and other infections, tight clothing and mild pain (pressure sores or ulcers). Treatment involves identifying and eliminating the stimulus, and pharmacological control of blood pressure and anxiety if required.

### Spinal tumours

Spinal tumours may be benign or malignant, primary or secondary (Chapter 21). Consideration should always be given to the tissue of origin. Most spinal tumours are metastatic malignant tumours. Breast, bronchus, kidney, prostate, thyroid, multiple myeloma and malignant melanoma are the most primary sites.

Tumours can also be categorised by their anatomical location (i.e. extradural or intradural). Intradural tumours may be extramedullary or intramedullary (Tables 16.7 and 16.8). Intramedullary spinal cord tumours account for approximately 2% of adult and 10% of paediatric CNS neoplasms. In adults, 85–90% of intramedullary tumours are astrocytomas or ependymomas. Ependymomas

account for approximately 60–70% of all spinal cord tumours found in adults, while in children 55–65% of intramedullary spinal cord tumours are astrocytomas. Haemangioblastomas account for 5% of tumours, whereas paragangliomas, oligodendrogliomas and gangliogliomas account for the remainder. Astrocytomas and ependymomas are more common in patients with neurofibromatosis type 2, which is caused by mutations in the *NF2* (neurofibromin 2 or Merlin) gene (over 200 different mutations have been described). Spinal haemangioblastomas occur in 30% of patients with von Hippel–Lindau syndrome, an autosomal dominant condition caused by mutations in the *VHL* (von Hippel–Lindau tumor suppressor) gene on 3p25.3.

Intradural tumours are now dealt with by microsurgical excision. This is aided in certain cases by the use of an ultrasonic aspirator where an en bloc excision is not feasible. Spinal cord monitoring using somato-sensory evoked potentials and motor evoked potentials improves the operative safety margin.

Ependymomas are usually resectable. Primary astrocytomas can occasionally be completely resected. Surgical excision is easier in children than adults. Complications for intramedullary tumours are common with most patients experiencing short-term neurological deterioration. The role of radiotherapy for intramedullary tumours is controversial. Repeat surgery should probably be considered first for tumour progression. Many of these tumours are slow growing so treatment effects are difficult to judge. In Brotchi's series of 239 patients with low-grade spinal tumours, 5% worsened, 50% stabilised and 40% improved. A patient's neurological function after surgical intervention depends on his or her pre-operative neurological condition. The goal of surgery is to prevent further neurologic dysfunction and to cure the neoplastic condition with complete resection.

Neurofibromas (schwannomas) are relatively easy to remove, with very low morbidity. This is because schwannomas usually arise from the sensory nerve root and the resulting spinal compression is slowly progressive.

Meningiomas arise from the meninges (Figure 16.18), are more common in women and most often affect the thoracic region. Surgical results are generally very good. Operative morbidity most commonly arises from dural defects producing leakage of CSF. Radical excision of the dural origin of the tumour will give the best chance of cure, minimising the risk of tumour recurrence.

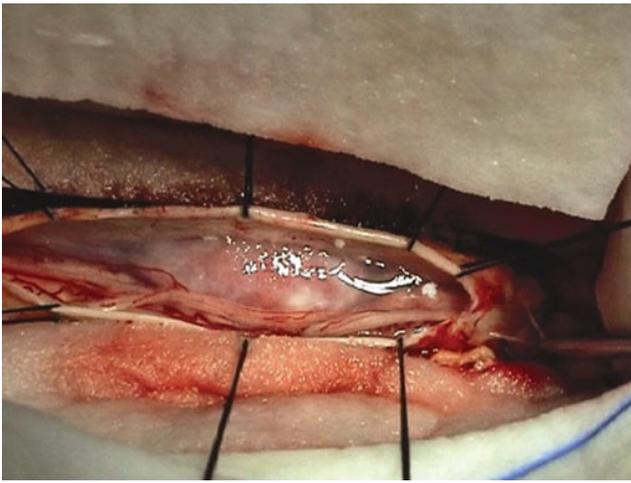

**Metastatic spinal tumours** Secondary bone tumours are becoming more common, partly as a result of an increasingly ageing population, and partly because of better treatments and longer survival for the primary tumour types. The goal of treatment for metastatic spinal tumours is to improve quality of life and functional independence,

**Table 16.7** Classification of intradural intramedullary spinal tumours.

Tumour type	Incidence in adults
Ependymoma	65%
Astrocytoma (fibrillary or pilocytic) WHO 2	30–35%
Glioblastoma WHO 4	1.5%
Haemangioblastoma (25% of patients have von Hippel–Lindau)	1–3%
Other glial tumours (Oligodendroglioma, ganglioglioma)	Very rare
Metastases	Rare
Cavernomas	Rare

**Table 16.8** Classification of intradural extramedullary tumours.

Meningioma
Neurofibroma/schwannoma including dumb-bell tumours
Paraganglioma
Metastatic including leptomeningeal disease
Arachnoid cyst
Perineural cysts including Tarlov cysts
Epidermoid

**Figure 16.18** Operative photograph of intradural microscopic exploration of spinal meningioma with overlying arachnoid intact. Stay sutures hold dura open, tumour arises from anterolateral dura mater.

rather than a definitive removal of the spinal tumour. Life expectancy is not generally increased by treating metastatic spinal tumours, but quality of life can be improved by treating spinal pain, instability or neurological compression. It is important to balance the potential gain in quality of life provided by surgery, chemotherapy and/or radiotherapy, with the known side effects of these treatments which are not insignificant, taking into account the prognosis and opinion of the individual patient.

Historically, surgery involved laminectomy for resection of posterior elements and extradural tumours. While this approach decompressed the spinal cord it further destabilised the spinal column. Most tumours metastasise to the vertebral body and therefore resection of the posterior elements removes the only sound bone in the vertebral complex therefore leading to instability, and deformity with ensuing neurological deterioration and pain. Findlay (1984) found that surgery (laminectomy) provided no better results than radiotherapy alone, and was associated with more complications. However, in a multi-centre randomised controlled series, Patchell *et al.* have recently demonstrated that surgery and radiotherapy are superior to radiotherapy alone. This study was stopped after planned interim analysis showed superiority of the surgical treatment arm. Outcome measures included pain, ambulation, neurological recovery and bladder control. All outcomes were better with surgical treatment. Other studies have shown surgery should precede radiotherapy. Radiotherapy followed by surgery is associated with a doubling of wound complications breakdown or infection.

**Spinal manifestations of neurofibromatosis type 1** Neurofibromatosis is dealt with elsewhere in this book (Chapter 26) but its spinal manifestations are especially important and so are outlined here. These include various tumour types but also varied and complex spinal deformities (kyphoscoliosis) and dural ectasia.

**Neurofibromas** The typical spinal nerve sheath tumours seen in neurofibromatosis type 1 (NF1) patients are benign neurofibromas. They consist of fibroblasts, nerve sheaths and nerve cells. The nerve cells are incorporated into the tumour mass, which complicates surgical removal of the tumour. The spinal nerve root neurofibromas in NF1 are often asymptomatic. A rapid increase in size may be a

sign of malignant change, albeit a rare complication; less than 5% of patients with NF1 develop neurofibrosarcomas. In most instances, malignant progression of the fibroblast component appears to be responsible for the development of malignancy, and molecular genetic studies suggest that inactivation of the p53 tumour suppressor gene is an important factor in the sarcomatous progression of neurofibromas.

Fusiform neurofibromas of spinal nerves are usually bilateral, extend to the branch fibres of the nerve and exceed 30 cm in length. They are seen on CT scans as tumours of low attenuation with areas of higher density, which enhance with intravenous contrast medium. MRI shows nerve sheath tumours to be iso-intense or slightly hyperintense with respect to muscle on T1, enhanced T1 and T2 sequences. In approximately 50% of cases, a target pattern with a peripheral hyperintense rim and central low intensity may be seen. This pattern corresponds histologically to peripheral myxomatous tissue and central fibrocollagenous tissue. This pattern is absent in lesions with cystic, haemorrhagic or necrotic changes.

Benign nerve sheath tumours usually have intradural extramedullary location. They extend extradurally and have a dumb-bell configuration through the intervertebral foramen in as many as half of cases. Solitary tumours may involve individual nerves, or multiple nerves may be involved in a plexiform fashion. The tumours are usually multiple, appear at different levels and show different stages of growth. Plexiform neurofibromas involve long segments of the spinal nerves and extend into the spinal cord. They appear more frequently in the second and third decades of life, and the cervical and thoracic segments are primarily affected.

In 1999, Thakkar *et al.* reported 54 patients with NF1 aged 5–56 years and found spinal tumours in 65%. A tumour was discovered in almost all symptomatic patients and in 40% of asymptomatic patients. The site of the tumour was intramedullary in 6%, intraspinal extramedullary in 33% and intraforaminal in 57%.

**Lesions of the bony spine in NF1** Spinal and skeletal changes are observed in up to 71% of NF1 patients. They can be classified as:

- 1 Bony erosions caused by a tumour
- 2 Pressure damage from intradural, extradural and paravertebral nerve sheath tumours affecting mainly the intervertebral foramen and the spinal canal
- 3 Osteomalacia from a genetic tubular defect
- 4 Congenital abnormalities, such as macrocranium, and
- 5 Mesodermal dysplasias, such as pseudoarthrosis of the extremities, local gigantism and scoliosis.

Abnormal spinal curvature is detected in up to 40% of patients with NF1. The majority of cases develop problems between 11 and 16 years of age. A short segment of angular scoliosis with five or fewer vertebrae primarily involved, usually located in the lower thoracic region, is diagnostic of NF1.

Kyphosis of varying degrees is usually associated with NF1 scoliosis. Kyphosis has been considered a poor prognostic sign because of its tendency to rapid progression and resistance to all types of treatment. Localised or multi-level dural ectasia with enlargement of the spinal canal is also a relatively common finding in neurofibromatosis and is strongly associated with kyphoscoliosis. On X-ray, dural ectasia is associated with vertebral scalloping or concavity of vertebral bodies. The cause of dural ectasia may be a congenital weakness of the dura, in which case the constant pulsation of CSF causes progressive enlargement of the dural sac with resultant scalloping of the posterior portions of the vertebral bodies and erosion of the pedicles. Scalloping of bone may also result from

NF1-related primary bone dysplasia. The damaged vertebra result in disorders of spinal alignment and are interestingly not necessarily directly related to an underlying neurofibroma.

**Primary bone tumours** These are comparatively rare. They may be benign (e.g. aneurysmal bone cyst, osteoid osteoma, osteoblastoma) or malignant. Some tumours occur much more commonly in younger age groups (e.g. aneurysmal bone cyst or Ewing's tumour). Osteosarcoma has a bimodal age distribution affecting young children and older patients, the latter being associated with malignant changes in Paget's disease. The most common tumours are those arising from the bone marrow, particularly multiple myeloma. A more detailed description of these tumours is outside the remit of this chapter. A working classification is based on tissue origin with tumour types differentiated into bone forming, cartilage forming, giant cell tumours, bone marrow tumours, vascular tumours, other connective tissue tumours, other tumours and tumour-like lesions. The simplified list in Table 16.9 contains examples of each tumour type and is based on the World Health Organization (WHO) classification.

**Table 16.9** Modified World Health Organization (WHO) classification of primary skeletal tumours.

Tissue type	Examples of lesion type
Bone	Osteoma (B)
	Osteoid osteoma (B)
	Osteosarcoma – central and peripheral (M)
Cartilage	Chondroma (B)
	Osteochondroma (B)
	Chondrosarcoma (different types) (M)
Giant cell	Osteoblastoma (B)
Bone marrow	Ewing's sarcoma (M)
	Lymphoma (M)
	Myeloma (M)
Vascular	Haemangioma (B)
	Lymphangioma (B)
	Glomus tumour (B)
	Angiosarcoma (M)
Other connective	Fibroma (B)
	Lipoma (B)
	Fibrosarcoma (M)
	Liposarcoma (M)
	Leiomyosarcoma (M)
Other tumours	Neurofibroma (B)
	Neurilemmoma (B)
	Adamantinoma (M)
	Chordoma (M)
Tumour-like	Simple + aneurysmal cysts
	Fibrous dysplasia
	Eosinophilic granuloma

B, benign; M, malignant.

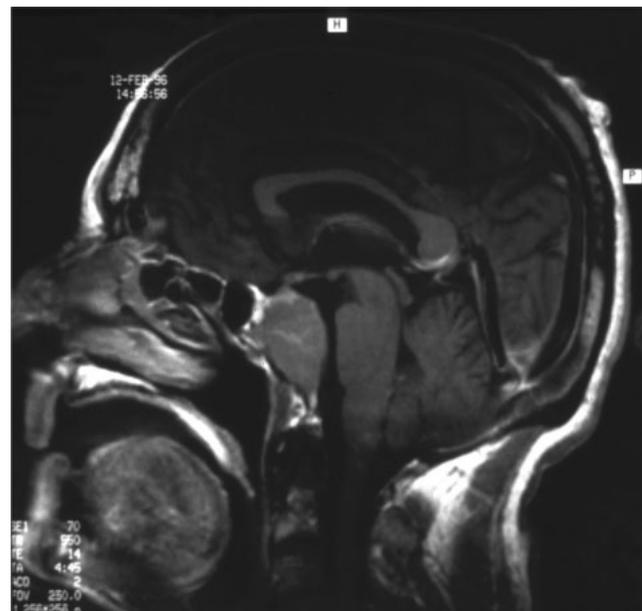

With the exception of Ewing's tumour, primary spine tumours are usually treated by excisional surgery. En bloc resection is useful for chordoma but is often not technically possible. Chordomas arise from the notochord remnants. The majority arise from the most rostral and caudal notochord remnants (craniocervical/clivus and sacral; Figure 16.19).

With the development of more reliable spinal fixation and reconstruction techniques, removal of the whole vertebra is now technically feasible either piecemeal or en bloc. However, in the cervical spine the vertebral artery prevents such an aggressive approach. In the thoracic and lumbar spine posterior en bloc resection is a favoured approach. Titanium mesh expandable cages or stackable carbon fibres cages allow reconstruction of the vertebral body. Spinal stability is also assisted by pedicle screw fixation (Figure 16.20)

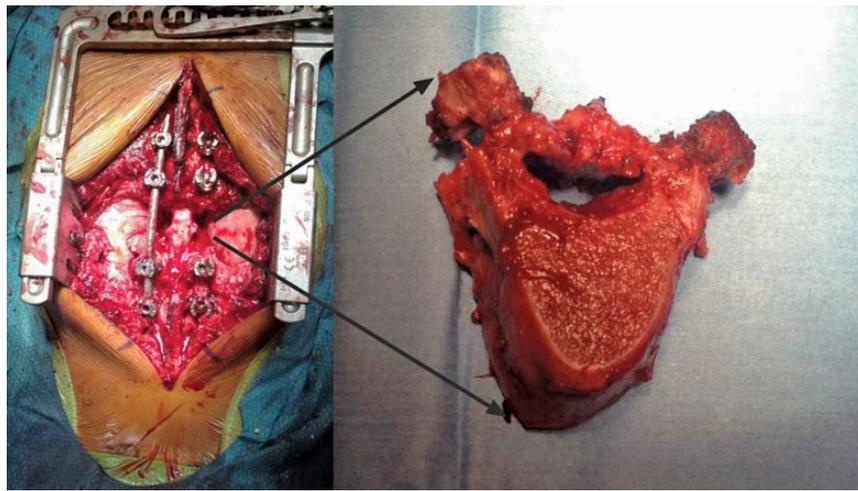

### Degenerative disease of the spine

**Cervical spine** Age-related degenerative disease in the cervical spine most commonly affects the mid cervical levels, reflecting the distribution of stress in the neck with upright posture and loading. In younger people, more movement occurs at C5–6 and C6–7 and these levels are the most commonly affected, whereas in older age groups C4–5 and C3–4 become affected in addition. Occasionally, involvement of the atlanto-axial joints and ligaments can produce instability and a soft tissue mass, or 'pseudotumour', in the position of the degenerate odontoid process. Cervical disc degeneration is associated with the formation of osteophytes around the annular attachments to the end-plates, with reciprocal degeneration and hypertrophy of the facet joints. Dehydration of the discs may result in reversal of the normal lordosis to produce a straight neck or even kyphotic deformity. Vertebral subluxations may occur.

Atlanto-axial instability may occur because of degenerative changes in the joints and ligaments at the cranio-cervical junction producing a pseudotumour around the degenerate odontoid process (Figure 16.21). When this occurs, treatment involves fusion of

**Figure 16.19** MRI showing clival chordoma.

**Figure 16.20** Showing spinal fixation and specimen.

**Figure 16.21** (a) Lateral cervical; spine with pathological collapse C3/4 disc space and C6 vertebra with retropharyngeal swelling. (b) T2- weighted sagittal MRI showing pre-vertebral swelling, kyphosis.

C1 and C2, with surveillance MRI to ensure the size of the odontoid mass does not increase. If the diagnosis is in doubt then a transoral biopsy should be taken. In the subaxial spine, osteophytosis can cause radiculopathy if stenosis of nerve root canals develops, or myelopathy if the spinal canal is sufficiently compromised.

Radicular pain usually follows a waxing and waning course, with intermittent exacerbations but, like lumbar radiculopathy, most symptoms of brachialgia settle down with time and surgery is often not required. Cervical myelopathy may occur because of disc herniation and osteophytic compression of the cervical cord. Furthermore, the anterior horn cells of the cervical expansion are affected by direct compression, arterial insufficiency, venous

congestion, repetitive minor trauma or a combination of these events. In general, 25% of patients with spondylotic cervical cord compression remain static, but 75% progressively deteriorate.

#### *Non-surgical management of cervical degenerative disease*

Treatment of musculoskeletal axial spinal pain initially involves removing exacerbating factors such as heavy lifting, and improving posture and muscles of core stability with physiotherapy and allied techniques. The patient should be encouraged to stay active with gentle exercise, such as walking, as far as possible. Simple back pain is usually self-limiting, and the majority of patients improve within a few weeks with conservative measures. Paracetamol and non-steroidal

anti-inflammatory medication are helpful, and occasionally stronger analgesics or benzodiazepine muscle relaxants may be required for short durations. Acupuncture, transcutaneous electrical nerve stimulation (TENS), ultrasound, heat or cold treatments, massage, hydrotherapy, chiropractic treatment or osteopathy may also be useful. If back pain persists for more than 6 weeks, the patient should be reviewed by a clinician to exclude other causes of pain including neoplasia, arthritides, osteoporotic fractures, infection or nerve root compression. Persistent mechanical pain may be treated with steroid injection to the facet joints, nerve roots, or epidural space depending on the presenting features and MRI findings.

Spinal cord or nerve root compression may require surgical management. Spinal cord compression (e.g. because of cervical disc prolapse) is likely to require decompression because patients tend to deteriorate with time. However, nerve root compression is common with increasing age and is not always associated with pain. Decompression should be performed for persistent or severe radicular pain that does not respond to conservative measures. The evidence for the benefit of nerve root decompression for the treatment of motor radiculopathy (in the absence of pain) is unclear.

**Surgical management of cervical degenerative disease** For cervical degenerative disease, surgery may be considered if symptoms fail to improve after 2–3 months, or if neurological signs progress. Surgery to decompress cervical roots may be by anterior or posterior approaches. Anterior cervical discectomy with decompression of the nerve roots is performed if there is any coexistent cord compression, or if the majority of root compression is caused by disc prolapse. Posterior foraminotomy is a simpler operation that may be used if there is no cord compression. This approach avoids the small risk of recurrent laryngeal nerve palsy that may occur with anterior operations, and does not require fusion of a motion segment, but is associated with more postoperative neck pain in the short term. There is an overall risk of spinal cord or nerve root injury during surgery, in approximately 1% of patients to varying extents, and this together with other possible complications need to be taken into consideration when deciding to proceed with surgical treatment.

In cervical myelopathy it is common to observe an initial deterioration followed by a period of stabilisation, but most patients will later progress further if untreated. The main aim of surgery is to prevent deterioration; however, improvement can occur. Surgical treatment may be performed anteriorly, by cervical discectomy and sometimes corpectomy, or posteriorly by laminectomy or laminoplasty. The method of decompression depends on the degree of lordosis or kyphosis of the spine, the main cause of the cord compression and surgeons' preference. If the cord compression is mainly caused by a disc prolapse in a kyphotic neck, then anterior decompression is preferable. Compression from hypertrophy of the ligamentum flavum in a lordotic neck is best treated by posterior decompression. After laminectomy there is a risk of progressive kyphosis because of removal of the posterior tension-band elements of the cervical spine, leading many surgeons to adopt the technique of spinal canal augmentation by laminoplasty which was originally developed in Japan for treatment of patients with ossification of the posterior longitudinal ligament

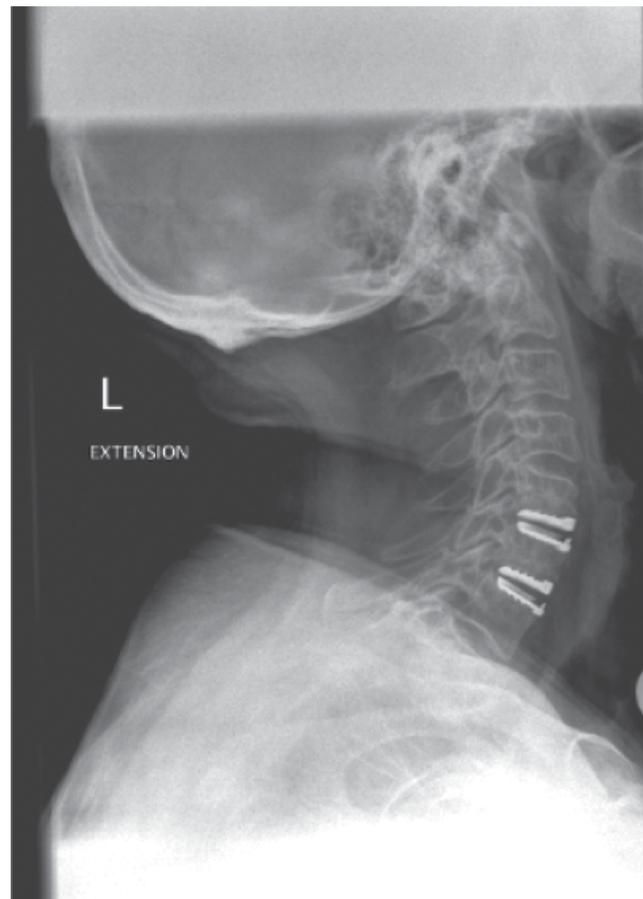

The overall results of anterior and posterior decompressive surgery for myelopathy are similar, although it should be remembered that the indications for each approach are different and therefore

not directly comparable. After laminectomy in one series, 56% of patients improved, 25% were unchanged and 19% slightly worse, and with anterior decompression 75% of patients improved.

Fusion after cervical discectomy has been the standard treatment for a number of years, but there is an increased incidence of accelerated degenerative disease in adjacent discs, because of the added mechanical stresses placed on adjacent discs after fusion of a previously mobile segment. Within 10 years of fusion, around 29% of adjacent discs will degenerate and require surgery. To avoid this complication, a number of different artificial disc implants have been developed that do not restrict movement after anterior decompression, and thereby minimise the development of adjacent segment disease (Figure 16.22). The short-term results of artificial disc implants have been favourable, but in the longer term it is unclear as to whether they will require replacement within a lifetime.

(a)

(b)

**Figure 16.22** (a) Photograph of artificial cervical disc implant. (b) Lateral cervical spine X-ray showing artificial disc implants at two levels.

**Thoracic spine** Degenerative disease in the thoracic spine is less common than in the cervical and lumbar spine because of the decreased movement that occurs at thoracic levels. Thoracic disc prolapses account for only 0.5% of all disc prolapses and usually occur in younger age groups (third to fifth decades) at T8–12 levels. Patients often present with a history of chronic pain with only subtle sensory or motor changes.

**Surgical treatment of thoracic disc disease** In symptomatic patients, discectomy is performed by an anterolateral approach, most commonly by thoracotomy. Direct posterior approaches are associated with a high risk of mechanical cord damage and should be avoided, although in some cases a posterolateral approach (transpedicular or costotransversectomy) may be appropriate. The spinal fusion is achieved in a similar way to cervical spine surgery if required.

**Lumbar spine** Lumbar canal stenosis may occur because of acquired degenerative changes such as hypertrophy of facet joints, ligamentum flavum, disc prolapse or spondylolisthesis, or congenital causes such as achondroplasia. If the spinal canal cross-sectional area diminishes below a critical value then radicular symptoms or neurogenic claudication may occur, either because of direct compression or ischaemia of nerve roots. Neurological examination may be normal, including straight-leg raising. The natural history if untreated is a slowly progressive course with most symptoms remaining the same, or gradually worsening over the next few years after diagnosis. Treatment is by laminectomy with or without discectomy; 60–80% of claudication improves after surgery.

Lumbar disc prolapse is a common cause of radicular leg pain, and is present in 1–3% of people with lower back pain. Approximately 80–90% of patients with radicular leg pain improve over the following few months without surgery. Long periods of immobilisation should be discouraged and gentle mobilisation and exercise can aid recovery. ‘Red flags’ of urinary incontinence, urinary retention, faecal incontinence, peri-anal numbness and leg weakness should prompt urgent referral for an MRI scan to exclude a central disc prolapse and cauda equina compression. Otherwise, unless the pain is refractory to medical treatment, 2–3 months of pain management is recommended before consideration of surgery.

The L4–5 and L5–S1 vertebral discs are the most common levels of disc prolapse. They produce L5 and S1 radiculopathies, respectively. A disc prolapse more commonly involves the nerve root of the level below. For example, at L4–5, although the L4 nerve root exits at that level, it has already exited lateral to the common position of a disc bulge and will not be caught by it unless the bulge is more laterally placed. Instead, the L4–5 disc bulge will usually catch the L5 nerve root *en passant*.

**Surgical treatment of lumbar disc disease** Lumbar microdiscectomy is the standard surgical technique for removing disc prolapses, although percutaneous techniques (using laser, thermocoagulation, chymopain or mechanical disruption with a nucleotome) and minimally invasive techniques are now sometimes used with limited efficacy. In a randomised controlled trial of microdiscectomy versus non-surgical therapies, surgically treated patients had better outcomes at 1 year, but the difference was not significant by 4 and 10 years.

### Low back pain and degenerative disc disease

Low back pain affects 70–85% of population at some point in their lives, with an incidence of 15% and point prevalence of 30%. The primary risk factor is age-related degenerative changes in

the lumbar spine. The intervertebral discs in particular show degeneration which can be appreciated as loss of hydration on MRI. By the age of 50 years 90% of the population show loss of hydration of the nucleus pulposus.

The disc comprises the nucleus pulposus, a gelatinous structure surrounded by the annulus fibrosus. With ageing there are changes in the collagen matrix, loss of hydration, apoptosis and loss of the blood supply. The hydrostatic mechanisms for dissipation of force are lost. This, coupled with weakening of the annulus, leads to an increased risk of rupture of the nucleus pulposus through the annulus fibrosus. This is most likely to occur during loading of the spine in flexion and torsion. Importantly, the nucleus pulposus is likely to be an immune privileged site. The evidence for this is that it expresses the FAS ligand like other immune privileged tissues, which induces apoptosis of FAS-positive invading T cells. The annulus fibrosus and notochord elements do not express FAS ligand. Extrusion of the disc into the epidural space sets up an intense inflammatory process with autoimmune reaction and inflammatory cell infiltration. There is a resulting increase in inflammatory cytokines especially interleukin 1, tumour necrosis factor  $\alpha$  (TNF- $\alpha$ ), interleukin 6 along with increased levels of prostaglandin E2. In degenerate discs there is an increase in matrix metalloproteinases (MMPs). MMPs are zinc-dependent enzymes that are involved in modelling of connective tissue. Experimental data implicates MMPs 1 and 2 in the pathogenesis of disc herniation. Ultimately, spontaneous resorption of herniated disc material may occur as the result of action of MMPs and cytokines.

The pain in degenerative spinal disease results from a variety of interacting mechanisms. A major contributor to the pain is the inflammatory response evoked by the disc herniation. There are important nociceptive contributions from the facet joints, vertebrae, muscles, ligaments and fascia. Nociceptive pathways involve the sinovertebral nerve, which arises from the ventral root and grey rami near the dorsal root ganglion to innervate a number of structures, particularly the posterior longitudinal ligament. There is also a nociceptive contribution from the dorsal root ganglion.

**Management of lower back pain** Pain may be managed by conservative and surgical methods. If radicular pain is very severe, then bed rest may be advised to minimise loading of the lumbar spine and nerve root foramina, with analgesia (including paracetamol and non-steroid anti-inflammatory drugs), and sometimes benzodiazepine muscle relaxants. However, prolonged bed rest beyond 3–4 days should be discouraged because it is usually associated with a worse outcome than a gradual return to normal activities and work. Heavy lifting, prolonged sitting and abnormal postures should be discouraged, and a program of gentle exercise and education established, often supplemented with physiotherapy. Correct posture, sleeping position and lifting techniques are important.

Chiropractics and osteopathy, acupuncture, epidural steroid and facet joint injections may help in the short term, but there is little evidence of long-term benefits. Spinal manipulation should not be performed in the presence of severe or progressive neurological deficit.

Surgical lumbar fusion is accepted practice in the presence of instability resulting from tumour, trauma, infection or degenerative disease, but its use for mechanical back pain alone is controversial. A randomised controlled trial comparing surgical fusion with an intensive rehabilitation programme revealed improvements in both groups after treatment, but no significant difference between surgery and rehabilitation. Whereas surgical fixation was associated with an improved outcome, there is limited evidence to support the

use of surgery in the absence of instability. In fact, surgical fusion of a mobile segment is associated with exaggerated adjacent disc disease in 20% of patients over the next 10 years after surgery. This has stimulated interest in artificial disc replacements, such as the 'ProDisc' and 'Charite' prosthetic lumbar discs, which have been associated with good outcomes in back pain and patient satisfaction after 2 years from operation. However, recent reports suggest that some of these disc replacements actually result in a fusion anyway, without changing the patient outcome.

### Spinal infections

All components of the spine are vulnerable to attack by bacterial, fungal, viral and parasitical infections. The structures involved include the vertebral column, most commonly the intervertebral disc (discitis) and the vertebra (osteomyelitis). Infection can spread to the extradural space with abscess formation and the intradural contents can also be affected. Intramedullary infection is very rare. Further detailed discussion of infectious disease of the nervous system and spine can be found in Chapter 9.

**Bacterial infections of the spine** In adults, lumbar bacterial infections often originate from urinary tract infections which drain via the Batson venous plexus. The respiratory system is a common source of blood-borne infection with spinal infection usually following the initial infection by some 1–8 weeks. Purulent material may break out of cortex of the bone anteriorly to form a paravertebral abscess or posteriorly to form an epidural abscess. Infection-related weakening of the bone may cause vertebral body collapse. Haematogenous osteomyelitis is seen more often in children than in adults. This is believed to be because the epiphyseal plate present in the growing skeleton of a child and absent in adults is more vulnerable than mature bone to blood-borne infection. Risk factors for bacterial spinal infection include an immunocompromised state, including diabetes, TB, HIV, malnutrition and intravenous drug use.

The risk factors for bacterial discitis are the same as those for osteomyelitis. Iatrogenic cases occur after disc surgery, therapeutic injections, lumbar puncture and epidural anaesthesia. The most common organism is *Staphylococcus aureus*, particularly *Staphylococcus epidermidis*. Methicillin-resistant *Staphylococcus aureus* (MRSA) can occur. *Streptococcus viridans* is the next most common infecting organism.

**Treatment of pyogenic discitis and spinal osteomyelitis** Blood cultures often identify the infecting organism and guide appropriate antibiotics use. Because of difficulty in obtaining a culture from blood, CT-guided biopsy of the infected area should always be considered prior to antibiotics. Epidural abscesses are usually considered to be a surgical problem but in a debilitated patient with a small thin abscess and a bacteriological diagnosis-appropriate antibiotic, chemotherapy alone is a reasonable approach.

Antibiotics are given for variable lengths of time and 2–3 months of parenteral therapy may be required. Before parenteral antibiotics are discontinued, the erythrocyte sedimentation rate (ESR) should have fallen to at least two-thirds of the pre-treatment level. In addition, the patient should be afebrile, without pain on mobilisation, and ideally improving from disease-related neurological complications. A persistently high ESR or C-reactive protein implies continuing infection, and additional intravenous antibiotics are indicated. In such an instance, additional biopsies for microbial culture may need to be taken.

Bracing or other forms of orthosis is strongly recommended to provide stability for the spine while the infection is being treated and the tissues are healing. The goal of spinal immobilisation is to provide opportunity for the affected spinal level(s) to fuse in an anatomically aligned position. Bracing is usually continued for 6–12 weeks, until either a bony fusion is seen on radiography or until the patient's pain subsides. A rigid brace is optimal and only need be worn when the patient is upright or mobile. Surgical fixation may be required if mechanical instability develops, or if the infection is refractory to conservative measures.

**Spinal tuberculosis** *Mycobacterium tuberculosis* (TB) of the spine is an uncommon form of tuberculosis occurring in less than 1% of patients with tuberculosis. TB typically first affects the intervertebral discs. The primary risk factors for TB infection in the United Kingdom are ethnicity and/or immunocompromise.

TB infection typically presents with local pain, fever, night sweats and general ill health including weight loss. If the disease spreads from the disc into the vertebral body osteomyelitis will occur with epidural abscess formation and/or vertebral body collapse. Pathological fractures will cause pain, deformity (kyphosis) and in some cases spinal cord compression.

The diagnosis is difficult in patients with no evidence of extraspinal TB. The clinical presentation together with the radiological appearances (plain X-ray, CT and MRI scan) of spinal TB and a positive tuberculin test usually suggest a diagnosis of spinal tuberculosis.

In Pott's disease, the spinal cord may become involved either because of compression by disrupted bone and/or disc and ligaments, expansion of a TB abscess or by direct invasion of cord and leptomeninges by granulation tissue. Primary tuberculoma of the spinal cord is rare. Neurological deficits when present usually develop gradually. A positive diagnosis is made from detection and culture of acid-fast bacilli from the bone or body fluids. Polymerase chain reaction (PCR) detection of mycobacterium DNA may speed the diagnosis but initiation of effective treatment should not be delayed if the clinical index of suspicion is high.

With the advent of effective combination chemotherapy in the early 1950s, the mortality rate among patients with spinal TB decreased from nearly 100% to 3%. It is important to note that while triple and quadruple therapy drug regimens remain highly effective for most cases of spinal TB, in immuno-compromised patients, especially those with HIV/AIDS, drug-resistant TB is an increasing problem.

**Role of surgery in spinal tuberculosis** The initial procedure introduced for the surgical treatment of spinal infections was laminectomy. However, this procedure did not allow access to anterior abscesses and contributed to spinal instability, which often resulted in progressive deformity. In 1960, Hodgson and Stock extensively reported on this procedure in the treatment of TB of the spine. Late spinal deformity was prevented with spinal fusion and instrumentation. The need for an anterior approach (by thoracotomy) was stimulated by the failures of posterior fusion in some of their patients, many of whom had TB involving four to eight vertebrae and such pronounced kyphosis as to make posterior fusion mechanically unsound. The current surgical management of spinal TB requires of radical débridement and anterior fusion. The anterior approach gives a wide access to the disease. The removal of all avascular bone is essential to ensure rapid sound bone fusion. Anterior fusion by bone transplantation after a thorough excision of the disease focus is successful in a very high proportion of cases.

The Medical Research Council (MRC) examined the role of surgery for spinal TB with antibiotic chemotherapy versus antibiotic chemotherapy alone. The first MRC trial, published in 1974, of the treatment of spinal TB revealed equivalent results at 5 years when chemotherapy alone was compared with radical surgical treatment combined with chemotherapy. The primary advantage of anterior spinal arthrodesis was a decreased tendency for progression of deformity. The role of surgery for spinal TB has been re-examined in a recent Cochrane review which concluded that the data were insufficient to be clear whether surgery with chemotherapy is better than chemotherapy alone. However, it is very important to note that very few patients in the MRC trial were neurologically affected. Furthermore, it is important to appreciate that the surgical approach analysed by the original MRC trials is not comparable to modern spinal surgery performed by specialist spinal surgeons with high-quality spinal instrumentation, modern anaesthesia, intraoperative neurophysiological monitoring with decisions informed by neurologists and infectious diseases specialists and by modern radiology (MRI and CT scanning). Surgery may be indicated in certain subgroups of patients, particularly those presenting with a significant neurological deficit, with progressive neurological deficits, those who develop neurological deficits on appropriate antibiotic therapy and those with an initial kyphosis angle greater than 30°, especially in a child with further skeletal growth potential.

**Fungal infections** Fungal infections of the spine are rare. Fungi such as *Cryptococcus*, *Candida* and *Aspergillus* are found worldwide, whereas *Coccidioides immitis* and *Blastomyces dermatitidis* are limited to specific geographical areas. *Aspergillus* and many *Candida* species are normal commensals of the body and produce disease in susceptible individuals when they gain access to the vascular system through intravenous lines, during implantation of prosthetic devices or during surgery. Other fungi produce spinal involvement usually as a result of haematogenous or direct spread of organisms from an initial pulmonary source of infection. Involvement of the vertebral bodies can lead to vertebral compression fractures and gross deformity of the spine. Spread of infection along the anterior longitudinal ligament can lead to psoas or paravertebral abscesses, similar to tuberculosis. Recognition of the disease requires a high index of suspicion, proper travel history and a detailed physical examination. Treatment relies on the early and effective pharmacotherapy and constant monitoring of clinical progress and is discussed in Chapter 9. Resistance to medical therapy, spinal instability and neurologic deficits are indications for spinal débridement and stabilisation with spinal fusion. Prognosis depends on the pre-morbid state of the patient, the type of fungal organism and the timing of treatment. Immuno-compromised patients fare badly.

**Acute viral infections** These are covered in greater details in Chapter 9. Acute myelitis may result from direct infection with a number of virus including the herpes group (herpes simplex virus 1 and 2, herpes zoster virus, cytomegalovirus and Epstein-Barr virus), enteroviruses and, especially in the United States, the flavivirus family.

**Subacute infections** These subdivide into bacterial viral and other. Typically, pyogenic bacterial infections are acute or subacute. Tuberculosis, syphilis, fungal infections, Lyme disease and *Mycoplasma* are subacute or chronic.

Specific viral infections causing myelopathy are human T-cell lymphotropic virus 1 and 2 (HTLV-1 and 2) and HIV.

Para-infectious and post-vaccine myelopathies have been described following exposure to herpes zoster virus, *Mycoplasma*, mumps, hepatitis B and rabies.

**Chronic viral infections of the spinal cord** Tropical spastic paraparesis (TSP) is a viral infection of the spinal cord that causes weakness in the legs due to HTLV-1 and 2 retrovirus. Symptoms may begin years after infection. In response to the infection, the body's immune response may injure nerve tissue, causing symptoms that include neurogenic bladder problems, leg pain and loss of feeling in the feet, tingling sensations and unpleasant sensations when the skin is touched. Patients with TSP may also exhibit uveitis, arthritis, pulmonary lymphocytic alveolitis, polymyositis, keratoconjunctivitis sicca and infectious dermatitis. Some factors that might have a role in transmitting the disorder include being a recipient of transfusion blood products (especially before 1989), breast milk feeding from a seropositive mother, intravenous drug use or being the sexual partner of a seropositive individual for several years. Not every HTLV-1 seropositive carrier will develop TSP; fewer than 5% will exhibit neurological dysfunction or, eventually, haematological malignancy such as adult T-cell leukaemia/lymphoma.

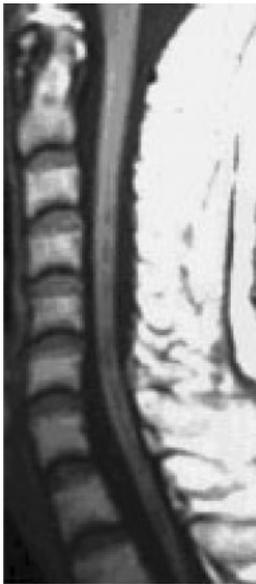

**Treatment of tropical spastic paraparesis** Initial trials of treatment using antiretroviral drugs have not produced neurological improvement nor have they convincingly shown a slowing of disease progression. Essentially there are two approaches. The first is to try to inhibit viral replication. This has been attempted with antiviral drugs: the reverse transcriptase inhibitor zidovudine (AZT) and the cytosine analogue lamivudine alone and in combination. However, in contrast to HIV, the virus replicates without the need for reverse transcription and although these drugs can produce a reduction in HTLV-1 pro-viral load, little clinical response was seen in a randomised double-blind placebo controlled trial of Combivir (zidovudine + lamivudine). The second approach has been to suppress the immune response both with steroids, steroid-sparing drugs and interferon-1 $\alpha$ . Although short-term improvements have been noted, no sustained clinical improvement or measurable reduction in disease progression is yet reported in rigorous analysis of the effects of these approaches. Future trials are in progress and are planned to assess the affects of ciclosporin, anti-TNF $\alpha$  and alemtuzumab (Campath 1H).

There are numerous acute viral causes of transverse myelitis which are discussed in the following section and in Chapter 9.

### Spinal cord inflammation

**Devic disease (neuromyelitis optica)** There is strong evidence that this disease is a separate entity from multiple sclerosis. It is characterised by episodes of myelopathy and optic neuropathy which are often severe. It is more common amongst the Japanese. The involvement of optic nerve and spinal cord is selective. The condition is discussed in Chapter 11. In the spinal cord the critical radiological differential diagnosis is from multiple sclerosis. It is strongly suspected if there is a contiguous segment of central spinal cord inflammation extending over three or more vertebral segments.

A Devic-like syndrome is also described in association with other autoimmune diseases including systemic lupus erythematosus (SLE). Neurological sarcoidosis may also present with a Devic-like picture of spinal and optic nerve inflammation (Figure 16.23). In these conditions there is a myelitis sometimes associated with optic neuropathy. Often, extensive investigation is required to look for evidence of SLE, CNS sarcoid, Behçet's disease, vasculitis,

**Figure 16.23** Sagittal MRI of cervical cord (T1-weighted) showing extensive intrinsic cord lesion with cavitation in case of Devic's disease.

infectious and para-infectious myelitis including acute disseminated encephalomyelitis (ADEM) and post-vaccine myelitis and para-neoplastic conditions. The differential diagnosis of transverse myelitis is very extensive (Table 16.10).

NMO antibodies are present in 50–70% of patients with NMO or NMO spectrum disorder (in contrast to multiple sclerosis, which is not an antibody-mediated condition). These antibodies target the protein aquaporin 4 which is found astrocyte membranes, and which as a channel for water transfer across the cell membrane. Originally felt to be highly specific, it has now been detected in patients with SLE, Sjögren's syndrome, Hashimoto's thyroiditis and paraneoplastic myelopathy. Nevertheless, in the appropriate clinical context NMO antibody determination is a very useful test.

### Vascular disorders of the spine

Vascular diseases including those of the spinal cord are discussed further in Chapters 5 and 26. Like vascular disease of the brain, the syndromes can be thought of in terms of infarction, haemorrhage, transient loss of vascular supply and vascular malformations.

**Vascular malformations** Spinal vascular malformations usually present subacutely unless there is acute haemorrhage (this does not happen with dural AVMs or fistulae). Dural fistulae present as a myelopathy with progressive motor sensory and sphincteric loss. There may be radicular involvement and lower motor neurone signs because of impairment of dorsal and ventral root blood supply as well as anterior horn cell loss. Intradural fistulae more typically present acutely with the effects of intramedullary or subarachnoid bleeding. Adhesive arachnoiditis of the spine may be a late complication of spinal haemorrhage but rarely is a presenting feature leading to the diagnosis of a vascular malformation that has bled previously. Cavernous malformations may present acutely with large intramedullary haemorrhage or with a subacute myelopathy resulting from venous bleeding and consequent spinal damage. The presentation of cavernomas is often with stepwise neurological deterioration.

**Neoplastic vascular lesions** Cavernous angiomas (also known as cavernomas, cavernous haemangiomas or malformations) consist of a mass of endothelial cells which form sinusoidal spaces filled with blood, without intervening parenchyma, surrounded by haemosiderin-stained spinal parenchyma. They may present with focal haemorrhage or with mass effect and spinal cord syndromes. Symptomatic cavernous angiomas should be treated by surgical excision to prevent further haemorrhage and progression of deficits, whereas asymptomatic lesions should be observed because the natural history of these lesions is unclear. Definitive treatment should take into account the accessibility of the lesion, age of the patient and degree of neurological deficit.

Haemangioblastomas are neoplastic masses consisting of endothelial cells, pericytes and stromal cells. They may occur sporadically, or as part of von Hippel–Lindau syndrome. They usually are intramedullary, but have contact with the pial surface, and may have an associated cystic component or syrinx. Prior to surgery it is important to localise the large feeding vessels supplying the tumour by angiography, to minimise bleeding during resection. Treatment is by surgical resection, staying on the tumour capsule and dividing feeding vessels as they are exposed, similar to the technique of AVM resection.

**Arteriovenous malformations** AVMs account for about 4% of primary intraspinal masses, and may be classified into the following four types (Table 16.11).

**Type I** Dural arteriovenous fistulas (AVFs) are the most common type of AVM. AVFs do not have a nidus of abnormal vessels like classic AVMs. Instead, there is a direct connection between an artery and vein, with either single or multiple feeders. The dural fistula is in the root sleeve at an intervertebral foramen, feeding directly into spinal draining veins which may be intradural or extradural (Figures 16.24 and 16.25). They usually present with progressive myelopathy in middle-aged adults, resulting from venous congestion and hypoperfusion of the spinal cord, and are more common in the thoracic spine. Treatment of AVFs involves occlusion of the fistula by surgery or embolisation by interventional radiology.

**Type II** Glomus AVMs consist of a nidus of compacted abnormal arteries and veins within the spinal cord which may be fed by multiple normal vessels, such as the anterior and posterior spinal arteries (Figure 16.26). The abnormal vessels are intramedullary, and are similar to the vessels seen in intracranial AVMs, either in a compact mass or diffusely arranged. The vessels in the nidus are usually high flow, resulting in myelopathy from the mass effect or steal phenomena. Treatment is by surgical excision of the nidus, embolisation, or both.

**Type III** Juvenile or metameric AVMs are large AVMs that are intradural and extradural, fed by multiple vessels, often involving neighbouring bone and soft tissues (Figure 16.27). They are very difficult to treat and require a multi-modal approach.

**Type IV** These are AVFs on the surface of the cord that are intradural but extramedullary.

Most AVMs present with a progressive neurological deficit over months to years as a result of venous congestion or arterial steal, but may also present with sudden parenchymal haemorrhage, subarachnoid haemorrhage, mass effect or cord infarction. A spinal AVM is an important differential diagnosis for patients with subarachnoid haemorrhage and normal intracranial angiography, especially when neck stiffness and pain is more of a feature than

**Table 16.10** Causes of transverse myelitis (Chapters 9 and 11).

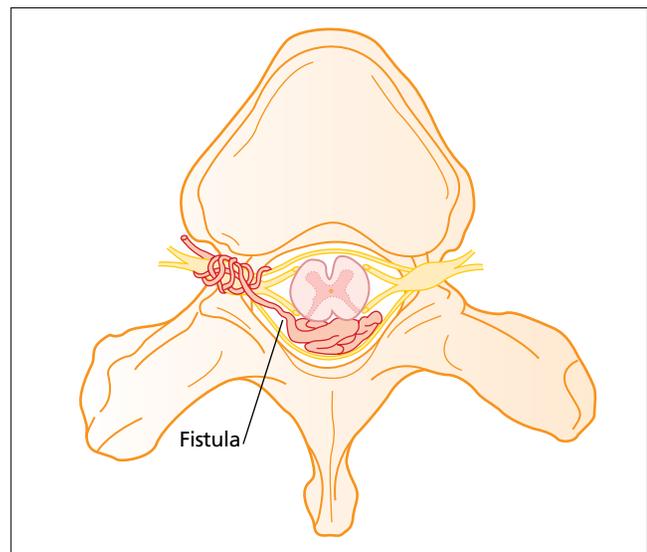

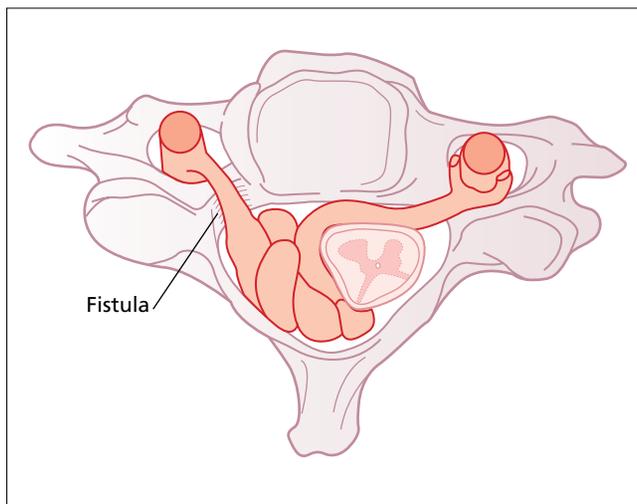

Infections	Bacterial	Especially staphylococcus including epidural abscess <i>Mycoplasma</i> TB <i>Borrelia</i> <i>Rickettsia</i> Syphilis Tetanus
	Viral	Enterovirus – coxsackie, poliovirus, enterovirus 71 Flavivirus – West Nile HZV, HSV 1, 2 HIV, HTLV-1 CMV, EBV Influenza
	Parasites	Schistosomiasis Toxoplasma Malaria Cysticercosis
	Fungal	
Post-infectious		Acute disseminated encephalomyelitis
Post-vaccination		Especially rabies vaccine, (numerous other case reports)
Primary demyelination		Multiple sclerosis Devic's disease
Inflammatory disorders		Systemic lupus erythematosus Mixed connective tissue disease Sjögren's disease Scleroderma Rheumatoid disease Antiphospholipid syndrome Sarcoid Vasculitides Ulcerative colitis Behçet's disease Serum sickness Post-haemopoietic stem cell infusion GVH Immune dysregulation and immune reconstitution in AIDS
Primary neoplasia		Gliomas Ependymomas
Secondary neoplasia		Especially lymphomas, metastases
Paraneoplastic		Especially associated with small cell carcinoma of lung and lymphoma (anti CRMP-5 and anti-amphiphysin)
Drugs		Heroin
Toxins		Subacute combined degeneration (B <sub>12</sub> deficiency) Snake and spider bite Arsenic Diethylene glycol Nitrous oxide Cyanide Intrathecal chemotherapy
Radiation		Dose-dependent. Acute and delayed
Miscellaneous		Decompression sickness Electrical injury

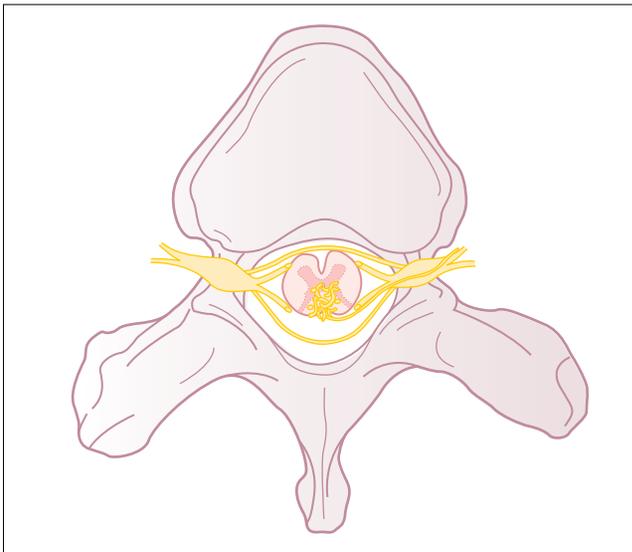

CMV, cytomegalovirus; EBV, Epstein-Barr virus; GVH, graft-versus-host disease; HSV, herpes simplex virus; HTLV, human T-cell lymphotropic virus; HZV, herpes zoster virus; TB, tuberculosis.

headache. MRI and spinal angiography are the investigations of choice for diagnosis and treatment planning.

#### Management of spinal vascular disease

There is no active treatment for acute spinal cord infarction. During high-risk vascular procedures pre-treatment with steroids and opiate antagonists has been advocated and neuroprotective agents have been examined experimentally. However, there is no clinical evidence for effectiveness of any of these approaches. Some vascular surgeons advocate spinal fluid drainage during surgery believing that through the lowering of CSF pressure spinal perfusion may be maintained during critical moments such as placing of the aortic cross-clamp during aortic aneurysm repair. The best safeguard against iatrogenic spinal cord infarction, however, is highly skilled surgical and anaesthetic practice.

Spinal epidural and subdural haematomas should be decompressed acutely by a spinal surgeon or neurosurgeon. Spinal AVMs and cavernomas can be excised. However, the majority are not amenable to this approach. Interventional radiology is the treatment of choice for dural fistulae and intradural AVMs.

The prognosis for functional recovery in established spinal infarction is poor with significant functional recovery leading to ambulation in well under 50% of those affected. The prognosis for spinal haemorrhage is more variable. In the case of compressive epidural and subdural haematomas it is dependent on the rapidity of decompression. In intradural bleeding it depends greatly on the site and source of bleeding. Haematomas caused by high-flow intradural AVMs are often catastrophic. The effects of bleeding from cavernomas may be milder and disability often progresses over many years. The natural history of cavernomas is still poorly understood and therefore the decision when and whether or not to intervene remains problematic.

**Metabolic diseases of the spinal cord** (Table 16.12; Chapter 19) Subacute combined degeneration of the cord resulting from vitamin B<sub>12</sub> (hydroxycobalamin) deficiency presents as a myelopathy with prominent dorsal column symptoms and signs. The characteristic clinical picture is of a patient complaining of paraesthesiae

**Table 16.12** Metabolic spinal syndromes.

#### Metabolic myelopathies due to a nutrient deficiency

- B deficiency
- Nitrous oxide toxicity
- AIDS-associated myelopathy (AIDS associated with impaired B<sub>12</sub> metabolism)
- Folate deficiency
- Copper deficiency
- Vitamin E deficiency

#### Metabolic myelopathies due to a possible toxin (geographical predilection)

- Cassava toxicity
- Lathyrism
- Fluorosis
- Subacute myelo-optico neuropathy (cloiquinol toxicity)
- Tropical myeloneuropathies

#### Metabolic myelopathies due to possible toxins (without a geographical predilection)

- Chemotherapy-related myelopathy
- Hepatic myelopathy
- Heroin myelopathy
- Organophosphate toxicity

and unsteadiness with mild upper motor neurone leg weakness, depressed knee and ankle jerks with extensor plantar responses and, most importantly, impaired joint position sense with Rombergism will lead many neurologists to recommend immediate vitamin B<sub>12</sub> administration before the serum vitamin B<sub>12</sub> levels are known. The treatment should be minimum of 5 × 1000 µg in the first 2 weeks followed by maintenance injections of 1000 µg/month for 3 months

and then 1000 µg every 3 months for life. There are case reports of severe subacute combined degeneration of the cord being helped by administration of high-dose steroids.

Neurological investigations of subacute combined degeneration of the cord may reveal dorsal column T2 signal change on MRI. The spinal fluid is typically normal. Somatosensory potentials are delayed. Nerve conduction studies may reveal an axonal sensorimotor polyneuropathy. Haematological and gastroenterological investigations can reveal a megaloblastic anaemia and vitamin B<sub>12</sub> malabsorption most commonly caused by pernicious anaemia. Humans are entirely dependent on dietary sources of vitamin B<sub>12</sub> and there are numerous dietary and malabsorption states that may lead to subacute combined degeneration of the cord. Risk factors for acquired vitamin B<sub>12</sub> deficiency include malabsorption states, pregnancy, drug use including anti-peptic ulcer treatments, HIV-AIDS and haematological conditions leading to increased haemopoiesis.

The spinal cord pathology of subacute combined degeneration of the cord reveals degeneration of myelin and axons. Gliosis is not prominent unless the case is very long-standing. These changes may be reversed with vitamin B<sub>12</sub> administration. The exact mechanism of spinal cord damage in vitamin B<sub>12</sub> deficiency is not known. However, vitamin B<sub>12</sub> is the cofactor for conversion of homocysteine to methionine and it is essential for conversion of methylmalonyl-CoA to succinyl-CoA. Unlike folate, vitamin B<sub>12</sub> is not known to participate directly in purine metabolism and thus DNA synthesis. While secondary effects are possible, administering high levels of folate can circumvent DNA synthesis impairment because of vitamin B<sub>12</sub> deficiency. Therefore, because neurological manifestations can develop independently of megaloblastic anaemia, it seems unlikely that problems with purine synthesis are responsible for the neuropathology. It is possible that abnormal myelination results from abnormal incorporation of methylmalonate and methylpropionate (these are precursors of cobalamin-dependent synthesis of succinyl-CoA) into branched-chain fatty acids. Furthermore, methionine deficiency secondary to failed conversion from homocysteine may lead to impaired synthesis of myelin phospholipids. However, these ideas remain speculative.

An important consideration is that of subacute combined degeneration with normal serum vitamin B<sub>12</sub> levels. Cases of 'functional' B<sub>12</sub> deficiency in which serum levels are normal but there is neurological damage because of B<sub>12</sub> lack are well described. In these syndromes there is elevation of the serum homocysteine and methylmalonic acid levels. Furthermore, cases in which nitrous oxide anaesthesia or during recreational use have provoked neurological vitamin B<sub>12</sub> deficiency are described. Exposure to nitrous oxide irreversibly inactivates cobalamin. Detailed metabolic investigation of the B<sub>12</sub> pathway is indicated in cases of 'functional' vitamin B<sub>12</sub> deficiency. The most important lesson is that the correlation between serum vitamin B<sub>12</sub> levels and the neurological syndrome is weak for complex reasons and the clinician should not be discouraged by normal initial serum B<sub>12</sub> levels from giving vitamin B<sub>12</sub> in a neurologically impaired patient with physical signs characteristic of subacute combined degeneration of the cord.

Folic acid deficiency could in theory produce a similar syndrome to that caused by vitamin B<sub>12</sub> deficiency. However, in practice, there is little evidence that isolated folate deficiency in absence of other risk factors (e.g. alcohol excess) actually causes neurological impairment. Folic acid supplementation, providing this does not induce vitamin B<sub>12</sub> deficiency, is straightforward.

Acquired copper deficiency causes a syndrome not dissimilar from subacute combined degeneration of the cord, with dorsal column and pyramidal signs and optic neuropathy. It can also cause a lower motor neurone syndrome and peripheral neuropathy. It is most commonly seen in patients with malabsorption states, those on enteral nutrition and in dialysis patients. Zinc ingestion lowers copper levels and indeed is a treatment of patients with Wilson's disease. Copper deficiency causes haematological as well neurological features and is diagnosed by estimation of serum copper, serum caeruloplasmin and 24-hour urinary copper. Zinc levels and excretion should also be checked. Treatment involves stopping zinc ingestion if present and providing copper supplementation. Congenital copper deficiency (Menkes syndrome is discussed in Chapter 19).

Vitamin E deficiency may be acquired as part of malabsorption state and typically presents as a spino-cerebellar degeneration. Genetic causes of a vitamin E deficiency are covered in Chapter 19.

Rare additional metabolic and toxic causes of myelopathy include hepatic failure, chemotherapy especially intrathecal drugs, heroin toxicity, organophosphate poisoning, nitrous oxide poisoning, flourosis (via skeletal deformity), lathyrism (probably caused by beta-N-oxalyl-L-alpha, beta-diaminopropionic acid (ODAP) poisoning from a chickpea staple diet) and cassava poisoning (probable cyanotoxin ingestion).

### Hereditary spastic paraplegia

Hereditary spastic paraplegia (HSP) is a term covering a genetically and clinically heterogeneous group of inherited disorders characterised by progressive spasticity and weakness predominantly affecting the lower limbs. The transmission of the conditions may be X-linked, autosomal dominant or recessive and they may be divided into pure (uncomplicated) and complicated forms (Table 16.13). In the former there is only spinal involvement but the latter are associated with other neurological abnormalities. To date, linkage to 56 loci and mutations in at least 41 genes have been described resulting in this syndrome.

In pure HSP, patients present with steadily progressive gait disturbance or, in childhood, with delayed motor milestones. There is usually progressive spasticity of the lower limbs with hyperreflexia and extensor plantar responses. However, there may be little or no pyramidal limb weakness and the examination continues to be characterised by dissociation between the severity of the spasticity and relatively mild weakness. Rarely, there may be wasting of the intrinsic muscles of the feet, urinary disturbance with urgency, frequency and hesitancy, anal sphincter disturbance, sexual dysfunction, pes cavus or mild proprioceptive sensory impairment, particularly in long-standing disease. Spasticity predominantly affects the lower limbs with brisk reflexes and ankle clonus but there may be mild signs in the upper limbs and pes cavus may be present.

In complicated HSP, spastic paraparesis is associated with a variety of other neurological manifestations in a variable phenotype: optic atrophy and retinopathy; extrapyramidal involvement (choreoathetosis, dystonia and rigidity); cerebellar signs (ataxia, dysarthria and nystagmus); cognitive impairment (dementia, mental retardation and neuropsychiatric manifestations); sensori-neural deafness and epilepsy (myoclonic, simple or complex partial, absence, atonic or grand mal). Peripheral neuropathy and amyotrophy, ichthyosis and cardiac deficits may also be associated.

**Table 16.13** Hereditary spastic paraplegia (HSP).

Gene	Inheritance	Locus	Protein	Notes
SPG1/L1CAM	X-linked	Xq28	L1 cell adhesion molecule	MASA syndrome, hydrocephalus, MR, hypoplasia of corpus callosum
SPG2/PLP1	X-linked	Xq22	Proteolipoprotein 1	Nystagmus, dysarthria, sensory disturbance, MR, optic atrophy; allelic to Pelizaeus–Merzbacher
SPG3A/ATL1	AD	14q11-q21	Atlastin 1	Early onset, pure HSP; 10% AD HSP
SPG4/SPAST	AD	2p22-p21	Spastin	Pure HSP; 40% pure AD HSP
SPG5A/CYP7B1	AR	8q21.3	Cytochrome P450–7B1	Pure HSP
SPG6/NIPA1	AD	15q11	Non-imprinted in Prader–Willi/ Angelman’s syndrome 1	Pure HSP
SPG7	AR	16q24.3	Paraplegin	Optic atrophy, nystagmus, cerebellar signs
SPG8/KIAA0196	AD	8q24.13	Strumpellin	Adult-onset pure HSP
SPG9	AD	10q23.3-q24.1		Cataracts, motor neuropathy, short stature, MR, skeletal abnormalities
SPG10/KIF5A	AD	12q13	Kinesin-5A	Pure HSP
SPG11	AR	15q21.1	Spatascin	MR, thin corpus callosum, dysarthria
SPG12	AD	19q13		Pure HSP, rapidly progressive
SPG13/HSPD1	AD	2q33.1	Heat shock protein 60	Pure HSP
SPG14	AR	3q27-q28		Motor neuropathy, MR
SPG15/ZFYVE26	AR	14q24.1	Spastizin	Retinal degeneration, MR, amyotrophy
SPG16	X-linked	Xq11.2		Quadriplegia, aphasia, visual impairment, MR
SPG17/BSCL2	AD	11q13	Seipin	Silver syndrome, amyotrophy of distal upper limbs
SPG18	AR	8p12-p11.21		MR, hypoplasia of corpus callosum, epilepsy
SPG19	AD	9q		Pure HSP, slow progression
SPG20	AR	13q12.3	Spartin	Troyer’s syndrome; distal amyotrophy, dysarthria, MR
SPG21	AR	15q21-q22	Masparidin/ACP33	Mast syndrome; adult onset, cognitive decline, extrapyramidal features
SPG23	AR	1q24-q32		Lison syndrome; abnormal skin pigmentation, neuropathy
SPG24	AR	13q14		Pure HSP
SPG25	AR	6q23-q24.1		Adult onset, intervertebral disk herniation
SPG26	AR	12p11.1-q14		Distal amyotrophy, mild MR
SPG27	AR	10q22.1-q24.1		Adult onset pure HSP
SPG28	AR	14q21.3-q22.3		Pure HSP
SPG29	AD	1–31.1-p21.1		Sensorineural deafness, neonatal hyperbilirubinaemia, hiatal hernia
SPG30	AR	2q37.3		Peripheral neuropathy, cerebellar atrophy
SPG31/REEP1	AD	2p11.2	Receptor expression- enhancing protein 1	Pure HSP
SPG32	AR	14q12-q21		Mild MR, thin corpus callosum, cerebellar atrophy
SPG33/ZFYVE27*	AD	10q24.2	Protrudin	Controversial – described mutation may be noncausative polymorphism
SPG34	X-linked	Xq24-q25		Pure HSP
SPG35/FA2H	AR	16q21-q23.1	Fatty acid 2-hydroxylase	MR, epilepsy, white matter abnormalities on MRI
SPG36	AD	12q23-q24		Pure HSP

(continued)

**Table 16.13** (continued)

Gene	Inheritance	Locus	Protein	Notes
SPG37	AD	8p21.1-q13.3		Pure HSP
SPG38	AD	4p16-p15		Silver syndrome; distal amyotrophy
SPG39/PNPLA6	AR	19p13.3	Neuropathy target esterase	Motor neuropathy with distal wasting
SPG41	AD	11p14.1-p11.2		Pure HSP
SPG42/SLC33A1	AD	3q25.31	Acetyl-CoA Transporter	Pure HSP
SPG43	AR	19p13.11-q12		Distal amyotrophy
SPG44/GJC2	AR	1q41-q42	Gap junction protein gamma 2	Allelic with Pelizaeus–Merzbacher like disease, hypomyelination
SPG45	AR	10q24.3-q25.1		MR, nystagmus, optic atrophy
SPG46	AR	9p21.2-q21.12		MR, thin corpus callosum
SPG48/KIAA0415	AR	7p21	Putative DNA helicase	Pure HSP, putative-based on 2 individuals

AD, autosomal dominant; AR, autosomal recessive; HSP, hereditary spastic paraplegia; MASA, mental retardation, aphasia, shuffling gait and adducted thumbs; MR, mental retardation.

Cranial and spinal MRI scans are usually normal but there may be spinal atrophy in some forms (e.g. SPG6 and 8). In complicated forms, imaging may show cerebral and cerebellar atrophy or hypoplasia of the corpus callosum.

The age of onset of the conditions varies from infancy to the eighth decade but is usually between the second and fourth decade. The prognosis is variable between families and to a lesser extent within families. Early onset HSP (>35 years) tends to be slower in its progression and most patients remain ambulant throughout their lives. However, the later onset forms of the condition (>35 years) tend to be associated with more rapid disease progression, with many patients becoming wheelchair bound in their sixties and seventies. However, there is no effect on prognosis according to the mode of transmission.

The management is entirely symptomatic with spasticity being treated with appropriate antispastic medication including baclofen, dantrolene and tizanidine. Severe spasticity may be helped by local injection of botulinum toxin. Early and regular physiotherapy is required to maintain the range of movements, strength and flexibility and to avoid the development of contractures. In complicated forms, cardiomyopathy can occur and requires specific treatment.

### Miscellaneous conditions affecting the spine and spinal cord

**Superficial siderosis** This is a condition in which there is abnormal subarchnoid haemosiderin deposition (Chapter 26). The condition affects many neurological systems and when taken together the symptoms and signs form a coherent and recognisable clinical picture. A literature review of 87 cases revealed the following clinical features: sensorineural deafness (95%), cerebellar ataxia (88%), pyramidal signs (76%), dementia (24%), bladder disturbance (24%), anosmia (at least 17%), anisocoria (at least 10%) and sensory signs (13%). Less frequent features included extraocular motor palsies, movement disorders and lower motor neurone signs secondary to anterior horn cell damage (5–10% each). Neck pain, low back pain and sciatic type pain are recognised clinical features. T2-weighted MRI studies are diagnostic, and reveal a dark rim, representing the paramagnetic effects of iron deposition, particularly around posterior fossa structures, the spinal cord and occasionally the cerebral hemispheres.

Previous spinal surgery is a recognised cause of superficial siderosis with chronic subarchnoid bleeding resulting from small

**Table 16.14** Causes of superficial siderosis.

Neurosurgery	Including late effects of CNS tumour removal in childhood
SAH	Caused by aneurysm, AVM or angiogram negative; SAH due to transthyretin (Asp18Gly TTR mutation) leptomeningeal amyloidosis; intracerebral and spinal cavernomas
Tumours	Pituitary, cerebellar, spinal astrocytomas, spinal teratoma, ependymoma, filum terminale preganglionomas, spinal meningeal melanocytoma
Nerve root trauma	Avulsion, pseudomeningocele
Miscellaneous causes	Neurofibromatosis type 1, CNS vasculitis, anticoagulation

AVM, arteriovenous malformation; CNS, central nervous system; SAH, subarachnoid haemorrhage.

blood vessel anomaly. Local spinal pathology affecting the dura such as a root lesion/avulsion or vascular anomaly are also recognised causes of the condition. The remainder of cases in which a cause may be identified usually result from subarachnoid haemorrhage or the late consequences of a major neurosurgical procedure such as hemispherectomy. However, as shown in Table 16.14, there are a number of other conditions implicated in the development of superficial siderosis. The serious long-term prognosis of the disorder means an exhaustive search for a bleeding source and CSF leak should be undertaken. A lumbar puncture can indicate recent bleeding but given that the problem can be intermittent, a clear CSF does not guarantee that there is no ongoing tendency to accumulate more blood products and therefore iron. Thorough investigation requires MRI of brain and whole spine and often a CT myelogram looking for a dural tear. Exploratory surgery of a region from which chronic bleeding could occur may be indicated (e.g. the site of previous surgery or a root avulsion). Successful surgical ablation of a bleeding source can arrest further iron deposition but will not affect the neurotoxicity of the iron already deposited. A blood patch is

**Table 16.15** Causes of arachnoiditis.

iatrogenic: spinal surgery, multiple lumbar punctures and spinal anaesthesia
Trauma
SAH including spinal SAH
Spinal infection, especially tuberculosis and suppurative pyogenic meningitis
Myodil (Pantopaque) radiological contrast agent (this has not been used in the United Kingdom since 1984)

SAH, subarachnoid haemorrhage.

also considered if there is evidence of a non-surgical CSF leak. The role of medical treatment with chelation therapy has not yet been established by randomised controlled trials. Trientine is almost certainly not helpful. There are recent data suggesting that the iron chelator deferiprone (Ferriprox), which crosses the blood-brain barrier, can reduce iron load on MRI. It is to be hoped that this MRI finding will translate into clinical benefit in an otherwise untreatable condition.

Cochlear transplants have been successfully performed for the hearing loss associated with siderosis and should be undertaken before VIIIth nerve function is lost.

**Arachnoiditis** Fibrosis and adhesions of the intradural space can occur after trauma, infection, surgery or subarachnoid bleeding, and usually involve the pia and theca as well as the arachnoid layers around the cord (Table 16.15). Pain and radicular symptoms arise because of involvement of the lumbar nerve roots, or myelopathy if the cord becomes tethered by these adhesions at any point or if the cord vasculature is compromised.

The diagnosis involves the exclusion of other causes of radicular pain or myelopathy, and the demonstration of arachnoiditis on MRI. The differential diagnosis includes intrinsic tumours and carcinomatous meningitis. Radiological arachnoiditis is seen in many asymptomatic patients who have had spinal surgery or myelography, and there is no clear evidence to associate radiological findings directly with symptoms. In postoperative patients therefore, arachnoiditis should not necessarily be assumed to be the cause of new symptoms.

In the lumbar region, nerve roots adhere to form bundles, or lie centrifugally in contact with the thecal sac, producing the appearance of an empty sac. In the thoracic spine, arachnoiditis produces intramedullary cystic changes with syrinx and cavity formation. The MRI appearances can be confusing (Figure 16.15). When arachnoiditis occurs in the thoracic regions, the cord may be tethered to the theca (e.g. at the point of surgical durotomy) or may produce arachnoid cysts as a result of poor communication of the CSF spaces.

Surgical detethering may treat a tethered cord in a patient with progressive neurological symptoms. Arachnoid cysts producing cord compression may be marsupialised or shunted but the problem is often recurrent. Lumbar arachnoiditis producing radicular pain is usually best treated by symptomatic control, including epidural injections of local anaesthetic and steroid, pain management techniques and analgesics. Despite attempts to inhibit fibrosis as yet no successful medical therapies capable of reversing arachnoiditis have been developed and the condition can relentlessly progress causing severe pain and disability.

# Cerebellar Ataxias and Related Conditions

Nicholas W. Wood

UCL Institute of Neurology

Ataxia derives from the Greek, meaning quite simply, disorder. In neurology the word is used to describe incoordination of muscular activity associated with dysfunction of the cerebellum and its connections. The causes of cerebellar dysfunction are numerous and impossible to cover in great depth here. This chapter thus adopts a structured approach to assessment and management of the ataxic patient, with descriptions of the main disorders affecting the cerebellum. There have been numerous classifications applied to the ataxias; none is without significant drawbacks. The approach used here is clinical, describing how one can sort through the differential diagnosis of an ataxic syndrome in a way that is systematic, robust and efficient.

## Approach to the patient with ataxia

### Symptoms

The assessment of patients with possible ataxia begins as they are seen to walk, when one can observe the gait and the ability, or otherwise, to sit down smoothly into the chair. As the symptoms are elucidated there is time to catch the explosive cerebellar dysarthria. However, many patients with ataxia have abnormalities in other neurological pathways in addition to those in the cerebellar system, so one may hear a spastic or dysphonic quality to the speech that can complicate the picture. The specific symptoms of cerebellar disease are problems with balance and general coordination of limbs. This can be described as a feeling of disequilibrium, sometimes called dizziness by the patient. Patients often have noticed a speech disturbance themselves or quite frequently this has been pointed out by family or friends. Limb ataxia may first be hinted at by the patient's deteriorating handwriting or that there is difficulty carrying a glass of fluid, or a tremor. Vertigo is generally more suggestive of neoplastic, inflammatory and vascular disease rather than the more slowly progressive degenerative processes.

It is useful to determine the age at onset and the course, including the mode of onset (e.g. a sudden rather than insidious course). An acute history may suggest a cerebellar haemorrhage. A haematoma is often associated with acute raised intracranial pressure symptoms and appropriate signs. If these features develop more slowly in the ataxic patient, then space-occupying lesions including a tumour or even an abscess should be considered and excluded by imaging.

The age at onset helps focus the differential diagnosis. Table 17.1 gives an outline of the broad range of diseases to consider in each category. In the field of ataxia, any symptom occurring in a patient over the age of 25 years is classed as late onset. The pattern of onset and subsequent course also helps in sifting the diagnostic possibilities. The length of the history should be established and it is worth asking about early motor milestones and athletic ability at school, which can indicate a much earlier onset than previously appreciated.

Having determined the mode and age at onset, concentrate on quantifying the current problems, how and when they emerged, with a particular emphasis on any extracerebellar features. This should include assessment of cognitive, sensory and any neuromuscular features.

Genetics has a significant role in the aetiology of ataxia: a detailed family history is required, even in the case of apparently sporadic ataxia. The family history needs to be elicited in detail as many of the inherited ataxias are complicated and it is possible that an affected relative may have presented with a clinical picture very different from the proband.

Vomiting, headache or vertigo frequently suggest a posterior fossa mass lesion. Direct questioning should also cover the urinary system, skeletal deformities and cardiac disease. A detailed enquiry of drug ingestion, for both medical and recreational purposes, including alcohol, and occupational exposure is also required.

### Physical signs

The examination has two main aims: to establish and delineate the cerebellar features and to determine the involvement of other systems both in the central nervous system (CNS) and other organs.

The range of potential diagnoses is usually evident from the clinical history and examination. More formal gait assessment should include any additional features, such as signs of parkinsonism or dystonia, Rombergism and any suggestion of pyramidal or neuropathic signs.

At the bedside the assessment of the extraocular movements is vital. It is extremely rare to see a patient with a cerebellar cause for their symptoms who does not have some abnormality in their extraocular movements. However, it may be necessary to search hard for such signs. In the primary position the presence of square wave jerks should be assessed. The assessment of ocular pursuit usually

**Table 17.1** Differential diagnosis of ataxia based on age and pattern of onset.

Course	Chronic/insidious onset ataxia	Subacute cerebellar syndrome	Acute cerebellar syndrome
Early	Congenital ARCA	Infective e.g. abscess Raised ICP Post-infectious Some drugs/toxins	Some infections and vascular causes
Adult	Alcohol ILOCA ADCA MSA-C Gluten ataxia FXTAS	Paraneoplasia SOL	Vascular causes

ADCA, autosomal dominant cerebellar ataxia; ARCA, autosomal recessive cerebellar ataxia; FXTAS, fragile X tremor ataxia syndrome; ICP, intracranial pressure; ILOCA, idiopathic late onset ataxia; MSA-C, multiple system atrophy type C; SOL, space-occupying lesion.

reveals a broken jerky quality, because of insertion of saccades into attempted pursuit. At its most extreme, normal pursuit is entirely absent and the eyes move entirely by use of the saccadic system. One can choose to stress this system more by assessment of the ability to inhibit the vestibular ocular reflex. Nystagmus may be found, and although this is the best known of the cerebellar eye signs, it is far from invariably present. The saccadic system should also be assessed both by eliciting voluntary saccades – with the instructions ‘look left, look right’ – and reflex saccades where one presents a target. Using these two methods one can assess the speed of initiation, the accuracy and the velocity of the saccades. Typically, in the patient with cerebellar dysfunction there are dysmetric saccades, either hyper- or hypo-, which are demonstrated by overshoot or undershoot, with a small corrective saccade to reach the target. A discrepancy between voluntary and reflex saccades may indicate a supranuclear gaze palsy or oculomotor apraxia. Some of these assessments at the bedside can be difficult and a true quantification can only be obtained by electrophysiological testing, but this is only rarely necessary. In some of the rarer complicated ataxias one may observe ophthalmoparesis – this is most common in mitochondrial disease and autosomal dominant cerebellar ataxias (ADCAs). The presence of opsoclonus may suggest paraneoplastic disease in an appropriate clinical setting. Downbeat nystagmus with symptoms of vertical oscillopsia suggests a structural lesion at the foramen magnum.

Ophthalmoscopy is necessary to assess the optic nerve, retina and macula, looking for signs of atrophy or pigmentary changes.

The classic limb signs of cerebellar disease in the upper limbs include intention tremor, dysidiadochokinesis, rebound and finger–nose incoordination, where one may observe dysmetria and past pointing. In the legs an assessment of heel–shin coordination usually suffices. It is quite usual to find that the legs are more severely affected than the arms (Chapter 4).

### Additional signs

Assessment of other systems should include signs of dysmorphism, skeletal abnormalities especially pes cavus and scoliosis, skin rashes and organomegaly. Neurologically, a full analysis of the other systems should include assessment of the pyramidal tracts, sensory impairment, neuropathy, extrapyramidal and autonomic features. The latter can be quickly assessed at the bedside by measuring supine and standing blood pressure (BP). It is best to measure BP at 1-minute intervals, for 3 minutes. If there is further concern more formal autonomic testing can be performed.

### Investigations

In certain ataxic disorders specialised ancillary tests are required; these are discussed later in the chapter. Here the broad approaches to investigating the ataxic patient are mentioned.

### Imaging

High-quality magnetic resonance imaging (MRI) has revolutionised practice in this area. MRI is useful in determining the presence and often nature of any space-occupying lesion, it can readily identify haemorrhage and is the investigation of choice if inflammatory causes are being considered. However, once these more common aetiologies are excluded, imaging plays a relatively small part in the assessment of the ataxic patient. In the long differential of the degenerative forms of ataxia, MRI will often show non-specific cerebellar atrophy, with or without brainstem or more generalised atrophy, all too often not providing specific diagnostic refinement. Research imaging methods are being developed to address some of these deficiencies, but they are not yet in clinical service.

### Electrophysiological tests

While imaging helps to define structural anatomy, a range of electrophysiological tools can be used to clarify the functional integrity of the nervous system, and can help delineate the involvement of other neurological systems. In assessing a complicated ataxia of uncertain origin, appropriate neurophysiological tests can be helpful. Neurophysiology is also helpful in considering:

- Is there a subclinical neuropathy?
- Visual system function, with evoked responses or electroretinography?
- Motor/sensory function, with somatosensory evoked responses and central motor conduction times.

The finding of an associated neuropathy may indicate a degenerative cause. For example, early onset ataxia with a significant sensory neuropathy may suggest either Friedreich's ataxia (FRDA), ataxia telangiectasia or abetalipoproteinaemia. In later onset cases, and some rare genetic forms of ataxia, an inflammatory cause such as Sjögren's disease needs to be excluded. It is helpful to differentiate axonal from demyelinating neuropathies. The vast majority of associated neuropathies in the degenerative ataxias are axonal. Occasionally, an early onset ataxia is associated with a demyelinating neuropathy and this might indicate the diagnosis of autosomal recessive ataxia of Charlevoix-Sagueney (ARSACS). This disorder is also associated with retinal layer hypertrophy which is best identified using optical coherence tomography.

**Table 17.2** Blood tests and the ataxic patient.

Blood test	Purpose	Notes
Routine blood tests (including thyroid function)	General investigation, and may show evidence of multi-system disease	Hypothyroidism is a very rare but treatable cause of ataxia
Autoantibodies and anticardiolipin	SLE, Sjögren's and antiphospholipid syndromes	Often subacute and complicated phenotype
Antigliadin and endomysial antibodies	Coeliac disease and gluten ataxia	Common in general population, so care not to overinterpret
Vitamins, especially B and E	Thiamine, B <sub>12</sub> and vitamin E deficiencies	All associated with ataxia
Antineuronal antibodies	Various cancers associated with subacute and/or aggressive cerebellar syndromes	(see Table 17.7 and Chapter 21)
Leukocyte enzymes	In particular, hexosaminidase A	Often concomitant LMN syndrome
Very long chain fatty acids	A variant of adrenomyeloneuropathy	Gene test is also available
Ammonia and lactic acid	Metabolic ataxias	Consider in early onset often subacute and variable phenotypes
Gene tests	See text for specific details	Becoming increasingly important for sporadic ataxia cases; SCA 6 and FRDA should be considered

FRDA, Friedreich's ataxia; LMN, lower motor neurone; SLE, systemic lupus erythematosus.

### Blood tests

There is a long list of potential tests that can be considered in a case of undiagnosed ataxia (Table 17.2), much as one would for complicated neurological disease of other causes, but some deserve special mention here. Despite their rarity, it is always worthwhile considering the treatable, so an assessment of B vitamins and vitamin E should not be forgotten. Hypothyroidism is frequently mentioned as a cause of ataxia; this is extremely rare. A range of antibody tests are now frequently employed, including an autoantibody screen, antiphospholipid syndrome, antineuronal antibodies and assessment for sensitivity to gluten. An assessment of lysosomal and other enzymes may also point to a specific neurometabolic disorder; hexosaminidase A is of particular relevance to the ataxic patient. There are now numerous gene tests widely available; these are discussed in more detail later.

### Ancillary tests

If an inflammatory disorder of the nervous system is being considered an assessment of intrathecal oligoclonal immunoglobulins may help (Chapter 11). These are found not only in cases of multiple sclerosis, but also in paraneoplastic disorders (Chapter 21) and other rarer inflammatory conditions such as neurosarcoidosis (Chapter 26). Autonomic features, such as postural dizziness and urinary urgency, may require a detailed assessment of the autonomic system, to both aid the diagnosis and guide treatment. Occasionally, electrophysiological assessment of anal sphincter denervation is helpful and may point towards a diagnosis of multiple system atrophy. In patients with early onset ataxia of a complicated nature, including severe epilepsy, myoclonus and/or cognitive decline, it may be necessary to perform biopsies of axillary skin and muscle.

### The ataxic disorders

There are several different ways of structuring discussion of the causes of ataxia. Here, whether or not a condition is inherited or acquired is used as the main dividing line, but even this is not always straightforward. As new genes are discovered, some patients previously thought to have sporadic acquired disorders move into the inherited group. Similarly there are intrauterine events or processes that can produce a syndrome reminiscent of ataxias of other patients with ataxias of genetic origin.

### Inherited ataxia syndromes

#### Congenital ataxias

This group of disorders, as the name implies, encompasses ataxic disorders of early onset; generally these are non-progressive. The clear identification of such early life onset in a developing infant is not always easy, and similarly the definition of non-progression in the growing child also presents difficulties. Moreover, as improvements in our understanding of the genetic bases of these disorders have developed it has become clear that the majority of these disorders have a genetic cause.

There are a number of well-recognised syndromes (Table 17.3) with a range of additional features including involvement of other organs and dysmorphism. The clinical clues that one might be dealing with a congenital problem include developmental motor delay; this can sometimes become apparent by a longer time than normal that a toddler spends crawling before taking independent steps. The demonstration of non-progression is difficult because as a child develops they acquire motor skills. Frequently, the history is that of a child, who although able to acquire new skills is always behind

**Table 17.3** Congenital inherited ataxic disorders. This is an incomplete list; numerous reports of often singular families. There is also some overlap with the autosomal recessive ataxias, some of which have congenital features (e.g. deafness), but have a progressive ataxia. The conditions listed here have, as far as it is possible to determine, non-progressive ataxia.

Syndrome	Additional features	Mode of inheritance	Gene defect
Joubert's syndrome	Episodic hyperpnoea, abnormal eye movements and mental retardation	Autosomal recessive Genetically heterogeneous	<i>AHI1</i> gene <i>NPHP1</i> gene <i>CEP290</i> Plus others with established and distinct loci
Gillespie's syndrome	Mental retardation and partial aniridia	Autosomal recessive	Pax 6
Congenital nystagmus	Hypoplasia of the macula in some cases	Autosomal recessive and X-linked	<i>NYS1-6p</i> <i>NYS2</i> , X-linked and others
Congenital hypoplasia and quadripedal gait	Mental retardation and seizures	Autosomal recessive	17p
Paine's syndrome	Spasticity, mental retardation and microcephaly	X-linked recessive ataxia	No gene identified

their peers and described as clumsy. As motor skills are acquired the child may actually report fewer problems with unsteadiness. Imaging can sometime help in some syndromes and there may be significant reduction in cerebellar volume, including signs such as 'molar tooth' an abnormally deep interpeduncular fossa with elongated, thick and maloriented superior cerebellar peduncles as seen with Joubert's syndrome. The combination of a very small cerebellum and associated structures on imaging in a child who is not profoundly ataxic points strongly towards a congenital explanation.

Other possibilities to be considered in these early onset cases are those caused by developmental abnormalities. Most of these are readily diagnosed with modern imaging techniques and include Arnold–Chiari malformation and Dandy–Walker cysts. These are discussed in more detail in Chapter 16.

### Autosomal recessive cerebellar ataxias

There is a long list of mutations inherited in an autosomal recessive manner and, as a general rule, onset of the autosomal recessive ataxias is before the age of 20 years (Table 17.4). FRDA is by far and away the most common cause, accounting for approximately 40% of autosomal recessive cerebellar ataxia (ARCA) cases. The remainder are all individually rare. Improvements in gene sequencing technologies are revolutionising the gene testing environment and it is likely that many previously untestable genes will become available soon.

### Friedreich's ataxia

This has an estimated prevalence of approximately 2/100 000. The condition is characterised by a progressive gait and limb ataxia and a number of additional features including an axonal sensorimotor neuropathy, pyramidal tract involvement, hypertrophic cardiomyopathy, skeletal abnormalities, optic atrophy, deafness and diabetes. Typically, it begins between the ages of 8 and 15 years. There are reported instances of later onset, even as late as the seventh decade; these are the exception. The chief invariable additional feature is the neuropathy, predominantly sensory and progressive.

Following the identification of the gene frataxin in 1996, it was shown that the predominant mutation is a trinucleotide repeat (GAA) in intron 1. Expansion of both alleles is found in over 96% of patients. The remaining patients have point mutations on one allele in association with an expansion on the other. This has permitted the introduction of a specific and sensitive diagnostic test, as it is a relatively simple matter to measure the repeat size. The normal GAA repeat length varies from 7 to 22 units, whereas the disease range is around 100–2000 repeats; the shorter the length of the repeat the later the onset and generally the milder the disease phenotype.

The frataxin protein has been shown to be involved in iron metabolism within the mitochondria and a number of therapeutic strategies based around improving mitochondrial function are being developed. No treatment to date has been shown to influence disease progression.

### Ataxic disorders associated with defective DNA repair

There are several rare disorders characterised at a molecular level by a reduced capacity to repair DNA. The most well known and most studied is ataxia telangiectasia (AT). This produces a mixed movement disorder with the presence of dystonia and chorea in addition to the progressive ataxia. Growth and sexual development can be delayed and mild learning difficulties are common but not invariable. The typical skin and eye lesions (Figure 17.1) usually develop between the ages of 3 and 6 years and are best seen on the conjunctival surface and the ear. AT is associated with abnormalities of both humoral and cell-mediated immunity and is caused by mutations in the *ATM* gene. There are variants of this clinical phenotype with absence of telangiectasia and later onset, also caused by mutations in *ATM*.

A rarer clinically similar disease caused by mutations in *hMRE11* has been identified and is termed AT-like disorder. Clinically related conditions xeroderma pigmentosum and Cockayne's syndrome (Table 17.4) are also caused by defects in DNA repair; they are much rarer and associated with additional features, most frequently skin abnormalities.

**Table 17.4** Autosomal recessive cerebellar ataxias (ARCA).

Syndrome	Gene defect	Clinical pointers	Notes
Friedreich's ataxia (FRDA)	GAA repeat (and some point mutations in <i>FRDA</i> gene)	Neuropathy, pyramidal signs, skeletal abnormalities, diabetes and cardiomyopathy	Most common ARCA
Ataxia telangiectasia (AT) AT-like disorder	<i>ATM</i> <i>hMRE11</i>	Oculomotor apraxia, mixed movement disorder, humoral immune deficiencies, increased cancer risk	Telangiectasia not always present or easily identified
Cockayne's syndrome	CS type A – <i>ERCC8</i> gene CS type B – <i>ERCC6</i> gene	'Cachectic dwarfism' Mental retardation Pigmentary retinopathy	
Xeroderma pigmentosum (XP)		Increased skin cancer in XP but not Cockayne's	
AOA1	Aprataxin	Oculomotor apraxia	
AOA2	Senataxin	Oculomotor apraxia	Probably second most common ARCA
ARSACS	Sacsin	Demyelinating neuropathy, hypertrophy of the retinal layer (detected using OCT)	Along with senataxin second in frequency to FRDA
Hypogonadism	RNF216	Hypogonadotrophic hypogonadism	a.k.a. Gordon Holmes' syndrome
Marinesco–Sjögren's syndrome	<i>SIL1</i> on chr 5q31	Cataracts and mental retardation	
Progressive myoclonic ataxia (Ramsay-Hunt syndrome)	Genetically complex	Epilepsy is frequently associated	Overlaps with differential of progressive myoclonic epilepsy
Behr's and related syndromes, e.g. 3-methylglutaconic aciduria type III (Costeff's syndrome)	No gene for Behr's yet identified <i>OPA3</i> gene	Optic atrophy (OA), spasticity and mental retardation	There are other cases with OA but not Behr's syndrome
Congenital or childhood onset deafness	Genetically complex	Several different families/syndromes reported	May cause overlap with Usher's syndrome
Autosomal recessive late onset ataxia	Heterogeneous	Clinically variable with a range of additional features	Relatively rare

### Ataxias associated with oculomotor apraxia

There are two genetically distinct but clinically similar disorders associated with the distinctive feature of oculomotor apraxia: ataxia associated with oculomotor apraxia (AOA) types 1 and 2. AOA is used to describe intermittent failure of the voluntary saccadic system, and should be suspected where the patient uses head thrusts or synkinetic blinking to help initiate a voluntary saccade. AOA1 has been shown to be caused by mutations in the aprataxin gene on chromosome 9p13. This is characterised by the association of ataxia with chorea early in the disease course, oculomotor apraxia, peripheral neuropathy and variable but mild learning difficulties. MRI reveals cerebellar atrophy; serum analysis may show hypercholesterolaemia and hypoalbuminaemia.

AOA2 is very similar clinically and also overlaps with the AT phenotype. Mutations in senataxin have been shown to cause this syndrome. Alpha-fetoprotein (AFP) is elevated in virtually all cases and is therefore a useful screen for this disorder. AOA2 appears to be more common than either AT or AOA1, accounting for approximately 8% of autosomal recessive ataxia.

### Ataxia caused by vitamin E deficiency

A relationship between spino-cerebellar dysfunction and vitamin E deficiency has been recognised for many years. Many cases have a demonstrable cause for their vitamin E deficiency such as abetalipoproteinaemia, chronic liver disease and malabsorptive states secondary to cystic fibrosis or bowel resection. In 1985, Harding *et al.* described

**Figure 17.1** Conjunctival telangiectasia in a patient with ataxia telangiectasia. (Courtesy of The Audio Visual Services Unit, National Hospital for Neurology and Neurosurgery.)

a patient with a progressive spino-cerebellar disorder who had isolated vitamin E deficiency with no evidence of malabsorption. The clinical features of this syndrome include progressive gait ataxia, incoordination of the limbs, areflexia and large fibre sensory loss. Homozygosity mapping led to the identification of a gene  $\alpha$ -tocopherol transfer protein ( $\alpha$ TTP) on chromosome 8q. These patients have an impaired ability to incorporate vitamin E ( $\alpha$ -tocopherol) into very low density lipoproteins in the liver. This function is necessary to maintain the adequate circulation of  $\alpha$ -tocopherol. A number of mutations have been described, but the mainstay of diagnosis is the measurement of serum vitamin E rather than genetic analysis. Despite its rarity, it is imperative not to miss such a diagnosis because replacement therapy helps to stabilise the situation and in some cases produces improvements. Generally, vitamin E deficiency caused by malabsorption requires substantially higher doses of replacement therapy than those caused by  $\alpha$ TTP mutations.

The most severe vitamin E deficiency state occurring in humans is abetalipoproteinaemia. The typical presentation is in the second decade, with progressive ataxia, areflexia, posterior column signs; a pigmentary retinopathy may also be seen. It is caused by mutations in the gene encoding a subunit of the microsomal triglyceride transfer protein and is associated with low levels of apoprotein B, which normally carries lipid from the intestinal cell to the plasma. This results in very low levels of circulating lipids, particularly cholesterol, and severe malabsorption of the fat-soluble vitamins A, D, E and K. Serum vitamin E concentrations are either low or undetectable from birth; acanthocytes are usually present in the peripheral blood.

Hypobetalipoproteinaemia is a molecularly related but genetically distinct disorder inherited in an autosomal dominant manner and characterised by moderately reduced serum concentrations of cholesterol, triglyceride and low-density lipoproteins. Most patients are asymptomatic but neurologically they may present with ataxia, absent reflexes and proprioceptive deficits.

#### Autosomal recessive spastic ataxia of Charlevoix-Saguenay

This condition was thought to be extremely rare and probably confined to a region of Quebec. However, following identification of the gene it is now recognised to be the second most common ARCA (with a similar frequency to mutations of *senataxin*) after FRDA. Clinically, it is distinguished by the presence of a demyelinating neuropathy and hypertrophy of the retinal layer.

#### Other metabolic causes of ataxia

These are nearly all autosomal recessive disorders unless otherwise stated.

#### Intermittent metabolic ataxias

These may be caused by abnormalities in the urea cycle, amino-acidurias and disorders of pyruvate metabolism. Most commonly, a high ammonia as a marker of urea cycle dysfunction is the explanation. All these conditions have a similar phenotype with ataxia, dysarthria, vomiting, confusion and involuntary movements. Seizures and a variable degree of learning difficulties may also be seen. Precipitants are not always identified but a history of prodromal illness or a large protein load should be sought. Treatment consists of protein restriction and intravenous fluid administration during acute episodes.

Ornithine transcarbamylase (OTC) deficiency is X-linked and is the most common urea cycle enzyme defect. Affected males die in the neonatal period, but severity varies considerably in females, from the presence of severe neurological deficit to no symptoms apart from mild protein intolerance. It can present in adult or even late adult life. A heavy protein meal, infection or the prescription of valproic acid therapy can precipitate an encephalopathy in an asymptomatic case.

Amino acidurias including Hartnup's disease also need to be considered in the intermittent ataxias. There is often a super-added involuntary movement disorder, psychiatric disturbance and a variable degree of cognitive decline. A pellagra-like rash may also be seen in this condition. Hartnup's disease is caused by mutations in *SLC6A19* which encodes a neutral amino acid transporter. Some amino-acidurias, including intermittent branched-chain ketoaciduria and isovaleric acidemia, present in a similar clinical pattern to the hyperammonaemias. In contrast to the urea cycle disorders, a high-protein diet and oral nicotinamide therapy may help.

Pyruvate dehydrogenase deficiency (PDH) is rare and genetically heterogeneous, although the majority of cases are caused by mutations in the gene for X-linked E1  $\alpha$  subunit of the enzyme. However, there is a high frequency of manifesting female heterozygotes with a wide spectrum of disease severity because of variable X chromosome inactivation. Generally, it is a disease with an infantile onset although in manifesting females later onset and slightly more benign course can be seen. In addition to the complicated clinical picture of spasticity, seizures and severe learning difficulties, dysplastic features on brain MRI may be seen. The diagnosis is made most readily by assay of PDH activity in cultured fibroblasts.

Very rarely, intermittent ataxia has been reported as a result of multiple biotin-dependent carboxylase deficiencies. The picture is complicated, with generalised seizures, myoclonus, nystagmus and hypotonia. There are associated defects of humoral and cell-mediated immunity. It is important to diagnose by checking serum biotinidase activity as biotin therapy may result in clinical improvement.

#### Progressive metabolic ataxias

There is a long list of storage and other metabolic disease that can produce ataxia as a component of the presenting features, usually minor. Also, as awareness and diagnostic accuracy is improving most of these patients are identified in early life, in paediatric clinics. The list includes the sphingomyelin lipidoses, metachromatic leukodystrophy, galactosylceramide lipidosis (Krabbe's disease) and the hexosaminidase deficiencies. Also within this group is adrenoleuko-myeloneuropathy, discussed later in this chapter.

A late onset form of hexosaminidase A deficiency may result in a progressive ataxia with predominantly proximal neurogenic weakness. On imaging there is striking and selective atrophy of the cerebellum. Ataxia may also be seen in Niemann-Pick disease type C,

combined with a supranuclear gaze palsy. Sphingomyelinase activity is usually within the normal range, but foamy storage cells are found in the bone marrow. Unlike Niemann–Pick types A and B, type C is not caused by abnormalities in the sphingomyelin gene but in the *NPC* gene on chromosome 18. The exact molecular events leading to the mishandling of lipid and cholesterol are unclear.

Cholestanolosis (also called cerebrotendinous xanthomatosis, CTX) is a rare autosomal recessive disorder caused by defective bile salt metabolism, resulting from a deficiency of mitochondrial sterol 27 hydroxylase encoded by *CYP27A1* gene. It usually begins after puberty and gives rise to ataxia, dementia, spasticity and peripheral neuropathy. Systemically, it leads to premature atherosclerosis, cataracts and tendon xanthomas. Treatment with chenodeoxycholic acid and a statin appears to improve serological parameters and stabilisation of the disease.

### Autosomal dominant cerebellar ataxias

This is clinically and genetically a heterogeneous group of disorders. There are currently some 30 identified loci for the dominant ataxias. These are numbered in the sequence of each locus as it is found. Spinocerebellar ataxia type 1 (SCA 1) was one of the first neurological diseases to have its gene mapped, reported in 1977. Not all the genes have been identified (Table 17.5). Some common themes at both a clinical and molecular level emerge. The molecular consequences of the most common type of mutation is an expanded CAG repeat and the salient points are made in Table 17.6.

The dominant ataxias have two broad classification systems, one clinical and the other based on the underlying SCA mutation. Despite the progress in the genetic field, the clinical classification system proposed by Harding in 1984 remains useful for structuring diagnostic thoughts and the approach to genetic investigation. This clinical classification is divided into three parts, with a roman numeral for each.

ADCA I is characterised by a progressive ataxic syndrome complicated, variably, by cognitive impairment, pyramidal signs, supranuclear gaze abnormalities, neuropathy and extrapyramidal signs. It is extremely rare to see all these features in one patient; the burden of involvement within each system varies both within and between families. One needs to bear this in mind when taking a family history. The disease usually starts after the age of 25, although occasional childhood onset has been reported – a feature that is a consequence of anticipation, the result of the unstable and expanding nature of the underlying repeating mutations (Table 17.6).

ADCA II is also complicated; some of the features of ADCA I may also be seen but it is the macular dystrophy that singles out this disease. This is the rarest of the clinical subtypes; virtually all cases are caused by mutations in the *SCA7* gene.

ADCA III is generally of later onset than the other two subtypes and is a so-called ‘pure’ ataxia. A note of caution, however: the signs in ADCA I and II emerge with disease progression, so it is sometimes difficult to be sure that a patient and/or their family are truly ‘pure’ without the benefit of a long history and/or examining other affected relatives. As a rule of thumb, a progressive ataxia without additional features after 10 years’ duration is strong clinical evidence of ADCA III. The tests most widely used and available are detailed in Table 17.7.

As a rough rule of thumb, testing for SCA 1, 2, 3, 6 and 7 identifies the causative mutation in 50% of those with a clinical diagnosis of probable ADCA. The remaining 50% is comprised of the rarer SCAs including SCA 12, 14 and 17 and of course those yet to be identified.

### Dentato-rubro-pallido-luysian atrophy

Dentato-rubro-pallido-luysian atrophy (DRPLA), an autosomal dominant disorder found mainly in Japan but reported worldwide, has a variable clinical presentation comprising various combinations of ataxia, dystonia, myoclonus, seizures, dementia and parkinsonism. This disorder is another expanded CAG repeat (Table 17.6).

### Investigations

The main investigation involves the identification of the underlying mutation. A fairly widely available and relatively simple panel of gene tests is now available and should be the first investigation undertaken in suspected cases. However, the clinician should explain to the patient, and family if appropriate, the implications of a positive test. This should include the facts that it is inherited in an autosomal dominant fashion, so siblings and offspring are at 50% risk and that the penetrance is high – close to 100%.

Research imaging studies have highlighted some regional differences in patterns of brain atrophy, but none of these is currently useful in the clinical setting. Neurophysiological techniques may be helpful in identifying peripheral nerve. A detailed neuro-ophthalmological assessment can be helpful.

### Treatment

All these diseases are progressive, currently incurable and with no proven disease-modifying therapies available. The predominant mutations accounting for at least 50% of cases are caused by an expanded CAG repeat in the coding segment of the gene. This triplet encodes glutamine and these diseases are known as the polyglutamine disorders. As discussed in Chapters 8 and 10, this mutation is also found in other neurological disorders, Huntington’s disease and Kennedy’s syndrome. This indicates that there is something common in the pathway of neurodegeneration between these clinically distinct disorders; this raises hope that discoveries in one of these diseases will have an impact upon the others.

### Genetic forms of episodic ataxia

This heterogeneous group of disorders is characterised by a marked periodicity in attacks of ataxia. There are many of these patients who describe paroxysmal worsening of their disorder. Some will have clearly defined metabolic syndromes, as described earlier. Some have a familial disorder with an autosomal dominant pattern: these are described here. Many more have an ill-defined syndrome without a clear reason for these episodes. The unusual history of such episodes, if their nature is not recognised, often leads to the mistaken view that these are psychological in origin. At a molecular and genetic level, it is perhaps unsurprising that ion channel mutations have been implicated in many of these disorders.

### Episodic ataxia type 1

This is a rare disorder characterised by attacks of brief duration, lasting seconds or a few minutes. The attacks may be frequent; some patients may experience many attacks each day. Attacks may be precipitated by sudden movement or shocks. The condition classically presents in childhood and attack frequency lessens with age, so it is important to seek early life history in older relatives. They are most often associated with peripheral myokymia which can be seen clinically in some, but may require electromyography (EMG) to diagnose.

Mutations in a potassium channel *KCNA1* gene have been shown to cause this syndrome. This channel is closely related to the peripheral neuromuscular potassium channel, attacked by autoantibodies in neuromyotonia (Chapters 10 and 21), which also causes myokymia. Treatment success is variable; acetazolamide may help.

**Table 17.5** The autosomal dominant cerebellar ataxias.

SCA no.	Genetic locus	Gene	Clinical pointers	Notes
1	6p22.3	Ataxin 1 CAG repeat	Complicated, including: neuropathy, cognitive decline, pyramidal and extrapyramidal features	
2	12q24.13	Ataxin 2 CAG repeat	As above, plus slow saccades and neuropathy	
3	14q32.12	Ataxin 3 CAG repeat	As above but a stronger extrapyramidal phenotype	Probably most common worldwide
4	16q24-qter	N/K	Associated with a neuropathy	
5	11q13.2	SPTBN2 beta-III spectrin D		Very rare
6	19p13.13	CACNA1A CAG repeat	Later onset (>45 years) and relatively pure	Point mutations in this gene produce either familial hemiplegic migraine or EA2
7	3p14.1	Ataxin 7 CAG repeat	Complicated, with slow saccades and prominent macular dystrophy	Shows the most marked anticipation in the known SCAs
8	13q21	Kelch-like 1 CTG repeat		Uncertain pathogenicity
9	SCA9	Reserved		
10	22q13.31	Ataxin 10 ATTCT repeat		
11	15q14-q21.3	Tau-tubulin kinase 2 point mutation		Pure ataxia
12	5q32	PPP2R2B CAG repeat	Prominent tremor	
13	19q13.33	KCNC3 point mutations		
14	19q13.42	PRKCG point mutations	Prominent dystonia	
15	3p24.2-pter	ITPR 1		
16	8q23-q24.1	Not known (NK)		
17	6q27 TBP	TBP CAG repeat	HD-like features	Rare
18	7q31-q32	N/K		Additional sensor-motor neuropathy
19	1p21-q21	KCND3		Allelic to SCA 22
20	11q12	Heterozygous duplication		A contiguous gene duplication syndrome
21	7p21.3-p15.1	TMEM230	Cognitive Impairment	
22	1p21-q23	KCND3		Allelic to SCA 19
23	20p13-p12.2	PDYN		
24	1p36	N/K		1 Family
25	2p21-p15	N/K		1 Family
26	19p13.3	EEF2		1 Family
27	13q33.1	FGF14 point mutations		
28	18p11.22-q11.2	AFG3L2		Can also cause AR spastic ataxia 5
Unspecified	16q22.1	Puratrophin 1 point mutations		Overlaps SCA 4 region, but not definitively SCA 4 gene

**Table 17.6** Core principles of the polyglutamine tract disorders.

- Several neurodegenerative disease are caused by the same type of mutation; namely, an expanded encoded CAG repeat – Huntington's disease, SCAs 1–3, 6, 7, 17, dentato-rubro-pallidoluysian atrophy (DRPLA) and Kennedy's disease
- The CAG repeat is polymorphic in both normal and disease-associated chromosomes. However, once above a critical threshold the repeat becomes more unstable and may expand from one generation to the next
- There is a tight inverse correlation of length of repeat and age at onset
- Anticipation is seen: this is the phenomena of earlier onset and often more severe disease in succeeding generations
- The greatest instability is seen in the paternal line and most cases of anticipation and *de novo* mutation occur on transmission of an allele from father to offspring
- The CAG codon encodes glutamine and this expanded glutamine tract is in some way 'toxic' to adult neurones

The prevalence of the individual disease varies worldwide and is in part determined by the proportion of high normal repeats in the general population. It is believed that this high normal repeat is an occasional feeder of the *de novo* mutations.

**Table 17.7** Clinical impact of the autosomal dominant cerebellar ataxias (ADCAs).

ADCA type	Genetic tests (widely available)	Relative contribution to each subclass (%)
ADCA I	SCA 1–3	50
ADCA II	SCA 7	99
ADCA III	SCA 6	50

### Episodic ataxia type 2

This is more common than EA1; clinically these attacks resemble a form of vertebro-basilar migraine attack. The attacks generally last hours, build up over several minutes and are associated with nausea, vertigo and often vomiting. The patients look pale and unwell. There may be an associated mild headache. The attacks may vary from daily to several months between. Again, attacks become less frequent as the patient enters adulthood. However, unlike EA1 a slowly progressive ataxia usually develops over the years. The typical picture is to see children or adolescents with episodes, with a parent with a more progressive permanent ataxia.

This disorder is caused by point mutations, usually of nonsense type, in the calcium channel gene *CACN1A*. This is the same gene that may cause familial hemiplegic migraine (Chapter 12) and SCA 6 (see Autosomal dominant cerebellar ataxias). This phenomenon, where different clinical disorders are caused by different mutations in the same gene, is called allelic heterogeneity.

Treatment by acetazolamide may be useful, but some have had more success with dichlorphenamide. There is no evidence currently that preventing attacks impacts on the progressive component of the illness, but as EA2 is a rare disorder this is hard evidence to obtain.

### Other episodic ataxias

There are families reported with episodic ataxia but no evidence of mutations in either of the above genes. EA3 describes a family with vertigo and tinnitus; there is evidence that the disease causing

mutation lies on 1q42. EA4 has been used to describe a family with periodic vestibulo-cerebellar ataxia (PATX). There are several other novel genes for EA recently described.

### X-linked ataxia syndromes

The ataxic syndromes associated with mutations on the X chromosome are generally rare and usually complicated. Moreover, the clinical picture points to the underlying diagnosis. A variant of adrenoleukodystrophy may produce ataxic features; the presence of a pyramidal leukodystrophic phenotype with a demyelinating neuropathy usually points to the correct diagnosis. A measurement of serum very long chain fatty acids is a useful screening tool and mutations in the underlying gene can be sought. Pelizaeus–Merzbacher disease can produce an early life onset complicated ataxia; mutations or rearrangements of the *PLP* gene can be detected. Neuro-acanthocytosis is described in more detail in Chapter 6; usually ataxia is overshadowed by the involuntary movements of chorea and dystonia. Autosomal dominant, autosomal recessive and X-linked forms have all been described. A wet blood film looking for 'thorny' red cells (acanthocytes) should be requested. The X-linked form, also called McLeod's syndrome, is associated with abnormalities of the Kell antigen.

Fragile X tremor ataxia syndrome (FXTAS) is a recent addition to the differential diagnosis of mid to late life onset progressive ataxia. Fragile X syndrome is the most common cause of mental retardation in males and is caused by an expanded (non-coding) repeat in the *FMR1* gene. In the 'normal' range of repeats there is a high normal or premutation repeat length (55–200 CGG repeats). Hitherto, this has been considered purely as a substrate for occasional expansion into the disease-associated range and the production of fragile X syndrome in male descendants. Jacquemont *et al.* (2004) reported an excess of pre-mutation carriers in patients with a late onset ataxia syndrome with prominent tremor and associated cognitive decline. Others have confirmed these findings and pathological examination has revealed the presences of novel proteinaceous nuclear inclusions in both neurones and astrocytes. They are ubiquitin positive but dissimilar to the inclusions of Parkinson's disease, Alzheimer's disease and other tauopathies, nor do they resemble the nuclear inclusions seen in CAG repeat disease. Imaging reveals generalised volume loss of cerebrum and cerebellum and signal changes in the middle cerebellar peduncles. Diagnosis of FXTAS in appropriately selected clinical cases is by genetic analysis of the *FMR1* repeat.

### Mitochondrial ataxia syndromes

The range of disorders that can be caused by mitochondrial DNA (mtDNA) mutations is described in Chapter 10. In brief, mtDNA is entirely maternal in origin so inheritance of any traits caused by mutations in the 16.5 kb circular DNA molecule is through the maternal line. Mitochondria are vital for oxidative phosphorylation and any defects in this system can have wide-ranging multi-systemic features. Ataxia is quite common in a number of well-characterised mtDNA syndromes. Kearns–Sayre syndrome is an early life (<20 years) disorder of ataxia, progressive external ophthalmoplegia, pigmentary retinopathy and raised cerebrospinal fluid (CSF) protein. Most commonly it is caused by a deletion of approximately 5 kb of the mtDNA molecule. This usually arises spontaneously and is non-transmissible and therefore is generally non-familial. Missense mutations may also cause complicated ataxia phenotypes including neurogenic ataxia and retinitis pigmentosa (NARP), caused by a mutation at 8993 and the point mutations at 3243 (MELAS) and 8344 (MERRF) syndromes. As a general rule, a complicated multi-systemic disturbance particularly those involving dementia, deafness and visual problems with or without lactic acidosis suggests a mitochondrial disease. A muscle biopsy may be required (Chapter 10).

There is also overlap with the so-called Ramsay-Hunt syndrome of ataxia and myoclonus. The differential diagnosis includes MERRF, DRPLA, ceroid lipofuscinosis, sialidosis, and Unverricht-Lundborg disease. Usually, seizures are common in these latter disorders.

Many of these disorders are now amenable to direct gene testing for the underlying mutation and it is worth checking with the local genetic laboratory for available tests.

### Next generation gene sequencing

The revolution in technologies that has allowed a huge increase in speed and accuracy of genetic testing coupled with a consequent massive reduction in cost has not only had a major impact on gene identification, but is also starting to influence the range of gene tests available. It is by the nature of this innovation that any statements in textbooks will be out of a date by the time of publication and it is often necessary to use the variety of genetic information available on the internet for the most up-to-date information. It is likely that over the next few years the remaining genetic disorders, including the ataxias, will be identified and there is also great optimism that genome sequencing will be made more available for diagnostic use.

### Acquired ataxia syndromes

Of the many acquired cerebellar disorders, chronic alcohol abuse is probably the most common, followed by various nutritional deficiencies. The more common acquired disorders are mentioned here.

#### Infective disease

In this section, only those infections that give rise to prominent cerebellar dysfunction are discussed. For a more detailed account of CNS infections, see Chapter 9.

#### Acute or subacute onset

Acute cerebellar ataxia of childhood is the most common acute ataxia and although attributed to a viral infection, serological evidence is usually lacking. The usual viral causes include echoviruses, coxsackie groups A and B, poliovirus, Epstein-Barr and herpes simplex virus. Very occasionally some bacteria produce a similar syndrome.

The condition usually presents between the ages of 1 and 8 years and a mild prodromal illness is sometimes reported. The illness worsens over hours or occasionally days; the child presents with severe ataxia particularly of the midline, with the limbs relatively spared. Additional features include myoclonus, opsoclonus or ocular flutter. Despite this dramatic presentation the outlook is good although it may take several months for full recovery.

Post-infective processes may also affect the cerebellum and its connections. Ataxia is particularly well recognised as part of the syndrome of post-infectious disseminated encephalomyelitis after varicella infection. It has also been reported following measles, rubella and mumps. There are a number of brainstem syndromes including Bickerstaff's encephalitis and the Fisher variant of acute inflammatory polyradiculoneuropathy, which may present with ataxia, but the clinical picture is complicated by brainstem signs such as ophthalmoplegia.

#### Progressive ataxia with a chronic or subacute course

Infections causing progressive ataxia are all rare. In childhood, one needs to consider the post-measles complication of subacute sclerosing panencephalitis. This rare but serious condition has a number of other features including myoclonus and cognitive decline. Congenital rubella may produce a pancerebellar syndrome in association with dementia,

optic atrophy and occasionally multifocal myoclonus with onset between the ages of 8 and 19 years. HIV infection has become the great mimic and may produce an encephalopathy with ataxic features.

In adulthood there are very few infective agents that produce a progressive cerebellar presentation. Of most importance are the various presentations of prion disease. These are discussed in more detail in Chapter 8. Ataxic features are most commonly found in the familial Gerstmann-Sträussler-Scheinker syndrome and in variant Creutzfeldt-Jakob disease. The iatrogenic form of spongiform encephalopathy also produces a predominant ataxic phenotype. This disease resulted from erroneous contamination and inoculation by a variety of means, including growth hormone replacement therapy, corneal and dural grafts. It has become rare, following its identification and the important public health measures that ensued.

Cerebellar involvement has also been described following infection by *Mycoplasma pneumoniae*, *Legionella pneumoniae* and *Toxoplasma gondii*, as well as in typhoid fever and tick paralysis. Lyme disease can produce an ataxic picture complicated by bilateral facial palsy and CSF lymphocytic pleocytosis. A number of tropical infections also need consideration in the appropriate clinical setting. A transient cerebellar syndrome lasting several weeks and resembling acute cerebellar ataxia of childhood has been reported following *Plasmodium falciparum* infection. Cerebellar signs, particularly gait ataxia, are common in the racemose form of neuro-cysticercosis (Chapter 9).

'Vanishing white matter disease' is one of the more prevalent inherited childhood leukoencephalopathies and is characterised by progressive neurological decline, and in particular cerebellar ataxia (Chapter 11). However, there is wide phenotypic variability and it may present in adulthood. It is an unusual disease in which there is a genetic defect (in one of five subunits of a translation initiation factor eIF2B) and yet its sensitivity to febrile infections is striking. MRI is usually extremely helpful in establishing the diagnosis.

Space-occupying lesions of the posterior fossa associated with fever require urgent imaging to identify the possibility of a cerebellar abscess. These usually present relatively subacutely with headache and symptoms and signs of raised intracranial pressure. TB may produce a more indolent condition.

#### Inflammatory disease

An isolated cerebellar syndrome is a rare presentation of multiple sclerosis. MRI shows white matter lesions, which is usually the reason multiple sclerosis is considered. The differential diagnosis of possible demyelinating disease or other inflammatory conditions are discussed in Chapter 11. They include sarcoidosis, systemic lupus erythematosus (SLE) and similar syndromes, antiphospholipid and Sjögren's disease. Investigation needs to be tailored to the clinical impression and but involves appropriate antibody tests, CSF examination, and ancillary tests such as lip biopsy in the case of sicca syndrome.

#### Vascular disease

Degenerative cerebrovascular disease can present with an abrupt onset cerebellar and/or brainstem syndrome. The presence of severe headache, raised intracranial pressure and impairment of consciousness suggest the possibility of a posterior fossa haematoma. This is a neurological emergency and requires urgent imaging to determine the necessity for neurosurgical intervention. Outcome is worse if diagnosis is delayed.

Thrombotic and embolic events cause an isolated cerebellar syndrome relatively rarely; commonly there are associated brainstem signs, such as diplopia and vertigo. These conditions are discussed in Chapter 5.

### Vascular anomalies

Cerebellar haemangioblastomas are vascular and cystic tumours that can present as mass lesions with a consequent cerebellar syndrome. The lesion usually takes the form of an expanding cyst, which causes the subacute deterioration. Appropriate imaging reveals the anatomy and extent of the cyst, and neurosurgical management is usually effective in resolving the symptoms. These tumours rarely bleed spontaneously, but once this has happened, they do need to be monitored. Generally growth results in progressive symptoms and signs and thus regular imaging is not always required.

These tumours can occur throughout life, but the development of a haemangioblastoma before the age of 40 raises the possibility of von Hippel–Lindau disease (VHL). The presence of two haemangioblastomas or a family history are almost diagnostic of this condition. This is important to establish, as the patient and at risk family members will need to be considered for genetic screening. Because VHL is a multi-system disorder, further investigation is required which should include neuro-ophthalmological examination for the retinal angiomas, abdominal imaging for multiple organ cysts, renal cell carcinomas and pheochromocytomas. Twenty-four hour urinary catecholamines should be measured in all cases. VHL is inherited in an autosomal dominant manner although there is a significant new mutation rate, so the absence of a family history does not exclude the diagnosis nor the need for relative screening once the diagnosis is confirmed.

Other vascular anomalies such as dural fistulae and arteriovenous malformations are discussed in Chapter 5; they are relatively rare causes of an ataxic syndrome.

Chronic bleeding, often from an unknown cause can result in superficial siderosis. This is a rare disorder, more common in males than females (3 : 1) that causes slowly progressive cerebellar ataxia, mainly of gait, and sensorineural deafness, often combined with pyramidal signs. It may also be complicated by dementia, bladder disturbance, anosmia, anisocoria and sensory signs. The MRI features are diagnostic, showing a dark rim around the posterior fossa structures and spinal cord on T2 images. These signal changes represent encrustation of the brain surfaces with haemosiderin. Treatment when possible relies on identifying the source of bleeding (Figure 17.2).

### Acquired metabolic disorders

These disorders includes Wernicke's encephalopathy, hepatic encephalopathy, pontine and extrapontine myelinolysis related to hyponatraemia, and hypothyroidism. The latter is only very rarely a cause of a cerebellar syndrome, but as it is potentially treatable it should always be considered. Generally, the other clinical features of these conditions point towards the appropriate investigation and although rare they are all potentially treatable, modifiable or avoidable.

### Toxins and physical agents

A large variety of toxins, drugs and other physical agents have been implicated in the pathogenesis of cerebellar disorders. They predominantly cause an insidious onset, slowly progressive clinical syndrome with variable degrees of atrophy on imaging. Direct evidence for causation is not always found and one is often left to take a pragmatic approach to toxin exclusion, where this is possible.

#### Ethyl alcohol (ethanol)

Ethanol is by far the most common toxin producing a cerebellar ataxia (Chapter 19). Acute toxicity produces the well-known effects of staggering gait and slurred speech. Chronic abuse may produce an insidious, slowly progressive gait and limb ataxia with associated dysarthria. This is generally a pure ataxia without pyramidal signs.

However, an alcohol-induced neuropathy is frequently also present and this may only be detected with neurophysiology. Imaging usually shows cerebellar atrophy. Lifelong abstinence is strongly advised but even then the disease may continue to progress. However, there is usually some stabilisation and very occasionally mild improvement. Thiamine supplementation is advisable.

### Drugs

Antiepileptic medication, especially phenytoin, carbamazepine and the barbiturates, can all cause an acute or subacute cerebellar syndrome when the dose is too high. This susceptibility varies from patient to patient and cannot be judged by serum level alone but should be based on symptoms and signs. The latter include nystagmus, dysarthria and gait ataxia. The symptoms may be transient and reflect peak dose levels. There is some evidence that chronic exposure may result in a permanent and progressive cerebellar syndrome in a small minority of cases. This syndrome is usually irreversible although cessation may stop or slow progression.

Lithium toxicity, or as a sequelae to an acute encephalopathy, may produce an irreversible and persistent deficit. There may be a history of an acute precipitant such as starvation or fever.

There is a rare reversible ataxia associated with a variety of drugs, including piperazine (for threadworm), high dose 5-fluorouracil and cytosine arabinoside.

### Solvents and solvent abuse

Acute exposure to solvents (Chapter 19) can produce a reversible syndrome but prolonged exposure has been reported to produce a persistent deficit. Additional features such as behavioural problems, confusion, cognitive deficits and even psychosis may be seen.

### Heavy metals

In the developed world this is an increasingly rare explanation of the usual progressive and complicated ataxias produced by heavy metals including thallium, lead and methyl mercury (Chapter 19). Features and complications vary. These include distal parasthesiae and cortical blindness (Hg), neuropathic features (Pb and Th) and hair loss (Th). Although often coming on abruptly, features may develop some weeks after exposure.

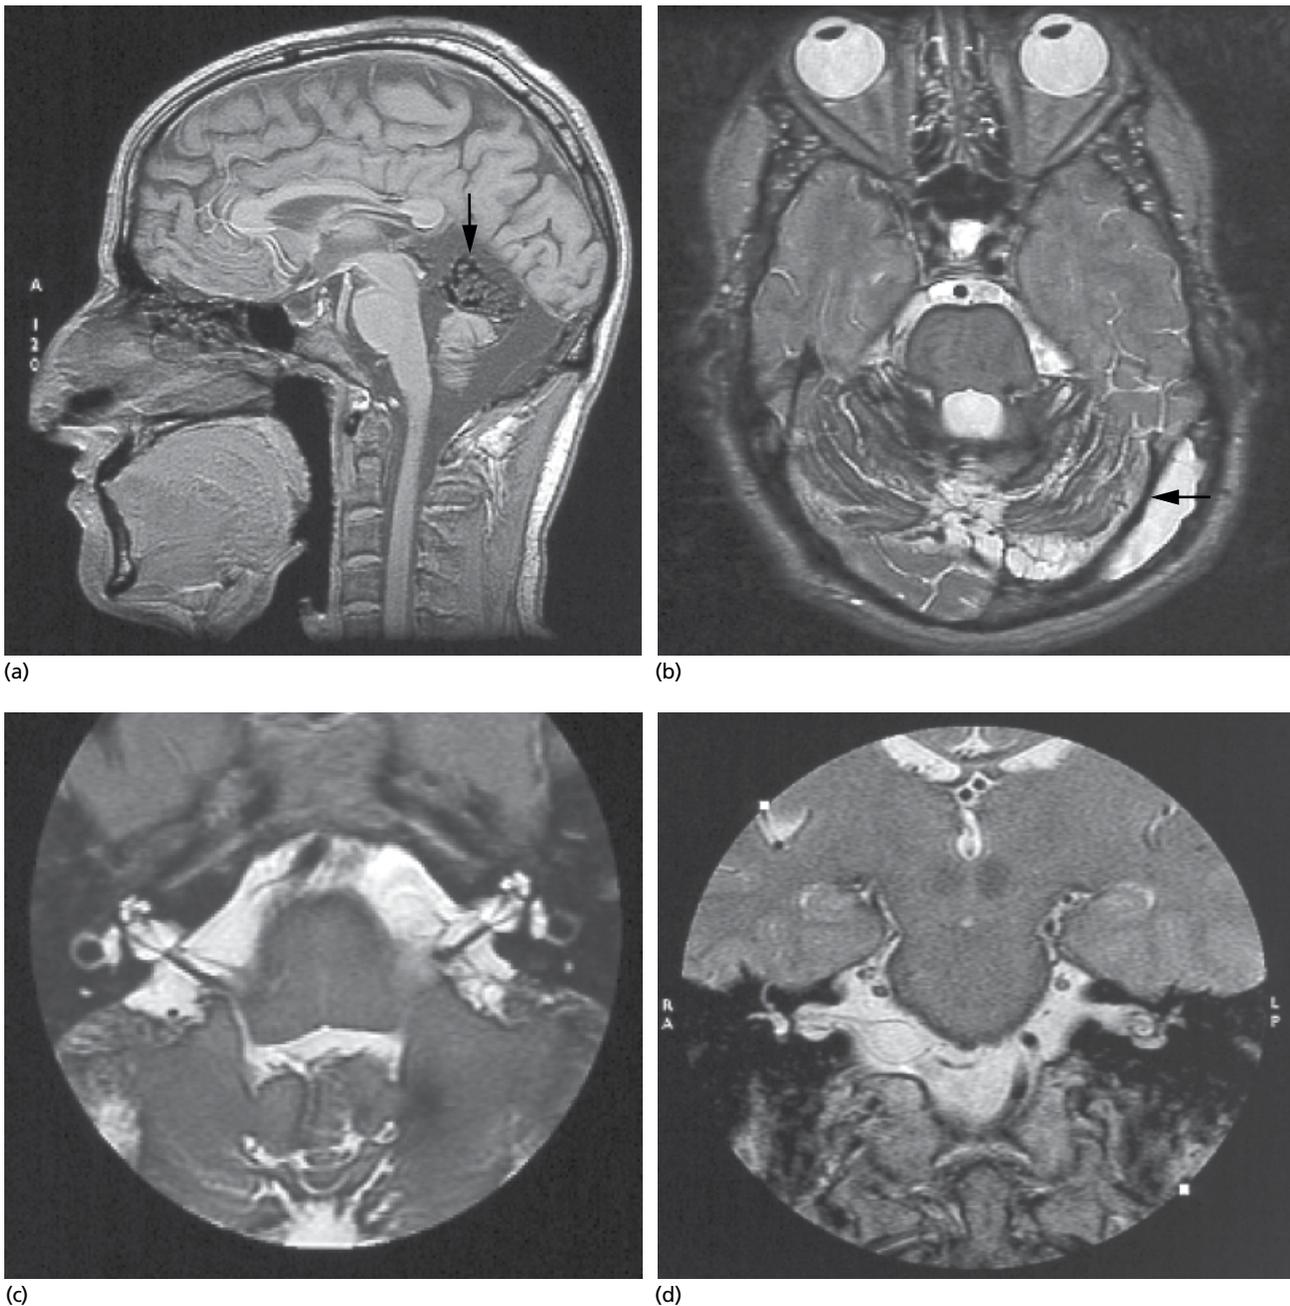

### Physical agents

Hypoxia, heat stroke and hypothermia (Chapter 19) may all produce cerebellar features and at autopsy quite profound Purkinje cell loss may be seen. However, these significant insults often produce generalised cerebral dysfunction that usually dominates the clinical picture.

### Paraneoplastic cerebellar degeneration

This syndrome is quite distinctive (Chapter 21), with generally a subacute onset, over weeks and months, of midline cerebellar ataxia, usually profound. Typically, patients lose independent mobility within 12–18 months. They may also have chaotic eye movements and oscillopsia. The diagnosis should be suspected in such aggressive cases with onset in later life. Imaging is helpful in that it is typically virtually normal: there are few conditions that produce such unimpressive imaging findings in the face of a major clinical syndrome. Another disease area to consider in this situation is prion-related ataxia.

General health questioning may reveal symptoms such as weight loss, general debility or symptoms suggestive of a primary tumour. There has been substantial progress in our understanding of these disorders and at the time of writing nine specific antibodies have been identified in patients with paraneoplastic cerebellar degeneration

**Figure 17.2** Magnetic resonance imaging (MRI) of siderosis in a 38-year-old man with progressive tinnitus, deafness and ataxia (courtesy of Queen Square Imaging Centre). (a) Sagittal MR showing hypointensity in cerebellum, with cerebellar atrophy. (b) T2-weighted axial MRI showing superficial hypointensity surrounding cerebellum. (c, d) T2-weighted MRI showing superficial hypointensity surrounding VIII and V.

(PCD). These are shown in Table 17.8. The major tumours associated with PCD are gynaecological, breast, lung and testicular cancers and Hodgkin's lymphoma. Frequently, the tumours are small and difficult to identify. The role of antibodies (if any) in causation is not clear. It would appear that there is an autoimmune response to the cancer, which may keep the tumour in check, and that this response produces antibodies that cross-react with cerebellar antigens. Management is based on identification and treatment of the underlying malignancy. Immunomodulation, mostly with intravenous immunoglobulin or plasma exchange, has been tried but with variable success.

There are some patients who present with a sub-acute ataxic syndrome in whom no neoplastic lesion can be found. A minority of

these patients have evidence of an immunological process (e.g. CSF oligoclonal bands  $\pm$  antibodies). The pathogenic role of the immunological dysfunction is frequently unclear. In some instances there are reports of an antibody association with cerebellar ataxia (e.g. anti GAD) the pathogenic role in such cases remains unclear.

### Late onset cerebellar degenerations

These conditions are probably the largest and least understood group of ataxias that present in adulthood to the neurologist. The aetiology is almost certainly heterogeneous and the syndromes that are recognised vary in some of their features.

**Table 17.8** Antineuronal antibodies (after Shams'ili *et al.* 2003).

Antibody	Clinical syndrome	Associated cancer	Immunohistochemistry
Anti-Yo	Cerebellar ataxia	Ovarian, breast	Cytoplasm of Purkinje cells and large brainstem neurones
Anti-Hu	Cerebellar ataxia, PEM/SN	SCLC	Nuclei of all neurones, nucleolar sparing
Anti-Ri	Cerebellar ataxia, OM	Breast, gynaecological, SCLC	Nuclei of all central neurones, with nucleolar sparing
Anti-Tr	Cerebellar ataxia	Hodgkin's lymphoma	Cytoplasm and dendrites of Purkinje cells
Anti-VGCC	Cerebellar ataxia, LEMS	SCLC (60%)	–
Anti-Ma	Cerebellar ataxia, brainstem dysfunction	Numerous	Nuclei and cytoplasm of neurones
Anti-Ta/Ma2	Limbic encephalopathy, cerebellar ataxia	Testicular	Nuclei and cytoplasm of neurones
Anti-CRMP5/CV2	PEM/SN, cerebellar ataxia	SCLC, thymoma, gynaecological	Cytoplasm of oligodendrocytes
Anti-mGluR1	Cerebellar ataxia	Hodgkin's lymphoma	Cytoplasm of Purkinje cells and brush cells, climbing fibres

LEMS, Lambert–Eaton myasthenic syndrome; OM, opsoclonus/myoclonus; PEM, paraneoplastic encephalomyelitis; SCLC, small cell lung cancer; SN, sensory neuronopathy; VGCC, voltage gated calcium channels.

### Multiple system atrophy

This is the most common clearly defined syndrome, accounting for up to 50% of the late onset cases. Multi-system atrophy (MSA) usually starts in the sixth to seventh decades and unfortunately is relentlessly progressive, with severe disability within 5–7 years. It may present with a parkinsonian syndrome (Chapter 6), with autonomic dysfunction (Chapter 24) or as a cerebellar syndrome. Whatever the initial presentation other features tend to develop with time, although usually one set of clinical features predominates. Associated extra features include urinary symptoms, postural dizziness and REM sleep disturbance. Additional clinical signs include signs of extrapyramidal disease; these may be mild and need careful clinical assessment to determine, lying and standing BP, antecollis and mini-myoclonus in the fingers.

There is no absolute diagnostic formulation for MSA; the internationally agreed criteria require typical pathological features for a definite diagnosis. MRI may reveal signs of brainstem and cerebellar atrophy and also the 'hot cross bun sign'. This is not entirely specific, but in the right clinical setting does strongly support the diagnosis. Sphincter EMG may also show evidence of denervation, and autonomic function assessment may help both diagnostically and to allow appropriate symptom management.

The management of MSA involves a coordination of expertise with input from a multi-disciplinary team. There is no satisfactory drug treatment for the cerebellar features but physiotherapy and other support services can be of benefit.

### Ataxia and sensitivity to gluten

This is the relatively newly described syndrome in which patients with mid and later life onset of progressive ataxia have been reported either to have clinical signs or intestinal biopsy features of gluten enteropathy

(e.g. coeliac disease), or have a range of antibodies (principally antigliadin) suggesting sensitivity to gluten. This manifests itself as a neurological disease, termed gluten ataxia. However, antigliadin antibodies are non-specific and relatively common in the general population; their actual role in the ataxia remains uncertain. Anecdotally, it is said that gluten exclusion does not appear to impact on the progression, but well-designed studies are needed to confirm this.

### Idiopathic late onset ataxia

This is an heterogeneous syndrome encompassing the significant proportion of cases of presumed degenerative ataxia in which no cause is found. Typically, the symptoms start in the sixth decade and beyond; patients present with a slowly progressive relatively pure ataxia. There are exceptions, and in particular mild pyramidal signs can be found, but the cerebellar features predominate. The prognosis in this group is generally somewhat better than those with the cerebellar presentation of MSA.

### Conclusions

The differential diagnosis of the ataxias is long, and often complex. However, there are some basic rules that are a valuable guide: the age at onset, pattern of onset and course provide a quick and fairly reliable initial screen. After these specific questions, the family history, alcohol exposure and additional neurological symptoms often lead to a clear diagnostic shortlist, even before examination. Examination is focused on delineating the cerebellar features and seeking evidence of involvement in other systems. Investigation is then tailored to the emergent differential list.

Unfortunately, the drug treatment of ataxia for either symptoms or disease modification is still very poor. However, there are a small

number of treatable or modifiable diseases; these should be rigorously excluded whenever they are suspected. Established balance problems are very resistant to any pharmacological intervention. Supportive therapies such as speech therapy and physical interventions are frequently required. It is hoped that as we further our understanding of the molecular and cellular processes involved that more targeted and rational therapies will emerge.

There are many opportunities for the prevention or reversal of disease, but health care systems worldwide are dominated by people with chronic diseases and conditions that in general have not been prevented and cannot be reversed. In the United States, patients with chronic conditions account for nearly 80% of health care costs. In the United Kingdom, neurological damage accounts for 40% of people who are severely disabled and require daily help, and for most of those with complex disabilities resulting from a combination of physical, cognitive and behavioural problems. Any health care system is thus confronted on a daily basis with a demand to meet this need from finite resources. This chapter addresses the nature of disability, how it can best be ameliorated, which training techniques and medical treatments are most effective, particularly after single incident brain injury, and the organisational structures required for their optimal delivery.

## The nature of disability and its optimal management

When reversal of pathology is incomplete, profound life changes may result from the consequences of a disease or condition, classified in a framework by the WHO International Classification of Functioning (ICF) in 2001 as:

- 1 Loss of physiological and psychological function or anatomical structure, collectively known as impairments,
- 2 Limitations in functional activities, and
- 3 Restrictions of participation in social roles (Figure 18.1).

In these circumstances, the majority of disabled people benefit from the goal-focused learning and problem-solving process termed rehabilitation, delivered by skilled multi-disciplinary rehabilitation teams. Although often not made explicit, aspects of this process are integral to the optimal management of many chronic disorders. In the context of neurological disease, rehabilitation goals are achieved via:

- 1 The prevention of avoidable secondary systemic, neurological and psychological complications of a disease
- 2 Functional compensation via behavioural adaptation and substitution, and modification of personal, environmental and social contextual factors, and
- 3 Neural restoration and substitution (Table 18.1), delivered by organised complex polymodal inpatient, residential or community-based intervention programmes.

As a result, functional independence is increased, or at least maintained, and avoidable deterioration prevented. In addition, the difficult process of adjustment to loss and change is made possible, so that life quality and personhood is subjectively improved, to make life really 'worth living'. These crucially important outcomes are easily forgotten during investigation and assessment at the level of impairment, for example during a functional imaging study, the injection of botulinum toxin or a physiotherapy session in the gym.

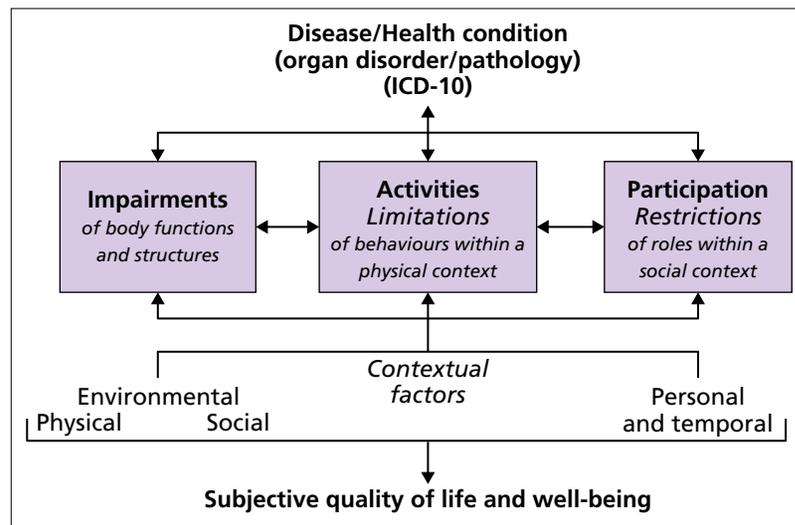

## Key aspects of multi-dimensional rehabilitation

A holistic biopsychosocial individualised multi-dimensional rehabilitation programme includes:

- Reiterative multi-disciplinary assessment,
- Problem definition and measurement,
- Goal-setting and treatment planning,
- Treatment delivery,
- Evaluation of effectiveness, and
- Reassessment with a view to further treatment.

Medical and surgical pathological diagnoses and treatments are combined with interventions, acutely and longer term, in parallel rather than in series (Figure 18.2), involving training and skill learning, in order to achieve attitudinal and behavioural change, reduce impairment and functional dependence, and facilitate social roles and life quality. Skill retraining is largely delivered via physical, occupational, speech and language and cognitive therapies, and may include facilitation of adaptation to loss by both the patient and family, the prescription of appliances and environmental modifications, and the development and application of new technologies and service delivery systems. In the context of disorders that affect brain function, and therefore learning, particularly well-defined and structured treatments are required to achieve skill learning.

Rehabilitation is thus a complex intervention, and is delivered via a menu of multi-disciplinary inpatient and community-based service delivery systems which differ by plant, personnel and process (Figure 18.3). A classification of these different service options, as a rehabilitation typology, remains to be agreed nationally and internationally, let alone cross-culturally but would facilitate the development of service delivery systems or networks via comparison

**Figure 18.1** A holistic biopsychosocial model of illness and health via an interactive classification of disease (ICD-10), function (ICF 2001) and subjective quality of life (sQoL).

**Table 18.1** Mechanisms of recovery after neurological damage.

---

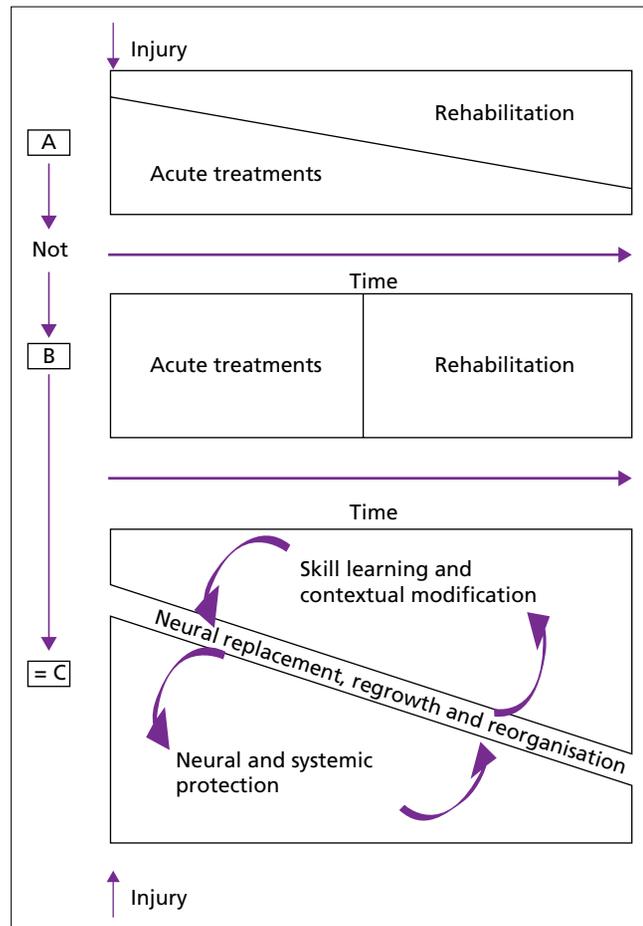

studies and audit of agreed guidelines. The use of each component of such a network is driven by a number of factors:

- Patient need
- Pre-injury characteristics
- Co-morbidities
- Time since injury
- Level of dependency
- Characteristics of the residual impairments
- Age
- Social back-up, and
- Resources available.

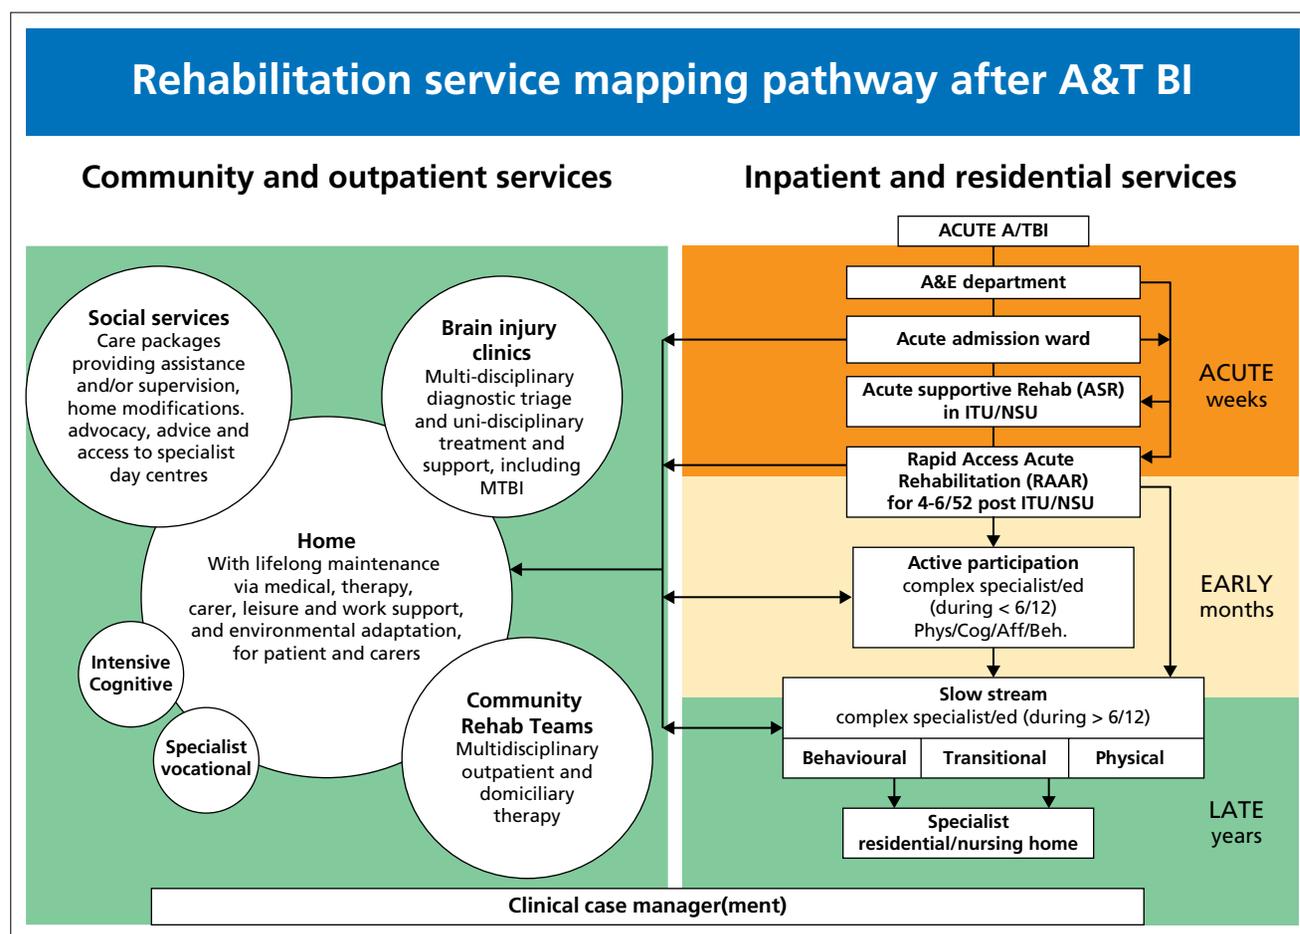

## Natural histories of neurological damage

The ways in which the inpatient and community-based components of rehabilitation service systems are configured, used and linked are driven largely by three differing natural histories of neurological disease and injury:

- 1 Single incident brain and spinal cord damage, and acute peripheral paralyses;
- 2 Deteriorating conditions including late stage multiple sclerosis, degenerative dementias, and motor neurone and Parkinson's disease;

**Figure 18.2** Acute treatments focus on neural and systemic protection, while rehabilitative strategies involve skill learning and contextual modification. Their use in parallel (a) rather than in series (b), combined with care and over time, is most likely to prevent complications and entrain the neurobiological processes contributing to neural restoration so that outcomes are optimised (c).

**Figure 18.3** Classification of rehabilitation services after single incident acquired and traumatic (A&T) brain injury (BI) by time, severity and need. Acute medical and surgical management varies by pathology and is described elsewhere. The rehabilitation options illustrated can be defined and coded to clarify gaps in service provision and clinical pathways. MTBI, mild traumatic brain injury.

3 Initially static conditions such as cerebral palsy, post-polio syndrome and the late effects of other single incident events sometimes acquired in childhood.

Inpatient and community-based components in each of these three clinical pathways should provide both regional (high-cost, low-volume) and local service options for patients with more or less severe and complex disability. Provision of a coordinated menu of services across health and social care boundaries is very difficult but essential because most of the work associated with managing any long-term condition is done in the individual's home and community, with only a small fraction occurring in a hospital or other residential environment. Both the affected individual and their family, if involved, require informed encouragement, support and advice to maintain a balanced access to different management strategies. This may fail at certain points during the disease trajectory and require specialist input.

The key to effective longitudinal management is to ensure that interventions are appropriate and timely. This requires effective and interactive verbal and written communication across health and social care sectors, and ongoing involvement with the individual and family. There are many benchmarks and models to guide best practice for the longitudinal provision of inpatient and community-based rehabilitation, work (re)entry, personal care and support, equipment

and accommodation, palliative care, and support for family and carers in the context of long-term neurological conditions.

### Resources, integrated care pathways, effectiveness and evidence base

In the United Kingdom, these were summarised in 2005 by the Department of Health's National Service Framework (NSF) for long-term neurological conditions, which sets out 11 evidence-based quality requirements 'to improve health and social care services for people with long-term neurological conditions and their carers', with the aim to promote quality of life and independence by ensuring patients received timely coordinated care and support planned around their needs and choices. Whether problems with the implementation of these recommendations, discussed by the UK National Audit Office in 2011, can be at least partially resolved by specialist nurses or clinical or organisational case managers, remains to be investigated.

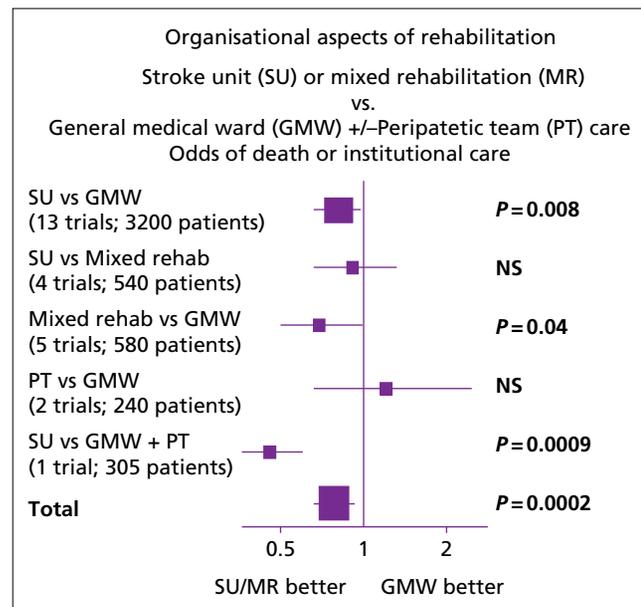

The composition of the multi-disciplinary teams that deliver these complex interventions differs depending on clinical need. Cohesive engagement of such a team requires a framework that makes explicit 'who does what, when, where and how' to achieve a commonly agreed aim, via a series of long and short-term goals,

agreed, if possible, with the patient. Linguistic harmonisation between disciplines, particularly between doctors, nursing and the therapies in an inpatient setting, and health and social services in the community, is crucial to success. In a clinical setting, this framework is provided by both generic and individualisable documentation that reflects, and thus measures, a classification of the consequences of a disease.

Integrated Care Pathways provide a multi-disciplinary team with generic evidence-based checklists, process and disease focused, which describe core clinical activities that underpin a patient's management longitudinally, and prompt and educate health care teams at all levels. A generic checklist of this type should be complemented by a regularly reiterated individualised formulation of a plan of care in which the patient, if possible, and each member of the team contributes in discussion to an Interdisciplinary Care Plan, which defines and documents at regular intervals the patient's problems, their needs and the action plans necessary to achieve agreed short and long-term goals en-route to an overall aim. Audit of clinical decision support systems of this type can be used to incentivise improvements in quality of care, reduce clinical risk and variation in standards, and minimise resource utilisation, and have been shown to significantly improve clinical practice in a variety of contexts, for example at the level of prescribing practices and serious medication errors, the delivery of preventive treatments and adherence to recommended care standards. This has been exemplified in the United Kingdom, since 1998, by a series of national audits which aim to improve the quality of stroke care by auditing the provision of care against evidence based standards (<http://www.rcplondon.ac.uk/projects/sentinel-stroke-national-audit-programme>).

The effectiveness, compared with historical controls, of organised multi-disciplinary care and rehabilitation, was demonstrated initially following spinal injuries sustained in the Second World War (1939–1945). Since then the opportunity to trial the effectiveness of the rehabilitation process has been provided by the high incidence and prevalence of stroke. Trials of different models of inpatient and community based care and rehabilitation after stroke have shown convincingly that organised care produces better outcomes than disorganised care, a result that has far-reaching implications for health care systems in general (Figure 18.4). Rigorous evidence to support complex interventions in the context of other single incident neurological conditions, or as a result of deteriorating or static neurological disorders, is sparse by comparison. The top-down systems approach, often using prospective randomised and blinded group methodologies, has been complemented by bottom-up and largely proof-of-principle investigation of neural reorganisation after neurological damage. After initially demonstrating the ubiquity of use-dependent plasticity in healthy controls, these studies have shown that the same process underpins later neurological recovery in the context of disease, and are beginning to explore how drivers of neural reorganisation can contribute to improved outcomes.

Interest in investigating the process of rehabilitation has arisen from two directions. One has resulted from the need to demonstrate how rehabilitation can maintain or improve quality of care without increasing resource use, often by using project and systems management techniques originally derived from industry, and more recently the implementation sciences, which emphasise cognitive and behavioural techniques to generate organisational and individual behavioural changes in professionals that achieve best practice. By contrast, advances in the basic and clinical neurosciences (Table 18.2) have provided explanations about how traditional rehabilitative treatments might work. They have been instrumental over

**Figure 18.4** Care in stroke (SU) or mixed rehabilitation units can be organised and is thus more effective than in general medical wards (GMW) with or without input from a peripatetic team (PT), where it remains disorganised. Source: Stroke Unit Trialists' Collaboration 2001. Reproduced with permission of Elsevier.

**Table 18.2** Evidence from the basic sciences over the last century initially denied and subsequently confirmed the suggestion that neural repair and reorganisation occurred in the central nervous system (CNS) after damage. This repair process is facilitated by the prevention of complications and driven by goal-focused task-related training during rehabilitation.

- Donaldson (1895): 'In the central nervous system the cell elements are plastic in the sense that their connections are not rigidly fixed, and they remember. By virtue of these powers, the cells can adjust themselves to new surroundings'
- Cajal (1928): 'In adult centres, the nerve paths are something fixed, ended, immutable; everything may die, nothing may be regenerated. It is for the science of the future to change, if possible, this harsh decree'
- Raisman (1969): 'The finding of heterotypic re-innervation in the septum implies that the nervous system can no longer be considered incapable of reconstruction in the face of damage'
- Finger and Stein (1982): 'Until very recently, prevailing concepts of brain function precluded the possibility of structural and neurochemical reorganisation of function; theoretically, once damage occurred, the possibility for rehabilitation was to train the patient to use alternative, but less effective, behavioral strategies'
- Neural reorganisation in lesioned animals (e.g. Jenkins and Merzenich 1987; Nudo et al. 1996) confirmed longitudinally by brain mapping techniques in humans after stroke.

the last 20 years in changing clinicians' perceptions from a view that therapies from physiotherapy to psychotherapy offered little more than homeopathy, to an acceptance of the need to explore and develop rehabilitation interventions at the level of impairment. We explore in this chapter the delivery and effectiveness of these two components of the rehabilitation process in neurological disease.

## Neural reorganisation and restoration

At present, clinical experience still emphasises that the most obvious functional gains following neurological damage result from the prevention of complications, whether physical, cognitive, behavioural or emotional, and from adaptive interventions that include environmental modification and personal adjustment, rather than from neural restoration. However, if complications are prevented, so that use can be allowed or even forced, then neural reorganisation in remaining neural structures and networks can follow, though for the foreseeable future still result in 'alternative, but (inevitably) less effective, behavioural strategies', and functional gain may still be largely the result of a learned increase in compensatory rather than normal behaviours.

After neural damage, successful restorative therapies depend on approaches that (i) encourage neural protection to minimise secondary neural damage and enhance neuronal survival, and (ii) facilitate three restorative treatment strategies:

- 1 Neural replacement
- 2 Neural regrowth and regeneration, and
- 3 Reorganisation of functionally useful activity-dependent neuronal maps and networks.

Damaged neurones in the adult mammalian spinal cord can regenerate with treatments that provide an environment that promotes growth via:

- 1 Cell-based therapies, which may operate largely via neurotrophic and anti-inflammatory mechanisms, and
- 2 Neurotrophic factors and inhibitors of axonal growth inhibitors, to facilitate neuronal survival and axonal sprouting.

Similar approaches are under consideration in the treatment of brain damage and/or degeneration, whether progressive as in Parkinson's disease or multiple sclerosis, or single incident following stroke or head injury. The successful application of techniques designed to promote neural replacement and/or repair is likely also to require an understanding of the drivers of use-dependent cellular and network remodelling that are needed to incorporate new tissue into functionally useful networks.

What encourages scientists and clinicians to believe that neural reorganisation is an important tool in the restorative therapies? There is now a wealth of evidence suggesting that central nervous system (CNS) reorganisation at least accompanies and often underpins much of the improvement in impairment that is frequently seen after injury, and during skill learning in healthy individuals. Experiments in both animals and humans show that many regions in the normal adult CNS, particularly the cortex but also in the spinal cord, have a capacity, which is learning dependent, to change structure and function in response to environmental change and memorise this change. This process, often referred to as plasticity, is the basis for skill learning and is now firmly grounded in evidence.

Work on focal brain damage in animal models has clearly demonstrated that for some months after injury, peri-lesional and distant brain regions have an increased capacity for plastic change. Developmental proteins not normally expressed in the adult brain re-emerge in the hours and days following focal brain injury. These proteins are involved in neuronal growth, apoptosis, angiogenesis and cellular differentiation. Structural changes, which include increased dendritic branching and synaptogenesis, occur. There is also evidence of peri-lesional and distant cortical hyperexcitability following focal cortical damage, which results from down-regulation of the  $\alpha 1$ -GABA receptor subunit and a decrease in GABAergic inhibition. Taken together, these changes suggest, particularly shortly after injury, that damaged brain is more amenable to

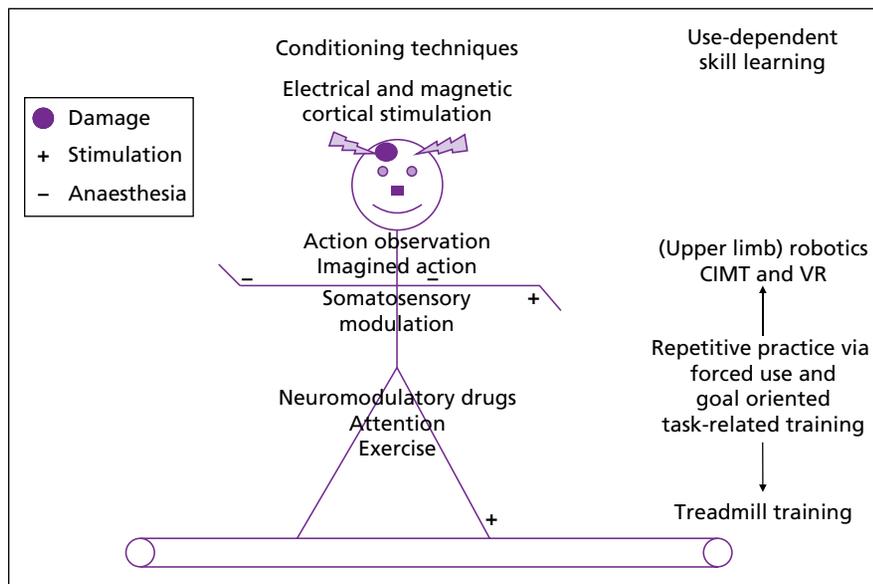

activity-driven changes in structure and function, and that the potential for plastic change is greater than in the normal adult brain.

In the human brain, similar injury-induced changes appear to occur. Research in humans is performed largely at the systems level, rather than the molecular or cellular level, using techniques such as functional magnetic resonance imaging (fMRI) and transcranial magnetic stimulation (TMS), often using stroke as a model. One of the most common and most devastating consequences of stroke is the loss of both power and dexterity in the limbs contralateral to the injury. This occurs as a result of damage to the cortico-spinal pathway (Chapter 2). The majority of cortico-spinal fibres originate in the primary motor cortex (M1), but there are smaller contributions from other cortical regions. In primates, M1, the dorsolateral premotor area (PMd) and the supplementary motor area (SMA) are each part of parallel independent motor networks with separate projections to spinal cord motor neurones as well as connections to one another at the level of the cortex, and to subcortical reticulospinal and rubrospinal pathways originating at brainstem level.

These observations have led to the suggestion that a number of motor networks acting in parallel generate an output to the spinal cord necessary for movement. It is possible that damage in one of these networks could be compensated for by altered activity in another. Functional imaging experiments have demonstrated that stroke patients rely on secondary motor regions in the brain including PMd, SMA, and subcortical pathways to a greater degree when there is damage to the main motor output from M1. However, the projections from these brain regions to spinal cord motor neurones are less numerous and less efficient than those from M1 and thus, although these patients improve as a result of recruitment of these secondary motor regions, they are unlikely to regain pre-morbid performance levels.

Thus, the extent of recovery of motor function is at least partially dependent on how much of the normal network is left intact. In the brain of a patient after stroke there is a new configuration of motor networks, less effective than that in the intact brain but able nevertheless to generate some form of motor signal to spinal cord motor neurones in the most efficient way possible. Longitudinal fMRI studies of stroke patients reveal an initial overactivation of many primary and non-primary cortical motor regions during the performance of a motor task. Thereafter, functional recovery is associated with a focusing of task-related brain activation patterns, as is seen during motor skill learning in healthy subjects. The brain activation patterns do not return to normal in all cases but, at least in the motor system, the focusing of activation will tend towards the most efficient system available. One of the roles of restorative treatments is to help this focusing process.

The functional organisation of skill systems post-injury will depend most obviously on the extent of the anatomical damage, but within these anatomical constraints there is room for more or less efficient reconfiguration of these networks. Alterations in this efficiency by reorganisation, rather than regeneration of tissue, are most likely to underlie therapy-driven reductions in impairment. There are a number of other factors that contribute to this process: how much and what type of treatment is delivered, the biological age of the subject, the pre-morbid state of their brain, current drug treatments, and probably their genetic status. All of these factors will influence the potential for skill-dependent and learning-dependent changes within intact brain networks – the proposed mechanism by which functionally relevant brain reorganisation occurs.

**Figure 18.5** Use-dependent and conditioning drivers of neural reorganisation that have the potential to enhance functional recovery after neural injury. CIMT, constraint induced movement therapy; VR, virtual reality.

Therapies, and other conditioning techniques (Figure 18.5), can be considered as inputs that interact with a system, in this case the damaged brain. The aim of this input is generally to optimise the functional reorganisation of the damaged system. It will succeed in driving functionally useful change only to the extent that the brain regions and networks with which it interacts are intact and able to influence output pathways. Adjuvant treatments are designed to condition the brain to make activity-driven change in response to afferent input more likely and more effective, and enhance the effect of therapy if delivered shortly before or during a treatment session:

- Non-invasive Brain Stimulation (NIBS) including repetitive Transcranial Magnetic Stimulation (rTMS) and transcranial Direct Current Stimulation (tDCS), and
- Drugs, for example monoaminergic noradrenergic, dopaminergic and serotonergic drugs such as amphetamine, levodopa or fluoxetine.

The success of these adjuvant treatments, which can be used either singly or together, will depend on a number of factors including whether the networks with which the therapy interacts are intact. Thus, non-invasive excitatory stimulation of the affected M1 is unlikely to have any success in patients with large middle cerebral artery territory infarcts, while inhibitory stimulation of a normal contralesional homologue may restore inter-hemispheric balance and improve motor or language function. As yet, the mechanisms of action of these interventions are not well understood, but the notion of residual functional anatomy may provide a model with which to improve prediction of outcome, and facilitate realistic expectations and goal setting, as well as the exploration of whether and how interventions of different types work in different patients (Figure 18.6).

In summary therefore, successful restorative therapies for patients with impairments secondary to either brain or spinal cord damage are likely to consist of multiple approaches that:

- Minimise secondary damage,
- Enhance neuronal survival,

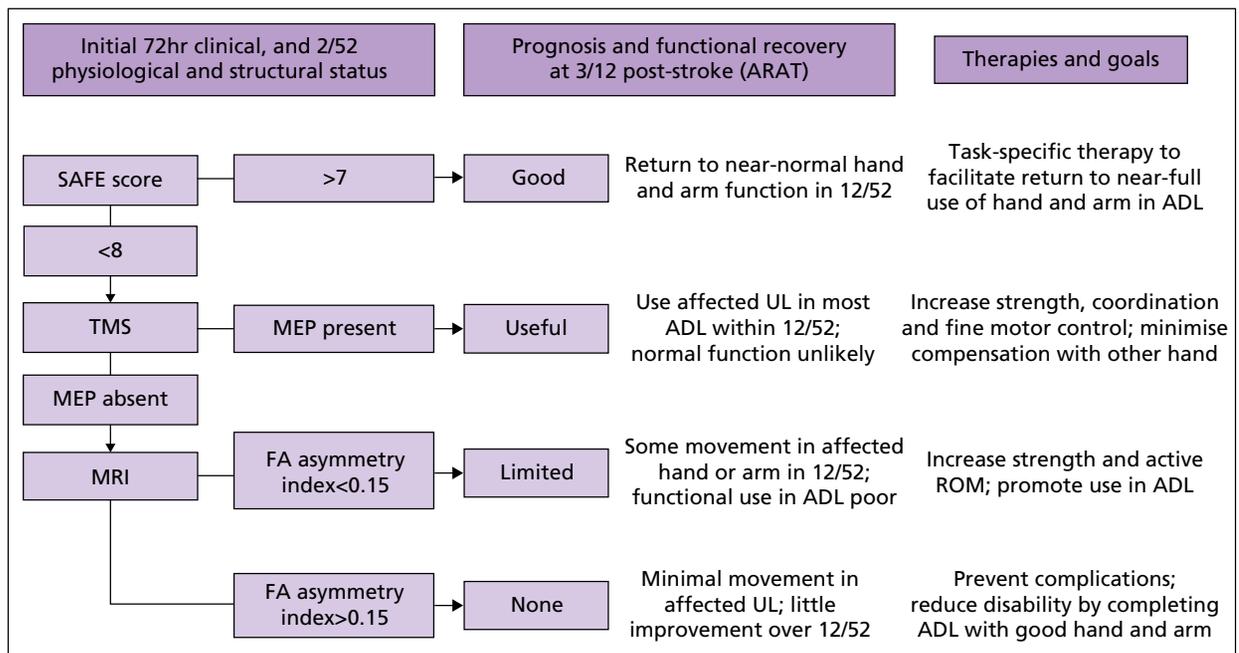

- Facilitate axonal regeneration, and
- Organise activity into functionally useful neuronal networks by behavioural training.

These therapeutic approaches need to be targeted, either singly or in combination, at those impairments that underlie a particular functional limitation. For example, mobility may be affected by leg weakness resulting from either a lack of descending neural drive, spasticity, sensory loss, ataxia and imbalance, or secondary muscle atrophy, or to biomechanical changes and compensatory strategies that have developed over time since the initial destructive lesion. Treatment strategies to help patients compensate for and adapt to their functional limitations have been used for many years, whereas those aimed at minimising impairments have received less attention. In order to effectively implement current and new treatments for impairment, it is imperative to ask whether and how coexisting impairments contribute to a given functional limitation, a task to which the clinical neurosciences can make a unique contribution.

## Treatment of neurological impairments and functional limitations

### Restorative and compensatory approaches, skill learning and task-related training

Non-invasive therapy interventions and task-related training in the context of neural damage are an integral part of the rehabilitation process after a neurological event, and aim to optimise a person's functional ability. They may be broadly divided into those that are restorative and those that are compensatory. Restorative approaches aim to improve function via measurable improvement in an underlying impairment of an aspect of body function and structure, for example muscle weakness or dysphasia, and can be contrasted with strategies that aim to improve function by compensating for an underlying impairment, which may not change despite measurable improvements in functional activities and social participation (Figure 18.1). Both strategies may be associated with recordable adaptive changes within neural systems. Compensatory strategies

**Figure 18.6** An algorithm predicting recovery potential (PREP) to enable reliable subacute prediction of functional recovery of the upper limb at 3 months post-stroke. First, the shoulder abduction and finger extension (SAFE) MRC score (range 0–10) is rated at 72 hours. Then, if the SAFE score is <8, at 2 weeks post-stroke the integrity of the cortico-spinal tract is assessed, initially physiologically using the TMS MEP from extensor carpi radialis in the affected limb, followed if necessary by a measure of the structural integrity of the affected posterior limb of the internal capsule using the fractional anisotropy asymmetry index.

ARAT, action research arm test; TMS, transcranial magnetic stimulation; MEP, motor evoked potential; MRI, magnetic resonance imaging; FA, fractional anisotropy; ROM, range of movement.

may be external, for example an ankle-foot orthosis (AFO) for a foot drop or a communication aid for dysarthria. These improve function while being used but have no effect on behaviour once removed. Alternatively, they may be internal and improve function by changing behaviour (strategy-based therapy), so that gains transfer to function outside the periods of therapy, for example hip circumduction during walking or alternative dressing strategies to achieve independence in personal activities of daily living (ADL). Compensation for the underlying deficit is by no means always detrimental, and may be the most efficient means of moving or communicating, and particularly important to people with long-term progressive conditions.

Early trials investigating specific therapy approaches failed to find clear evidence of effectiveness. This has resulted over the last 20 years in the investigation of the efficacy of individual components and principles of training, and of the underlying type, structure, timing and intensity of therapy interventions. Functional imaging studies in both animals and humans have shown that adaptive changes within the CNS result not only from repetition, but also task-orientation, attention and reward.

Both task-related practice and impairment based intervention may promote functional gain, sometimes via the use of compensatory strategies. The severity of the neurological deficit may influence the effectiveness of these approaches. In a study comparing task-related reaching to strengthening, patients with poor motor recovery only improved their paretic limb coordination with task-related practice. By contrast, in patients with better recovery whose kinematics were fairly normal, only progressive resistance training resulted in a decrease in the compensatory trunk movements that often accompany reaching with the paretic limb.

Studies on healthy subjects suggest that skill learning may also be optimised by varying practice structure, and the instructions and support given by the therapist. Skills are mostly performed in an unpredictable environment, so-called open skills. Many factors can vary even during the performance of a simple task such as speaking a sentence or picking up a cup: the location of the cup, its orientation, weight and frictional qualities, as well the presence of adjacent objects, the availability of sensory cues and the subsequent action such as drinking or placing the cup in a cupboard, all affect the planning and execution of the task. Coordination between reaching and grasping phases, and grip and load forces while manipulating the object all need to be adapted. Acquisition of these open skills requires variable practice in which task parameters are randomly changed to reflect the normal variation in the environment. By contrast, skills performed in a predictable environment, closed skills, benefit from constant practice conditions. The type of skill to be achieved can also determine practice structure. The interdependence of successive stages of a skill determine whether breaking a skill into simpler constituent parts, which are then practiced individually, termed part practice, will result in an overall improvement in the parent task. This may be effective for certain serial skills that are composed of a string of discrete stages, while it may not be as effective for continuous skills, such as walking, where each stage is interdependent.

During the initial stages of learning, feedback involving verbal instruction, manual guidance and demonstration of skill may be required as the learner determines what to do, what the goals are and how to achieve saturation of gains achieved in-session in order to optimise between-session consolidation. However, the use of

continuous therapist-derived or augmented feedback about task performance in the later stages of learning may result in the learner becoming reliant on this type of feedback to the detriment of using their own internal feedback via visual, vestibular and somatosensory information. Fading the amount of therapist feedback across trials, or providing feedback only if the task falls outside pre-set criteria can avoid this. In addition, the type of therapist-derived feedback required for optimal learning in the context of deficits in motor programming or sensory feedback may be determined by lesion location: for example following a sensorimotor cortex or basal ganglia stroke, explicit instruction may disrupt implicit motor learning, a problem that does not occur in healthy controls or following cerebellar stroke.

Evidence for the optimal timing of intervention in humans is scant but thought to be within the first 3 months after insult, based on evidence from animal studies that show a brief window of heightened plasticity between roughly 5 days to 3–4 weeks post brain infarct. The point at which therapy should be terminated is equally unclear. After stroke it is often recommended that therapy should finish when patients reach a plateau and fail to respond to rehabilitation. However, this may be partly the result of adaptation to a therapy programme and, as in healthy subjects, the performance of an exercise regime over time. Further improvements may be observed after a modification in intensity and/or specific intervention. It is now recognised that the potential for reorganisation and improvement in function exists in health as well as in the chronic stage post-injury.

Animal and, more recently, human studies suggest that high intensity of therapy is beneficial, but at present clear-cut guidelines for intensity of intervention in humans are seldom available. Overall, an increased intensity of a motivating and appropriate therapy seems beneficial. Possible cost-effective means of doing this include the use of group training rather than individual therapy, constraint of the non-affected limb during waking hours, or a conversation partner. Greater intensity might also be provided by emerging interventions such as the use of automated robotics, virtual environment practice, mental imagery and the use of tele-rehabilitation described later.

### Physical therapeutic interventions for motor disorders Bobath approach and Motor Relearning Programme

In the past 60 years, various physiotherapy treatment approaches have been adopted which use different underlying theoretical assumptions about the control of movement and the mechanisms underlying recovery. Early approaches proposed by Rood, Brunstromm, Knott, Voss and Bobath were underpinned by neurophysiological theory, in particular the role of afferent information in facilitating movement. In the last 20 years, theoretical assumptions and knowledge gleaned from biomechanics and motor learning have resulted in the modification of existing approaches and the development of other approaches such as the Motor Relearning Programme (MRP). In the United Kingdom, the long-favoured Bobath approach now tends to be integrated with new evidence into a more eclectic approach, while the motor re-learning approach is more commonly used in Australia, its country of origin. Techniques used in the Bobath and motor re-learning approaches have many similarities. Both emphasise the need for task-specific practice and maintenance of muscle length and joint alignment. The motor re-learning approach emphasises time spent practicing task-specific activities and strength training, with verbal instructions to direct and correct movement performance. By contrast, the Bobath approach emphasises the need to manually facilitate components of

normal movement that are absent, and to normalise tone. Despite these differences, studies comparing the effectiveness of these and other approaches have revealed no difference in their efficacy. This may be because of similarities in the techniques, or the fact that therapy only forms a small part of a patient's day.

### Impairment based treatment techniques

Muscle weakness after a CNS lesion is common and is often the result of a primary deficit in central control. A lack of descending control results in alterations in motor unit recruitment, firing patterns and inappropriate agonist–antagonist co-activation. With time, changes in muscle fibre type, and alterations in muscle length and the length–tension relationship occur; disuse atrophy may also develop as sensorimotor deficits limit a person's normal level of activity. Muscle weakness in turn predicts poor function; for example lower limb weakness is associated with reduced walking speeds and stair climbing ability post-stroke. Progressive resisted strength training post-stroke can result in an increase in upper and lower limb muscle strength without any increase in spasticity. Such strength gains can in turn lead to functional improvements. Optimal strength training is thought to be achieved by  $2 \times 8$  repetitions at 80% of 1 repetition maximum (1RM), but whether this is best performed as concentric or eccentric movements during open or closed kinetic chain exercises has not been fully established.

Muscle strength can also be maintained and improved by electrical stimulation in upper and lower limbs, but effects on ADL may be minimal. Most studies have assessed the effects of stimulating distal musculature such as the wrist extensors and tibialis anterior. Neuromuscular stimulation may also be initiated by electromyography (EMG) signals recorded from the target muscle. This technique may result in larger gains in motor control because active participation optimises motor relearning, but in clinical trials transfer of these improvements to functional abilities has been minimal.

Sensory facilitation techniques use the application of stimuli such as muscle stretch, tactile input and weight-bearing through the affected limb to achieve muscle activation. Many of these inputs modulate spinal cord circuitry, as the effects are seen in paretic muscle of people with complete spinal cord lesions, and supraspinal modulation may also occur. These passive sensory stimuli facilitate muscle responses less than voluntary activation, and therefore active participation should be encouraged wherever possible.

In the management of upper motor neurone induced hypertonia, the contribution of neural and non-neural components needs to be established as their treatments differ and should be addressed separately. Although this is possible experimentally, it is not an easy task in the clinical setting, and there are no good outcome measures available. Neural contributions to hypertonia, caused by an increase in stretch reflex evoked muscle activity, as spasticity, are amenable to pharmacological interventions, which should be given in conjunction with therapeutic goals and follow-up. Although the severity of spasticity correlates with functional limitations it is still not clear to what extent this is causal.

Physical interventions focus on the non-neural aspect of hypertonia, namely increased stiffness of the intramuscular and peri-articular connective tissue. Maintenance and restoration of muscle length and muscle compliance may be achieved using a variety of techniques including active and passive stretches, standing regimes, splinting, orthoses and optimising sitting posture in a wheelchair.

However, the evidence to support this is limited, and the best type and duration of stretches remains unclear. These interventions are likely to influence the enhancement in stretch evoked activity, possibly via inhibitory sensory input resulting from the patient's active movement and positioning, in much the same way as transcutaneous electrical stimulation (TENS) and specific cutaneous nerve stimulation have been shown to inhibit stretch reflexes in people with spasticity, possibly via modulation of presynaptic inhibitory interneurons.

### Constraint induced movement therapy

Constraint induced movement therapy (CIMT) following stroke or traumatic brain injury (TBI) involves constraining the non-paretic upper limb for up to 90% of waking hours while performing intensive (forced use) task-oriented therapy on the paretic limb. The training involves general task practice and shaping, part practice when the behavioural goal is approached in small steps, and feedback about task performance is given at each step. Only 20–25% of stroke survivors have sufficient sensori-motor function for inclusion in CIMT studies. Large-scale studies investigating this approach have shown significant improvements in functional ability and motor impairment in both chronic and acute stroke patients. The EXCITE trial recruited 222 stroke patients 3–9 months post-stroke to CIMT versus usual care and found significant gains in affected upper limb function which persisted at 1 year. Subsequently, TMS and fMRI studies have demonstrated that alterations in cortico-spinal conduction, motor maps and movement-related activation patterns accompany the behavioural changes. The time spent training during CIMT is longer than reported for other approaches, up to 6 hours of practice for 10 out of 14 days, and may explain the large effect size. One study has reported no difference in the degree of motor recovery when this technique was compared with conventional therapy of a similar intensity level.

Modified CIMT (mCIMT), in which the training hours and the constraint time are reduced to 1 or 2 hours and 3–4 hours a day respectively, but over a longer period of 10 weeks, in a distributed rather than massed practice schedule, has been reported in a number of studies to produce similar benefits when given to patients at various time points after stroke, to patients with various stroke severities, after TBI, and in combination with other interventions, including botulinum toxin injections. Further studies are ongoing to determine the optimal protocol and time-frame of intervention.

### Balance and posture

Balance, posture and mobility require the integration of multi-sensory information (visual, vestibular and somato-sensory) at multiple levels of the CNS, and as a result of this distributed control are often affected by neural damage. Postural stability is a vital prerequisite for all functional movements, and without postural stability the upper limbs are often used to aid balance. Positioning and specialised seating may be required to substitute for impaired mechanisms of postural control, and can improve limb function, and prevent progression of deformity such as scoliosis and windswept limbs, as well as spread pressure distribution and thus prevent pressure sores and associated complications. The provision of an appropriate manual or electric wheelchair can also greatly improve mobility. Compensatory approaches to gait rehabilitation and mobility include the use of walking aids and orthoses. Such interventions may not increase gait asymmetry, as previously thought, and can reduce energy expenditure.

### Treadmill training, functional electrical stimulation, cueing, fitness and mental imagery

Treadmill training with body weight support via a harness system and robotic assisted step trainers allow safe, repetitive practice of the entire act of walking. The task can be progressed by varying the treadmill speed and incline, and decreasing the assistance given by the therapist and the amount of body weight support. This increases balance requirements and the need for antigravity muscle activity. Unexpectedly, to date these techniques have produced equivalent rather than greater benefit in trials, for example the Spinal Cord Injury Locomotor Trial (SCILT) and the Locomotor Experience Applied Post Stroke (LEAPS) trials, when compared with similar amounts of conventional over-ground therapist-led gait training in patients with stroke, spinal cord injury, multiple sclerosis, cerebral palsy and Parkinson's disease, and the place of these technologies needs further exploration.

Functional electrical stimulation (FES) of a peripheral motor nerve and the muscles supplied may be used to compensate for muscle weakness. A variety of foot-drop stimulators are available which compensate for the presence of foot drop. Onset of swing phase is detected either by a heel switch or a goniometer that detects knee position and triggers common peroneal nerve stimulation via surface, cuff or subcutaneous electrodes. The contraction of the tibialis anterior muscle results in dorsiflexion during the swing phase and can result in increased walking speed following stroke and multiple sclerosis. With prolonged use, an increase in walking speeds without the stimulator may also be observed, possibly by increasing muscle strength.

Multi-channel FES has also been used to retrain standing, weight transference and gait. Stimulation may be via surface or subcutaneous electrodes, and more recently direct stimulation of the nerves via cuff electrodes. In people with paraplegia a minimum of four channels are required for ambulation when used in combination with a walking aid. Stepping can be induced via common peroneal stimulation resulting in ankle dorsiflexion and a flexor withdrawal reflex, while stimulation of the quadriceps provides knee control during the stance phase. Hand or foot switches are used to trigger alternate leg movements and the person requires sufficient arm strength to provide balance via a walking aid. Multi-channel FES systems have been used in combination with orthoses, providing hybrid assistive systems with greater external symmetry. Reports of people with paraplegia achieving independent stance and gait have been described. However, many use such systems for exercise and the physiological and psychological benefits of standing rather than for functional tasks. Muscle fatigue, high energy expenditure with the use of this system, abnormal muscle activation patterns due to hypertonia, and the time to don and doff these systems still fail to make them a realistic clinical tool, and, as a result of unrealistic expectations, many people discontinue the systems within a year.

In Parkinson's disease gait cadence, stride length and velocity have been shown to be improved by cueing. Cues can be provided either internally, by paying attention to step length, or externally as auditory or visual cues. These have been used as well as treadmill training to overcome freezing, festination and falls of patients with Parkinson's disease. Six to eight weeks of physiotherapy and exercise training, with or without auditory cueing, improve mobility and independence, but permanent cueing systems and follow-up training are needed to sustain these improvements in the longer term.

Cardio-respiratory training and exercise classes may reverse the detraining effects of immobility and reduced activity seen in many chronic conditions. One month after stroke, aerobic capacity,

measured by peak oxygen consumption on maximal exercise testing, is reduced to about 60% of normal, making the performance of ADL effortful and fatiguing. Although ADL exert a training effect so that exercise capacity improves, aerobic capacity remains reduced at 6 months and probably in the long term. Activity intolerance is thus common among stroke survivors who may work close to their individual maximal exercise capacity, compared with age- and weight-matched controls, while engaged in only domestic chores. Aerobic training, muscle strengthening or both usually improve targeted outcomes including balance and walking speed and distance, although not consistently ADL. Various recommendations have been made by the British Association of Sports and Exercise Sciences. All adults should perform at least 150 minutes of moderate or 75 minutes of vigorous activity per week. In people with mild to moderate static MS, mild to moderate endurance exercise as well as moderate resistance exercises are well tolerated and have a beneficial effect. Even 3 minutes of very strenuous exercise three times a week appears to be very helpful for some people, and is a realistic target for all.

Mental imagery and sensory stimulation techniques can be used to facilitate motor retraining. Mental imagery of an action activates areas of the brain that overlap with those involved in motor control. Imagined motor tasks have been trialled as an adjunct to help the rehabilitation of functional movements. After stroke, improvements in upper limb use and of ADL have been reported after mental imagery of the paretic limb, but further evidence is needed to establish which patients benefit and what protocol is most effective. Evidence to support sensory retraining post-stroke is still limited. Training regimes vary but tend to include a progression from localising to discriminating different tactile and proprioceptive stimuli, and practice in tasks requiring stereognosis. Functional gains in upper limb tasks have not been demonstrated.

### Robotics and virtual reality

Two emerging technologies, robotics and virtual reality, are likely to provide new opportunities for skill retraining after neural injury, and may be used to increase and/or prolong the amount of therapy, but they have not yet been shown to produce better results than conventional therapies delivered at the same intensity. Robotic devices may be used to provide appropriate assistance or resistance to a movement depending on the person's level of impairment. They have the advantage of being able to control and record movement-associated forces and kinematics, and so the intensity of therapy can be accurately determined instead of simply stating the total duration of therapy. Studies using robotic devices to retrain proximal upper limb movements in stroke have demonstrated significant improvements in motor impairment, which have not always translated into improved functional ability. Similarly, robotic gait machines are now being used to aid walking rehabilitation in people with stroke and incomplete spinal cord injury. Such devices are as effective as treadmill training but significantly reduce the need for the therapist to facilitate paretic leg swing and weight transference on to the paretic stance limb.

Virtual reality technology provides a virtual two- or three-dimensional visual environment. The display may be head mounted or movement of the head can be used to produce movements of the visual scene as in the real world, and it is also possible to give haptic (touch) force feedback from a virtual object via a manipulandum. It is thus possible to create a complex variable environment for intensive retraining of sensori-motor function, factors lacking in many conventional therapy approaches. Upper limb training in a virtual environment after stroke has resulted in improvements in

motor function that transfer to the natural situation. The ability to manipulate the visual scene is also an advantage for the rehabilitation of balance, particularly in those subjects who have over-relied on visual information to balance while not using remaining vestibular and somato-sensory information, for example after central and peripheral vestibular lesions.

### Language disorders: speech and language therapy and communication aids

Normal language function is usually dependent on an intact left hemisphere. However, current neuroscientific evidence points to a network of nodes and connections, both within and between hemispheres, that support individual language operations. For instance, naming is subserved by an extensive network that is vulnerable to damage at many of its nodes, which is why most aphasic patients suffer from anomia. It is beyond the scope of this chapter to review the evidence for and utility of the behavioural classification of aphasia subtypes, but we believe that documentation of impairments in the main language areas (speaking, writing, listening and reading) is more useful for guiding therapies than clinical classification. Descriptions of the various classical speech disorders are given in Chapter 4, and neuroanatomy is outlined in Chapter 2.

Acquired language impairment (dysarthria or aphasia) is the second most common major symptom caused by stroke and is common in all major forms of dementia, with a prevalence of more than 90% once patients have reached the moderately affected phase. The treatment evidence base is derived almost solely from post-stroke aphasia studies although trials in dementia are ongoing, particularly in patients with progressive non-fluent aphasia.

Despite occasional high profile papers that appear to show that speech and language therapy (SALT) is no better than non-specialist interventions, the evidence for the overall effectiveness of SALT in post-stroke aphasia is pretty clear. A Cochrane review indicates: 'We identified 39 trials involving 2518 randomised participants that were suitable for inclusion in this review. Overall, the review shows evidence from randomised trials to suggest there may be a benefit from speech and language therapy but there was insufficient evidence to indicate the best approach to delivering speech and language therapy.'

Bhagal *et al.* took a different approach, segregating positive from negative SALT studies and asking what the systematic differences between them were. The answer was compelling: positive studies had on average 100 hours of therapy (delivered at a rate of 9 hours each week) while patients in negative studies clocked-up only 45 hours in total (at a rate of 2 hours/week). Intensity was clearly conflated with total dose, but the weight of evidence from other studies, including those into expert human performance, suggests that dose is the more important of the two. The issues over exactly what type of therapy to give (phonological or semantic cues) or how to provide feedback to patients (error-full, errorless or error-reducing learning) remain unanswered, but the key principles are clear. These are:

- Outcome-based therapy, be it at the level of impairment or activities and participation,
- Mass practice,
- Adaptive, that is, appropriate to the patients current abilities, not too easy or difficult, and
- Feedback to promote learning, especially as some patients with aphasia have difficulty recognising their own errors.

One solution to the dose issue is to utilise computer-based therapy programmes. Many exist and at least one has proved

effective in a small-scale clinical trial. A list of current electronic therapy packages of varying quality can be found here ([www.aphasiastsoftwarefinder.org](http://www.aphasiastsoftwarefinder.org)).

A large range of drugs have been trialled in aphasia. A thorough review is beyond the scope of this chapter, but well-designed studies (placebo-controlled, double-blind) have been carried out that show significant improvements when levodopa, memantine or donepezil are used. In studies where the drug was paired with behavioural therapy, the SALT effect sizes average at a fairly consistent 0.3 while the drug effects can be substantially higher than this but are patchy by comparison.

Another promising adjuvant is NIBS as tDCS, when a small current is passed through the brain using a battery and scalp electrodes. Because the current is continuous, there is no sensory stimulation to the scalp which makes this an easy technique to double blind. It is not clear which regime to use (strength of current, exact placement of leads, activation of left, right or both hemispheres) but if tDCS effects on language follow in the footsteps of motor systems research, then modest gains of about a third can be expected, compared with the effect of practice alone.

The therapies discussed thus far are all aimed at improving standard language communication, and can be considered under the rubric of restorative techniques. Some patients with a severe speech output aphasia (often a mixture of anomia and apraxia of speech) may not be able to mount much of a vocabulary even with mass practice. Such patients tend to have intact semantics and non-verbal communication skills and so can benefit from using a different mode of communication, such as gesture therapy. The evidence is weaker than for conventional speech therapy, but in a sub-set of the more severely impaired patients this may represent the best approach. In neuroscience terms this is a strategy-based compensatory therapy but one that changes both behaviour and brain connectivity.

There are many types of communication aids available. These change patients' interactions with other people but, when the aid is removed, performance falls back to previous levels, as no neuroplastic changes are induced. Some aids require an intact language system (e.g. Lightwriter SL40) and are for patients with isolated articulatory failure, such as motor neurone disease. Others use pictures for patients to point at. Modern mobile devices are moving the field forward quickly and software tools such as text-to-speech, e-readers and a variety of other apps are taking over from the older, more bulky aids (<http://www.stroke.org.uk/sites/default/files/Communication%20aids%20&%20computer%20therapy.pdf>).

### Visual loss and restorative therapies

We cover this large and complex field by anatomical site of visual impairment, and results from damage to the retina, the visual tract causing hemianopia, and the association visual cortices to cause neglect and visual-perceptual disorders.

There are myriad causes of primary visual failure which can be congenital (rare) or acquired. In older age the leading cause of visual loss is macular degeneration which is age-related and affects people in their fifth decade and beyond. The dry form is most common and progression can be slowed with antioxidants plus zinc. The wet form (associated with the formation of neovascular membranes) can be treated with the monoclonal antibody ranibizumab, which is recommended by the National Institute for Health and Care Excellence (NICE) for a sub-set of patients. There is good evidence that low vision services improve outcomes in such patients. These interventions include counselling and prescription, provision of low-vision devices with some sessions provided by a

low-vision therapist to teach use of assistive devices and adaptive strategies to perform daily living tasks independently. An interesting strategy-based therapy for patients with severe visual loss is echo location. Patients make ingressive tongue clicks and, with training, learn to interpret the resulting echoes which allows them to construct a 3D image from the reflected echoes of objects; a sensation referred to as 'flash sonar' by the developers. Functional neuroimaging studies have shown that skilled users recruit occipital cortex when performing echo-location tasks; this effect is larger in congenitally or early blind individuals.

Hemianopia is a loss of vision to one side of fixation and is usually caused by damage to the visual tracts after they have partially crossed (decussated) at the optic chiasm. The most common causes are stroke, traumatic brain injury and tumors. From stroke alone the incidence in the United Kingdom is ~10 000–15 000 people per year. The best estimate for its prevalence comes from an Australian study that found 0.8% of adults 49 years or older had a hemianopia, which equates to at least 80 000 in the United Kingdom. The visual field defect rarely improves 6 months after the onset and affects a whole host of activities of daily living.

There are three main approaches to treatment: visual restoration, eye movement strategies and prisms. There are two main types of visual restoration and each comes with its own patented hardware. One aims to improve high acuity, conscious vision at the borders of the field defect, NovaVision VRT (visual restoration therapy), while the other, Neuro-Eye therapy, improves vision deep into the impaired field. Both rely on mass practice of detecting stimuli at the border of the blind field (NovaVision) or deep within the blind field (Neuro-Eye therapy). There has been much controversy over whether NovaVision VRT really is effective, and, if so, by what mechanism; this will be dealt with later. Neuro-Eye therapy is less controversial, as the stimuli (Gabor patches) are presented deep in the blind field and probably rely on sparse, non-V1 pathways by which visual stimuli can be processed but do not always reach conscious perception (the definition of blindsight). The practice effects are retinotopic; that is, performance gains are only seen in those parts of the visual field where stimuli were shown although this requires thousands or tens-of-thousands of trials. The problem for visual rehabilitation is this: how functionally useful is blindsight? It is certainly better than nothing and may help reduce collision rates, but to date there have been no studies addressing the carryover or impact that these training regimes may have on patients' ADL.

Visual restitution therapy appears much more promising in terms of potential carryover as the claim is that, with sufficient practice, patients can restore high acuity, conscious vision. The main problem has been that any visual field gains have only been seen on using the visual field test that is bundled with the therapy package. This is an issue, as the visual field test relies on the same stimuli that are used in the training or therapy part of the programme. Obviously, if vision is really being restored, it should not matter what method is being used to test any visual field gains. The prevailing view is that the training results in more efficient eye movements into the damaged field and not genuine field expansion. Patients care much less about the mechanism of action than duelling scientists, and there is good evidence that the therapy does improve visual function.

The most convincing and consistent evidence for improving visual function in patients with hemianopia comes from studies that retrain eye movements. This involves mass practice using stimuli that provoke a specific type of eye movement. Unlike the visual restitution therapies, these have a clear carryover effect on to

untrained stimuli. There are over 10 published studies in this area and a recent Cochrane review of the more rigorous ones concluded: 'There is limited evidence which supports the use of compensatory scanning training for patients with visual field defects.' A further study published since then very nicely demonstrated the specificity of these techniques. In a randomised, cross-over design, reading therapy and 'visual exploration training' were provided to 36 patients with homonymous visual field defects. The results were very clear and showed that the training-related improvements in reading and visual exploration were specific and task dependent; the combined effect size was 0.47 for visual search and 0.28 for reading speed. Interestingly, the cross-over therapy had no effect (positive or negative) on the other task; that is, when undergoing the second therapy block, gains made from the first block remained stable, suggesting that therapy gains persist in the short to medium term. While the specificity was no great surprise (although this was the first study to explicitly test this), it is good news that there was no interference. There are now two, free-to-use, web-based therapies for patients with hemianopia causing hemianopic alexia ([www.readright.ucl.ac.uk](http://www.readright.ucl.ac.uk)) or problems with visual search: [www.eyesearch.ucl.ac.uk](http://www.eyesearch.ucl.ac.uk)). Both contain testing and therapy materials and are designed for home use by patients.

The evidence for therapeutic interventions in more complex perceptual disorders (pure alexia, prosopagnosia, simultanagnosia) is sporadic and weak and it is difficult to make any specific recommendations. Spatial neglect or inattention is more common and has a stronger evidence base although the presumed efficacy for the main therapy (prism adaptation) has been questioned in a recent well-conducted review. Drug therapies have also been tried, with a recent study showing a small but significant (10%) improvement in table-top tests of selective attention when transdermal rotigotine, a dopamine agonist, was compared with placebo.

### Cognitive impairments

The cognitive sequelae of neurological disorders are evaluated by means of detailed neuropsychological assessment which identifies both strengths and weaknesses in the patient's profile. This section focuses on intervention relating to attention, memory and executive deficits. Neuropsychological interventions invariably involve a preliminary phase of psycho-education as part of 'brain-injury education': an explanation in terms of brain-behaviour relations, to patients and/or their carers of the nature of and reason for the deficits the patient is experiencing. This is important, not least in providing them with a vocabulary with which to speak about symptomatology that is unfamiliar and often bewildering. Following this didactic phase, intervention may comprise any or all of the three approaches described elsewhere in this chapter: environmental manipulation (adaptive interventions); training in the use of compensatory strategies; and retraining with the aim of restoring specific impairments.

### Environmental manipulation and compensatory strategies

Environmental manipulation involves modifications that improve well-being by changing living, training or working conditions. These may include such things as provision of a quiet, relatively distraction free space; the overt breaking down of tasks into their components with smaller sub-goals; and external monitoring of performance and feedback to aid adjustment of behaviour to goals. Such modifications are reliant on others for their implementation, but while quite simple in themselves can significantly improve the patient's ability to perform a task.

Compensatory strategies focus on trying to make good the functional deficit rather than resolving or reversing the problem impairment. This may include non-technological aids including use of a diary or calendar for daily routines, appointments, special occasions, or future events; and a daily checklist in a prominent place as a reminder to complete certain tasks, such as 'lock the door', 'turn off the iron', and so on. Assistive technologies for patients with severe cognitive deficits include prospective memory aids such as the NeuroPage system, which uses automated radio-paging or SMS (text message) technology to send reminders of things to do, such as taking medication, or non-specific alerting messages ('STOP') to reduce goal neglect. Small voice recorders can be loaded with reminder messages including appointments, telephone numbers, grocery lists or prescription refills, while mobile phones with touch screen capability allow easy input and access to notes, telephone numbers, dates, daily reminders and to-do lists. There is good evidence that prospective prompting devices of this sort are useful for people with memory impairment, and similar evidence is being acquired to support the use of devices (e.g. the SenseCam), which support retrospective autobiographical memory.

### Restorative approaches

Restorative approaches aim at recovery of lost function through re-training and practice of specific cognitive skills. Attention training is based on the premise that attentional abilities can be improved by activating particular aspects of attention through a stimulus drill approach. The repeated stimulation of attentional systems via graded attention exercises is hypothesised to facilitate changes in attentional functioning. Memory re-training is based on the demonstrated link between encoding and retrieval processes in normal subjects. Training focuses on visual imagery or elaborative encoding including acronyms or rhymes to aid recall of new information. Sometimes, retraining strategies combine some of these elements.

### Executive function, retraining and behavioural modification

The term executive function describes a set of cognitive abilities, for which the pre-frontal cortex is key, that are necessary for behavioural regulation in the context of goal-directed behaviour: the ability to initiate and stop actions, to monitor and change behaviour as needed, and to plan, and execute, future behaviours when faced with novel tasks and situations. These skills are closely allied to those involved in social cognition, which involves the ability to empathise, and recognise emotions and mental states in other people, and if damaged result in 'personality' changes and inappropriate social behaviours, including disinhibition or emotional indifference. Both skill sets are crucial to independent living, community re-entry and the resumption of social roles.

Because of the extensive connectivity of the prefrontal cortex, executive and social cognition deficits frequently result from abnormal functional connectivity after brain injury, irrespective of the precise location of pathology. At the same time, the complexity of this aspect of cognition – still an area of considerable theoretical discussion – makes targeted re-training difficult. Some strategies focus on goal maintenance. Goal Management Training (GMT), for example, is a method of remediating executive dysfunction that is based on theories of sustained attention, and addresses higher order executive deficits. When sustained attention is compromised following a brain injury, a person may become distracted from achieving their goals by either habits or environmental influences. The primary focus of GMT is to teach the patient to periodically

stop ongoing behaviour, in order to monitor and adjust goals in order to stay on task. Other interventions are based on problem-solving: patients are trained to reduce the complexity of a multi-stage problem by breaking it down to sub-goals.

Although the training tasks in each cognitive domain may bear little resemblance to tasks encountered in everyday life, it is argued that re-training the cognitive processes underlying functional activities will result in generalisable gains. In general, there has been some evidence of improvement on tasks practiced, and some other neuropsychological measures tapping similar functions, especially in patients with focal rather than diffuse pathology, but to date there has been no consistent evidence that such training has a significant impact upon the everyday functioning of the brain-injured person.

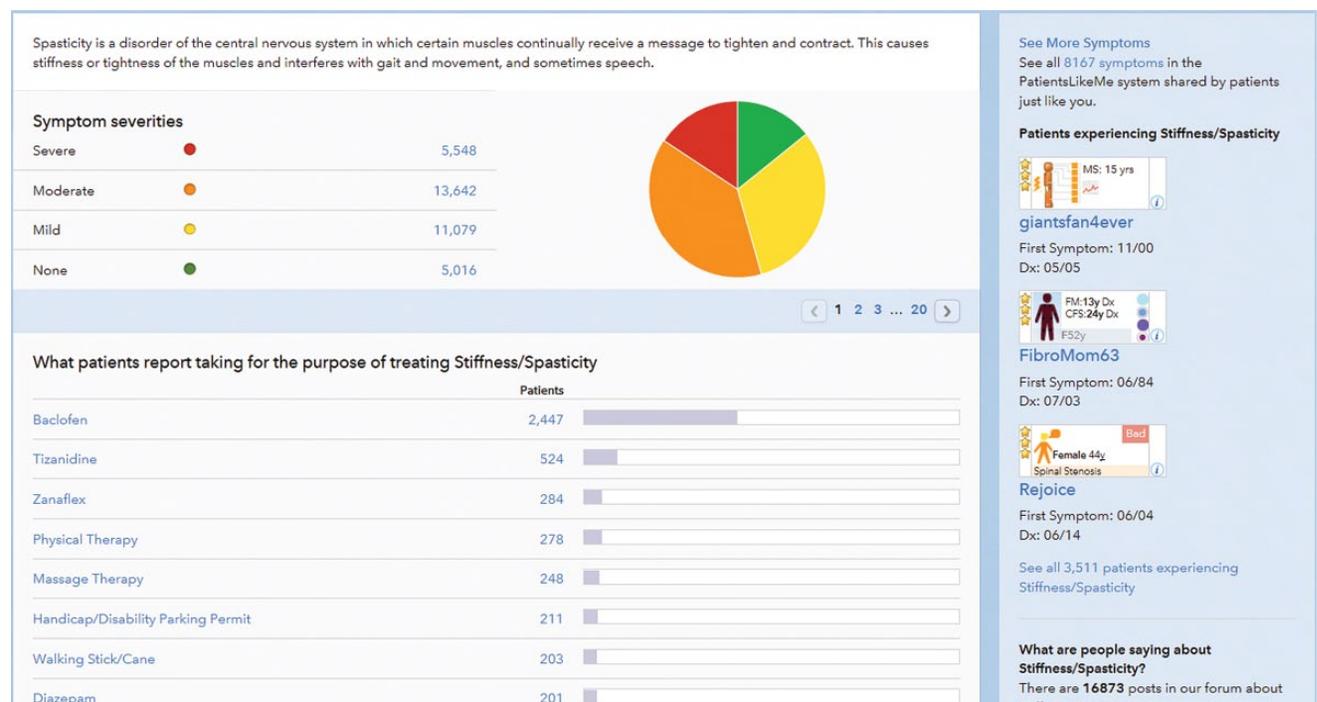

The cognitive rehabilitation of patients with brain injury must address not only the specific focal neuropsychological deficits that result from localised brain lesions, but also more generalised complaints that are common to most kinds of cerebral pathology, irrespective of aetiology, lesion location or distribution of pathology. These include cognitive fatigue and reduced speed of information processing, both of which also impact upon one another to the detriment of cognitive efficacy and stamina.

Finally, it is impossible to think about the cognitive rehabilitation of a brain-injured patient without also thinking about the person's psychological status more generally. Even mild residual problems following a head injury can constitute a significant trauma to the person's sense of self. In addition to whatever other kind of rehabilitation strategy is used, psychological support is then also required to assist the person with brain injury or illness and their close others in coming to terms with lasting personality and lifestyle changes, and forming a new post-injury identity.

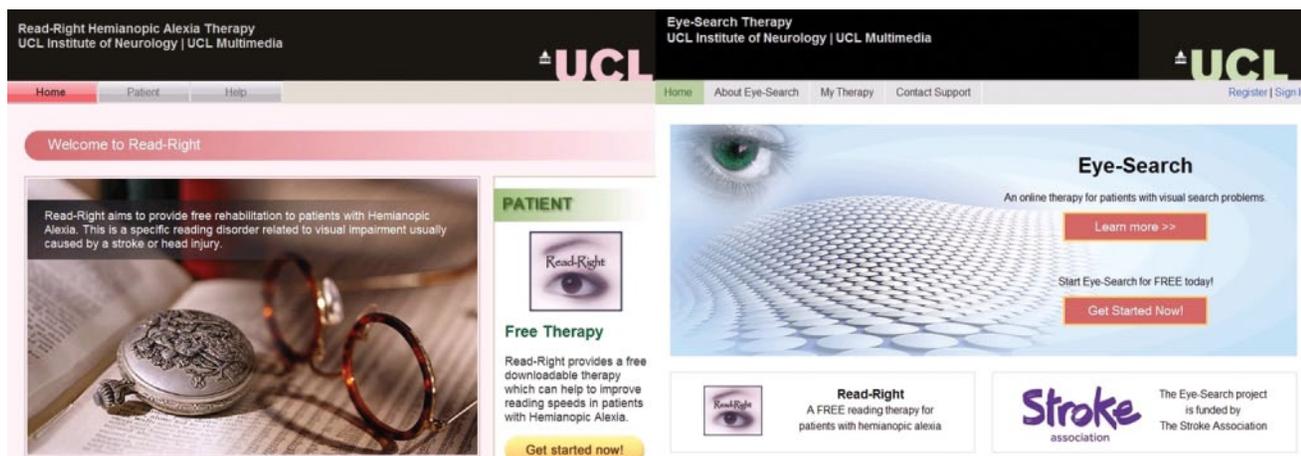

## Telerehabilitation

We know that behavioural therapies are effective, but patients' responses are critically dependent on the amount of time spent practicing with them. Given this, rehabilitation at a distance, or telerehabilitation, and using social media seem promising strategies to ensure that patients receive the correct dose of the right sort of therapy. This is a rapidly growing topic and so we can only touch on the main issues here, but telerehabilitation can be applied to all the main areas of neurological rehabilitation. We cover: information sharing and peer-to-peer support; assessment at-a-distance; and teletherapy, either with or without a therapist's direct involvement.

Peer-to-peer support via the provision of information is an important part of rehabilitation as it helps patients and their carers adjust to and self-manage their condition. There are a large number of websites offering information didactically, but the more interactive ones allow patients to share information with each other, either via chat rooms or in a more innovative manner such as utilised by the forum PatientsLikeMe ([www.patientslikeme.com](http://www.patientslikeme.com)). This site allows patients to share experiences of their symptoms and also their evaluations of interventions. While claiming to cover all disorders, the site was historically built up by patients with motor neurone disease and this currently remains the best-covered disorder. The number of patients adding their own data is impressive; the totality of their experiences is very likely to speak to any incoming patient's situation. For example, one can type in a symptom such as spasticity and see how many patients using the site have reported this symptom, what their underlying condition is, what they are using to treat it and, crucially, how effective they perceive the given therapy to be. This symptom alone has 20 000 ratings (Figure 18.7).

Most tele-assessment provides a specialist clinical opinion without the clinician having to be in the same place as the patient. There often needs to be a therapist/clinician alongside the patient and two-way visual and auditory links are important. An example of how this works can be seen on [www.bbc.co.uk/news/health-11644278](http://www.bbc.co.uk/news/health-11644278). There are now many other examples, such as speech and language therapy and real-time, internet-based, remote, telefluoroscopic evaluation of oropharyngeal swallowing. There are ongoing trials assessing the effectiveness of this new practice. Therapy as well as assessment can be delivered in this way; however, these examples all require therapists and clinicians to interact directly with the patient, in real-time. While this solves the problem of having to transport patients to specialists, it does not solve the problem of how to deliver a greater dose of therapy to patients given the limited number of therapists.

There are a wide variety of digital or electronic teletherapy programmes that can be bought for home use. The majority are designed for use with a therapist; that is, patients get on with their exercises at home and then meet up with a therapist who reviews their progress and sets new therapy goals. However, stand-alone therapies are also available and these either allow the patient to control the task difficulty or automatically adapt to the patient's performance. Two examples of this sort of web-based therapy are housed on UCL servers (Figure 18.8). Web-based and other digital therapies are becoming more sophisticated and are increasingly using 'peripherals' such as hand-held devices or motion detectors to allow patients to interact more imaginatively and realistically with the therapy programme. Given the costs of one-to-one therapy, and given the amount of time and practice required to make improvements in neurological rehabilitation, 'smart' digital packages that can sense patients' responses and help them to adapt their behaviour look like promising solutions. Providing an effective form of feedback, which is critical for volitional learning, particularly for patients with cognitive difficulties, is perhaps the most challenging yet exciting issue.

## Vocational rehabilitation

Sir Ludwig Guttman, a pioneer of spinal injury rehabilitation in the United Kingdom in the 1940s, stated that the successful outcome of rehabilitation was the return of the patient to tax-paying status. This approach may be welcomed by the Exchequer, but it reflects

assumptions that may be erroneous, both about the relative value that an individual places on return to work, and about the fact that resumption of employment can only be achieved at the expense of a reduction in other valued aspects of life, such as social, sexual and leisure activities. A broader definition recognises that adults need meaningful occupation, and covers voluntary activity as well as education, home-making and leisure activities. Although a popular view is that work is onerous and stressful, there is clear evidence that work leads to better quality of life, improved mood and greater life expectancy. Nevertheless, until recently, proactive vocational rehabilitation has been neglected.

The following paragraphs reflect the situation in the United Kingdom, but the principles are widely applicable. At diagnosis, 98% of people with progressive neurological conditions such as MS are in work. Within 10 years most are unemployed. With stroke 30% are under 65 years of age. Most do not return to work. The rate of work return for people with spinal cord injury and paraplegia is 15% in the United Kingdom and 60% in Canada. In the United Kingdom, most people receiving state financial benefit have relatively minor disability and expect at some time to return to work. Only 0.7% of recipients of incapacity benefit have had a stroke, 0.2% have tetraplegia and 0.9% have MS.

The chances of returning to work after 1 year on UK incapacity benefit (now known as Employment and Support Allowance) are less than 20%. The reasons for this are complex but include the demands imposed by the job itself, the limitations imposed by illness or disability and the barriers and expectations created by the society we live in. Vocational rehabilitation aims to overcome the barriers faced by an individual with an injury, illness or disability when retraining, returning to or starting work. It includes the support needed by both the individual and by the employer. Typically, this involves:

- 1 Retraining (e.g. for a bricklayer who has become paraplegic).
- 2 Capacity building (e.g. increasing exercise tolerance in an individual who has become physically unfit).
- 3 Return to work management by employers (e.g. a graded return to work over a period of weeks or months following meningitis).
- 4 Disability awareness – being aware of how society and individuals perceive people with disability, how this is reflected in the media, literature and the arts and how this influences behaviours.

- 5 Symptom management (e.g. being aware of the roles of other professionals such as occupational therapists and physiotherapists in vocational rehabilitation).
- 6 Adjustment counselling.
- 7 Reasonable adjustments at work.

Such adjustments include:

- Changing recruitment and selection procedures.
- Modifying work premises (e.g. making ramps, modifying toilets).
- Changing job design, work schedules or other work practices (e.g. swapping duties among staff, permitting people to work from home or regular breaks for those with fatigue).
- Modifying equipment (e.g. the provision of voice-activated software for those with upper limb problems or an amplifier-adapted telephone for the hearing impaired).
- Providing training or other assistance (e.g. induction programmes for staff with a disability and co-workers who ensure staff with a disability can gain access to training).

Most adults who acquire disability through neurological disease use the hospital consultant or the general practitioner as their first point of contact. Early and mild disability such as fatigue, or more effortful walking, can impact on work before impacting on other areas of life. No matter how good individuals' clinical treatment may be, if they lose their job unnecessarily then treatment has, in part, failed them. Early intervention has two main advantages. The individual can identify the best way to disclose their illness and disability within the workplace which is very different from disclosure to family and friends. Secondly, means of ameliorating the impact of disability can be identified, so work performance can be maintained and loss of goodwill within the workplace avoided. The individual's ability to access timely advice and support therefore depends upon clinicians, who should consider the following steps:

- Ask about work, the impact of work on the disease and the disease upon work.
- Discuss disclosure, and support them in explaining their needs to an employer when they decide to disclose.
- Identify if the individual has access to an occupational health department.
- Remind and inform the patient of the terms of the Equality Act.

One of the major roles of the occupational health physician is assessment of disability and fitness to work. In the United Kingdom, as few as 30% of employees have access to a specialist occupational health service. The UK Equality Act enshrined in law that disabled people should not be treated less favourably than others for a reason related to their disability. Employers have to make reasonable adjustments for disabled people. Such adjustments include making adjustments to premises, such as removing physical barriers or providing distraction free environments; altering hours of working or training; assigning people to a different place of work or training; allowing absence during working or training hours for rehabilitation, assessment or treatment; acquiring or modifying equipment such as voice-activated software; modifying instructions or reference manuals; modifying procedures for testing or assessment; providing a reader or interpreter; providing supervision or other support. Schools, colleges, universities and providers of adult education and youth services also have to ensure that they do not discriminate against disabled people.

Other practical measures include:

- Referral to vocational rehabilitation or occupational therapy services. As few as 10% of people with long long-term neurological conditions access any form of vocational rehabilitation. Such services should perform a comprehensive assessment, and

deliver job retention interventions, which include clarification of the responsibilities of all parties under the Equality Act, and work site visits to meet employers and other interested parties to discuss needs and adjustments, design vocational rehabilitation interventions including practice of specific tasks, and adjustment counselling.

- Making individuals aware of the role of Disability Employment Advisors (DEAs) and the Access to Work scheme. DEAs provide specialist support for those wishing to move into employment or retain an existing job in the event of disability and are based in JobCentrePlus. The Access to Work scheme provides funding for costs that an employer may incur because of an employee's disability, and most commonly is used to provide support with transport costs to work for individuals who cannot use public transport or drive. Other support can be provided such as a powered wheelchair for use at work, adapted desks, specialist software or adaptations to premises.
- Supporting people who decide to decrease their hours, or retire, by signposting access to benefits and financial advice, and providing support with identifying other forms of occupation.

### Medical treatments for specific problems

Symptoms related to neurological impairments caused by either single incident or chronic progressive conditions can cause distress and impact on function. Each person's needs differ and their optimal function and well-being will only be attained if individualised treatment goals, functionally relevant to the patient, are defined. This approach facilitates learning and self-management techniques, skills that do not result from generic prescription for a given impairment. Optimal management often involve several different disciplines working across health and social care sectors to enable the individual to incorporate treatment strategies into their daily life, and to ensure that interventions take place in an effective and timely fashion.

### Spasticity

The impact of spasticity on an individual is extremely varied. On one level it may be useful, perhaps to allow standing or walking when weakness would otherwise preclude it, but it can also cause discomfort, pain and sleeplessness, or result in devastating loss of function with development of long-term problems such as pressure sores and contractures. The impact on function is variable; walking may be slower, falls more frequent, the ability to self-propel a wheelchair or transfer reduced, and many ADL such as washing, dressing, toileting and sexual activity compromised. Poorly managed spasticity can also have serious long-term physical consequences. Muscle shortening and tendon or soft tissue contractures can lead to restriction of passive movement and physical deformity, and can have major functional implications, causing difficulties with personal hygiene or dressing, problems in positioning and seating, and thus restricted community mobility and social isolation. The development of pressure sores may in turn increase spasticity and spasms, to cause a vicious circle of further contractures and dependency. Early identification of these factors enables timely intervention to minimise development of secondary complications.

The mainstay of management of spasticity is education of the individual and, if applicable, their family or carers in strategies to self-manage; these include the implementation of an effective regime of physical therapy including stretching and, if possible, standing with or without assistance. Knowledge of the triggers and

aggravating factors detailed in Table 18.3 is particularly important to prevent exacerbation of spasticity and its associated features, and ensure drugs are used at appropriate times and dosages.

There is no agreed evidence-based model available for the systematic pharmacological management of spasticity and much of what is done is based on a logical and pragmatic approach. The identification of appropriate treatment goals will help optimise choice of agent, and also timing and dose. For example, painful nocturnal spasms may best be managed with a long-acting agent that has sedative side-effects taken at night-time. Alternatively, stiffness and spasms

that interfere with an individual's morning transfers and personal care may benefit from medication taken on waking, prior to transferring out of bed. Dosages for those who are walking, and who may rely on their spasticity to do so, are often lower than in those who use a wheelchair for mobility. The general rule to 'start low and go slow' will limit any deleterious effects on function or unwanted side effects. The most common side effects reported are drowsiness, and weakness caused by unmasking underlying weakness by removing tone and reducing spasticity which was functionally useful.

The oral agents most commonly used are baclofen, tizanidine, benzodiazepines, dantrolene, gabapentin, pregabalin and cannabinoids; all can be used alone as monotherapy or in combination (Table 18.4). Most of the clinical trials of baclofen, tizanidine, dantrolene and benzodiazepines in the management of spasticity took place over 20 years ago. Most involved patients with either multiple sclerosis (MS) or spinal cord injury. Although most studies have shown a positive effect in reducing hypertonia and spasms, little attention has been paid to functional benefit. Four small double-blind placebo-controlled randomised studies of gabapentin have been performed to date. Two of these were in patients with MS, one was in spinal cord injury alone and another included patients with any cause of upper motor neurone syndrome. All showed a beneficial effect for gabapentin on measures of spasticity without excessive side effects. There are no placebo controlled trials of pregabalin in those with spasticity, but case series and anecdotal reports have suggested a positive effect. Nabiximols (Sativex®) is an oromucosal spray that delivers 2.7 mg delta-9-tetrahydrocannabinol (THC) and 2.5 mg cannabidiol (CBD) in each 100 µL spray. Sativex has been licensed on the basis of an enriched study which

**Table 18.3** Common cutaneous and visceral stimuli that may aggravate spasticity.

Cutaneous stimuli	Visceral stimuli
Altered skin integrity: Red or inflamed skin Broken skin Infected skin Pressure sores Ingrown toenails	Any systemic or localised infection Bowel dysfunction (e.g. constipation, overflow or diarrhoea) Bladder dysfunction (e.g. infections or incomplete emptying) Deep vein thrombosis
Tight fitting clothes or urinary leg bag appliances	
Uncomfortable orthotics or seating	

**Table 18.4** Oral antispasticity agents.

Drug	Starting dose	Maximum dose	Side effects
Baclofen	5–10 mg/day	120 mg/day, usually in 3 divided doses	Drowsiness, weakness, paraesthesiae, nausea, vomiting
Tizanidine	2 mg/day	36 mg/day, usually in 3 or 4 divided doses	Drowsiness, weakness, dry mouth, postural hypotension * Monitor liver function
Dantrolene	25 mg/day	400 mg/day, usually in 4 divided doses	Anorexia, nausea, vomiting, drowsiness, weakness, dizziness, paraesthesiae * Monitor liver function
Diazepam	2 mg/day	40–60 mg/day, usually in 3 or 4 divided doses	Drowsiness, reduced attention, memory impairment * Dependency and withdrawal syndromes
Clonazepam	0.25–0.5 mg, usually at night-time	3 mg, usually in 3 divided doses	Same as diazepam
Gabapentin	300 mg/day (can start at 100 mg/day)	3600 mg/day, usually in 3 divided doses	Drowsiness, somnolence, dizziness, weight gain
Pregabalin	5–75 mg/day	600 mg/day in 2 doses	Drowsiness, somnolence, dizziness, weight gain
Cannabis and cannabinoids, e.g. nabiximols (Sativex)	1 oromucosal mouth spray nocte	12 sprays/day	Dizziness, drowsiness, disorientation

**Table 18.5** Goal-based outcome measures.

Outcome measure	Author	Date	Description
Self Identified Goals Assessment (SIGA)	Melville and Nelson	2001	Developed from research in older people, this is designed for occupational therapists to use with clients in subacute rehabilitation and nursing homes. It is the only goal-based outcome measure that provides a protocol to elicit patient identified goals, based on an exploratory interview. Each goal is assigned a rating 0 (unable to do) – 10 (can do) on a visual analogue scale. Post-therapy intervention the patient rates their performance and change scores are compared
Goal Attainment Scaling (GAS)	Kirusek <i>et al.</i>	1994	A five-point scale. The expected outcome (goal) is assigned the position of zero on the scale. Better than expected and much better than expected levels of outcome are +1 and +2, respectively. Worse and much worse than expected are –1 and –2. A high level of skill needed on part of the therapist to quantify various levels of goal achievement. This has been used in a variety of settings, demonstrating acceptable inter-rater reliability and concurrent validity (Emmerson and Neely 1988)
Canadian Occupational Performance Measure (COPM)	Baptiste <i>et al.</i>	1993	Designed for occupational therapists to use with clients to set goals. Standardised instrument with semi-structured interview format that elicits patient identified goals and quantitative patient ratings of these goals. Change scores between assessment and reassessment are the most meaningful scores derived from this assessment
Self Assessment of Occupational Functioning (SAOF)	Baron and Curtin	1990	Based on the Model of Human Occupation (Kielhofner 1995) which promotes collaborative treatment planning between patient and occupational therapist. This instrument elicits written responses to predetermined items
Satisfaction with Performance Questionnaire	Yerxa and Baum	1986	Quantitative scale of satisfaction with performance in daily occupations and community living. The scores highlight areas of decreased satisfaction with performance. Goals are negotiated between the therapist and patient on that basis

demonstrated a 50% responder rate defined as a 20% improvement in a numerical rating scale, and is usually trialled over 4 weeks to assess responder status. While not a therapy for spasticity, two Phase III studies have demonstrated that prolonged release fampridine improves walking speed by 20% in about one-third of people with MS resulting in a European Medicines license being issued in 2011. Two recent studies have failed to show a specific effect on spasticity in spinal cord injury but further studies are underway to explore the role of prolonged-release fampridine in other conditions such as cerebral palsy and stroke.

Botulinum toxin (BTX) type A is the most widely used focal treatment for spasticity. The toxin irreversibly inhibits release of acetylcholine at the neuromuscular junction, but its clinical effect is reversed by nerve sprouting and re-innervation which leads to functional recovery of the muscle over a few months. The toxin is injected directly into the targeted muscle and takes 10–14 days to have a visible effect. Several studies have shown BTX is effective at reducing tone and improving passive function; benefits in active function have been more difficult to demonstrate. It is essential that BTX injections are followed by goal-focused physiotherapy to obtain the maximum benefit (Table 18.5). Common goals include hand and perineal hygiene, dressing, pain, hand movement and limb position. Local injection of ethyl alcohol or, more commonly, phenol is an alternative option to BTX for focal management of spasticity. Chemical neurolysis is irreversible and results in destruction of neural tissue by protein coagulation. Injections may be targeted at peripheral nerves or motor points, areas of muscle most sensitive to electrical stimulation. Partial nerve regeneration and sprouting may subsequently occur so that the clinical effect

may wane after several weeks or months. If necessary the injections can be repeated. Those most commonly applied are medial popliteal blocks to aid spastic foot drop, or obturator nerve blocks either in ambulatory patients with scissoring gait or with the aim of improving ease of perineal hygiene and seating posture in more dependent patients.

Intrathecal therapies should be considered if oral medication in combination with appropriate physical measures is not tolerated or fails to control lower limb spasticity, for example to enable safe seating or hoist transfers. The concentration of GABA receptors in the lumbar spinal cord allows very small dosages of intrathecal baclofen (ITB) to be effective without causing any systemic side effects. A programmable pump is implanted into the abdomen and a catheter conveys the baclofen into the intrathecal space. ITB has been shown to be an effective treatment option in the management of severe spasticity of either cerebral or spinal origin; more recently it has been shown to be effective in improving gait. Intrathecal phenol is a cheap and less invasive treatment than ITB and can be extremely effective. As phenol is a destructive agent that indiscriminately damages motor and sensory nerves, it is reserved for those individuals who have no functional movement in their legs, who have lost bladder and bowel function and who have impaired sensation to their legs. The effect of a single injection is usually permanent though if wearing off is seen it can be repeated if necessary. Selective dorsal root rhizotomies involve sectioning some of the rootlets of each targeted dorsal root to reduce the afferent input while preserving sensory and sphincter function. This is generally reserved for children with cerebral palsy.

### Ataxia

Cerebellar ataxia is unfortunately an extremely challenging symptom to manage. The effects on the individual are variable and may cause only minor problems with finger dexterity in some patients but in others catastrophic loss of upper limb function, mobility and even loss of sitting balance. Severe tremor and head titubation may occur and can be very distressing. Physio- and occupational therapy are the mainstay of management. By optimising the individual's sitting position, posture and the provision of distal supportive aids, the ease and quality of functional tasks such as feeding, self-care and keyboard use can be improved. Drug therapy is of limited value because of poor efficacy and adverse effects; drugs that are often tried with variable success include isoniazid (with pyridoxine), clonazepam, carbamazepine, gabapentin, mirtazepine and propranolol.

For severe cases it may be appropriate to consider deep brain stimulation, historically of the ventral intermediate (VIM) nucleus of the thalamus and more recently the ventralis oralis posterior (Vop) a basal ganglia outflow nucleus, and zona incerta (ZI); nearly 90% of patients report at least some sustained improvement in tremor control. Effects on function have been less consistently reported, and preoperative patient education about what functional changes are realistically likely to occur is extremely important. Although a potentially useful technique, side effects can include hemiplegia and dysphagia; complete cessation of tremor is rarely achieved, and frequent reprogramming is often necessary.

### Pain

Pain is common in neurological conditions and can be very debilitating for the individual, interfering with mobility and sleep and contributing to depression. It may be neurogenic in origin or secondary to mechanical factors. Back pain is particularly common in wheelchair users, in whom spasticity, immobility, abnormal postures, and often an extremely effortful and abnormal gait affect the paravertebral musculature and lumbar spine. Early physiotherapy is essential to aid in spasticity management, to correct posture and/or gait and to limit further damage. Pain relief should include local measures such as heat pads and transcutaneous electrical nerve stimulation (TENS), though medication may be necessary and includes short-term use of non-steroidal anti-inflammatory drugs and simple analgesia. During the first 6 months after stroke, shoulder pain occurs in over 60% of patients and may increase in incidence after discharge. It causes considerable morbidity and once established is difficult to treat. Its occurrence correlates with pre-stroke shoulder pain, severe upper limb weakness, neglect, sensory loss, visual field defects and gleno-humeral subluxation, but their role in its pathogenesis remains uncertain and shoulder subluxation is not clearly a cause. Autonomic changes in the limb, shoulder-hand syndrome and reflex sympathetic dystrophy may also be seen but should not be confused with the painful shoulder. Other disorders of the shoulder including fractures should be excluded. Prevention, particularly in patients at high risk, should include support of the flaccid arm when in bed or a wheelchair, and appropriate handling techniques to avoid traction injury; patients may benefit from neuromuscular electrical stimulation (NMES). Local steroid injection should be avoided unless there is clear evidence of an inflammatory component to the pain, and supra-scapular nerve block has been shown to be an effective treatment.

Neurogenic pain results from injury to peripheral or central afferent pathways. Its characteristics and management are summarised elsewhere (Chapter 23). It is seen in 60–70% of patients with spinal cord damage, usually of traumatic origin, when it is treated in the same way as central pain following stroke or other brain injury. If

refractory, patients may be considered for spinal or deep brain stimulation. Pain is reported in 28–86% of patients with MS. Most have chronic pain but an estimated 10% have acute paroxysmal pains, the most common of which is trigeminal neuralgia which occurs more commonly in MS patients than in the general population. It usually responds well particularly to carbamazepine, but also to gabapentin. Other paroxysmal pains also occur in MS and include dysaesthetic burning pains precipitated by touch, movement or hyperventilation, sometimes with painful tonic spasms, which may be helped by carbamazepine, gabapentin or lamotrigine.

Central post-stroke pain (CPSP) is reported to develop in about 8% of stroke patients, and is moderate to severe in 5% of patients. Usually, individuals present with CPSP within 1–2 months after a stroke, but occasionally it may be as long as 1–6 years after injury. Symptoms may be vague and hard to characterise, making an early diagnosis difficult. Failure to make the diagnosis can cause prolonged suffering and reduce the potential for successful rehabilitation. The pathophysiology is thought to involve altered somato-sensory processing at thalamic and cortical levels. The clinical features are extremely varied and include muscular sensations, dysaesthesias, hyperpathia, allodynia, shooting pains or visceral pain such as bloating or fullness of the bladder. Treatment is similarly varied and may include opioids, tricyclic antidepressants, anticonvulsants and even intravenous lidocaine.

### Bladder, bowel and sexual dysfunction

Bladder and bowel dysfunction is extremely common in neurological conditions, particularly when there is autonomic involvement or spinal cord damage (Chapters 16 and 25). Urinary incontinence after stroke or head injury is usually the result of disruption of the suprapontine inhibition of bladder contractility, causing detrusor hyper-reflexia; detrusor hypo-reflexia and retention may occur after damage to the micturition centre in the dorso-lateral pons. Occasionally, frontal lobe damage causes inability to suppress the urge to void (a frontal function in health) leading to uninhibited sphincter relaxation. To these difficulties may be added functional incontinence caused by cognitive and communication difficulties and mobility problems. Evidence for the effectiveness of methods promoting continence after brain damage is currently derived largely from trials in other patient groups and after exclusion of outflow obstruction, as a result of prostatic hypertrophy or occasionally of stricture caused by previous catheter traction in acutely agitated patients. Management often includes a combination of specialist assessment, anticholinergic drug therapy and behavioural management, most commonly used in residential settings for elderly or demented people, by prompted and/or timed voiding.

In MS, estimates of bladder dysfunction are of the order of 75% and bowel dysfunction approximately 50%. Common bladder symptoms are those of frequency, urgency and nocturia. As bladder dysfunction increases, incontinence, retention and urinary tract infections occur. Most of these are a result of a combination of detrusor hyper-reflexia causing urgency and incontinence, and sphincter dyssynergia causing failure to empty and thus increased residual volumes. As urinary symptoms are often of mixed aetiology it is essential to assess bladder emptying by measuring the post-micturition residual volume, by either catheterisation or preferably trans-abdominal ultrasound, before initiating any therapy. If there is no residual volume, then detrusor hyper-reflexia can be treated with anticholinergic agents such as oxybutynin or tolterodine. If nocturia fails to be controlled with anticholinergics, the use of desmopressin (DDAVP) delivered by a nasal spray can be considered, although

caution must be taken to avoid overdose and potentially dangerous hyponatraemia. When urgency or incontinence cannot be managed medically, patients should be offered intravesical botulinum toxin type A, but it is important to note that this may cause incomplete emptying or retention requiring catheterisation. Detrusor sphincter dyssynergia can be treated using clean intermittent self-catheterisation (CISC). Often, patients require a combination of CISC and an anticholinergic but bladder control is usually greatly improved. Occasionally, control remains poor and modulation of somatic afferents by either percutaneous posterior tibial nerve stimulation (PTNS) or sacral nerve stimulation, or an indwelling catheter need to be considered. In the event of long-term catheterisation, a suprapubic catheter is usually preferred.

Bowel dysfunction is less frequent than urinary dysfunction in the context of MS or stroke but can be extremely distressing and may occasionally result in bowel perforation or lead to pseudo-obstruction. Usually, individuals complain of constipation and urgency; incontinence is less frequent. Management of constipation is easier than incontinence and may be helped by avoiding the use of constipating anticholinergic drugs, improving toilet access and education. The establishment of a routine is probably important. Often, treatment with oral agents including lactulose, senna or stool softeners (macrogol) used regularly is enough, but glycerine suppositories and micro-enemas can be extremely useful, and trans-anal rectal irrigation may be needed particularly after spinal injury. Incontinence often linked to urgency can be helped with loperamide, and more recently PTNS has been shown to be an effective treatment.

Sexual dysfunction is a problem often overlooked by health professionals but is common in people with neurological disorders (Chapter 25) and is often accompanied by bladder dysfunction. Hyposexual behaviours are most commonly reported after stroke and TBI, and in the context of Parkinson's disease and MS, in which the incidence of erectile dysfunction is in the order of 70%. Psychological factors in either patient or partner may play a part. Psychosexual counselling should be considered in all cases alone or in combination with other therapies. The advent of the phosphodiesterase-5 inhibitors such as sildenafil, tadalafil and vardenafil, which are fast-acting oral drugs, have reduced the need for more invasive techniques such as intracavernosal injection of alprostadil (prostaglandin E1). Women complain most frequently of vaginal dryness and difficulty reaching orgasm. The use of lubricating gels may be helpful and there is some evidence that sildenafil may help some women although the response is less clear than in men.

### Fatigue

Fatigue is particularly problematic for people with MS, TBI and stroke. Patient-derived stroke-specific health-related quality of life (HRQoL) measures identify lack of energy as one of the four most impacting problem areas following stroke. If severe, fatigue may limit education, employment and social opportunities. Its occurrence following stroke is predicted by pre-stroke fatigue and the degree of dependence and depression post-stroke, but it occurs independently in some patients as primary post-stroke fatigue, and often results from stroke-disordered attention in association either with physical impairment, sleep-disordered breathing and obstructive sleep apnoea, or incidental systemic co-morbidities. Initial therapy for all causes of fatigue should be aimed at optimising sleep pattern, by treating nocturnal spasms, nocturia or depression and instigating a personalised fatigue management programme. Occupational therapists can be of help in devising

such programmes, which include looking at the individual's daily routine to incorporate fatigue-limiting strategies and introducing regular rest periods. In MS, amantadine has been shown in small studies to be of some benefit as has aerobic exercise. CNS stimulants such as pemoline are best avoided because of side effects and dependency. Other agents such as modafinil and 3, 4-diaminopyridine have been investigated but efficacy is not clear and side effects limit routine clinical use.

### Dysphagia

The importance of effective dysphagia management, to prevent its attendant and sometimes life-threatening risks of dehydration, malnutrition, aspiration and chest infections in the context of single incident or deteriorating neurological conditions, is difficult to over-emphasise. It occurs clinically in about 50% of all stroke patients admitted to hospital, with video-fluoroscopic and instrumental evidence of a swallowing abnormality in some 80% of patients. Aspiration, particularly silently, predicts chest infection. Video-fluoroscopic and flexible endoscopic evaluation of swallowing increase the reliability with which aspiration can be identified when selecting which patients need tube feeding. After stroke, the FOOD trials in 859 stroke patients, randomised to nasogastric feeding within 1 week versus more than 1 week post-stroke, found that absolute mortality was reduced by 5.8% in the early group. Percutaneous endoscopic gastrostomy (PEG) feeding was associated with an absolute increase in risk of death of 1.0% and an increased risk of death or poor outcome of 7.8% in 321 patients randomised to PEG versus nasogastric tube a median of 1 week post-stroke. Thus, nasogastric feeding should be used for dysphagic patients early post-stroke, although it may not prevent chest infections, while PEG feeding is reserved for patients in whom nasogastric feeding is not tolerated or is required in the longer term. Non-invasive swallowing therapies in adults with neurogenic dysphagia, using modification of posture or the consistency of food and fluid, oral motor exercises, pharyngeal stimulation, or a combination of techniques may reduce aspiration on clinical testing. However, there is still no robust evidence to show that these therapies reduce the incidence of chest infections or improve nutritional status in the context of either single incident or progressive neurological conditions.

### Neuropsychiatric problems

Psychiatric disorders are covered in detail in Chapter 22. There is a high cumulative incidence of psychiatric disorders in any physical illness, predicted by physical and social inactivity and a premorbid history of depression and mental disorder. It is important that they are recognised, as they may impact on participation, stall progress in rehabilitation, and determine outcome and placement. After brain injury, additional factors relating to lesion location may also be relevant, for example left anterior damage affecting frontal-subcortical circuits resulting from stroke, head injury and MS predisposing to depression (Table 18.6). Disordered mood may be complicated by organic cognitive and behavioural problems, and can be difficult to diagnose in the presence of a language disturbance, anosognosia, abulia or confused agitation.

Depression after stroke is probably under-recognised and undertreated. In one recent meta-analysis, the frequency in 51 studies was 29–36% with a mean of 33%. In the majority of patients, depression resolved spontaneously within a few months. The main predictors for its development are premorbid vulnerability, and stroke severity measured by physical disability and cognitive impairment. Its presence predicts increased mortality and resource

**Table 18.6** Avoidable generic and specific complications after brain injury and their management.

Complication	Management
<b>Co-morbidities</b>	
Hyper-/hypo-tension	Antihypertensives/treat cause
Cardiac events	Specific medical treatments
Fever	Antipyretics
Gastrointestinal bleeding	? Prophylaxis; avoid NSAIDs
Drug side-effects	Drug withdrawal
Musculoskeletal pain	Physical therapies
Polytrauma	Refer to other specialties
<b>Physical dependency ± neural injury</b>	
Pressure sores and skin breaks	Pressure care, and 24-hour handling
Contractures and shoulder pain	Handling, positioning, NMES, steroid or botulinum toxin injection, suprascapular nerve block
PEs and DVTs	Thromboprophylaxis
Falls	Risk assessment
Constipation and faecal impaction	Bowel regime and toileting programme
Aspiration and chest infections	Tracheostomy and dysphagia management
Urinary tract infections	Toileting programme, ± drugs
Malnutrition and dehydration	Dysphagia management and dietetics
Detraining	Aerobic exercise programmes
<b>Brain injury</b>	
Hydrocephalus, mass effects and re-bleeds	Neurosurgical management
Confusion and agitation	Environmental management ± drugs
Autonomic storms	Time and drugs
Epilepsy	AEDs if no other trigger
Sleep-disordered breathing	CPAP ventilation
Spasticity	Spasticity management
Vegetative and minimally aware states	Avoid misdiagnosis

**Table 18.6** (continued)

Complication	Management
Emotionalism	Time and antidepressants
Heterotopic ossification	Etidronate ± NSAIDs
Syndrome of the trephined	Timely cranioplasty
Late maladaptive behaviours	Behaviour modification programmes
Involuntary movements	Drugs and DBS
Central pain	Pain management techniques
Fatigue	Exclusion of treatable causes; fatigue management
Hypothalamic–pituitary axis dysfunction	Endocrine testing and replacement
<b>Catastrophic illness</b>	
Critical illness neuromyopathy	Multi-disciplinary retraining
PTSD, depression and anxiety	CBT ± drugs
Family breakdown	Information + training

AEDs, antiepileptic drugs; CBT, cognitive–behaviour therapy; CPAP, continuous positive airway pressure; DBS, deep brain stimulation; DVT, deep vein thrombosis; NSAID, non-steroidal anti-inflammatory drug; PE, pulmonary embolism; PTSD, post traumatic stress disorder.

utilisation, and early treatment has been reported to benefit functional outcomes. The functional gains reported in the recent FLAME study to result from the early prescription for 3 months of fluoxetine after stroke are not obviously the result of an antidepressant effect.

There is an increased risk, often initially evident at 6–12 months but also in the very long term, of a number of psychiatric disorders after mild, moderate and severe TBI. Major depression occurs in about 15% of patients after mild head injury and about one-third of patients after moderate and severe TBI, when it is predicted by pre-injury educational or employment difficulties, psychiatric illness, and alcohol and substance abuse. The risk of anxiety disorders, including obsessive-compulsive, but also panic and post-traumatic stress disorders, is also increased. Psychosis and suicide are more common in people who have had a TBI than in the general population but usually occur in individuals who were vulnerable to these problems pre-injury, and thus at risk of injury including TBI. Drug treatment with a selective serotonin re-uptake inhibitor (SSRI), sometimes combined with a mood regulator such as carbamazepine for accompanying anxiety disorders, may be useful but should take into account the increased susceptibility to drug side effects of patients with TBI. Although cognitive and psychotherapeutic interventions are advocated after severe TBI, rigorous evidence for their efficacy is lacking to date; cognitive–behavioural therapy reduced anxiety and depression up to 5 years after mild and moderate injury in a small randomised waiting-listed controlled study. Endocrine replacement, as a result of hypothalamic–pituitary axis dysfunction, is necessary in about 5% of

patient after moderate and severe TBI, but appears to be more common after blast injury.

Psychiatric symptoms may also develop in patients with MS but are usually mild and commonly include low mood, irritability, poor concentration and anxiety. Rates of depression in community samples have ranged between 25% and 40% and tend to be higher in nursing home settings. Psychological support or cognitive-behavioural therapy is often helpful. If medication is indicated it should be used as it is in the healthy population but with greater attention to possible adverse effects, particularly exacerbation of bladder or sexual dysfunction.

### Single incident brain injury

Stroke and traumatic brain injury (TBI), the most common causes of focal and diffuse acquired brain injury (ABI), respectively, are also two of the most prevalent neurological conditions affecting the CNS. They involve very different populations, with contrasting clinical needs and expectations, and highlight important questions relating to neural protection and restoration, delivery of rehabilitation, and routes to improving participation and life quality. In white populations, about 90% of stroke patients are over 65 years of age compared with some 20% of patients following TBI. Both conditions result in an annual incidence of hospital admission of 1–3/1000 adults. Following TBI, only 10–20% of patients remain in hospital for more than 3 days, because 80–90% of injuries are mild, while after stroke such brief admission is now the exception. Because younger age groups are over-represented in the TBI population, and usually have a near-normal life expectancy of 30–40 years even after severe injury, the prevalence of stroke and TBI related disability is similar at about 1%.

Not only are the personal costs of single incident brain injury enormous, but also the economic consequences. In the United Kingdom the annual costs of direct and informal care and lost productivity after stroke was estimated by the National Audit Office in 2005 at £7.0 billion; these costs will increase as the population ages. Similar data describing the overall economic burden of head injury in the United Kingdom are not available but must be of at least similar magnitude assuming the prevalence outlined above; costs estimated at about \$60 billion annually in the United States are very similar to those after stroke.

Guidelines for hyperacute thrombolysis and neurosurgical management, and intensive and high dependency care after stroke and head injury are established and continue to evolve (Chapter 5). High dependency care, following that required for thrombolysis, is now being investigated acutely after stroke, to assess the benefits of providing continuous rather than manual monitoring for hypoxia, hyperglycaemia, hypotension, cardiac arrhythmias and elevated body temperature during the first 48–72 hours after admission. Whether these new technologies will improve outcome at discharge in previously more dependent patients, and reduce mortality in patients with severe injury without increasing the prevalence of dependency, is not at present obvious.

During the first few weeks after a significant single incident brain injury of any cause, acute inpatient rehabilitation should focus on the prevention of systemic and neurological complications, while resolution of cerebral oedema, toxic metabolic dysfunction and intracranial mass effects take place, and provide a basis for ongoing neuro-protection in parallel rather than in series with the initiation of preventative and restorative strategies (Figure 18.2).

During the subsequent several months, early rehabilitation programmes focus on skill learning to reduce dependency in personal care and domestic and community-based ADL, while late

programmes particularly address social and work related roles, and issues of life quality. The time post-injury when the components of these programmes (Figure 18.3) should begin and end varies with a number of factors, particularly injury severity. Many of these issues are addressed in evidence and expert opinion based guidelines produced in relation to stroke, and accessible via [www.strokecenter.org/prof/guidelines.htm](http://www.strokecenter.org/prof/guidelines.htm), and, in the United Kingdom, <http://publications.nice.org.uk/stroke-rehabilitation-cg162>, and head injury and other acquired single incident brain injuries in the Department of Health's National Service Framework (NSF) for Long-term Conditions (2005). Evidence, summarised later, for the effectiveness of components of these systems is largely derived from trials after stroke. Its application to rehabilitation after head injury is tempting but largely unproven.

### Stroke

In the United Kingdom, stroke is the most common single cause of severe physical disablement in people living at home, and is likely to become more prevalent as the population ages. Motor impairment is the most common impairment post-stroke, and 6–12 months post-stroke only 60% of patients presenting with hemiplegic stroke have achieved independence in personal care. Of survivors, 30–40% are depressed, 10–15% severely so. Over half need help with housework, meal preparation or shopping. A similar number lack a meaningful social, recreational or occupational activity during the day.

These disabilities, or limitations in activities and restrictions in participation (Figure 18.1), are the result not only of motor impairments, but also impairments in sensory, perceptual, cognitive, communication and affective function, which can be measured by standardised stroke-specific or generic rating scales, perhaps drawn from the ICF, or, for example, a stroke-specific battery of impairments, the National Institute of Health Stroke Scale (NIHSS), combined with a generic neuro-cognitive score, which can be combined with physiological and anatomical, and possibly biochemical, measures of damage, and used to monitor progress and the effect and choice of interventions, and to predict outcome.

Organised acute and early inpatient, and increasingly community-based, rehabilitation, via a reiterative multi-disciplinary goal-setting process, has been investigated in depth after stroke. A Cochrane meta-analysis of 21 trials ( $n = 3994$ ) comparing care and rehabilitation in a stroke unit (SU) with an alternative services, usually in a general medical or geriatric ward with or without a visiting stroke team, showed that patients who receive unit-based inpatient care, particularly in a discrete ward, do not stay longer in hospital and are more likely to be alive, independent and living at home 1 year after the stroke, regardless of gender, age and stroke severity (Figure 18.4). Subsequent secondary analysis has shown that similar benefits occur after either ischaemic or haemorrhagic stroke. Compliance with post-acute SU guidelines (Table 18.7) has been shown to correlate with outcome. The reduction in SU deaths probably results from fewer complications of immobility rather than neurological or cardiovascular complications. The increased number of patients discharged home, rather than to institutional care from SUs, is largely attributable to an increase in the number of patients returning home physically independent (Rankin score 0–2), rather than dependent (Rankin score 3–5).

Aspects of care common to acute and rehabilitation SUs include:

- Comprehensive medical, nursing and therapy assessments,
- Integration of nursing care within the multi-disciplinary team,
- Early mobilisation and treatment of hypoxia, hyperglycaemia, and suspected infection and avoidance of urinary catheterisation, and
- Formalised goal-orientated multi-disciplinary team care, with early discharge planning and education and involvement of carers.

**Table 18.7** Compliance with these dimensions of process during post-acute rehabilitation correlates with functional outcome after stroke.

1	Multi-disciplinary team coordination
2	Baseline assessment
3	Goal setting
4	Treatment plan
5	Monitoring of progress
6	Management of impairments/disabilities
7	Prevention of complications
8	Prevention of recurrent stroke
9	Family involvement
10	Patient and family education
11	Discharge planning

Many of these aspects of care are not delivered by a peripatetic specialist stroke team (PSST). In one study, complications including stroke progression, chest infections and dehydration were less frequent in the SU. More patients were dead or institutionalised (30% vs. 14%;  $P < 0.001$ ) and fewer were alive without severe disability (66% vs. 85%;  $P < 0.001$ ) in the group allocated to the PSST.

Remarkably, the differences between SU and alternative care persist for many years. Even 10 years after randomisation to an acute and rehabilitation SU or a general ward, fewer SU patients had died (75.5% vs. 87.3%;  $P = 0.008$ ), and more were at home (19.1% vs. 8.2%;  $P = 0.018$ ). More were at least partly independent with a Barthel Index (BI) score of  $\geq 60$  (20.0% vs. 8.2%;  $P = 0.012$ ), if not independent with a BI score of  $\geq 95$  (12.7% vs. 5.4%;  $P = 0.061$ ). Increased survival times have been observed 5 years after randomisation to a SU versus a general medical or geriatric ward.

Early discharge of medically stable patients with support by a multi-disciplinary outreach team after mild and moderate stroke, with an admission BI of  $>9/20$ , adds to initial SU gains. A meta-analysis of individual patient data from 14 trials of early supported discharge (ESD) versus conventional care in patients moderately disabled at discharge (median discharge BI 15/20) showed:

- A reduced risk of death or dependency ( $P = 0.02$ ) in the ESD group,
- Hospital stay shortened by 7 days ( $P < 0.0001$ ), and
- Significant improvement in extended ADL ( $P = 0.05$ ), although not in subjective health status or mood in either patients or carers.

Two other studies found that these gains can include better life quality, assessed by the Nottingham Health Profile, at 1 year, and that gains in domestic and extended ADL are still evident after 5 years.

Once in the community, patients are known to be at risk of deteriorating after stroke as a result of multiple health problems including falls, depression, physical and social inactivity, and isolation, in addition to age-related co-morbidities. HRQoL declines in the 6 months after discharge. The place for, and optimal process in, residential service systems other than SUs for patients later after stroke remains to be examined. A meta-analysis of trials of therapy-based outpatient or domiciliary rehabilitation, delivered by either a multi-disciplinary team or by a physiotherapist or occupational therapist, with the goal of improving task-orientated behaviours, has shown that deterioration is prevented ( $P = 0.009$ ) and dependency in personal care reduced ( $P = 0.02$ ). The effective components and best location for this type of service

need further exploration, but benefit has been consistent in trials of community-based occupational therapy. A meta-analysis of eight trials showed that intervention was associated with improved personal, extended and leisure-based ADL depending on the intervention target. These findings are confirmed in more wide-ranging systematic reviews of occupational therapy for stroke patients. Most studies of physiotherapy in patients in the community after stroke investigate the effect of a particular physiotherapy treatment on improving upper or lower limb function at the level of impairment and mobility, which may improve, rather than limitations in activity and independence, which if examined may not. Domiciliary physiotherapy within 6 months post-stroke has been shown to reduce risk of re-admission after an average of only 2.9 (range 1–8) visits and reduces dependency at less cost compared with day hospital attendance. In patients more than 1 year post-stroke as few as 4–5 physiotherapy sessions produced a clinically small but significant improvement in mobility.

Informal carers should be recognised as an important resource. They enable patients to remain in the community and their support is likely to facilitate patient outcomes. The levels of depression in the patient are greater in those who feel poorly supported. Formal support for carers, rather than assistance for patients, is often more difficult to obtain. Trials of psychosocial interventions to support stroke carers using information packages, specialist nurses, a mental health worker or family support workers have failed to show functional or psychological benefit in patients and only modest psychosocial benefit for carers. By contrast, there is evidence to suggest that carer adjustment is increased by education and counselling or by training in social problem-solving skills. Training informal carers in basic nursing skills and facilitation of personal care techniques reduces costs and caregiver burden; this improves psychosocial outcomes for both carer and patient, although there is no change in patient mortality, institutionalisation and disability.

### Traumatic brain injury

It seems likely, although unproven, that many of the lessons learned from trials of programs providing acute, early and later rehabilitation after stroke are applicable to those required after diffuse, rather than focal, ABI (Figure 18.3). This is most frequently traumatic in origin, though there is now an increasing number of disabled patients surviving after hypoxic-ischaemic brain injury. However the evidence base derived from group studies of TBI is meagre by comparison with that after stroke. This reflects both the relatively small numbers of patients requiring inpatient care for more than a few days after head injury, and the difficulties involved in community follow-up of the larger number of patients with less severe injuries, many of whom are disadvantaged and peripatetic pre-injury and additionally cognitively impaired post-injury.

By contrast with stroke, long-term disability after diffuse ABI results largely from cognitive, affective and behavioural, rather than physical, impairments in a younger population with a longer life expectancy. A number of studies over the last 20 years have shown how over time post-injury, mobility and independence in personal care are least affected while the ability to fulfil social and work-related roles remains problematic. There is thus a high incidence of TBI in the prison and homeless populations, and, in the community, after TBI people often require supervision rather than hands-on care; their needs thus impact on less easily identifiable impairments and budgets than stroke, over a longer period. Whether the increased long-term mortality seen after even mild TBI is caused by an ongoing inflammatory or degenerative process initiated by injury, or the difficulties there are in delivering effective rehabilitation and 'an enriched environment' in these circumstances, or other factors, for

example the long-term effects of hypothalamic–pituitary axis dysfunction or the metabolic syndrome, is not known.

As long-term functional outcomes depend largely on residual cognitive and behavioural problems, which in turn are usually dependent on the initial severity of injury, unsurprisingly measures of the severity of cognitive and behavioural impairment early post injury, using the initial Glasgow Coma Scale score, and the duration of unconsciousness or unawareness (absence of command following), and of post-traumatic amnesia (PTA), estimated either prospectively or retrospectively, are still the most reliable predictors of long-term outcome after TBI, while imaging characteristics, and neurophysiological and biochemical markers of injury remain unhelpful except possibly in hyper-acute settings. When pre-injury factors, particularly related to disadvantaged or elite performance, and ongoing comorbidities, particularly those caused by pain and psychiatric problems, are also taken into account, these data enable the realistic prediction, and thus discussion with family members and carers, and some patients, of probable ceilings to achievable functional recovery long-term. This in turn assists engagement in realistic short and long-term goal setting and rehabilitation planning.

For those patients initially in low awareness states, longitudinal studies of outcome show that some who achieve partial independence in the longer term may not have begun to improve until 4–5 months post-injury, and of patients in a low awareness state at 1 month post injury, about 20% will achieve independence in the community by 5 years. In the long term, in general a PTA of:

- 10 days is almost invariably associated with residual cognitive problems, but does not preclude a return to a person's old job, possibly with some restrictions,
- 4 weeks precludes a return to a previous, but not to an altered, work role, and
- 3 months precludes a return to regular paid work, but not to voluntary work or community independence.

After coma emergence there is initially a period of agitated and combative behaviour during PTA, similar to that seen during hyperactive delirium, followed by confusion and anxiety without aggression, before the ability to form continuous memories is restored despite longer term background cognitive deficits, which often particularly involve executive and attentional skills rather than memory. These behaviours put patients, and sometimes their carers, at risk of injury as a result of falls and absconing, and prevent participation in training. Hitherto patients have been policed largely pharmacologically, but drug side effects and their prolongation of PTA, particularly as a result of the protracted use of sedative doses of neuroleptics, especially haloperidol, which down-regulate dopaminergic brain function, has meant that management now focuses on environmental adjustments and behavioural techniques, rather than the administration of drugs, to reduce stimulation and unpredictability via a framework of timetabled activities and interventions including rest periods, while restraint is minimised, and measures to prevent falls and their consequences are put in place. Early institution of these measures possibly shortens the duration of PTA and time for which high dependency and hospital care is required. Extreme acute agitation can leave little choice about the use of an intramuscular or intravenous sedative, usually using either a shorter acting benzodiazepine or a neuroleptic, often as lorazepam or haloperidol, respectively. In less extreme circumstances, if initial environmental modification fails to reduce hypervigilance and over-arousal, once pain, infection and other co-morbidities have been treated, and the sleep–wake cycle optimised, most authors recommend minimal doses of an atypical neuroleptic rather than a benzodiazepine (e.g. quetiapine) to optimise compliance in training and procedural learning.

Whether other drugs that contain agitated behaviours and reduce anxiety late after severe head injury (e.g. beta-blockers, mood-stabilising anticonvulsants or antidepressants) also have a part to play during PTA remains virtually unexplored.

For those patients requiring protracted inpatient rehabilitation after severe TBI, historical evidence emphasises the importance of preventing the physical complications of immobility, just as it does after spinal injury. Studies in the late 1960s from the United States documented frequent pressure sores, joint contractures and frozen shoulders in patients late after severe head injury, problems that should now not be seen. Since then, a few small studies, mostly retrospective and comparison, rather than prospective and randomised, have investigated whether organised acute rehabilitation (AR), on discharge from ITU, with or without subsequent facilitation of the rehabilitation care pathway, improves long-term outcome, at less cost, than delayed or less organised care. They include a recent prospective but non-randomised Norwegian study which compared outcomes in two groups of patients, all of whom received acute rehabilitation, before being transferred either seamlessly to sub-acute rehabilitation or, as a result of bed availability, via a local hospital or nursing home, and found shorter hospital stays (88 vs. 124 days;  $P = 0.07$ ) and, at 12 months post-injury, better functional outcomes (Extended Glasgow Outcome Scale [GOSE] 6–8 71% vs. 37%;  $P = 0.007$ ) and more frequent home discharge (Home/NH 81/13 vs. 53/23;  $P = 0.06$ ) in the 'seamless' group.

Other group studies of inpatient rehabilitation after head injury address the benefits of early (sub-acute) inpatient rehabilitation, which in the United Kingdom still starts 1–4 months or more after injury, rather than acute rehabilitation in parallel with and immediately after neurosurgical treatment. Most, from North America or the United Kingdom, are non-randomised retrospective or prospective comparisons of two groups. They still emphasise the economies in resource use resulting from reduced lengths of hospital stay in rehabilitation rather than acute care, with at least equivalent (if not improved) functional outcomes that are said to result from early transfer to rehabilitation. One two-centre study investigated outcome after moderate and severe injury in 24 patients who were randomised prospectively to receive supplemented inpatient rehabilitation versus 27 patients who received the usual programme. The supplemented group made greater gains in functional independence by the time of discharge during a similar length of stay.

Prospective randomisation of the far greater number of less severely injured patients early after injury presents fewer methodological problems because there are more patients and cheaper treatment options. These patients have usually mobilised and moved into the community but experience many cognitive, affective, behavioural and somatic post-concussional symptoms. However, compliance with follow-up and treatments is difficult to ascertain unless trial entry is limited to patients who are not premorbidly disadvantaged (e.g. athletes or military personnel). A US trial prospectively randomised military personnel, who had recovered independent mobility and returned home with supervision within 3 months of moderate and severe head injury, to either 8 weeks of an inpatient cognitive–behavioural community and vocational re-entry programme costing \$51 840 ( $n = 67$ ) or a low cost (\$504) cognitive and exercise-based home programme with weekly telephone support from a psychiatric nurse ( $n = 53$ ). Both treatments were followed by a 6-month graded return to limited military duties. About 40% of patients recruited to the study had a PTA of 7 days or more and 35% had been unconscious for 24 hours or more. At 1 year post-treatment, overall there was no difference in the two groups in return to work or quality of life measures, but of patients unconscious for more

than 1 hour initially ( $n = 75$ ), 80% were fit for duty in the hospital group versus 58% in the home-based group ( $P = 0.05$ ). There was a trend ( $P = 0.13$ ) in favour of the home-based group in patients ( $n = 44$ ) unconscious for an hour or less.

Other prospective randomised group studies early after injury have recruited less severely injured patients and investigated the effect on post-concussional symptoms of psychological interventions including reassurance, information giving and advice. These have found that intervention is associated with significant reduction in the intensity and number of symptoms and quicker return to work. One study investigated outcome at 6 months in all patients admitted to hospital after head injury. Cases were randomised to usual care or a programme of face-to-face interviews with written advice about likely prognosis and recovery times, and the management of post-concussional symptoms. These included reduced speed of information processing, memory problems, the interaction of cognitive and emotional stress, post-concussion symptoms, post-traumatic stress and a graduated return to normal levels of activity. This found that in patients with a PTA between 1 hour and 7 days, intervention was associated with significant reduction of concentration difficulties, headaches, fatigue, sleep disturbance and irritability with improvement in the patient's relationship with a partner, ability to cope with family demands, participate in social activities and enjoyment of leisure activities. Only 12% had more than one face-to-face contact. The economic benefits of this relatively low cost intervention in these patients, 70% of whom still had post-concussional symptoms and/or psychosocial problems at 6 months post-injury, has not been investigated. Other studies after mild TBI have also found early single educational interventions effective in reducing later anxiety and complaints. The cornerstones of treatment after mild traumatic brain injury (concussion) sustained in sport are physical and cognitive rest until symptoms resolve, followed by a graded program of exercise prior to return to play, preceded and accompanied by an explanation of the mechanism of symptom generation, with specific treatment, if needed, for example of the symptoms of post-traumatic migraine or a traumatic peripheral vestibulopathy.

Late after moderate and severe injury, gains in community and vocational function and life quality are usually limited by residual cognitive, affective and behavioural problems, rather than physical difficulties. However, adaptive change may continue for years, especially in younger patients, and with the judicious prescription of goal-focused interventions and ongoing support, which may need to be life-long. A United Kingdom study prospectively randomised 110 patients a median of 1.37 years after largely severe injury to either a multi-disciplinary outreach programme twice a week for a mean of 27 weeks or to written advice. Two years after recruitment there were still significant gains in outreach treated patients in measures of community independence and self-organisation but not in socialising, productive employment or mood. After severe injury, the high rate of unemployment in this young population of 50–70% compared with rates of 10–20% pre-injury is now well documented. Work retraining and supported employment models have been described over the last 20 years. Their efficacy, sometimes achieving employment rates of above 50% late after severe injury, has so far been gauged against a pre-intervention baseline rather than a prospectively randomised control and tends to assume rather than demonstrate improved life quality with employment. Nevertheless, specialist programmes of this sort are important aspects of the rehabilitation menu in clinical practice.

Residual cognitive problems most commonly involve speed, attention, executive function and memory, and are often accompanied by irritability, impulsivity and verbal aggression, triggered by anxiety resulting from difficulties problem solving in the context of increases

in environmental demand. They may be containable by informed family and non-specialist support in the community, but may become complicated by late secondary depression as insight increases. Less frequently, neurobehavioural disability is caused by more obvious disorders of behaviour and social cognition, which result in reports of the subject's personality being 'changed', as described in Phineas Gage, and also occurs after other types of damage that particularly involves ventro-medial prefrontal cortices. These affective and behavioural problems may deteriorate with time, particularly in the absence of rehabilitation provision. Problem behaviours are more difficult for carers to tolerate and manage than long-term physical and cognitive deficits, and are well-recognised causes of marital breakdown, social isolation and recurrent unemployment. Management is advocated with programmes of various intensities on an outpatient, day-patient or residential basis to deliver cognitive rehabilitation, cognitive-behavioural therapy and psychotherapeutic strategies, sometimes with adjunctive drug treatment such as carbamazepine or an antidepressant. These programmes are intended to promote insight and a self-managed framework within which it is possible to plan and set realistic goals, and thus reduce anxiety, indifference and other maladaptive and isolating antisocial behaviours. The clinical usefulness of other drug treatments, for example amantadine or methylphenidate to improve attentional skills and speed of processing, and reduce irritability, or modafinil to reduce excessive day time sleepiness, remains unpredictable. Aggressive or sexual behaviours sufficiently aberrant to require residential behaviour modification are uncommon although resource demanding, particularly when accompanied by psychiatric disorders, which may be pre-existing. They require the application of behavioural frameworks that can modify and reduce aggressive behaviour even years post-injury. Improvement in life quality resulting from these complex cognitive and behavioural interventions has so far proved difficult to demonstrate.

The long-term change in independence and social roles that occurs as a result of severe brain injury may require support life-long if optimal function is to be maintained and deterioration prevented. Complications such as falls and further injuries, depression and social isolation, fits or substance abuse are largely avoidable, given adequate support. Provision for those patients who are mobile in the community should include low cost specialist day centres, as Headway Houses in the United Kingdom, and if possible access to a professional with experience of the consequences of acquired brain injury to provide case management and support, particularly at times of change, and to facilitate change over extended periods of time.

Over the last 10–15 years, the use of advanced imaging techniques to investigate the capacity for category specific mental imagery has shown how the responsiveness of some patients apparently in low awareness states, particularly after traumatic rather than hypoxic-ischaemic brain injury, is limited by failure of motor outflow rather than a failure of understanding or the ability to reason, even years after injury. These findings have encouraged a reappraisal of the neurological basis of consciousness, ethical decisions about the withdrawal of nutrition and hydration, and real-time communication with these patients using brain-computer interfaces. Recent reports of patients in low awareness states, either vegetative or minimally conscious, regaining the ability to demonstrate reliable awareness after very long periods, with or without neural stimulation or drugs, confirms that late and slow, albeit functionally relatively minor, improvement in less disabled patients may also occur over many years, and begs the question as to whether the changes seen are the result of structural plasticity, how much these changes depend on the quality and level of training and care provided, and, if so, whether and how this input can be afforded.

## Service delivery

### Organisational behaviours and interdisciplinary assessment

Delivery of any organised complex multi-disciplinary service, especially involving disciplines with different professional training backgrounds and languages, as is the case in rehabilitation, demands definition not only of structure, as plant and personnel, but also process, which has the following key elements:

- Inter-disciplinary assessment and problem definition
- Treatment planning and delivery
- Evaluation of effectiveness and reassessment.

### Assessment

An interdisciplinary assessment is very different from that offered by a physician working independently. Patients with complex disability, when multiple factors affecting functional performance present as a single problem, benefit from comprehensive assessment by a rehabilitation team. These teams can work in different ways depending on the setting, and on the needs of the individual. Multi-disciplinary working involves a group of different professionals working alongside one another towards a common overall long-term aim, with different disciplines delivering interventions to achieve goals in parallel rather than in close collaboration. A more integrated approach is offered by an interdisciplinary team that works together to achieve a series of agreed goals toward a long-term aim. Team members have a fuller understanding of each other's roles and skills and work together in a holistic way, ensuring that different interventions complement each other. This approach is encouraged by settings in which staff are in geographical contact on a regular basis, either in inpatient rehabilitation units or in the community.

The advantages of an interdisciplinary assessment are that different disciplines identify different contributing problems, and can develop an appropriately ordered plan to deal with these contributing causes. For example, a patient with MS may present with a small sacral pressure sore. The contributing factors include immobility, incontinence, under-nutrition, lack of insight and motivation, low mood and spasms. The spasms may be aggravated by constipation and incomplete bladder emptying, as well as pain caused by the pressure sore; the tone problems can be ameliorated by seating the patient correctly; the provision of a pressure-relieving cushion may counter the impact of immobility; and cognitive-behavioural therapy or an antidepressant may help depression. This analysis of the problems demands nursing, psychology, medical, occupational therapy and physiotherapy diagnoses. Interdisciplinary teams provide a more accurate assessment, and decrease the need for hospital admission.

When a team of different disciplines work together they need a framework for assessment and description of an individual's abilities and difficulties. The ICF (Figure 18.1) provides such a framework. It classifies health at the level of body functions or structure, the whole person, and the whole person in a social context. Disabilities, formerly termed disablements, result from:

- Impairments (losses or abnormalities of body functions and structures)
- Activity limitations (previously disabilities), and
- Participation restrictions (formerly termed handicaps).

A person's disabilities and their level of functioning are outcomes of multiple interactions between health conditions and contextual factors. Two sorts of contextual factors are identified:

- Social and physical environmental factors (e.g. social attitudes, access to buildings, legal protection), and
- Personal factors which include gender, age, other health conditions, social background, education, overall behaviour pattern and other factors that influence how disability is experienced by the individual.

These interactions help explain why apparently similar patients have different outcomes. An individual patient may complain of difficulty walking, and not only the causes but also the consequences of the problem, including their subjective perception of life quality, are likely to differ in different individuals.

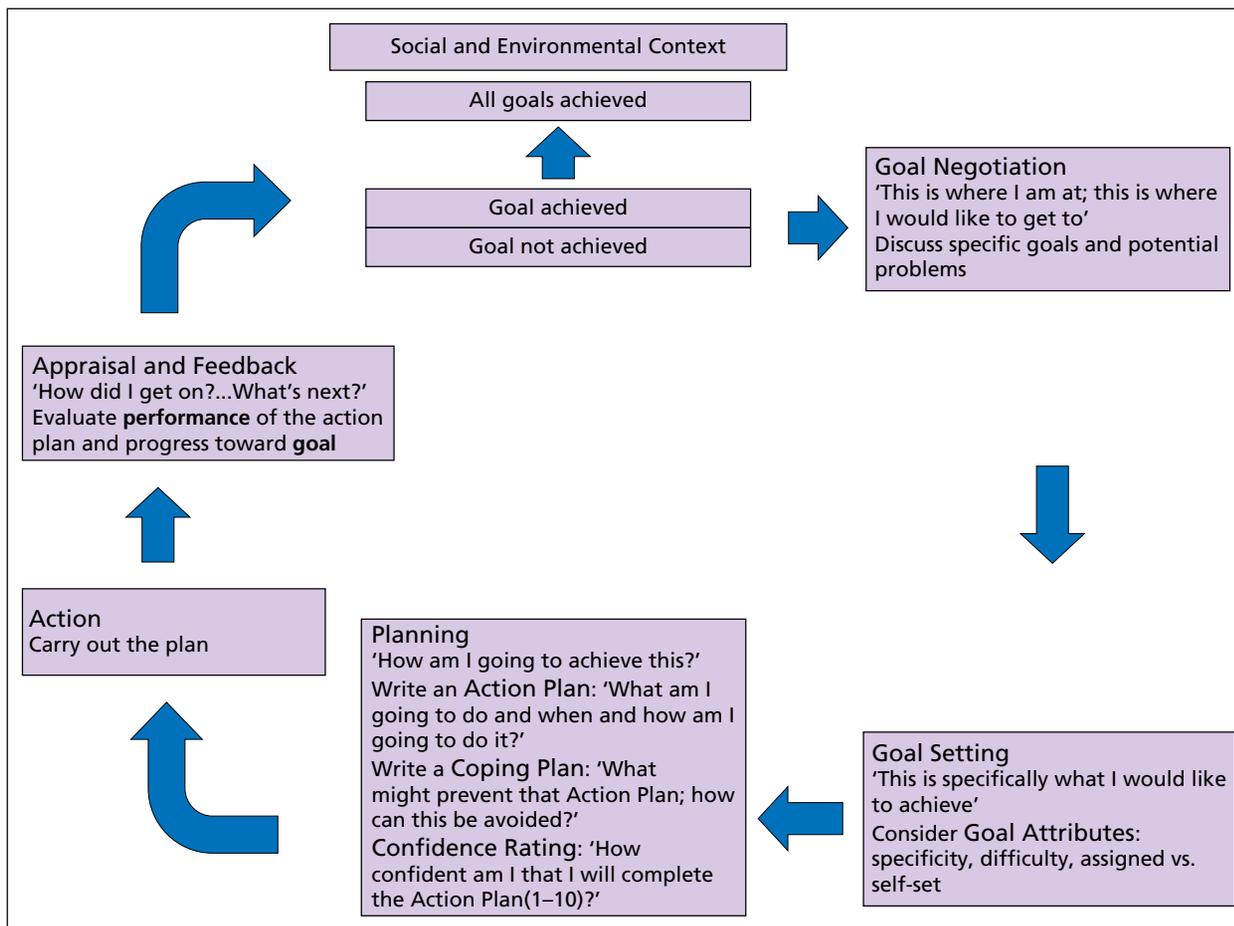

### Goal-setting

Having completed an interdisciplinary assessment and identified the individual's capabilities, disabilities and priorities, the next step is to devise a treatment plan. This treatment plan is usually articulated as a treatment goal. Goal setting may therefore be regarded as a key skill for rehabilitation professionals, and indeed any professional involved in complex interventions. There is a growing clinical literature on the subject of goal-setting, but the evidence base for goal-setting was originally derived from the organisational psychology literature of the 1970s.

In 2002, Locke and Latham synthesised studies of over 40 000 participants and 100 different tasks in eight countries and in field, laboratory and simulated settings into a theory of goal-setting. They define a goal core, mechanisms, moderators and other factors. The goal core defines the task, the level of difficulty and specifics of how, and in what timeframe, the goal should be completed. In other words, goals need to be formulated to be SMART: specific, measurable, achievable, relevant, and time-limited. Goals affect performance via a number of mechanisms, including directing attention and effort toward goal-related activities and increasing effort and persistence. Challenging goals have been demonstrated to lead to greater effort than low-level goals. The benefits of goal-setting can be moderated by factors such as the individual's commitment to the goal, the importance of the goal to them, their belief that the goal can be attained (self-efficacy), the extent of feedback about goal progress and performance, and the complexity of the task. Thus, the final outcome of goal-setting will depend on the balance between these mechanisms and moderators of the goal-setting process, and their satisfaction with the process. Thus, when considering the specifics of goal-setting it is important to recognise a number of other factors, including the importance of the individual's relationships and their previous experience of health service professionals, the impact of the disease itself, particularly in relation to prognosis and disease course, and the views of their family.

A number of studies of goal-setting in the rehabilitation environment have been reported. Earlier studies suggested that people with disabilities and particularly those with TBI should be allocated goals and treatment interventions. In a randomised control trial of 16 adults with TBI, the experimental group were actively involved to a high level in the goal-setting process, by prioritising wooden blocks that had activities of daily living written on them. In contrast, the controls were involved at a low level. Although both groups initially improved in goal attainment (as measured by Goal Attainment Scaling), at the assessment 2 months following discharge, those experiencing the higher level of involvement had maintained their therapeutic gains in contrast to the low involvement group, who had returned to pre-test level.

The part played by goal difficulty and goal origin (self-set goals versus assigned goals) on the performance of adults with brain injury has been assessed by a simple arithmetical task. Eighty-seven patients with a diagnosis of stroke or TBI were randomly assigned to one of three groups: a specific high goal was assigned; a 'do your best' goal was given; or a personal goal had to be stated. Results showed that assigned difficult goals led to better performance than assigned easy goals, and that self-setting a goal did not increase performance to the same level as the assignment of a difficult goal. These findings suggest that goal origin (assigned or self-set), and

**Figure 18.9** Goal setting and action planning practice framework. Source: Scobbie 2011. Reproduced with permission of Sage.

goal difficulty are important moderators in the goal-setting process and influence performance.

In addition, the association between participation in goal-specific outpatient occupational therapy and improvement in self-identified goals in adults with brain injury has been investigated. Using a repeated measures design, standard therapy designed to achieve specific goals was followed by a period of no treatment. Thirty-one participants with brain injury were recruited at three sites located in different regions of the United States. Participants completed the Canadian Occupational Performance Measure (COPM) and the Community Integration Questionnaire (CIQ) at admission, discharge and 1 and 18 weeks after discharge. In addition, Goal Attainment Scales were developed at admission and scored on discharge. Of the 149 goals identified by participants, 81% were achieved. Goal Attainment Scores improved significantly ( $z = 7.52$ ;  $P < 0.001$ ), with a large effect size ( $r = 0.94$ ). The COPM scales showed significantly greater gains during the treatment (average 15.3 weeks) compared with the no treatment period (average 9.9 weeks). It was concluded that participation in goal-specific outpatient occupational therapy that focuses on teaching compensatory strategies was strongly associated with achievement of self-identified goals and reduction of disability in adults with mild to moderate brain injury. However, these results may not be generalisable to the broader brain-injured population.

More recently, recognising the difficulties of establishing patient centred goal-setting in practice, qualitative studies have focused on barriers to goal setting and perceived benefits. These studies suggest that patients perceive that monitoring progress towards meaningful goals helps achieve practical goals, such as independence and returning

to work, reduce emotional impact and support coping. Patient-related barriers to goal setting may result from poor understanding of and lack of information about the process, so that patients avoid exposing their incompetence at setting goals that results from not knowing or understanding prognosis, cognitive impairment and distress about the impact of a sudden onset disabling condition such as stroke. System-related barriers include issues such as limited time set aside for goal setting, and the prioritisation of 'hands on' treatment. As a result, most studies suggest that goal setting is not patient centred.

These qualitative studies have highlighted the need for a good underpinning theory of goal-setting in rehabilitation, which is reflected in clinical practice by developing structures and processes that support staff to deliver patient-centred goal-setting and patients to participate. Recently, Scobbie *et al.* have identified the theoretical constructs that are thought to influence patient behaviour in relationship to goal-setting as self-efficacy, outcome expectancies, goal attributes (specificity, difficulty), action planning and coping planning, and appraisal and feedback (Figure 18.9). In practical terms, this converts to a framework with four key intervention points:

- 1 Developing goal intentions by appraising their current situation, when staff work with the patient to increase patient self-efficacy and motivation.
- 2 Setting a specific goal.
- 3 Activating goal-related behaviour by defining an action plan specifying who will do what when, and a coping plan that details potential barriers and how these will be managed.
- 4 Appraisal and feedback.

The variables hypothesised to effect change in patient outcomes were self-efficacy and the action plan. Work of this sort, combined with goal setting timetabled into the working week, as recommended by the 2013 NICE stroke rehabilitation guidelines (Clinical guideline 162), should lead to greater understanding and implementation of patient-centred goal-setting.

## Outcome measurement

Outcome evaluation of the success of any rehabilitation can examine process or functional outcomes. At the simplest level, achieving a specified goal is a measure of outcome. The difficulty of using goals as outcome measures is that because when they are unique to an individual patient, they cannot be used to describe groups or compare outcomes between groups. Where suitable outcome measures exist, and are appropriate to both the disorder and the intervention, it may be preferable to examine outcomes other than goal achievement.

Traditionally, physicians have used measures to tell them something about the presence, natural history and severity of a disease. Direct measurement of the extent of the pathology is often impossible, but often there are markers of the disease activity, for example MRI changes in MS or [<sup>18</sup>F]dopa positron emission tomography (PET) in Parkinson's disease. There is now increasing interest in patient-based outcomes that focus on aspects of health considered important by the patient. These measures typically focus on HRQoL. Rating scales measure either generic aspects of health or focus on one particular aspect. Generic measures, such as the Medical Outcomes Study Short Form 36 (MOS SF-36) health status scale, allow different patient populations to be compared and allow the inclusion of a control population in a study. Typically, the usefulness of such scales may be limited by their inability to capture a range of outcomes relevant to the particular patient populations studied, and so they may be unresponsive to change in a clinical condition. Alternatives include disease-specific measures such as the Parkinson's Disease Questionnaire-39 (PDQ-39) or the Multiple Sclerosis Impact Scale (MSIS); site-specific scales such as the Disabilities of the Arm, Shoulder and Hand (DASH) outcome questionnaire; or dimension-specific measures that measure one aspect of quality of life such as well-being (e.g. the General Health Questionnaire [GHQ]).

Clinically useful instruments should be easy to administer, clinically appropriate, brief, cheap and easy to analyse, and measure the outcome that is relevant to the intervention and to that disease group. They should also be acceptable to patients, being neither intrusive nor upsetting. Since about 1990 there has been a marked increase in the numbers of papers that address outcome. Typically, these papers report a new or previously described scale in terms of its psychometric properties. Traditional psychometric approaches inform users about the scientific properties of the scales. Scientifically sound instruments are valid, reliable and responsive. A valid instrument measures what it is intended to measure. Validity cannot be proven but evidence in support of validity can be gathered. Content validity is the extent to which the measure represents the full range of the conceptual domain it addresses. Criterion-related validity compares the measure against a gold standard. Construct validity compares the measure in different situations. Does it correlate with other measures of related entities (convergent validity)? Does it fail to correlate with measures that purport to measure a different concept (discriminant validity)? Does it detect differences in groups known to be different in the concept measured?

A reliable instrument performs in an accurate, consistent and reproducible manner that is stable over time. The purpose of reliability testing is to determine the extent to which random error is present

in the measurement. To be reliable, scales need clear descriptions of the meaning of individual points on the scale. There is evidence that idiosyncrasies of performance represent a major source of variability in rating scales. Stability of the scale over time is assessed using test-retest reliability. Inter-rater reliability is the agreement between two or more raters, intra-rater reliability is the agreement between two ratings made at different times by a single observer on the same patients. Responsiveness describes the ability of the scale to measure clinically relevant change, such as the impact of rehabilitation, or the effect of a new drug.

## Indices of outcome

There is now a range of measures used commonly in rehabilitation. The Barthel Index (BI) is the most commonly used assessment of limitations in personal ADL. It consists of 10 items measured on either a two, three or four point scale, with a maximum score of 20. The BI has been well studied in a number of settings and its general validity has been established. It correlates well with clinical impression, with motor loss after stroke and with scores on other ADL scales. It is reliable and simple to use but its content is only relevant to people with moderate and severe disability – it has a floor and ceiling, which need to be populated by other measures. However, despite being widely used and having been evaluated using traditional psychometric approaches, it is clear that there remain a number of problems. First, the Barthel is an ordinal scale and is typically reported using a summed score out of the maximum total summed score of 20. However, the raw scores are simply ordered points. The intervals between them are not equal, thus a total score of 16 may represent many different patterns of disability. In addition, because the scale is not linear, it is not possible to compare scores from two different scales (e.g. the BI and Functional Independence Measure [FIM]), which measure the same construct, because the relationship between the scales will vary according to the level of disability being measured.

More recently, scales have been assessed using two new psychometric methods: Rasch analysis and Item Response Theory, which overcome some of these difficulties. Both approaches model the probability of an individual's response to an item, in that a person with high levels of function will have an increased probability, relative to an individual with low levels of function, of scoring more than zero on any item, whether rating, for example, dressing or toileting. These psychometric methods use statistical techniques that can be used to transform ordinal scales into interval scales. Thus, the relationship between one point and another can be given a specific value. This has a number of potentially exciting consequences. First, it will allow different scales to be anchored to a common point thus allowing large item banks to be created from scales that address the same underlying construct (e.g. upper limb function). Secondly, when a calibrated item bank is developed, testing programs can be made more flexible and appropriate, which allows more accurate measurement of both individuals and groups, and makes it easier to assess the impact of treatment. The ability to measure change more accurately means that the numbers needed to detect significant differences between groups may be smaller. Thirdly, it will be possible to compare groups measured using different scales, with enormous impact on our ability to interpret systematic reviews and perform meta-analyses.

## Service quality

One of the difficulties in evaluating a rehabilitation service is that many markers of a quality service may not directly affect outcome. Given the difficulty in running efficient coordinated services, systems that allow the evaluation of the rehabilitation process are invaluable. Evaluating process is facilitated by the development of

an Integrated Care Pathway (ICP). An ICP is a document that maps the interventions that should occur during a specific episode of patient care. Typically, the ICP allows evidence-based practice to be operationalised for a specific setting. The benefits of ICPs lie in specifying the best possible method of delivering care and in describing the patterns of variances. A variance sheet may be used to record either departures from the pathway as a procedural variance or the reasons for non-achievement of goals. Individual variances are neither good nor bad; they are simply a method of recording what happened to a specific patient and the reasons for it, thus allowing for individualised patient care. The patterns of variances across a group of patients will identify strengths and weaknesses in the processes around particular episodes of care, and permit incorporation of new ideas and remediation of problems. When combined with measurement tools it is possible to identify which aspects of care impact positively or adversely on outcome.

## Conclusions

Adequate widespread longitudinal provision of strategies that prevent complications and secondary deterioration, and drive neural reorganisation have not yet been achieved even by health services in industrialised economies. To do so requires major structural reorganisation, so that goal-focused care and retraining programmes using individualised current best practice can be routinely provided, life-long if needed. A regime change of this sort would probably result in further significant reduction in morbidity and mortality long term after neural injury. It is likely to be facilitated by an increase in the translation of examples of effective delivery of complex treatments in other clinical areas, and of ideas from the science of organisational behaviour, into the implementation of clinical networks, multi-disciplinary team working and individualised treatment programmes.

This clinical process will benefit from, and can initiate, continued investigation of new technologies and restorative treatments, studied in cohorts triaged by robust subject and disease-related variables. Treatments that simultaneously prevent complications and drive the induction of structural plasticity in useful directions are likely to produce most functional gain. Such a conjunction fortuitously occurs in CIMT, which uses both constraint to induce, or force, use of an under-used motor system, and movement therapy, as massed practice, to drive motor output and shape use. This was shown to be functionally effective in the ground-breaking Phase III EXCITE trial in the United States, at a cost of \$7.5 million over 5 years. Its clinical implementation is inevitably limited by its functional entry criteria and intensive treatment schedule, which requires constraint of the less affected hand for most of 14 consecutive days, and one-to-one training of the affected hand for 6 hours a day for 10 of those days; as a result, even patient recruitment to the trial occurred at a rate of only one patient per month per site. Thus, the perception, at least in the United Kingdom, that CIMT has failed to translate into routine clinical practice may be more apparent than real, although if modified CIMT, for shorter sessions over longer periods, proves equally effective, clinical use might increase.

Similar delivery issues, relating to questions of therapy intensity and duration, real-world effectiveness and when post-injury treatments should be given, apply to many other efficacious training therapies and techniques, as well as robotic training, drugs that modulate neural replacement, regrowth and reorganisation, and non-invasive magnetic and electrical stimulation techniques of the central and peripheral nervous system, all of which might increase the effectiveness of training therapies and their longer term effects.

Chosen therapies and conditioning techniques need first to be standardised and then investigated in proof-of-concept and mechanistic Phase II studies before Phase III trials can be achieved, after which clinical implementation requires further investigation. This framework potentially underpins an industrial number of studies, at national and international levels, using both impairment based and functional entry and outcome measures, to define which treatment or treatment combinations work, how and when to use them following neural injury, and for what type and level of impairment. Just as functional imaging's major, if inadvertent, contribution to clinical practice has been to change attitudes to the prescription as well as the practice of rehabilitation, so the demonstration in small studies in the laboratory that restorative treatments can result in useful functional change is likely to encourage the addition of an exploratory element to many patients' coping strategies, and increase recruitment to Phase II and III trials intended to translate these treatments into the clinical domain.

# Toxic, Metabolic and Physical Insults to the Nervous System and Inherited Disorders of Metabolism

Robin Howard<sup>1</sup>, Jeremy Chataway<sup>1</sup>, Mark Edwards<sup>2</sup>, Simon Heales<sup>1</sup>, Robin Lachmann<sup>1</sup>, Alexander Leff<sup>2</sup> and Elaine Murphy<sup>1</sup>

<sup>1</sup>National Hospital for Neurology & Neurosurgery

<sup>2</sup>UCL Institute of Neurology

Toxic, nutritional and metabolic derangements can cause damage to the nervous system by a variety of mechanisms and lead to a wide spectrum of characteristic neurological disorders. Exposure to toxic substances, which can be accidental or deliberate in the context of substance abuse, can cause encephalopathy, stroke, seizures or neuropathy. Nutritional deficiencies are probably the most common worldwide cause of neurological disease and are manifest as a number of well-characterised, usually reversible but potentially serious neurological disorders. Metabolic encephalopathy is brought about by the consequences of organ failure or exposure to endogenous or exogenous toxins or drugs that can affect the central nervous system (CNS). The cause of these conditions can be unclear at presentation and often requires detailed clinical and laboratory analyses before the correct diagnosis is made and appropriate therapy instituted. Similarly, neuromuscular abnormalities can occur as a consequence of toxic exposure or nutritional deficiency.

## Neurological disorders associated with exposure to toxic substances

Environmental factors and toxins are important causes of neurological disease. They are often under-recognised and are difficult to diagnose as the onset of symptoms can be slow and the clinical pattern can mimic other common conditions. This chapter includes a review of the effects of accidental and deliberate exposure to industrial and environmental toxins and drugs of addiction including alcohol. Some of the more important toxins that affect the nervous system are shown in Table 19.1 and the patterns of neurological involvement in Table 19.2.

### Heavy metals

Exposure to heavy metals or industrial toxins is usually cumulative, developing over a prolonged period of months or years as a consequence of environmental or occupational exposure. However, these agents can be acutely toxic with accidental or deliberate ingestion of excessive amounts. The adverse effects of acute or chronic exposure develop earlier and more rapidly in the young and the consequences differ from those in adults. Heavy metals impair the function of the nuclei or cytoplasmic structures, particularly mitochondria. Acute exposure often leads to encephalopathy with confusion, attention deficit and seizures, while chronic involvement is of a more

insidious onset with mood disturbance, memory and cognitive impairment. Systemic features usually accompany neurological manifestations.

### Lead

Lead is the most common source of heavy metal intoxication because of its extensive commercial use and presence in Ayurvedic medication. Occupational exposure occurs in workers in smelting and metal foundries, battery manufacture and industrial plants. Accidental ingestion occurs in children with pica (eating dirt and the coating of pipes); however, exposure has diminished with the phasing out of leaded petrol and diminished use of lead-based paints. Inorganic lead is absorbed from the gastrointestinal tract and children are particularly vulnerable.

Lead binds to erythrocytes and is distributed throughout the body. It is incorporated into the brain and other soft tissues where it may persist for prolonged periods. It is toxic to the nervous system and leads to altered migration of neurones during development. It also interferes with cell membranes, myelin, neurotransmitter function and calcium metabolism.

Lead toxicity has a number of effects in the nervous system leading to acute encephalopathy (particularly in children) and polyneuropathy in adults. Lead encephalopathy may follow gastrointestinal symptoms and patients present with headache and fatigue leading to confusion, altered level of consciousness, behavioural change and focal or generalised seizures. Other signs include ataxia, impaired motor function and coma. In children, lead is a significant neurodevelopmental toxin, which produces mild learning difficulties. In adults, chronic exposure leads to a similar but slower onset encephalopathy characterised by headache, myalgia, paraesthesia, irritability, sleep disturbance and loss of libido evolving into progressive confusion and stupor. Pure motor neuropathy can occur affecting the upper more than the lower limbs. The onset is usually symmetrical and often associated with prominent gastrointestinal disturbance. There can be bilateral wrist or foot drop with marked atrophy and occasional fasciculation, which can mimic motor neurone disease. Although the sensory component is usually minor, the neuropathy may be particularly painful. Lead toxicity can cause a blue line at the gingival margin (Figure 19.1).

Investigations will show elevated concentrations of lead in the blood, there is a hypochromic microcytic anaemia with basophilic

Botulinum toxin

stippling of the red cells (Figure 19.1), hyperuricaemia, reduced blood  $\gamma$ -amino-laevulinic acid and raised zinc and lead protoporphyrins. Nerve conduction studies show a marked axonal neuropathy with denervation although there can be mild motor conduction slowing. Nerve biopsy confirms axonal degeneration although paranodal demyelination can be present.

The mortality of acute severe lead encephalopathy can be >25%. Treatment is initially supportive and involves eliminating the source

of lead exposure. Chelation therapy is used, if lead concentrations are markedly elevated, to remove lead before it can be incorporated into the CNS or soft tissues. This involves treatment with EDTA, dimercaprol (2,3-dimercaptopropanol) or BAL (British anti-Lewisite). Early treatment usually leads to improvement in the neuropathy but the prognosis of the encephalopathy is less certain.

### Mercury

Mercury exists in an elemental inorganic or organic form. The inorganic form is absorbed rapidly following inhalation during industrial exposure in the production of thermometers, barometers or batteries and historically was also accidentally ingested during hat-making. The organic form, methylmercury, is far more toxic and occasionally poisons water supplies, as was the case in the Minamata outbreak in Japan in the 1950s and 1960s.

Chronic industrial exposure to elemental or inorganic mercury causes systemic manifestations with renal, skin, pulmonary and gastrointestinal involvement including gingivitis, cutaneous erythema (Pink's disease), anaemia and proteinuria. Patients develop progressive rest and intention tremor ('hatter's shakes'), ataxia and myopathy; there is memory and cognitive impairment, social withdrawal, personality change with anxiety, excitability, emotional lability and insomnia. Eventually, drowsiness, confusion and stupor supervene. Methylmercury is bio-amplified by aquatic species and following ingestion causes paraesthesiae, tremor, ataxia, spasticity, progressive visual field and hearing loss with encephalopathy, progressing to stupor, coma and death.

The diagnosis is confirmed by demonstrating elevated blood and urine mercury. Treatment is by facilitating the elimination of mercury with prompt chelation using penicillamine and providing supportive care. The role of chelation therapy with dimercaprol is controversial.

### Arsenic

Inorganic arsenic has been extensively employed in herbicides and pesticides and as a timber preservative in the past, although current use is mainly restricted to the production of glass, electronics and computer microchips. It also occurs in a non-toxic organic form in seafood. Exposure occurs by drinking contaminated well water, especially in the Indian subcontinent, or as a consequence of mining lead or copper smelting; arsenic is sometimes found in herbal medications. It has been used as a poison because it is odourless, tasteless and highly toxic.

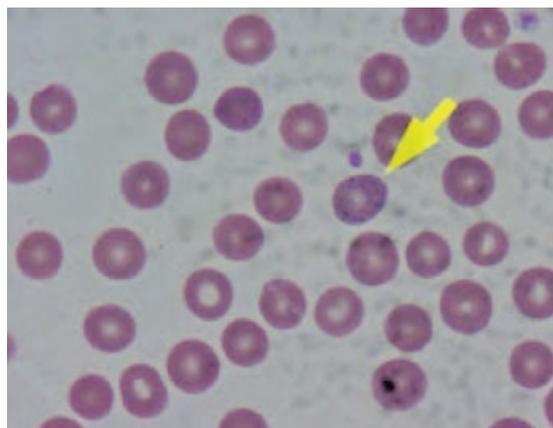

Arsenic disrupts protein structure and enzyme activity leading to inhibition of mitochondrial function and oxidative metabolism. Acute or subacute exposure is associated with nausea, vomiting, abdominal pain and bloody diarrhoea, followed by progressive encephalopathy. Autonomic features including hypotension, tachycardia and vasomotor collapse develop culminating in arrhythmia, myoglobinuria, acute renal failure, obtundation, acute confusional state, coma and death. Low dose chronic exposure causes weight loss, severe alopecia and white horizontal striations on the nails (Mees' lines) (Figure 19.2). There is usually severe gastrointestinal disturbance and skin changes include melanosis, keratosis and malignancy. There can be personality disturbances with confusion, irritability, delusions and visual hallucinations; optic nerve and spinal cord involvement can also occur. Arsenic neuropathy is a sensori-motor neuropathy which is predominantly axonal although demyelinating features occur soon after exposure. It usually develops within several weeks of the acute exposure and is characterised by distal pain and progressive weakness initially in the lower limbs,

**Table 19.2** Patterns of neurological involvement caused by toxins.

Syndrome	Clinical features	Causes
Acute encephalopathy	Non-specific – headache, nausea and vomiting, fatigue, irritability Confusion, disorientation Amnesia Cerebellar – ataxia, slurred speech Seizures, clouding of consciousness, coma	Organic solvents inc. toluene (acute exposure) Lead, arsenic, thallium, manganese, mercury
Chronic behavioural and cognitive impairment	Non-specific – headache, nausea and vomiting, fatigue, irritability Mood disturbance, anxiety, psychosis	Lead, chlorinated hydrocarbons
Delayed post-exposure encephalopathy	Delayed development of confusion and unresponsiveness	Carbon monoxide
Extrapyramidal	Tremor Rigidity Parkinsonism – bradykinesia Postural instability	Manganese
Myelopathy / myeloneuropathy	Gait ataxia Pyramidal signs – slow movement, weakness, hyperreflexia, extensor plantar responses Distal weakness and sensory loss	Cobalamine deficiency, nitrous oxide, copper deficiency
Polyneuropathy	Distal weakness and sensory loss	Lead, Arsenic, Thallium, Toluene

(a)

(b)

**Figure 19.1** (a) Lead lines (blue pigmentation seen along gum lines, arrow). (b) Basophilic stippling seen within the red blood cell.  
Source: Tsutsui 2013. Reproduced with permission of the New Zealand Medical Journal.

subsequently spreading to the upper limbs with areflexia and distal sensory loss. The neuropathy is associated with respiratory muscle weakness.

There can be anaemia, pancytopenia, basophilic stippling, myoglobinuria, elevated liver enzymes and raised cerebrospinal fluid (CSF) protein. Arsenic binds to keratin and therefore can be detected in hair, nail, bone, teeth or urine. It is cleared rapidly from the circulation so urine levels are a better guide to toxicity than are serum levels. Nerve conduction studies show motor and sensory

axonal neuropathy with occasional demyelinating features. Nerve biopsy confirms axonal degeneration.

The treatment involves removal of exposure, decontamination of the gastrointestinal tract and aggressive support. Chelation therapy can be undertaken with derivatives of dimercaprol such as DMSA (2,3-dimercaptosuccinic acid), DMPS (2,3-dimercapto-1-propanesulfonic acid) (Unithiol), BAL or D-penicillamine but there is little evidence to suggest this helps in the later stages of arsenic neuropathy. Exchange transfusion and forced alkaline diuresis can be necessary.

**Figure 19.2** Mee's lines. Source: Chauhan 2008. Reproduced with permission of Elsevier.

### Manganese

Manganese is present in all living organisms and functions as an enzyme cofactor. It is widely used as a fuel additive and also in fertilisers and fireworks. Toxicity occurs as a consequence of its industrial use in iron and steel manufacturing and in welding but exposure can also be iatrogenic as a consequence of poorly balanced total parenteral nutrition.

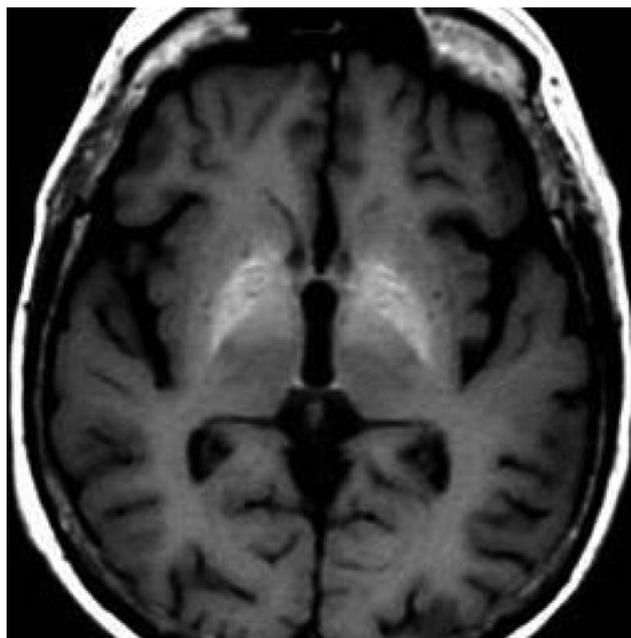

Acute exposure can lead to a progressive encephalopathy ('manganese madness') characterised by fatigue, apathy, insomnia, auditory and visual hallucinations, personality change, compulsive behaviour, irritability and aggression culminating in progressive memory disturbance. More chronic exposure leads to a characteristic pattern of extrapyramidal abnormalities with selective degeneration of the pallidum but relative sparing of the substantia nigra, characterised by parkinsonian facies, hypersalivation, micrographia, bradykinesia, rigidity and severe dystonia with occasional myoclonic jerking. The tremor is characteristically of low amplitude, bilateral and symmetrical, present on action and posture. There is often early development of speech and gait abnormalities, dystonia and action myoclonus with a poor response to levodopa. There can be an associated encephalopathic component including emotional lability and progressive cognitive impairment.

The diagnosis is confirmed by the presence of elevated serum manganese, and urine concentrations can also be helpful. Magnetic resonance imaging (MRI) scan can show abnormal signal intensities in the globus pallidus and subthalamic nucleus (Figure 19.3).

Management necessitates removal of the toxic sources and chelation with EDTA is occasionally helpful. The response to levodopa is variable. Dialysis may be necessary and liver transplantation has been reported to result in the reversal of parkinsonism.

### Aluminium

Aluminium is abundant and is extensively used in packaging, food containers and cooking utensils and in water treatment. Industrial exposure can occasionally occur after smelting or inhalation of aluminium dust but this is rare.

**Figure 19.3** Manganese toxicity: bilateral and symmetric high signal intensity in globus pallidus on T1-weighted images.

Acute intoxication leads to progressive agitation, confusion and myoclonic jerking, sometimes with generalised tonic-clonic seizures progressing to coma and death. More chronic exposure causes a progressive tremor, incoordination and ataxia with the development of focal epilepsy. Dialysis dementia (Chapter 20) is at least partly brought about by the toxic effects of aluminium in the dialysis fluid and in phosphate binders. Aluminium retention occurs in the uraemic state and progressive cognitive impairment, dysarthria and encephalopathy can develop after several years of dialysis.

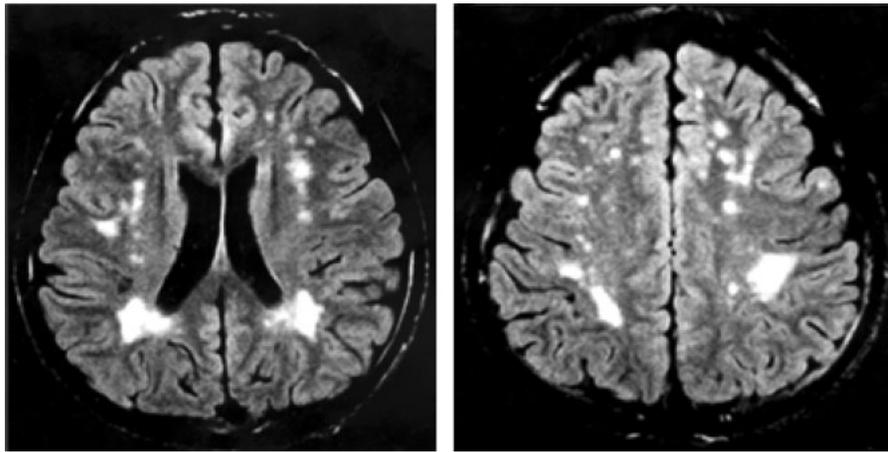

The treatment includes de-ionisation of the dialysate and avoidance of aluminium-containing phosphate binders. However, aluminium intoxication can occur as a consequence of chelation therapy that actually displaces sequestered aluminium from bone and this should therefore be avoided.

### Thallium

Exposure to thallium is now relatively rare as its use has been banned in pesticides. There is still an occasional incidence of deliberate exposure by attempted murder or suicide.

Acute exposure can lead to an encephalopathy characterised by hallucinations, paranoia and cognitive impairment. Systemic involvement is similar to arsenic in causing abdominal cramps, vomiting and diarrhoea. Alopecia develops after several weeks and is a key diagnostic clue, and Mees' lines are seen in the nails. There can be a progressive encephalopathy with ataxia, chorea and confusion culminating in cardiac and respiratory failure and coma. Chronic exposure leads to a progressive predominantly sensory axonal neuropathy which is painful and associated with distal sensory loss, weakness and areflexia. Neurophysiology confirms progressive axonal loss. High thallium levels can be detected in blood, urine and hair samples.

The treatment is with gastric lavage, laxatives and haemodialysis. Absorption from the gastrointestinal tract can also be reduced by Prussian blue or activated charcoal, both of which bind thallium.

**Figure 19.4** Toluene exposure: MRI T1-weighted scan showing extensive white matter change.

### Tin

Tin is extensively used in the manufacture of electronics and in soldering. The inorganic form is not associated with any abnormal neurological features but the organic forms (in particular triethyl tin), which can be inhaled, lead to progressive neurological dysfunction characterised by raised intracranial pressure with headache, apathy, cognitive impairment and hallucinosis culminating in seizures and coma. There may also be behavioural disturbances including emotional lability and cognitive impairment with confusion and disorientation. Abnormal eye movements, papilloedema and a cerebellar syndrome also occur.

Blood levels are a poor guide; urine levels may be more reliable. Treatment is by use of chelating agents, plasma exchange and D-penicillamine.

### Bismuth

Bismuth is contained in some surgical dressings and is sometimes used in the treatment of peptic ulcers and to bulk stools after colostomy. Excessive intake can lead to a progressive behavioural disturbance including depression, apathy and irritability, culminating in a florid encephalopathy with hallucinosis, tremor, myoclonus, ataxia and dysarthria leading to convulsions and coma. The myoclonus is characteristically stimulus-sensitive and can be multi-focal or generalised. Chelation treatment with dimercaprol is often effective.

### Solvents and toxins

CNS dysfunction can occur as a consequence of an accidental exposure to a high dose of industrial solvents or to more prolonged chronic exposure to moderate levels in the workplace or as a drug of abuse. The long-term symptoms of prolonged exposure to solvent vapour include progressive cognitive deficits affecting attention, memory and executive function and causing visuo-spatial disturbance with subsequent cerebellar or motor involvement.

### Toluene

Toluene (methyl benzene) is a volatile hydrocarbon solvent used in the manufacture of paints, glues and petrol. Exposure occurs relatively commonly during manufacture or industrial processes and the condition can be unrecognised. However, much of toluene poisoning is attributable to deliberate inhalation, such as in glue sniffing.

Toluene is highly lipid-soluble and so crosses the blood-brain barrier readily. It causes CNS demyelination, with secondary neuronal damage. It also causes a mixed axonal-demyelinating neuropathy. Acute exposure leads to progressive headache, nausea, vomiting and dizziness. There can be cardiorespiratory symptoms secondary to pulmonary hypertension before the development of cognitive impairment including euphoria, disorientation, memory loss and focal neurological signs such as dysarthria, ataxia and intention tremor with progression to stupor and coma. Long-term exposure is associated with toxic encephalopathy, progressive intention tremor and stimulus-sensitive myoclonus, dementia and there can be a progressive optic neuropathy with opsoclonus.

MRI scan may show cerebral atrophy or diffuse symmetrical abnormalities in the basal ganglia, thalamus or cingulate gyrus or extensive white matter high signal change (Figure 19.4). There are elevated urinary hippuric acid levels and blood toluene can also be a valuable guide.

Treatment is by removal of the source of the exposure and supportive care.

### Trichloroethylene and tetrachlorethylene

The chlorinated hydrocarbons, trichloroethylene (TCE) and tetrachlorethylene (perchloroethylene; PCE) are industrial solvents particularly used as degreasers and in dry-cleaning fluids. Exposure occurs by inhalation, contamination of drinking water or in recreational abuse because of their euphoric effects. Acute toxicity causes encephalopathy characterised by progressive nausea, dizziness and headache leading to disorientation, stupor and coma. Chronic exposure is associated with trigeminal neuropathy causing progressive sensory impairment spreading from the nose in a trigeminal distribution leading to facial and buccal numbness. Weakness of the muscles of mastication and facial expression may then develop with progressive ptosis, ophthalmoplegia, retrobulbar neuritis, optic atrophy and vocal cord involvement. Further exposure leads to a chronic sensorimotor neuropathy with mixed axonal and demyelinating features and progressive impairment of attention, memory and orientation.

The level of TCE metabolite trichloroethanol can be measured to monitor exposure.

Treatment is by removal from exposure. Patients who have been acutely exposed should have oxygen administered and be treated

with gastric lavage and haemodialysis. Improvement in trigeminal and other cranial nerve involvement is usually incomplete.

### Ethylene oxide

Ethylene oxide is used to sterilise heat-sensitive medical equipment and as an alkylating agent in industrial synthesis. It is highly toxic, causing a severe progressive reversible encephalopathy. Long-term exposure leads to a sensorimotor axonal neuropathy and mild cognitive change. Improvement generally follows discontinuation of exposure.

### Hexacarbon solvents

Hexacarbon solvents, and in particular n-hexane and methyl n-butyl ketone (MnBK), are commonly used in industrial solvents and household glues. They are neurotoxic and are liberated during petrol production and refining. They are also present in most glues and solvents and are widely abused for recreational reasons.

A reversible acute encephalopathy is common in those who take solvents for recreational reasons, leading to euphoria, dizziness, ataxia and progressive cognitive impairments, encephalopathy and coma. However, chronic exposure causes a progressive distal sensorimotor axonal peripheral neuropathy associated with autonomic involvement and parkinsonism. N-hexane exposure also causes facial numbness, maculopathy or optic neuropathy. The management is cessation of exposure.

### Xylene and styrene

Xylene and styrene are structurally similar to toluene and found in solvents, paints and varnishes. Acute exposure occurs by inhalation or absorption from the skin and can lead to acute encephalopathy with disturbances of cognition, attention and behaviour. Chronic exposure to lower levels can cause mild but progressive disturbance of behaviour, psychomotor performance and visual function.

### Carbon disulfide

Carbon disulfide is used as a solvent in varnishes and insecticides, in the manufacture of plastics including rayon and cellophane as well as the vulcanisation of rubber. It is a potent neurotoxin with exposure caused by inhalation and oral ingestion rather than by transdermal exposure. Acute exposure to high levels leads to encephalopathy with progressive drowsiness and disruption of behaviour with mood swings, hallucinations, psychotic disturbances and memory loss. A similar encephalopathy occurs with chronic exposure but a distal demyelinating sensori-motor peripheral neuropathy may occur and there may also be parkinsonism, retinopathy, optic neuropathy, cerebellar involvement and a small vessel vasculopathy.

Blood and urine carbon disulfide levels give a guide to exposure. The treatment is removal from the source but no agent is available to neutralise the effects of carbon disulfide which can be present for many years.

### Cyanide

Cyanide blocks trivalent iron in cellular respiration enzymes and inactivates cytochrome oxidase. This leads to an immediate cessation of cell respiration with hypoxia and respiratory arrest. Exposure usually occurs as a consequence of deliberate poisoning. However, cyanide poisoning can also occur during accidental smoke inhalation or from ingestion of incorrectly prepared cassava flour (see Konzo). Acute exposure affects structures with high oxygen requirements leading to haemorrhage necrosis. Presentation is with

dizziness, headache, vertigo and agitation, culminating in seizures, respiratory arrest and death. Chronic ingestion can cause progressive cognitive impairment, parkinsonism and delayed dystonia. MRI shows bilateral areas of hyperintensity in the lentiform and caudate nuclei also the striatum and globus pallidus.

Treatment involves immediate administration of 100% oxygen followed by hydroxycobalamin and sodium thiosulfate.

### Acrylamide and acrylonitrile

Acrylamide is used as an adhesive and grouting agent. Inhalation or cutaneous exposure can occur during manufacture or in the polymerisation process. Acute high-dose exposure can cause an encephalopathy characterised by confusion, hallucinations, drowsiness and ataxia. More commonly, however, chronic exposure leads to a characteristic progressive distal sensorimotor axonal neuropathy which initially develops in the lower limbs before affecting the upper limbs. Autonomic involvement is common with hyperhidrosis and dermatitis. There can be a progressive cerebellar ataxia and occasionally pyramidal signs occur. It is associated with dermatitis, palmar erythema, fatigue and weight loss.

Nerve conduction studies confirm the presence of an axonal sensorimotor polyneuropathy initially affecting large myelinated fibres and biopsy shows distal axonal degeneration. Acrylonitrile is used to make plastics for pipes and building components. It is absorbed by inhalation and through the skin and converted to cyanide which is responsible for the associated acute toxicity. Chronic toxicity is associated with fatigue, headache, nausea and nasal irritation.

### Allyl chloride

Allyl chloride is used in the preparation of epoxy resins and insecticides. It can cause a mixed motor and sensory distal axonal neuropathy which only recovers after prolonged discontinuation.

### Methyl bromide

Methyl bromide is widely used as a refrigerant, in fire extinguishers and as a soil fumigant. Acute exposure causes a progressive encephalopathy with convulsions and delirium leading to hyperpyrexia, coma and death. Chronic exposure to lower levels causes systemic features including nausea, vomiting, headache and mucosal irritation before CNS deficits develop which can include progressive speech disturbance and cerebellar ataxia, incoordination, seizures and myoclonus. Long-term exposure leads to a distal sensorimotor polyneuropathy, occasionally upper motor neurone signs, and visual disturbance including optic atrophy.

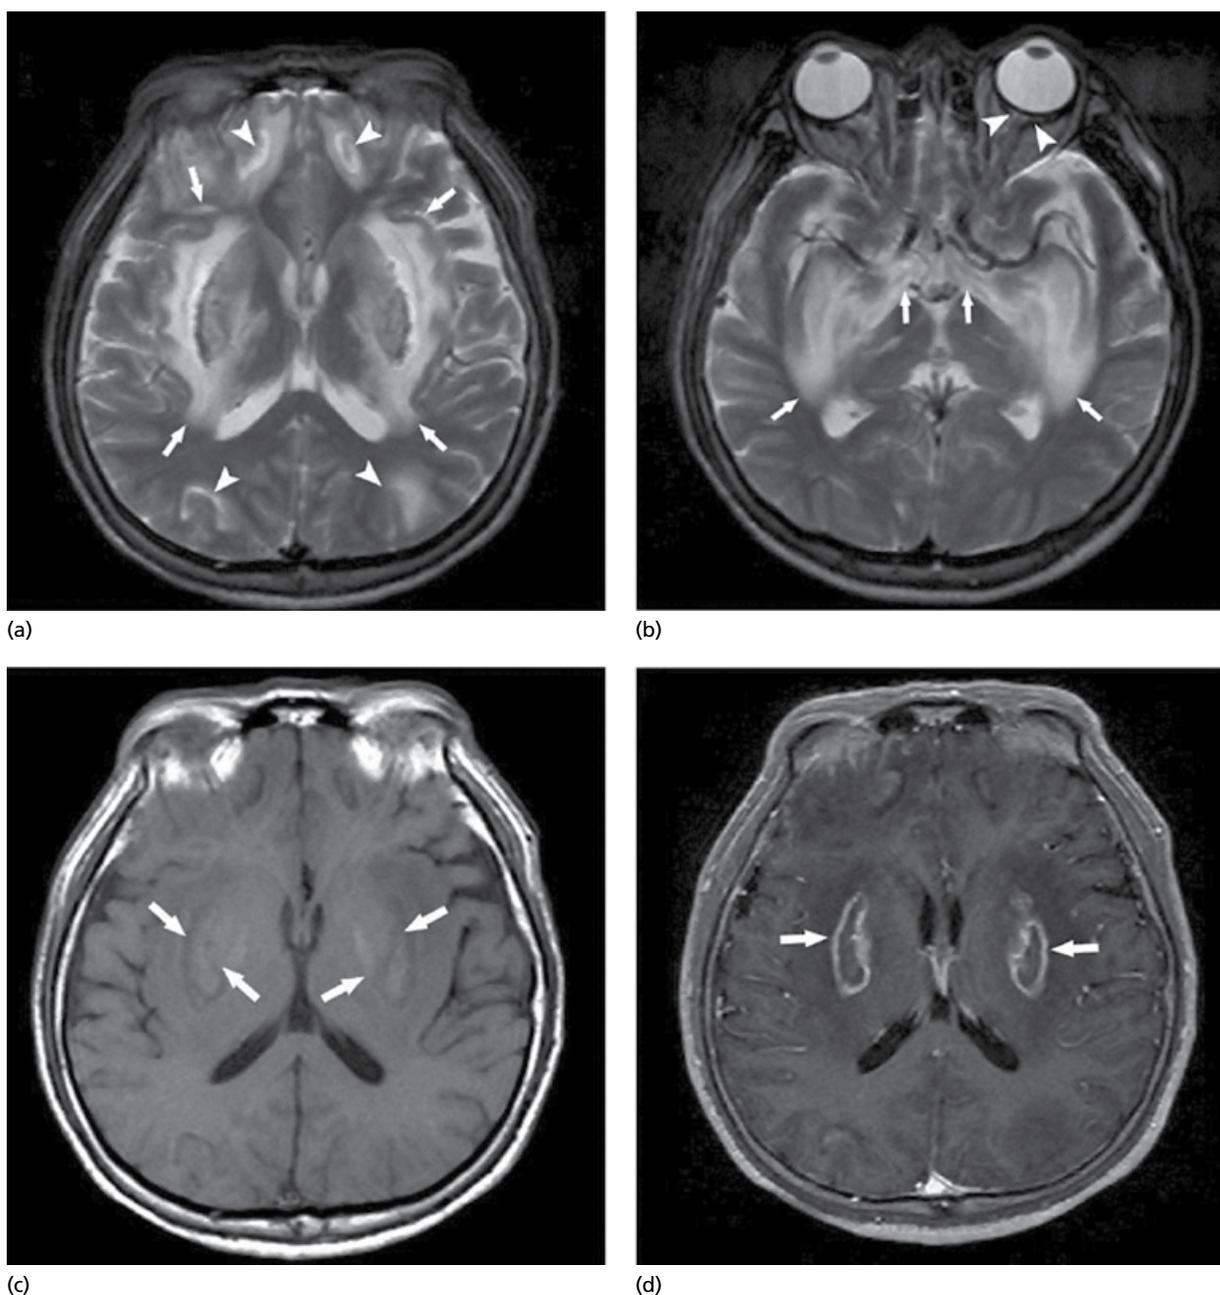

Management is supportive but dialysis can be necessary to remove bromide.

### Methyl chloride

Methyl chloride is a methylating agent used in the production of lead, rubber or polystyrene foam. Toxicity is associated with inhalation or absorption through the skin. There is CNS depression which can cause headache, dizziness, confusion, speech abnormalities and diplopia with incoordination. Severe prolonged exposure can lead to seizures or stimulus-sensitive myoclonus.

### Methyl alcohol (Methanol)

Methyl alcohol is used as an industrial solvent and as an adulterant to denature ethanol and prevent its abuse. Toxicity results from the formation of formaldehyde and formate. Acute toxicity causes

**Figure 19.5** MRI on day 15 after methanol intoxication. (a) T2-weighted image showed high signal abnormalities in bilateral basal ganglia (arrows), frontal, and occipital subcortical white matter (arrowheads), consistent with oedematous change. (b) T2-weighted image showed oedematous change involving bilateral optic tracts and optic radiations (arrows). High signal oedematous change was also noted in the optic disc of left eye (arrowheads). (c) T1-weighted image showed slightly high signal component in bilateral basal ganglia, indicating the haemorrhage (arrows). (d) T1-weighted image with gadolinium administration showed marginal enhancement in bilateral putamen, indicating breakdown of the blood–brain barrier. Source: Yang 2005. Reproduced with permission of Macmillan.

encephalopathy with prominent visual symptoms due to toxic optic neuropathy, and seizures. It is associated with headache, abdominal pain, nausea and vomiting (see Alcohol abuse). MRI shows characteristic infarction or haemorrhage in the putamen (Figure 19.5).

Treatment is with haemodialysis and inhibition of the conversion to formaldehyde by fomepizole or ethanol and correction of the accompanying metabolic acidosis with sodium bicarbonate.

#### Nitrous oxide

Exposure to nitrous oxide ( $N_2O$ ; 'laughing gas') occurs in patients receiving prolonged general anaesthesia or by intentional inhalational abuse. Nitrous oxide oxidises cobalamin and therefore disrupts  $B_{12}$ -dependent pathways rendering methycobalamin inactive; this inhibits methylation reactions, which are in turn important for production of myelin. The clinical pattern of toxicity

is therefore identical to subacute combined degeneration with extensive spinal cord, brain and peripheral nerve demyelination. There is a progressive distal sensory neuropathy beginning in the hands with proprioceptive loss secondary to involvement of large sensory nerves and dorsal columns. Progressive spasticity and hyper-reflexia due to a myelopathy then develops.

Nerve conduction confirms slowing of motor and sensory conduction velocities with secondary axonal loss. Vitamin B<sub>12</sub> replacement may help in the management but this does not always reverse the neuropathy. MRI findings include hyperintense T2 signal in the dorsal and lateral columns.

### Organophosphates

Forty per cent of pesticides contain organophosphates; they are also found in herbicides, lubricants, flame retardants and as a petroleum additive. Exposure usually occurs in agricultural settings although ingestion may occur in children or in suicide attempts. Organophosphates inhibit cholinesterases leading to cholinergic toxicity and in acute exposure this is typically manifest within 4 days and resolves over 3–4 weeks. Presentation is with salivation, lacrimation, diarrhoea, urinary frequency, mydriasis, bradycardia, bronchoconstriction and diffuse muscle weakness involving respiratory, bulbar and proximal limb musculature leading to respiratory failure. Acute central effects are also seen causing confusion, dizziness, ataxia, blurred vision and impaired memory culminating in seizures and coma. Chronic exposure ('sheep dipper flu') is characterised by transient symptoms including headache, rhinitis, pharyngitis and myalgia. However, a longer term mild impairment of cognitive and memory functions occasionally occurs. Prolonged exposures can also lead to a late onset sensorimotor axonal peripheral neuropathy and occasionally ataxia and upper motor neurone involvement with spasticity.

Organophosphates are easily absorbed through the skin and therefore it is important that those with potential exposures use protective masks, gloves and appropriate clothing. The skin should be carefully washed following exposures and it is essential to maintain the airway because of the risk of aspiration. Prolonged treatment with atropine, pralidoxime or obidoxime and benzodiazepines can be necessary.

### Carbon monoxide

Carbon monoxide (CO) is clear, colourless and odourless. It is commonly used in attempted suicide but exposure also occurs from leaking car exhausts or incorrectly installed domestic gas-powered boilers. Occasional exposure occurs in miners and gas workers. Carbon monoxide has a greater affinity for haemoglobin than does oxygen itself and therefore binds preferentially to oxygen-binding sites to form carboxyhaemoglobin. This limits dissociation of oxygen in the tissues resulting in relative tissue hypoxia. Carboxyhaemoglobin also inhibits oxygen binding and oxidative phosphorylation in the mitochondria, further exacerbating functional hypoxia in tissues with a high metabolic demand. Acute exposure causes headache, dizziness, confusion, disturbance of consciousness and behavioural change. Visual disturbance and progressive shortness of breath develop rapidly with subsequent loss of consciousness, seizures, coma and cardiac arrest. Exposed individuals can have pink-red skin, or may be cyanosed. Prolonged acute intoxication is fatal in 25% of exposed individuals. A high proportion of survivors have residual neurological features including extrapyramidal signs. Patients with initial transient choreiform movements can develop progressive tremor, parkinsonism, dystonia

and urinary incontinence. A delayed onset encephalopathy may develop after a period of apparent partial or complete recovery with cognitive and personality impairment with memory dysfunction, apathy, mutism, pyramidal signs and the progressive development of vegetative features. There may be elevated levels of carboxyhaemoglobin and MRI shows diffuse symmetrical high intensity white matter change also involving the caudate with bilateral pallidal necrosis (Figure 19.6).

Treatment of acute exposure is by removal from the source and the provision of 100% oxygen. Hyperbaric oxygen can enhance recovery from acute symptoms. However, the prognosis for neurological recovery after carbon monoxide exposure is poor. Insidious chronic low-grade exposure to carbon monoxide can be associated with industrial exposure or badly ventilated and faulty household heating appliances. The syndrome of chronic occult carbon monoxide poisoning is manifest as headache, fatigue, dizziness, paraesthesiae, visual disturbance with chest pain and palpitation associated with ventricular arrhythmias. The diagnosis of low-grade exposure depends on recognition of the syndrome and demonstration of elevated levels of carboxyhaemoglobin. Management depends on identifying the source of carbon monoxide and prompt removal. Oxygen therapy, as discussed earlier, may be necessary.

### Marine toxins

Marine toxins are difficult to detect as they are often without colour, taste or odour. Furthermore, most are unaffected by cooking, freezing or salting. They can be divided into:

- *Ingested*: elaborated by marine micro-organisms and ingested in seafood (i.e. ciguatera, puffer fish [tetrodotoxin] and shellfish).
- *Contact* (jellyfish, sea anemone, venomous fish and stingrays)
- *Envenomation toxins* (sea snakes and cone snails): neuropeptides secreted directly by marine creatures which then sting or bite to kill prey or envenomate humans.

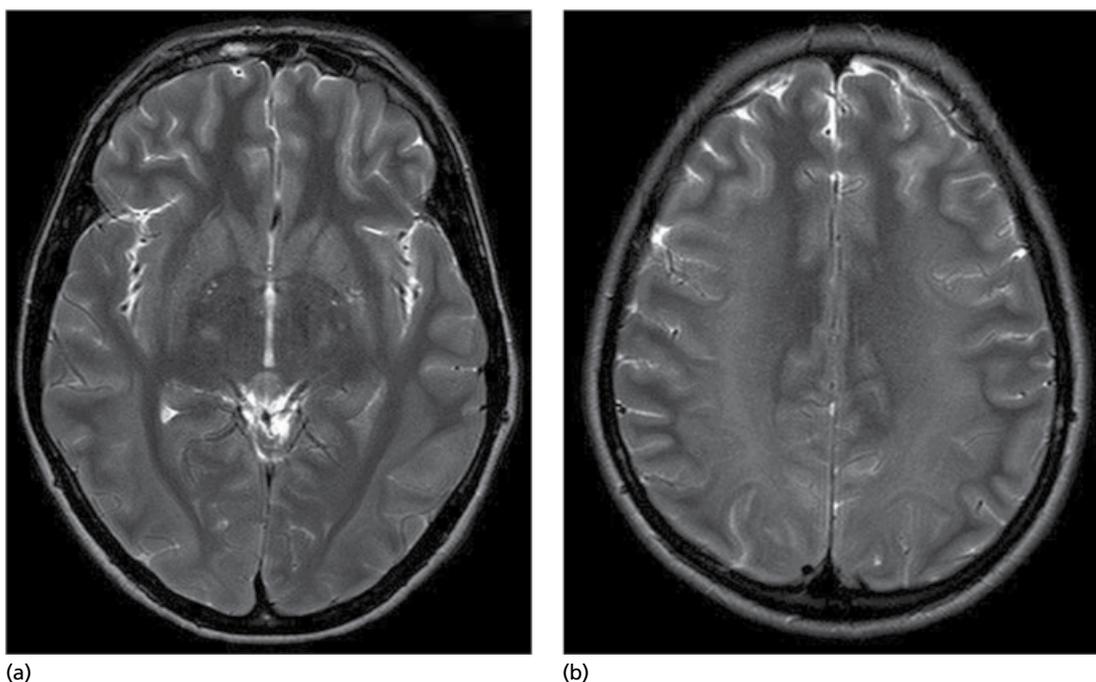

### Ingested toxins

**Ciguatera** Ciguatera is the most common form of poisoning associated with seafood. The toxin (ciguatoxin) occurs in reef fish (e.g. snapper or barracuda) who consume an apophytic dinoflagellate which then elaborates the toxin. There are at least four neurotoxins which cause voltage-gated sodium channels to open.

Poisoning leads to the rapid development of acute abdominal cramp, nausea, vomiting and diarrhoea. Peri-oral, limb and trunk paraesthesiae develop 12–48 hours after ingestion of contaminated fish. In the most severe cases there is a characteristic cold allodynia ('temperature reversal'). Cranial nerve palsies, polymyositis or a rapidly progressive sensorimotor and autonomic polyneuropathy affecting bulbar and respiratory muscles can occur. This rarely progresses to limb weakness, flaccid quadriplegia, areflexia and respiratory muscle impairment. Although the condition generally resolves spontaneously within a few days, fatalities are caused by respiratory insufficiency and cardiac dysfunction may occur. Bioassay of the toxin is possible.

Treatment is supportive although parenteral mannitol may prevent the obligate influx of intracellular water as intracellular sodium increases.

**Tetrodotoxin** Tetrodotoxin (TTX) occurs in the liver and ovaries of puffer fish, toad fish and some types of crabs. The toxin is elaborated by marine bacteria and blocks the action potential of voltage-gated sodium channels in skeletal and cardiac muscle and sensory and motor nerves. TTX blocks voltage-gated sodium

**Figure 19.6** Carbon monoxide poisoning following domestic radiator leak. MRI showing (a) symmetrical high intensity basal ganglia and (b) white matter change (axial T2-weighted image).

channels at nanomolar concentrations. Onset is with numbness of the lips and tongue followed by worsening paraesthesiae in the face and limbs with a sense of euphoria and systemic features including gastrointestinal and cardiac disturbance. With ingestion of large amounts of TTX there is worsening neuromuscular paralysis involving the limbs, trunk, cranial nerves bulbar and respiratory muscles leading to death if artificial ventilation is not instituted.

The early fatality rate is high (50–80%). Supportive treatment is successful in most cases because the condition is fully reversible, although it is important to note that patients can be fully conscious in spite of total paralysis. Atropine treatment can be necessary to treat bradycardia.

**Scombroid** Scombroid poisoning is common as it is caused by poor storage of tuna and similar fish. Toxicity differs from the other marine toxins as it has a histamine-like effect. The onset is rapid and resembles an acute anaphylactic response with pruritus, throbbing headache, erythema, urticaria, paraesthesiae and palpitation; poisoning tends to be self-limiting.

Treatment is with intravenous histamine receptor blockers and supportive care.

#### Shellfish

- Saxitoxin is a heat-stable water-soluble toxin that is concentrated in shellfish and acts by blocking voltage-gated sodium channels. There is a rapid onset of paraesthesiae, particularly peri-orbital, and limb weakness. There may be severe respiratory involvement including the diaphragm with significant mortality.
- Shellfish toxicity may be caused by secondary infectious agents such as *Vibrio cholerae* and hepatitis A and occurs with bivalve molluscs including clams, mussels, scallops and oysters.
- Neurotoxic shellfish poisoning is caused by brevetoxins which act by opening slow sodium channels. There is simultaneous onset of gastrointestinal and neurological symptoms including tremor,

dysphagia, pupillary paralysis and hyporeflexia. The features are similar to ciguatera but milder.

- Amnesic shellfish poisoning, due to associated algal blooms, is caused by the toxin domoic acid which stimulates kainate-type glutamate receptors and has a toxic action on the limbic system leading to severe anterograde and retrograde amnesia, myoclonus, seizures and status epilepticus and coma. Systemic symptoms include labile blood pressure, cardiac dysrhythmia and myoglobinuria. The syndrome can improve gradually over 3 months but permanent residual profound amnesic deficits occur.

**Contact toxins** contain multiple substances including small polypeptides, large proteins, phospholipids, glycoproteins, amines and carbohydrates. These venoms are generally thermally instable and act by blocking sodium channels.

#### Other biological toxins

##### Snake venom

Snake venom from many members of the Elapidae family, which includes the banded krait and sea snakes, contains toxins that cause neuromuscular junction blockade resulting in a myasthenia-like syndrome, particularly affecting the muscles of neck flexion and the ocular, bulbar and proximal limb muscles, occasionally leading to respiratory paralysis. Onset is often with local pain, swelling and erythema in the region of the bite with local lymph node involvement. The onset of systemic symptoms depends upon the site of the bite and the species, but over 1–12 hours muscle fasciculation, weakness and hypotension can develop with eventual shock.

Presynaptic neuromuscular junction dysfunction occurs with  $\beta$ -bungarotoxin envenomation by banded kraits while  $\alpha$ -bungarotoxin causes an additional post-synaptic neuromuscular junction blockade. Snake bites generally cause death not because of the paralysis but because of the systemic effects of proteolytic toxins

acting on blood constituents and tissues, often causing extensive haemorrhagic or thrombotic change. Nevertheless, the neurological features can aid diagnosis and choice of appropriate anti-venom.

### Spider toxins

The female black widow spider produces a neurotoxin ( $\alpha$ -latrotoxin) which acts presynaptically to trigger massive spontaneous neurotransmitter release, from the neuromuscular junction as well as other synapses. There may be intense pain in the region of the bite with a characteristic erythematous target lesion. This is followed by the development of involuntary spasms in the abdominal muscles which spreads to involve the limbs. The funnel-web spider, indigenous to parts of Australia, produces a toxin that affects sodium channels and causes a severe dysautonomia, piloerection, sweating and diaphragm involvement culminating in respiratory arrest.

Treatment is by supportive care in intensive care with anti-venom if available. Muscle spasm is treated with benzodiazepines.

### Scorpion toxin

Scorpions elaborate a toxin that has both presynaptic and postsynaptic effects. These may lead to local symptoms followed by the development of progressive severe autonomic impairment with muscle fasciculation and progressive bulbar, respiratory and cardiac involvement. Occasionally, encephalopathy may occur secondary to CNS involvement.

### Ticks

Tick toxin has not been isolated or characterised. It causes a rapidly developing, progressive flaccid motor weakness affecting ocular, bulbar, respiratory and limb musculature because of presynaptic inhibition of acetylcholine. It is essential for the tick to be removed immediately.

### Fungal poisons

Fungal poisons are highly diverse, and neurotoxic compounds occur in several of the most toxic species. Some members of the Amanitaceae family such as the fly agaric (*Amanita muscaria*) contain molecules that act at GABA, glutamate and acetylcholine receptors (muscimol, ibotenic acid and muscarine). However, the high fatality associated with death cap (*Amanita phalloides*) ingestion is mainly associated with amatoxin, which inhibits mRNA synthesis and leads to hepatic and nephrotic toxicity. Some members of the Psilocybe family are used recreationally because of their psychoactive effects. Psilocybins are structural analogues of serotonin and produce LSD-like effects with euphoria, hallucination, tachycardia and eventually seizures.

### Lathyrism

Lathyrism occurs in countries where the chickling pea (grass pea) *Lathyrus sativus* is grown, and generally only under conditions of food deprivation. It is endemic in parts of Bangladesh, India and Ethiopia. It is caused by the neurotoxic amino acid  $\beta$ -N-oxalylamino-L-alanine (BOAA), which acts as an agonist at the AMPA subclass of glutamate receptors. There is prominent degeneration in Betz cells of the motor cortex and pyramidal tracts. The condition develops with an insidious onset of gait unsteadiness characterised as a lurching and scissoring gait and development of a spastic paraparesis with normal sensory examination. There is no involvement of cognition or cerebellar function. A peripheral sensory neuropathy, which is predominantly demyelinating, can occur in a minority of patients. A related toxin,  $\beta$ -methylamino-L-alanine

(BMAA) is present in the fruit of the cycad palm, and has been implicated in the amyotrophic lateral sclerosis–parkinsonism–dementia complex amongst the Chamorro population. However, it remains unclear whether the epidemiological evidence can be explained by consumption of this toxin. Neurolathyrism can be prevented by mixing grass peas with cereal or detoxification by aqueous leaching.

### Konzo

Konzo occurs in epidemics in East and Central Africa. It affects children above the age of 3 years and women of childbearing age, causing sudden-onset symmetrical non-progressive permanent spastic paralysis, predominantly affecting the lower limbs but spreading to involve the upper limbs and the optic nerves. The pathology resembles lathyrism with involvement of cortical Betz cells directed towards the lower extremities and their corresponding corticospinal tracts. It is believed to be associated with high dietary levels of cyanide caused by the intake of poorly prepared bitter cassava, particularly if there is protein malnutrition, but the aetiology of Konzo continues to be debated.

### Subacute myelo-optico neuropathy

Subacute myelo-optico neuropathy (SMON) is a myeloneuropathy with optic nerve involvement which occurred in Japan between 1955 and 1970. Epidemiological studies suggest that SMON was caused by the antiparasitic drug clioquinol which is a copper chelator and may have led to copper deficiency.

### Tropical myelo-neuropathy

This term has been used to describe a number of syndromes caused by various nutritional and toxic causes including malnutrition, cyanide intoxication from cassava consumption and lathyrism. A particular epidemic in Cuba was associated with optic neuropathy, sensori-neural deafness, dorsolateral myelopathy, dysautonomia, bulbar weakness and axonal neuropathy. The condition was associated with an irregular diet, heavy smoking, alcohol and excessive sugar consumption. Treatment with B-group vitamins and folic acid led to marked improvement.

### Radiation-induced neurological disease

Exposure to radiation occurs naturally but this is low intensity and carries few risks. Increased levels are associated with exposure to occupational or therapeutic radiation and, rarely, to nuclear weapons. Radiation can be divided to non-ionising and ionising. Non-ionising radiation (e.g. ultraviolet, infra-red, microwaves, radio waves, laser radiation and visible light) has low energy and is therefore unable to break chemical bonds and cause ionisation; thus, injury is caused by local heat production and is generally mild, although damage to retinal and optic nerve fibres can occur. However, ionising radiation is considerably more serious. This radiation is caused by high energy particles or electromagnetic waves (X-rays and gamma rays) which can break chemical bonds and therefore produce ionisation within tissues leading to DNA damage and mutation. Ionising particulate radiation is caused by  $\alpha$  particles, electrons, neutrons or protons. Alpha particles (composed of two protons and two neutrons) are produced by uranium, radium and polonium. They lead to high levels of ionising radiation but are usually blocked by paper or clothing and are therefore only toxic if ingested or inhaled (see Neurobiological weapons). Beta particles are high energy electrons emitted from decaying isotopes of strontium 90 which are commonly used to generate X-rays

and radiotherapy. Toxicity also occurs with ingestion. High energy neutrons are only produced with nuclear fission but are a serious radiation risk following detonation of a nuclear reaction or if a reactor becomes critical. Proton exposure also occurs naturally from cosmic radiation.

The early effects of radiation, seen after exposure to large doses delivered over a short period of time (>1 Gy), affect rapidly dividing tissues including skin, bone marrow and gut epithelium. The onset is with prodromal gastrointestinal symptoms before the condition manifests with bone marrow suppression, loss of intestinal mucosal cells leading to bowel disturbance and sepsis, and finally cerebrovascular involvement. Management involves meticulous decontamination at the site of exposure and supportive care with transfusion and treatment of sepsis.

Late toxicity following accidental or therapeutic exposure to radiation is usually seen in organs with slowly dividing cells such as the CNS, kidney and liver, causing radiation necrosis. The characteristic delayed complication is malignancy, particularly of the thyroid gland, breast or leukaemia.

### Therapeutic radiation

Therapeutic radiotherapy creates ionised oxygen which reacts with cellular DNA. Healthy cells have a greater ability than tumour cells for DNA repair and therefore the cumulative effects of unrepaired DNA result in cell death (apoptosis of tumour cells while healthy cells are more able to repair themselves). Acute complications of therapeutic radiotherapy include encephalopathy which can occur during or up to 1 month after radiotherapy has commenced. It is associated with headaches, nausea, changes in mental state and symptoms suggestive of increased intracranial pressure because of breakdown of the blood–brain barrier and secondary cerebral oedema. The acute effects of therapeutic radiotherapy also include hypersomnolence, encephalopathy, memory disturbance and there can also be gastrointestinal symptoms. MRI shows increased oedema with contrast enhancement which resolves over several months. The condition is caused by damage of the blood–brain barrier and is steroid responsive (Chapter 21).

### Early-delayed radiation encephalopathy

Early-delayed radiation encephalopathy develops 1–4 months after radiotherapy and is caused by injury to oligodendroglia producing demyelination and vasogenic oedema. This can present with somnolence, decline in long-term memory and encephalopathy. There can also be brainstem involvement with diplopia, nystagmus, dysarthria and ataxia. This form of radiation encephalopathy resolves over several weeks but occasionally may progress to profound encephalopathy, coma and death. Subacute encephalopathy can also be associated with a myelopathy and a transient brachial plexopathy.

### Late-delayed radiation encephalopathy

Late-delayed radiation encephalopathy develops several months or years after cranial irradiation and is associated with diffuse cerebral atrophy, focal radiation necrosis or secondary vascular change. The pathological findings are of demyelination. There can also be signs of raised intracranial pressure. The patient presents with cognitive decline, personality change and gait disturbance developing 6–18 months or more after total brain irradiation. There can be a more indolent intellectual impairment leading to dementia. Delayed effects of radiotherapy also include endocrine dysfunction because of hypothalamic impairment, optic neuropathy, progressive cranial

neuropathy, myopathy or chronic progressive myelopathy. The incidence of delayed radiotherapy effects is related to total radiation dosage and the size of fractionated doses. A total dose of >5500 Gy carries a 5% chance of developing radiation necrosis. Risk is increased with a higher daily dosage, if there has been concurrent chemotherapy or if there are underlying vascular risk factors. It can be extremely difficult to distinguish brain radiation injury from the effects of brain tumours by conventional imaging. The hypometabolic state of radiation necrosis may be reflected in metabolic imaging such as fluorodeoxyglucose positron emission tomography (FDG-PET). Brain biopsy will show extensive necrotic tissue without predominance of malignant cells. There is involvement of the white matter with loss of oligodendrocytes and demyelination. There may also be thickened vessels with endothelial proliferation, fibrosis and moderate infiltration of lymphocytes and macrophages (Chapter 21).

### Transient radiotherapy myelopathy

Transient radiotherapy myelopathy usually occurs within the first 6 months of treatment, particularly to the cervical spinal cord, although it can continue to develop for 2 years after treatment. It is most commonly seen in patients treated for lymphoma or neck and thoracic neoplasms. Presentation is with mild sensory impairment and Lhermitte's phenomenon. The condition itself is self-limiting and relates to demyelination in the posterior columns. Chronic, usually progressive, myelopathy is a delayed syndrome which develops more than one year after radiotherapy for tumours in the head and neck, cervical or mediastinal region. Focal neurological deficits related to spinal cord involvement include progressive sensory impairment in the lower limbs followed by progressive myelopathy. There may be a transverse myelitis or Brown-Séquard syndrome with sphincter disturbance.

Treatment is with corticosteroids but this only leads to a temporary improvement and there is generally secondary necrosis and atrophy of the cord because of vasculopathy.

### Radiation plexopathy

Plexopathy can affect the brachial or lumbar plexus and follows radiotherapy in these regions. It is important to distinguish the development of progressive radiation plexopathy from direct neoplastic involvement of the plexus. The onset is characterised by paraesthesiae and dysaesthesiae with pain and progressive atrophy and weakness developing over several months. It develops 1–3 years or longer after radiotherapy and is particularly associated with high doses of radiotherapy (>6000 Gy), large daily fractionations, lymphoedema, induration of the supraclavicular fossa and myokymia on electromyography (EMG). The condition seems to be caused by small vessel damage and fibrosis; it responds poorly to steroids. Positron emission tomography (PET) imaging of the brachial plexus can distinguish malignant infiltration from radiotherapy-induced plexopathy.

Radiation administered to the neck can also accelerate the development of carotid artery atherosclerosis. This can develop as early as 1 year after treatment but is often delayed by 10 years or more. It is associated with a high treating dose and daily fractionated dose. Cerebral ischaemia can be caused by atherosclerotic embolisation to the brain or haemodynamically significant arterial stenosis. Histologically arterial damage cannot be distinguished from typical atherosclerosis but it occurs in the radiotherapy field.

## Lightning and electrical damage to the nervous system

Fifty people are struck by lightning in the United Kingdom each year, with three fatalities. In the United States there are around 100 fatalities per year. For injuries related to technical electricity (at work and at home), the UK annual estimate is approximately 3000 incidents with 30 fatalities. There are some 1500 deaths from electrocution annually in the United States.

### Mechanisms of lightning and other electrical damage

#### Lightning: initiation and pattern of contact

Intra-cloud lightning is the most common form of lightning, but it is cloud-to-ground lightning that causes human injury. Usually, a highly branched discharge, known as the stepped leader, appears below the cloud base and heads toward the ground at a speed of  $10^6$  m/s. When the tip of the leader approaches within 30 m of the ground, the induced electric field produces an upward connecting discharge, usually from the nearest tallest object(s). When the two discharges meet, the first return stroke begins; this is an intense wave of ionisation that propagates up the leader into the cloud at close to the speed of light. This is followed by a series of further ionising strokes between the cloud and the ground each lasting some 500 ms with 40–80 ms gaps. These gaps are long enough to allow for retinal resolution of the individual strokes – which is why lightning is seen to flicker. The repeated earthbound strokes do not always follow the path of the initial leader, which is why lightning can appear forked. The large current of the return stroke causes the air in the surrounding channel to heat up to about 30 000°K in a microsecond, the channel pressure rises to 20 atmospheres or more; the decay of this pressure wave is heard as thunder.

Although the electrical forces associated with lightning strike are enormous (10<sup>6</sup> V, 30 000 amps), the damage caused to a person struck is limited by the very short duration of the passage of current. In contrast, in accidental electrical injury, the power sources are much less, but contact can last for seconds or even minutes leading to severe thermal injury of tissues in and around the current path.

The prelude to a strike, familiar to many mountaineers, is the build-up of atmospheric charge with buzzing of metallic equipment, skin tingling and hair standing on end. This is a signal for immediate evacuation from prominent features such as a summit or crest of a ridge, if this is feasible. It is unusual for lightning strikes to occur in aircraft, cars or ships at sea because these vehicles act as ‘faradic cages’; that is, containers made from a conductor that shields its contents from external electric fields. Because the conductor is an equipotential there is no potential difference within the container.

A major factor that determines injury in lightning strikes is whether the heart or CNS is involved in the current path (either can result in cardiorespiratory arrest), this in turn depends on the way the strike reaches the subject.

- 1 Direct strikes are the most damaging as the head is usually involved.
- 2 Side flash occurs when lightning strikes a nearby object such as a tree, and the current arcs to flow through the subject.
- 3 Ground current injuries are caused by lightning striking the ground near the subject; as the current dissipates, it reaches the subject and passes through them, usually via the legs if they are standing.
- 4 Most indoor injuries are minor and occur when the subject is shocked by current dissipating along telephone or other wiring. Many people can be injured at the same time as all of the above mechanisms of current transfer can occur in a single strike; at Ascot

racecourse, United Kingdom, in 1956, 46 people were injured, two of them fatally.

#### Electrical injuries: high and low-voltage

Electrical injuries are usually categorised on the basis of the voltage exposure: high (>1000 V) or low. Low-voltage injuries usually result from exposure in the home, are relatively common but rarely severe (although death can occur from contact with as little as 25 V). High-voltage injuries usually affect those whose occupations bring them into contact with high-tension power lines or electrified rails. Members of the public can be involved in accidents that bring them into contact with these sources – children, anglers carrying their rods, those erecting or using aerials, parachutists and those attempting deliberate self-harm. High-voltage exposure is the cause of some 70% of electrical injuries and death. The voltages and currents associated with electrical exposure are much less than with lightning; however, the period of exposure is longer which magnifies the heating effects of current passage through the body leading to deep tissue necrosis, a complication rarely encountered in lightning strikes. Alternating current can increase this effect if tetanic contraction is induced in flexor muscles of the grasping hand, with periods of exposure approaching a minute or beyond in some cases.

#### Nervous system complications of lightning and electrical injury

Neurological sequelae can be split into four categories:

- 1 Immediate and transient (IT)
- 2 Immediate and prolonged/permanent (IP)
- 3 Delayed and progressive (DP)
- 4 Secondary trauma caused by lightning or electrical exposure (e.g. head or spinal injury caused by falls, usually secondary to a loss of consciousness). Complications are generally shared by both types of exposure.

Transient loss of consciousness is the most common symptom associated with both types of electrical exposure, occurring in 70–80% of patients. Confusion, amnesia, paraesthesiae and limb weakness are also common IT symptoms. A specific IT syndrome said to be pathognomic of lightning strike is known as keraunoparalysis (*kerauno*, Greek for thunderbolt; literally, ‘smasher’). This is sometimes known as Charcot paralysis; he provided the first description – of short-lived complete lower limb paralysis with spared sphincter function and marked vasoconstriction with limb coolness, lividity and peripheral cyanosis. The symptoms abate over hours or, rarely, days. The pathophysiology is poorly understood. This syndrome should be differentiated from the much rarer true spinal cord syndromes that complicate lightning or electrical injury, which are usually of the IP or DP type.

The neuropathological mechanisms that result in IP or DP symptoms are not fully understood, but probably comprise a mixture of thermal and non-thermal effects of current passage through affected tissues culminating in cell membrane breakdown. Thermally driven cell membrane damage occurs at temperatures as low as 43 °C, although exposure needs to be for 4 hours or more to cause thermal disruption of the bilipid layer. Non-thermal mechanisms include electroporation, a process driven by supraphysiological rises in transmembrane electric potential that causes permanent holes in the cell membrane leading to fatal loss of the ionic gradient. Micropathological CNS lesions vary and include haemorrhage (both gross and petechial), neuronal cell death, myelin breakdown and glial proliferation. Cerebral oedema is seen in cases complicated by hypoxic brain injury secondary to cardiopulmonary

arrest. The three most reported DP syndromes affect motor neurones, basal ganglia and the spinal cord. Stroke-like syndromes (particularly venous sinus thrombosis), seizures, extrapyramidal syndromes, isolated cerebellar dysfunction (rare) and spinal cord syndromes at any level (also rare) are all described.

Delayed syndromes are the least common. There is often doubt over any causative link, especially as the time since exposure can be many years. This is well illustrated by a study of psychological morbidity in a series of 165 patients with chronic sequelae of lightning and electrical injury. The mean symptom lag from time of exposure was 4.5 years; the majority of the symptoms reported were suggestive of depression.

There is even less evidence for IP or DP syndromes affecting the peripheral nervous system causing a mononeuropathy or polyneuropathy, with the exception of direct thermal damage causing full-thickness burns through individual nerves. Complex regional pain syndromes are also described and are hard to evaluate.

### Non-nervous system complications of lightning and electrical injury

#### Cardiac

Cardiopulmonary arrest is the most common cause of death in lightning and electrical injuries. Although this can be neurogenic, it is usually caused by the direct effect of current passing through the heart leading to asystole or ventricular fibrillation. Cardiopulmonary resuscitation in these circumstances is often much more successful than out-of-hospital arrests from other causes.

#### Skin and muscle damage

Fern-shaped superficial cutaneous burns are sometimes seen following lightning strikes; these heal, but discoloration can persist for some years, or even permanently. Lightning rarely causes major skin or deep tissue burns; however, electrical injury, especially of high-voltage type, can be devastating to deep tissues. It is not possible to predict the amount of deep tissue injury from the overlying skin involvement. Striated muscle is particularly sensitive to AC current and high-voltage exposure is often complicated by rhabdomyolysis, subsequent renal failure, compartment syndromes and surgical amputation following overwhelming limb damage. Cataracts complicate lightning and electrical injuries that involve the head and neck in the current path, including lightning strikes that dissipate along telephone wires.

#### Management

Initial management includes basic resuscitation and CPR. All patients suffering lightning strike or high-voltage electric injury require transfer to hospital for appropriate therapy and, in some cases, ECG monitoring. Asymptomatic patients with low-voltage injuries in the absence of nervous system, cardiac or skin involvement need not be admitted. The neurologist, like members of other specialist teams, is most likely to be called upon to help with patients with moderate to severe injuries following lightning or electrical injury. There is no good evidence base for particular treatment of neurological symptoms caused by electrical current exposure; symptoms should be treated on their own merits.

#### Heat stroke

Heat stroke is present if the core body temperature exceeds 40°C (104°F). It can occur either as a result of vigorous and prolonged exertion or during excessively hot weather, when it affects those

who have difficulty with heat regulation including children, the elderly or those with chronic medical problems causing impairment of the mechanisms of heat loss (e.g. dermatological disease or following ingestion of anticholinergic drugs).

In non-exertional heat stroke, presentation is usually with progressive impairment of consciousness manifest as irritability, confusion, delusions and hallucinations culminating in coma. There is usually anhidrosis and patients can also develop cranial nerve abnormalities, early cerebellar dysfunction (ataxia, tremor and dysarthria), seizures and opisthotonus, and the development of cerebral oedema with decerebrate posturing and status epilepticus. Systemic involvement leads to a hyperdynamic circulation with tachycardia and postural hypotension (caused by vasodilatation of cutaneous vessels and venous pooling), dehydration, congestive cardiac failure, systemic inflammatory response syndrome, multi-organ failure, myocardial damage and rhabdomyolysis.

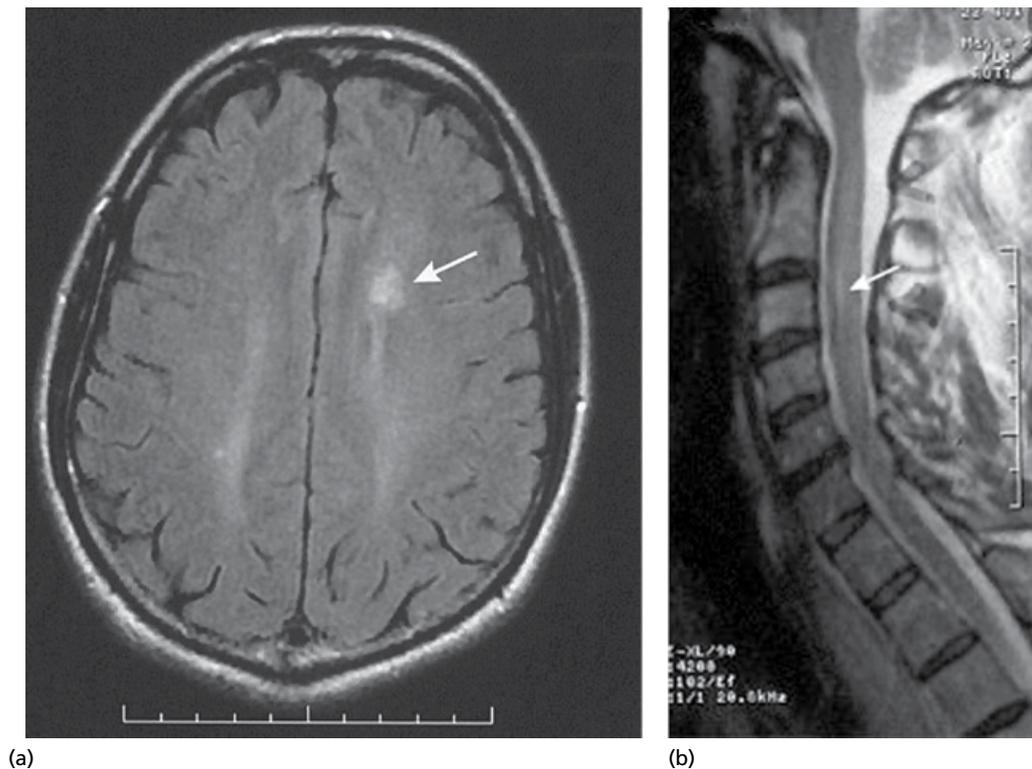

Following exertional heat stroke, non-specific symptoms of heat exhaustion are often unrecognised before impairment of consciousness develops: fatigue, weakness, nausea, vomiting, abdominal pain, muscular cramp, headache and syncope. Predisposing factors include exercise in inappropriate clothing (e.g. wet-suits), viral illness, obesity, dehydration, poor physical fitness, excessive alcohol and illicit drugs (e.g. cocaine and amphetamines). When heat stroke becomes established the clinical features are identical to those patients with non-exertional causes.

Treatment is with rest, removal from the hot environment and correction of dehydration and electrolyte disturbances. Gentle cooling and oral rehydration is adequate in mild cases but in more severe cases ventilatory support, intravenous fluids and intensive monitoring of fluid, electrolyte balance and cardiac and neurological function is necessary. Cold gastric or peritoneal lavage or the use of cooling devices or controlled hypothermia can be of value. Iced water immersion is an efficient form of reducing the core temperature rapidly but is usually impracticable in patients with impaired consciousness and highly uncomfortable for those patients who are awake. Evaporation techniques are safer and as effective as immersion.

A poor prognosis is suggested by the development of lactic acidosis, acute renal failure, hypercalcaemia, coagulopathy or prolonged coma (>4 hours). Muscle necrosis may lead to a grossly elevated creatine kinase level. Death occurs as a consequence of cerebral oedema and herniation. It is essential to recognise persons at risk of heat stroke and to ensure they are not exposed to excessive heat and maintain adequate fluid replacement.

#### Hypothermia and non-freezing cold injury

Accidental hypothermia is the unintentional decline in core temperature below 35°C (95°F). Primary hypothermia is caused by exposure to cold; secondary hypothermia occurs when a disease causes failure of thermoregulation (e.g. CNS tumour leading to hypothalamic impairment, exposure to toxins or neurodegenerative disorders). Hypothermia causes bradycardia because of decreased depolarisation of cardiac pacemaker cells which is not mediated by the vagus and is resistant to therapies such as atropine. Hypothermia progressively depresses the CNS. With mild hypothermia there is confusion, lethargy, loss of fine motor coordination with ataxia, dysarthria and slowed reflexes. Severe hypothermia (<28°C) is characterised by rigidity, areflexia, reduced consciousness and eventually coma. At core temperatures <25°C, brain electrical activity becomes abnormal and below 20°C the EEG can be flat and consistent with brain death.

**Figure 19.7** Decompression sickness: (a) MRI T2 high signal lesion (arrow); (b) high signal at C3–C4 (sagittal (arrow) T2WI). Source: Jallul 2007. Reproduced with permission of Macmillan.

Management is aimed at preventing arrhythmias, particularly ventricular fibrillation, ensuring adequate oxygenation and initiating external and core rewarming using warm intravenous fluid, abdominal lavage and, if necessary, cardiopulmonary bypass. Intensive intervention is indicated, even in those who appear dead. Hypothermia is neuroprotective; some patients recover completely.

Non-freezing cold injury describes persistent painful and autonomic symptoms, usually in the feet, following exposure to temperatures approaching 0°C. Symptoms can persist for many years and are occasionally permanent.

## Diving

The effects of diving relate to the high pressure environment and the consequences of decompression. Barotrauma occurs when divers descend beyond a depth of 100 m breathing gas mixtures of helium and oxygen. Damage occurs because the volume of a gas decreases under a high pressure (Boyle's law). At depth, the body space fails to equate with the external environmental pressure. Barotrauma can also affect the middle or inner ear, sinuses, teeth or gastrointestinal tract causing headache, facial pain, vertigo, hearing loss and abdominal pain. Direct high pressure injury to the CNS leads to a progressive rest or intention tremor, myoclonus, hyper-reflexia and transient cognitive and memory disturbance.

### Decompression sickness

Decompression sickness (DCS) occurs because the solubility of a gas increases under high pressure (Henry's law). Therefore, nitrogen dissolved in the tissues at depth will be released as gas as the diver ascends to a higher atmospheric pressure. DCS ('the bends') occurs when surfacing to a lower pressure causes the release of air

bubbles (usually composed of nitrogen) into the bloodstream and tissues. DCS usually develops within 2 hours of surfacing but can be delayed by up to 36 hours. DCS type I is characterised by limb and joint pain, while DCS type II causes cardiorespiratory impairment and involvement of the CNS because of direct mechanical effects of the air bubbles or because of arterial gas emboli. Cerebral DCS usually involves the arterial circulation leading to alteration in the level of consciousness, weakness, headache, gait disturbance, fatigue, diplopia or visual loss. There can be acute hemispheric dysfunction causing hemiparesis, aphasia and hemianopia and/or progressive encephalopathy, coma and death. Pathologically, the condition is characterised by oedema, haemorrhagic infarction and axonal degeneration with demyelination. Occasionally, brain-stem involvement may lead to vestibular disturbance. Spinal cord DCS presents with partial myelopathy that localises to the thoracic cord although the level can vary from C4 to L1. The onset is often acute (<3 minutes of surfacing) with the development of weakness, paraesthesiae and numbness of the legs with early bladder involvement. The severity can vary from mild sensory involvement to dense limb weakness. MRI may show high signal lesions on T2-weighted imaging (Figure 19.7).

The treatment of established DCS requires the urgent provision of hyperbaric oxygen. While most cases resolve, the prognosis is uncertain and residual deficits occur in some patients.

### Arterial and venous gas emboli

Arterial gas emboli formed in the tissues can also enter the venous circulation. There is a particular risk, even following a shallow dive, if there is a patent foramen ovale with a right to left cardiac shunt that air will enter the systemic arterial circulation resulting in cerebral air embolism.

## Altitude medicine

### Acute mountain sickness and cerebral oedema

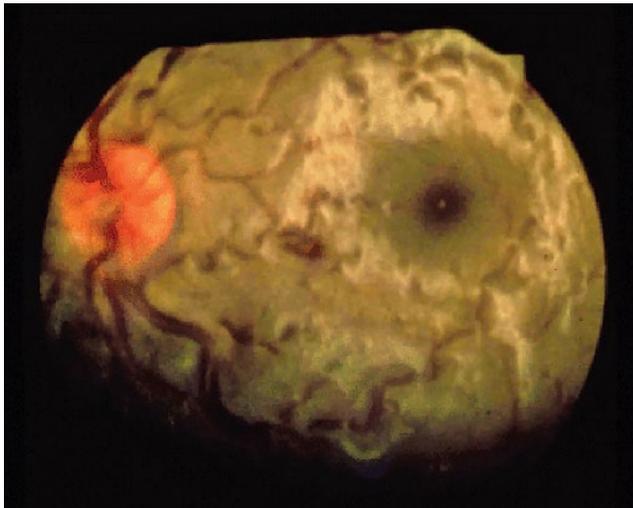

Acute mountain sickness (AMS) is a relatively common condition occurring in unacclimatised subjects ascending rapidly to 2500 m or above. It is usually self-limiting with appropriate management. A small proportion of patients develop the far more serious complications of cerebral and pulmonary oedema (usually >4000 m). AMS is manifest as headache, fatigue, weakness, dizziness, difficulty sleeping and gastrointestinal symptoms such as anorexia, vomiting and nausea. A chronic form can occur as a consequence of persisting hypobaric hypoxia causing persistent malaise and headache. AMS may be prevented by slow ascent (height should be gained slowly above 2500 m at the rate of 300–500 m/day) carrying little and with frequent rests. Symptomatic treatment includes analgesics and antiemetics. Acetazolamide, a carbonic anhydrase inhibitor, is also widely used for prevention but is associated with significant toxicity and it is recommended that a therapeutic trial should be undertaken at sea level before use. Dexamethasone may also help.

With continued ascent, pulmonary and cerebral oedema can occur. On a 6000-m peak there is only 50% of sea level oxygen and the arterial  $pO_2$  is approximately 50 mmHg. Brain perfusion (cerebral blood flow) increases at even modest altitude to 3500 m in response to hypobaric hypoxia and can lead to the development of

cerebral oedema. Presentation can be gradual or acute. Onset is usually with severe headache and progressive ataxia. There can be neuropsychological effects including impairment of short-term memory, defects in verbal fluency and cognitive function with the development of hallucinations. Papilloedema (Figure 19.8) and focal signs including cranial nerve palsies, hemiplegia and seizures can develop and impaired consciousness evolving from drowsiness to coma may develop over 12–72 hours. Sudden devastating altitude-related cerebral oedema may develop unpredictably at extreme altitude (usually >7000 m) in climbers who have been well acclimatised.

Investigations are not usually possible but where MRI has been undertaken in high altitude cerebral oedema there are features of brain oedema (Figure 19.9) and posterior reversible leukoencephalopathy with changes in the splenium of the corpus callosum. In fatal cases there are ring micro-haemorrhages in the brain, arterial and venous thrombosis (Figure 19.10).

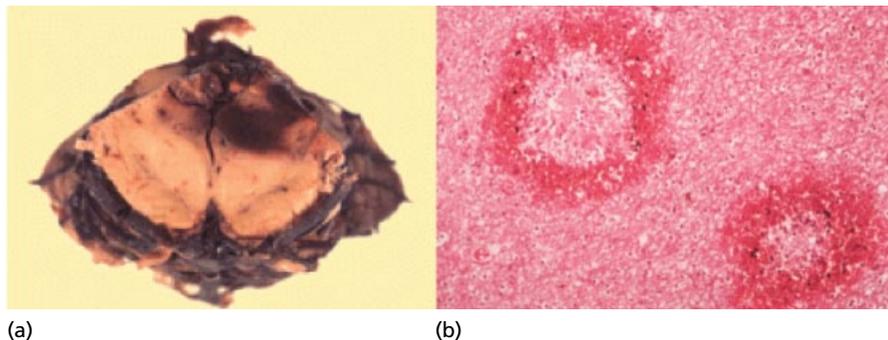

It is essential to have a high index of suspicion for these conditions. Exercise should be avoided and the patient should descend as soon

**Figure 19.8** Abrupt retinal oedema at extreme altitude: papilloedema, retinal oedema and venous congestion.

**Table 19.3** Treatments for severe forms of altitude illness.

Manoeuvre/drug	Regimen	Comment
Descent	250 m as a minimum	Essential, if possible
Dexamethasone	8 mg + 4 mg every 6 h (IV, IM, oral)	Often helpful in minutes, used primarily for brain oedema
Nifedipine	10 mg + 20 mg sustained release every 12 h	Mainly for pulmonary oedema
Oxygen	2–4 L/min by mask or cannula	Always helpful, calming
Portable chamber	2–4 psi for 2–3 h	Never truly portable/clostraphobia

IM, intramuscular; IV, intravenous.

**Figure 19.11** Symptomless retinal haemorrhages at 5500 m.

and as fast as feasible – most deaths occur because the subject remains at a high altitude. Treatment is with 8 mg dexamethasone by mouth or injection and then 4 mg dexamethasone 4-hourly for several days before gradually weaning the dose over a week. Oxygen inhalation (6 L/minute initially) or hyperbaric oxygen administered by a portable pressure chamber should be used if available (Table 19.3).

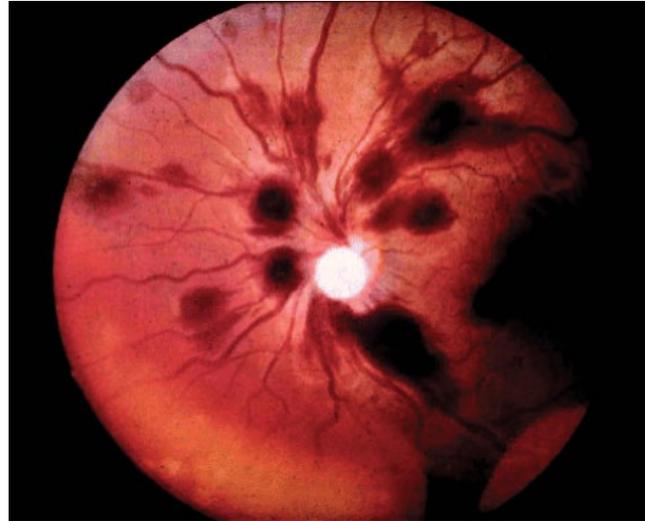

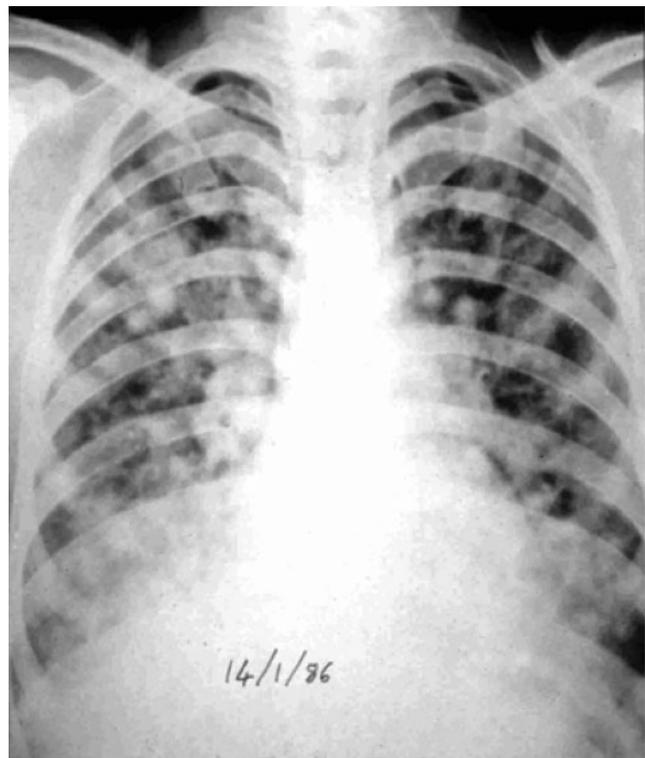

Retinal haemorrhages are common at >5000 m but rarely cause visual loss and usually resolve spontaneously (Figure 19.11). They are not a manifestation of high altitude cerebral oedema. Cerebral infarction manifest as stroke or transient ischaemic attack (TIA) occurs more commonly than expected and is probably related to dehydration and polycythaemia secondary to hypoxia. Retinopathy with permanent visual loss can occur (Figure 19.12).

### High altitude pulmonary oedema

High altitude pulmonary oedema is also caused by hypoxia but is often less obvious than cerebral oedema. It is manifest as breathlessness at rest, dry cough, dyspnoea, crackles in the lung bases and the production of copious pink frothy sputum. Once again the patient must be evacuated immediately to a lower altitude and rapidly provided with oxygen inhalation at a minimum of 2 L/min. Acetazolamide 250 mg 6-hourly may also be valuable and nifedipine and prophylactic salmeterol have also been used (Figure 19.13).

### Neurobiological weapons

Biological weapons, although simple to produce, can be highly potent and difficult to detect. Indeed, recognition that a chemical or biological attack has occurred can be extremely difficult because of

**Figure 19.12** High altitude retinopathy with permanent visual loss. Retina showing extensive haemorrhagic change.**Figure 19.13** Chest X-ray showing high altitude pulmonary oedema.

the delay before clinical manifestations become apparent. Diagnosis may depend on recognising a pattern of clustering or atypical illness in animals or humans, possibly occurring at an unusual age. Potential biological agents of terrorism are listed in Table 19.4.

### Modes of release

Aerosol release of infectious particles is the most efficient form of dissemination and can be accomplished relatively easily and particles remain suspended in the air for many hours increasing the infective capabilities. In contrast, contamination of food and water is more difficult to undertake as large amounts of infective agents are required. Dissemination using bombs or missiles would be of limited value because much of the infective agent is lost at impact or explosion. Contamination of mail items or direct injection can only be undertaken on a small scale and is unreliable. Finally, dissemination of infectious diseases could theoretically be undertaken by infiltrating a contagious person.

### Nerve agents

#### Organophosphates

Organophosphates (see Neurological disorders associated with exposure to toxic substances) act as cholinesterase inhibitors to precipitate the rapid onset of cholinergic crises by hyperstimulation of muscarinic and nicotinic receptors. Unless a specific reactivator (an oxime) is administered, recovery will not occur for several months until acetylcholinesterases can be resynthesised. Organophosphates have been used in attacks in Japan, Iraq and Syria.

*Sarin, Sabin, Tabun, Soman, Cyclosarin, VX* These nerve agents are all liquids at room temperature and are tasteless and odourless. However, most are spontaneously volatile and evaporate rapidly and spontaneously apart from VX, which is an oily liquid that evaporates more slowly. All are toxic via inhalation or skin absorption. The agent that has been the most likely to be used is sarin, which is usually absorbed by inhalation and has been deployed against civilian populations in recent conflicts.

The onset of symptoms is with headache, pupillary constriction leading to blurred vision and cholinergic symptoms of rhinorrhoea, sialorrhoea and bronchorrhoea with secondary bronchoconstriction and respiratory distress. There may be nausea, vomiting, abdominal cramps and diarrhoea, bradyarrhythmias, tachyarrhythmias and hypertensive crisis. Progressive cholinergic muscle involvement leads to fasciculation, weakness and respiratory muscle impairment causing apnoea and respiratory arrest. VX is a viscous liquid that degrades rapidly on exposure to the atmosphere but is easily absorbed through the skin and is extremely toxic, causing rapid involvement of the neuromuscular junction leading to irreversible muscle contraction and a complete paralysis of all musculature. VR, a structural isomer of VX, also leads to cholinergic crisis with profound irreversible cholinergic weakness, seizures and cardiorespiratory arrest.

The management of nerve agents involves decontamination, supportive care and the administration of specific antidotes. Seizures require urgent benzodiazepine therapy with im or buccal midazolam. Decontamination is undertaken by immediate removal of all clothing to prevent continuing exposure and careful scrubbing with water and antiseptic. Supportive care can require intubation and ventilatory support. Atropine is recommended as a first line treatment, this competes with acetylcholine at the post-synaptic muscarinic receptors and may prevent cholinergic crisis, thus drying secretions and resolving bronchoconstriction. It may

be necessary to administer repeated doses of atropine every 5–10 minutes and extremely high doses may be required. Oximes (pralidoxime, obidoxime) cleave the nerve agent into harmless and rapidly metabolised fragments, thus restoring normal catalytic activity. They also react directly with acetylcholinesterases and therefore work equally at mixed cholinergic sites. Pralidoxime chloride is the drug of choice but its use is limited because binding leads to a chemical change in the nerve agent that blocks the ability of the oxime to reactivate the complexes. Prior to exposure

pyridostigmine can be of value as it reversibly binds a proportion of acetylcholinesterase allowing it to become gradually available to counteract the effects of the permanent blockade caused by the nerve agent. This can be of use for rescue workers. The long-term effects of nerve agents remain unclear.

### Other toxins and poisons

**Antitoxin A** Antitoxin A is elaborated by a freshwater bacterium and is an acetylcholine agonist that causes cholinergic crisis with fixed permanent muscle contraction as it is not released from the receptor. Furthermore, the toxin inhibits acetylcholinesterase leading to a further cholinergic stimulation. A severe flaccid paralysis with respiratory muscle involvement leads to apnoea. Management is with supportive care as there is no specific antidote although oximes may have some value.

**Mycotoxin** Mycotoxins are produced by fungi and can be used as biological agents as they are resistant to destruction and rapidly absorbed through the skin. The mechanism of action involves the blocking of protein synthesis leading to inhibition of mitochondrial metabolism. There may be rapid cutaneous, respiratory and CNS toxicity. Management requires decontamination and supportive care.

**Ricin** Ricin is extracted from the bean of the castor plant. It inhibits DNA replication leading to cellular necrosis when internalised in cells. Historically, it has been used to assassinate individuals rather than as a weapon of mass destruction. It can be administered as an aerosol, droplet or by injection and leads to rapid tissue necrosis in the gastrointestinal tract, kidney and heart. Convulsions may occur. Management is supportive.

**Marine toxins** (see neurological disorders associated with exposure to toxic substances) Marine toxins are discussed above.

**Dioxin and Agent Orange** These were particularly used during the Vietnam War as defoliants and herbicides. The long-term consequences are now recognised and there may be cognitive and neuropsychiatric impairment as well as a distal sensory peripheral neuropathy particularly affecting the lower limbs.

**Radioactive toxins** Polonium 210 is an  $\alpha$  emitter that is highly toxic and causes damage to organic tissue if ingested, inhaled or absorbed, but does not penetrate epidermis and therefore is not hazardous if the source remains outside the body.

**Botulinus toxin** Botulism has been discussed in Chapter 9. The toxin is highly potent and can be readily aerosolised and absorbed by inhalation or ingestion into the gastrointestinal tract, persisting in this state for many weeks. The toxin is relatively easily degraded by exposure to heat, acidity or sunlight for >12 hours. Recovery follows only after there is regeneration of new axons which can take many months. Presynaptic inhibition of cholinergic autonomic (muscarinic) and motor (nicotinic) receptors leads to an extensive flaccid paralysis.

**Anthrax** Spores of the Gram-positive organism *Bacillus anthracis* can be inhaled, ingested or absorbed through the skin and cause a severe haemorrhagic bacterial meningitis in addition to primarily

pulmonary, cutaneous and gastrointestinal toxicity. The diagnosis is made difficult by the prolonged interval from exposure to presentation. Involvement of the CNS greatly increases the risk of mortality. Ciprofloxacin is the treatment of choice but doxycycline, clindamycin or rifampicin are also effective. Pre-exposure vaccination may have some protective effect. *B. anthracis* is easy to produce, the spores are hardy, highly infectious and remain in the environment for many years. They can be stored almost indefinitely and can only be removed by filtration with small pores or by formaldehyde. Aerosol deployment of dry spores risks secondary infection and spores could be effective in water or food supplies.

**Tularemia** This is caused by *Francisella tularensis*, a non-motile aerobic Gram-positive coccobacillus that is highly infective and can cause a meningitis or encephalitis although an atypical pneumonia is more frequent. First line treatment is an aminoglycoside antibiotic (streptomycin or gentamycin); alternatives include doxycycline, chloramphenicol and ciprofloxacin.

**Smallpox** Smallpox is a potentially devastating infection caused by variola, which is a DNA virus and infectious in droplet form. The last known case was in 1977 but intact virus remains in a number of laboratories, and is a potential neurobiological weapon. The Variola virus invades mucosal cells of the respiratory system before viraemic dissemination to bone marrow, spleen and lymph nodes. Immediate vaccination following exposure is essential and the subject should be isolated as soon as possible.

**Other viruses** Arboviruses, causing viral haemorrhagic fever, might be used as biological weapons because of high infectivity, low infectious dose and the absence of any specific treatment. However, most forms of arbovirus encephalitis are self-limiting. With supportive care patients recover well from these forms of infection although fatal encephalitis can occur. Vaccines are of limited benefit and treatment is with supportive care.

## Vitamin deficiencies and toxicity

The vitamin deficiency syndromes are summarised in Table 19.5.

### Vitamin A

Vitamin A deficiency occurs in fat malabsorption syndromes and leads to a variety of ophthalmic disorders. Retinol is required for the synthesis of rhodopsin, a visual pigment necessary for normal rod function in the retina; its deficiency leads to night blindness. There can also be corneal ulceration and carotenisation of the conjunctiva. 'Bitot spots' are white foam-like lesions, which appear on the side of the cornea and are characteristic of vitamin A deficiency.

Vitamin A toxicity is associated with ingestion of carotene-rich liver and proprietary treatments and may cause idiopathic intracranial hypertension. The skin is often dry and pruritic and generalised joint and bone pains occur. Serum retinol levels may be helpful to establish the diagnosis.

### Vitamin B<sub>1</sub> (thiamine)

Thiamine is found in most food and cereals but reduced intestinal absorption occurs in alcoholism and malabsorption syndromes. Deficiency is also associated with malnutrition, inadequate parenteral nutrition, haemodialysis, uraemia or repeated vomiting.

**Table 19.5** Vitamin deficiency syndromes.

Vitamin	Solubility	Name	Principal deficiency syndromes
A	F	Retinol	Night blindness
B <sub>1</sub>	W	Thiamine	Congestive cardiac failure (wet beri beri) Sensory axonal neuropathy (dry beri beri) Wernicke–Korsakoff syndrome
B <sub>3</sub>	W	Niacin (nicotinic acid)	Pellagra (dermatitis, diarrhoea, dementia)
B <sub>5</sub>	W	Pantothenic acid	Paraesthesiae and dysaesthesiae (burning feet syndrome)
B <sub>6</sub>	W	Pyridoxine	Peripheral neuropathy (ataxic, axonal, sensorimotor)
B <sub>12</sub>	W	Cobalamine	Subacute combined degeneration (axonal sensorimotor neuropathy and myelopathy) Optic atrophy Progressive cognitive impairment
Biotin	W		Non-specific – myalgia, dysaesthesiae, anorexia, nausea, dermatitis
Folate	W		Mild cognitive impairment, depression, elevated homocysteine levels (risk factor for vascular disease)
C	W	Ascorbic acid	Scurvy – impaired collagen synthesis with disordered connective tissue – ecchymosis, bleeding gums, petechiae, coiled hair, impaired wound healing, weakness
D	F	Cholecalciferol, ergocalciferol	Proximal myopathy, osteomalacia, rickets
E	F	Tocopherol	Spinocerebellar degeneration with limb ataxia, sensory axonal neuropathy
K	F	Phylloquinone	Haemorrhagic disease

F, fat; W, water.

Thiamine depletion can develop acutely and is a medical emergency because of the development of congestive cardiac failure and peripheral oedema (wet beri-beri), an axonal sensory neuropathy (dry beri-beri) or Wernicke–Korsakoff syndrome (cerebral beri-beri). The effects of thiamine deficiency are discussed later.

### Vitamin B<sub>3</sub> (niacin, nicotinic acid)

Niacin deficiency leads to the syndrome of pellagra. The condition occurs in populations that are dependent on corn but has decreased in frequency as white bread is now enriched with niacin. Clinically, pellagra is characterised by the development of dermatitis, diarrhoea and dementia (the three D's). The onset is usually with gastrointestinal symptoms including anorexia, diarrhoea and stomatitis. Skin changes are also frequently seen and erythema particularly affects the face, chest and dorsal surfaces of the hands and the feet. There can be mood changes, fatigue, malaise, lethargy and confusion with progression to neuropsychiatric disturbances including apathy, inattentiveness and memory loss or the development of spastic paraparesis with startle myoclonus. The cognitive impairment, which occurs in chronic alcoholics even with adequate thiamine replacement, is probably caused by niacin deficiency and is characterised by a defect in recent memory, visuospatial ability, abstract reasoning and speed of information processing. Treatment is with oral niacin replacement, often provided in food supplements.

### Vitamin B<sub>6</sub> (pyridoxine)

This is important in the metabolism of many amino acids. Deficiency often occurs in infancy because of feeds containing inadequate levels of B<sub>6</sub>. In children there can be hyperirritability, exaggerated auditory startle and recurrent convulsions leading to status epilepticus. Neonatal pyridoxine deficiency can cause seizures and all neonatal seizures should be treated with pyridoxine if the cause is not immediately obvious (Chapter 7). In adults, pyridoxine deficiency is usually secondary to medication including isoniazid, hydralazine and penicillamine. There can be peripheral neuropathy with distal weakness and painful sensory loss, absent tendon reflexes and Romberg's sign. High dose pyridoxine also causes a distal sensory axonal neuropathy with sensory ataxia.

### Vitamin B<sub>12</sub> deficiency (see Chapter 16)

Vitamin B<sub>12</sub> is abundant in meat, fish and animal by-products. Approximately 90% of total body B<sub>12</sub> is stored in the liver. Because of the large body stores, even with severe impairment of B<sub>12</sub> absorption, the symptoms and signs of B<sub>12</sub> deficiency can take many years to evolve. Daily requirements are small and only rarely can B<sub>12</sub> deficiency arise because of dietary insufficiency. It is associated with pernicious anaemia caused by defective intrinsic factor production by the gastric parietal cells but can also follow gastrectomy or small intestine disorder including surgical resection of the terminal ileum

**Figure 19.14** T2-weighted sagittal (a) and axial MRI (b) of the cervical and upper thoracic spinal cord of a patient with subacute combined degeneration of the spinal cord.

and blind loop syndrome. The elderly, vegetarians and patients taking H2 blockers for ulcers are at particularly high risk.

Systemic manifestations of vitamin B<sub>12</sub> deficiency include gastrointestinal involvement, characterised by the development of glossitis and a pan-enteropathy with diarrhoea and malabsorption of nutrients. Neurological features occur in up to 40% of patients with B<sub>12</sub> deficiency but these evolve over several months or longer. Symptoms develop insidiously with progressive paraesthesiae in the hands and feet with weakness and unsteadiness of gait culminating in peripheral neuropathy and myelopathy. Central manifestations include confusion, depression, progressive hallucination and mental slowing. Patients occasionally present with isolated cognitive or psychiatric disturbances but any direct relationship between B<sub>12</sub> and dementia remains unclear. There can also be optic neuropathy.

#### Subacute combined degeneration of the cord

This effect of B<sub>12</sub> deficiency is characterised by a sensorimotor axonal neuropathy and myelopathy. Neuropathic manifestations include distal paraesthesiae, numbness, gait ataxia and diminished proprioception in the lower limbs, while the myelopathic component leads to variable motor impairment because of pyramidal tract dysfunction with extensor plantar responses; the reflexes are variable depending on the extent of cord and peripheral nerve involvement. Incontinence of bowel and bladder with impotence and postural hypotension occur as part of the myelopathy. Visual impairment is also associated with B<sub>12</sub> deficiency with the development of optic atrophy, impaired acuity and centro-caecal scotoma. Brainstem and cerebellar signs are occasionally present.

Progressive cognitive impairment is characterised by memory loss, behavioural affective changes and occasionally stupor and coma. The blood film shows the development of a macrocytic anaemia with hypersegmented neutrophil nuclei and megaloblastic change in the bone marrow. Serum cobalamin levels can be used as a screening test and the Schilling test is valuable in demonstrating impaired absorption of vitamin B<sub>12</sub> even if serum levels are normal. Elevated levels of methylmalonic acid (MMA) and plasma total

homocysteine (HCy) are useful but limited ancillary tests. MRI may show extensive white matter change which can become confluent with disease progression culminating in leukoencephalopathy. The spinal cord shows abnormalities in the lateral and posterior columns with enhancement and residual changes may persist after treatment (Figure 19.14). Visual and somatosensory evoked potentials are delayed. Nerve conduction studies reveal small or absent sensory action potentials reflecting an axonal neuropathy in approximately 80% of patients.

The clinical features of nitrous oxide intoxication, copper deficiency and the vacuolar myelopathy of AIDS are identical to those of subacute combined degeneration because they are associated with cobalamin inactivity or deficiency.

The pathological changes of subacute combined degeneration of the spinal cord include spongy change with focal loss of myelin and axonal destruction in the white matter of the spinal cord particularly affecting posterior and lateral columns of the cervical and upper thoracic spinal cord. The peripheral nerves show axonal degeneration without significant demyelination. There may also be involvement of the optic nerves and cerebral white matter.

With adequate treatment, some of the deficits of B<sub>12</sub> deficiency can be reversible with most improvement occurring within the first 6 months of treatment. The myelopathy is least likely to make a complete recovery. B<sub>12</sub> replacement should be given a minimum of twice weekly for 2 weeks, followed by monthly injections. If there is malabsorption of B<sub>12</sub> then injections should be continued every three months for life. With full treatment at least partial improvement occurs in most patients but daily oral supplementation with large amounts of cobalamin may be necessary.

#### Folate deficiency

Absorption of folate takes place in the jejunum and ileum with levels being reduced in chronic alcoholism and following small bowel resection or disease. A number of drugs interfere with folate metabolism including sulfasalazine, methotrexate and azathioprine. Overt neurological deficit is unusual in folate deficiency but

there can be mild cognitive impairment, depression and an increased risk of stroke or neural tube deficit in pregnancy. A syndrome resembling subacute combined degeneration of B<sub>12</sub> deficiency can occur and folate deficiency leads to elevated homocysteine levels, a risk factor for the development of cerebrovascular, cardiovascular and peripheral vascular disease. Folate is administered orally but can be given parenterally in acutely ill patients and in pregnancy.

### Vitamin D

Vitamin D deficiency is associated with hypoparathyroidism, hypophosphataemia, chronic renal failure, malabsorption, dietary deficiency or inadequate exposure to sunlight. Neurological presentation is as a proximal myopathy which can be associated with osteomalacia. There is proximal weakness with a characteristic waddling gait but no involvement of bulbar or ocular musculature. Creatine kinase is elevated, EMG shows myopathic change and biopsy will confirm evidence of type II muscle fibre atrophy. Treatment is vitamin D replacement which leads to a slow recovery of the weakness.

### Vitamin E

Vitamin E is fat-soluble and acts as a free radical scavenger and antioxidant. It is normally stored in large amounts so that clinical symptoms only become apparent after many years of deficiency, usually secondary to malabsorption in cystic fibrosis, adult coeliac disease or because of abnormalities of specific vitamin E receptors (e.g.  $\alpha$ lipoproteinaemia). There is progressive spinocerebellar degeneration with limb ataxia, because of involvement of the posterior columns, and an axonal, predominantly sensory, peripheral neuropathy with prominent involvement of proprioception. Rarely, pyramidal features can develop with extensor plantar responses and ocular signs including ptosis, nystagmus, external ophthalmoplegia and optic neuritis. Investigation shows evidence of spiky red blood cells (acanthocytes) as well as retinal pigment change. Low serum vitamin E can be shown on assay but CSF is normal. Nerve conduction studies confirm a mild axonal neuropathy and occasionally the MRI scan shows high signal in the posterior columns. Treatment is with the recommended daily requirement of vitamin E of 10 mg/day. If the vitamin is deficient then the therapy should be given with water-soluble tocopherol 200–600 mg/day.

## Alcohol abuse

Alcohol abuse is extremely common and is associated with important cultural, economic and environmental influences and consequences. It affects all socio-economic strata of society. Primary alcoholism is defined as addiction to alcohol in the absence of an underlying cause. Physical dependence can become such a strong compulsion that psychopathology develops with neglect of self and family. This culminates in severe disruption of general health, behaviour and cognitive function leading to loss of personal relationships and occupation. Secondary alcoholism occurs when excessive drinking is the consequence of other major psychiatric illness (e.g. drug addiction, schizo-affective disorder or manic depression).

### Metabolism of alcohol

Alcohol is rapidly absorbed from the gastrointestinal tract and is metabolised in the liver where it is oxidised to acetaldehyde by the action of alcohol dehydrogenase and other enzymes. The role of acetaldehyde in alcohol toxicity is uncertain but it is highly

cytotoxic and is also readily metabolised to acetate by the mitochondrial enzyme acetaldehyde dehydrogenase. Tolerance to alcohol is the acquired resistance to its effects. Intoxication occurs because alcohol crosses the blood–brain barrier.

The clinical manifestations of alcohol can be divided into:

- 1 Effects of acute intoxication
- 2 Effects of alcohol substitutes
- 3 Withdrawal syndrome occurring after sudden abstinence, and
- 4 Chronic disorders associated with prolonged alcohol abuse.

### Effects of acute intoxication

The consequences of acute alcohol intoxication are widely tolerated by many societies, particularly amongst young people. The initial behavioural effects of euphoria, social disinhibition, loss of restraint and reduced psychomotor capacity are well-recognised but progression to behaviour disturbance, irritability, slurred speech, ataxic gait, aggression and loss of control can have serious consequences with high levels of intoxication. Depressant effects including drowsiness, stupor and coma can supervene with the risk of vomiting, aspiration and respiratory impairment. Acute intoxication is associated with psychotic disturbances including an acute paranoid state with auditory hallucinations, anxiety, agitation, outbursts of aggression and inappropriate violent or even destructive social behaviour of which the individual can have no recollection. These periods of amnesia, in which there is no ability to retain short-term memories, increase in duration and persist into periods when sober and fully conscious. Symptoms occur with serum levels as low as 50–150 mg/dL (10–31 mmol/L) but in those with previous alcohol intake and induction of the hepatic enzymes, symptoms develop at a higher concentration of blood alcohol. Extreme intoxication (>300 mg/dL or 65 mmol/L) results in cerebellar impairment (ataxic dysarthria and nystagmus) and coma associated with hypotension, respiratory depression and hypothermia, with death occurring from brainstem depression if the blood alcohol level exceeds 400 mg/100 mL. Because alcohol is rapidly absorbed acute intoxication may require sedation and treatment of agitation with haloperidol or chlorpromazine. Eventually, ventilatory support and haemodialysis may be necessary, especially if there is a suggestion of methanol intake in addition.

### Effects of alcohol substitutes

#### Methyl alcohol (methanol)

This is commonly used as a solvent and in antifreeze. It may be abused as a substitute for ethyl alcohol in 'meths'. It is directly toxic to the CNS as a depressant and is oxidised to formaldehyde and formic acid, which inhibit cytochrome oxidase and have a direct toxic effect on the putamen and optic nerves (see solvents & toxins). Acute intoxication can be delayed for many hours. Delirium can develop at the onset but a rapid progression occurs to cause visual field loss, blindness secondary to retinal oedema, pseudobulbar palsy and cognitive impairment. Severe toxicity culminates in metabolic acidosis and cerebral oedema leading to respiratory failure, coma and death. In patients who recover from acute intoxication there can be residual blindness and parkinsonian features. Treatment involves reversing the acidosis with large doses of sodium bicarbonate, retarding the mechanism of methanol with ethyl alcohol or fomepizole and, where necessary, haemodialysis.

#### Ethylene glycol

This is also commonly used as a solvent, in antifreeze, air conditioners and fire extinguishers. It can contaminate proprietary alcoholic drinks or be ingested in suicide attempts. Intoxication is

associated with lethargy and progressive hypersomnolence, hyperventilation with seizures and hypotension. There is a metabolic acidosis with an anion gap. Anuric renal failure develops which is also associated with seizures. With high levels there can be the delayed onset of a cranial neuropathy, which resolves slowly. Treatment is by haemodialysis with intravenous sodium bicarbonate and, if necessary, ethanol. Fomepizole (4-methylpyrazole) is also used as a competitive inhibitor of alcohol dehydrogenase.

### Withdrawal syndromes

The severity of withdrawal symptoms is proportional to the level of previous alcohol intake and the abruptness of cessation. Withdrawal of alcohol in the chronic abuser sometimes leads to the development of delirium tremens (the 'DTs') with CNS hyperexcitability, initially characterised by tremulousness with anxiety, insomnia, confusion, hyperactivity, hallucinations and seizures. The symptoms progressively worsen over several hours before settling, up to 72 hours after the last intake of alcohol. The tremor is generalised, present at rest and on action and can involve the face and tongue. It is associated with irritability and is usually present in the morning, but progressively worsens and increases in duration with prolonged withdrawal. There is usually an associated gastrointestinal disturbance with nausea, vomiting and autonomic hyperactivity with tachycardia, hypertension and sweating. Disturbing vivid auditory and visual hallucinations develop and these can persist for several days after the physical symptoms have settled. The patient frequently awakes lucid with no recollection of the acute delirious phase. Recurrence is common and, in severe cases, death supervenes. It is essential to consider the possibility of alcohol withdrawal in patients who develop confusion, tremor or seizures after being admitted to hospital for more than 12 hours. Severe withdrawal delirium tremens occurs in about 5% of patients and is associated with hyperpyrexia, ketoacidosis and circulatory collapse. Isolated hallucinations may occur in up to one-quarter of patients following withdrawal. They are often visual but occasionally auditory. Patients often lack insight into their hallucinations and their development indicates a poor prognosis with significant mortality.

### Withdrawal seizures ('rum fits')

These typically occur within the first 24–48 hours of withdrawal. They are generalised, tonic-clonic convulsive seizures, which usually occur singly or in brief clusters although status may develop. The EEG shows mild changes, sometimes with photosensitivity, and generally reverts to normality within a few days. Even if status develops, the condition is usually self-limiting and patients often do not require antiepileptic medication although acute treatment with lorazepam or diazepam may be necessary.

### Management of alcohol withdrawal

Minor symptoms can be managed with simple reassurance and nursing in a calm quiet well-lit environment although benzodiazepines can be helpful. Moderate symptoms, including autonomic hyperactivity and irritability, necessitate an incremental dose of benzodiazepines. Thiamine and glucose should be given to prevent the development of metabolic encephalopathy. Severe symptoms associated with confusion, poor cooperation, restlessness and aggressive behaviour can require intravenous diazepam (Diazemuls) given by slow injection and, if further treatment is necessary, haloperidol 5–10 mg intramuscularly or 5 mg twice daily up to 20 mg/day is the treatment of choice. Chlordiazepoxide, clomethiazole or clonidine are also effective.

## Chronic disorders associated with prolonged alcohol abuse

### Wernicke's encephalopathy

This is a complex of symptoms and signs resulting from an acquired nutritional deficiency of thiamine (vitamin B<sub>1</sub>) rather than any direct toxic effect of alcohol. It is characterised by encephalopathy, oculomotor disturbances and ataxia. Thiamine and other B vitamins act as co-enzymes in glucose and lipid metabolism, amino acid production and neurotransmitter synthesis. Because thiamine stores are relatively small and there is a large daily turnover, deficiency can occur within 2–3 weeks of low intake. The brain is particularly sensitive to disturbance of complex B vitamin-dependent metabolism of glucose.

Wernicke's encephalopathy can present as an acute or slowly evolving disorder, often precipitated by an intercurrent medical event or metabolic stress such as trauma or infection. In addition to alcohol, it is caused by other conditions in which a depletion of thiamine can occur:

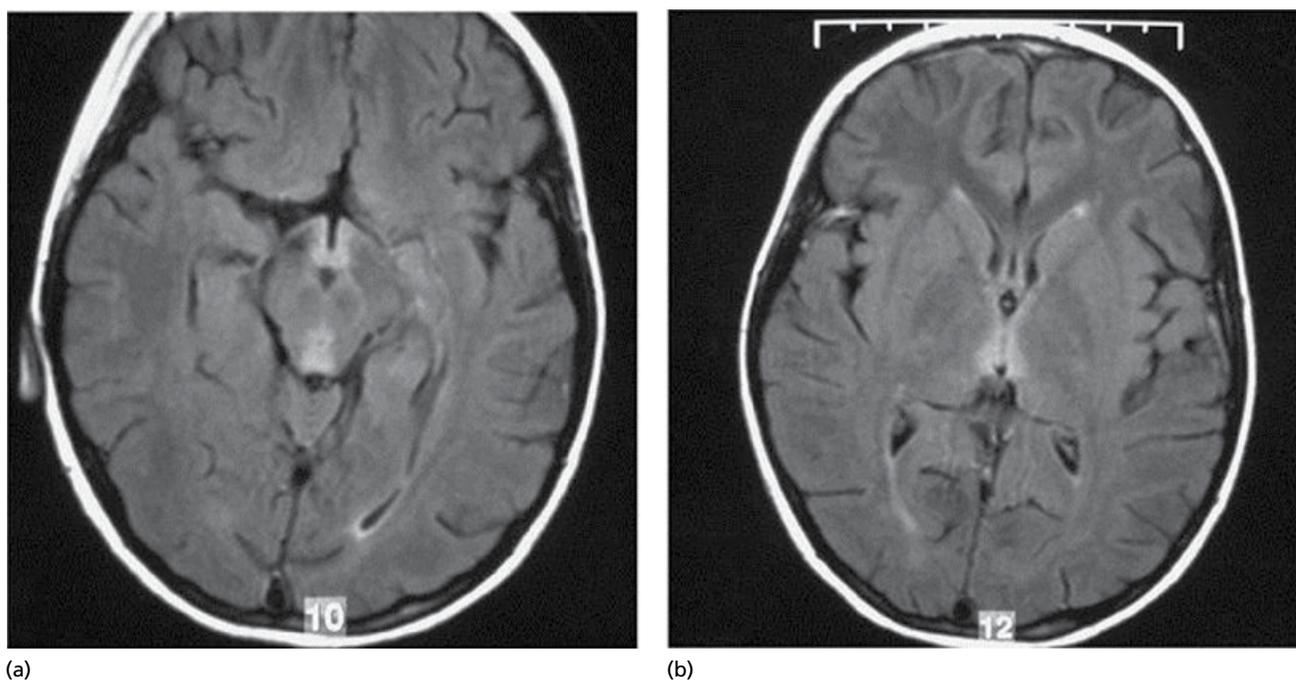

- Hyperemesis of pregnancy
- Systemic malignancy
- Haemo- or peritoneal dialysis
- Gastrointestinal surgery
- Prolonged intravenous feeding
- Anorexia,
- AIDS.

The acute syndrome is characterised by apathy, confusion, impairment of ocular motility and cerebellar ataxia lapsing into an encephalopathy with progressive disturbance of behaviour, personality, orientation and cognitive function developing over days or weeks leading to stupor, coma and ultimately death. There can be hallucinations, perceptual disorder and agitation. Ocular signs are characteristic and include ophthalmoplegia, nystagmus and conjugate gaze palsy. The ophthalmoplegia is initially caused by paresis of the lateral recti with subsequent involvement of other ocular muscles leading to total ophthalmoplegia. Nystagmus can be both horizontal and vertical and there is also sluggish pupillary response to light with light-near dissociation. Fundal examination shows small retinal haemorrhages and occasionally optic neuropathy develops. Progressive truncal and gait ataxia is common but the limbs are rarely involved.

MRI shows high T2 signal in the peri-aqueductal and the paraventricular region of the medial thalamus and hypothalamus while the mamillary bodies appear shrunken (Figure 19.15). CSF is characterised by elevated protein, while serum thiamine and erythrocyte transketolase activity are reduced. The pathology in Wernicke's syndrome shows symmetrical haemorrhagic and necrotic change predominantly affecting the mamillary bodies, dorsal medial nucleus of the thalamus and peri-aqueductal region as well as the tegmentum of the pons. Treatment is by thiamine given immediately commencing at 50–100 mg parenterally in the acute stages. Untreated Wernicke's encephalopathy is associated with a significant mortality but with adequate treatment the signs resolve rapidly.

### Korsakoff's syndrome

This is a progressive and severe amnesic syndrome that is incompletely reversible. Memory is preferentially involved in comparison to other cognitive function with a profound impairment of both retrograde and anterograde memory with relative preservation of distant past memory, language and calculation abilities. There may also be perceptual difficulties and loss of insight although this is often less marked. Patients show striking loss of memory with

**Figure 19.15** Wernicke syndrome. Axial fluid-attenuated inversion recovery (FLAIR) images showing increased signal in the (a) mammillary bodies and dorsal midbrain and (b) thalami. Source: Cooke 2006. Reproduced with permission of Macmillan.

disorientation in time and place but retain alertness, attention, calculation and, at onset, normal social behaviour. The condition is characterised by confabulation, with intrusion of false memories.

Pathologically, the memory impairment of Korsakoff syndrome is associated with selective necrosis of the basal septal nuclei of the frontal lobes, the temporal lobes and diencephalon (Figures 19.16 and 19.17). In alcoholism, Korsakoff syndrome is caused by thiamine deficiency but can also occur following:

- Infarction
- Anoxia
- Trauma
- Tumours involving the frontotemporal regions
- Herpes simplex encephalitis
- Temporal lobe epilepsy.

Treatment requires urgent and high doses of thiamine replacement and should be continued until a noticeable improvement has occurred and for as long as clinical improvement continues. Improvement in memory function is slow and usually incomplete. Up to one-quarter of patients show no recovery while only slight improvement occurs in the remaining patients. Complete recovery is rare.

Wernicke–Korsakoff syndrome can be difficult to detect and a high index of suspicion is necessary in all patients who abuse alcohol and those with poor diet or gastrointestinal disturbance including diarrhoea and vomiting.

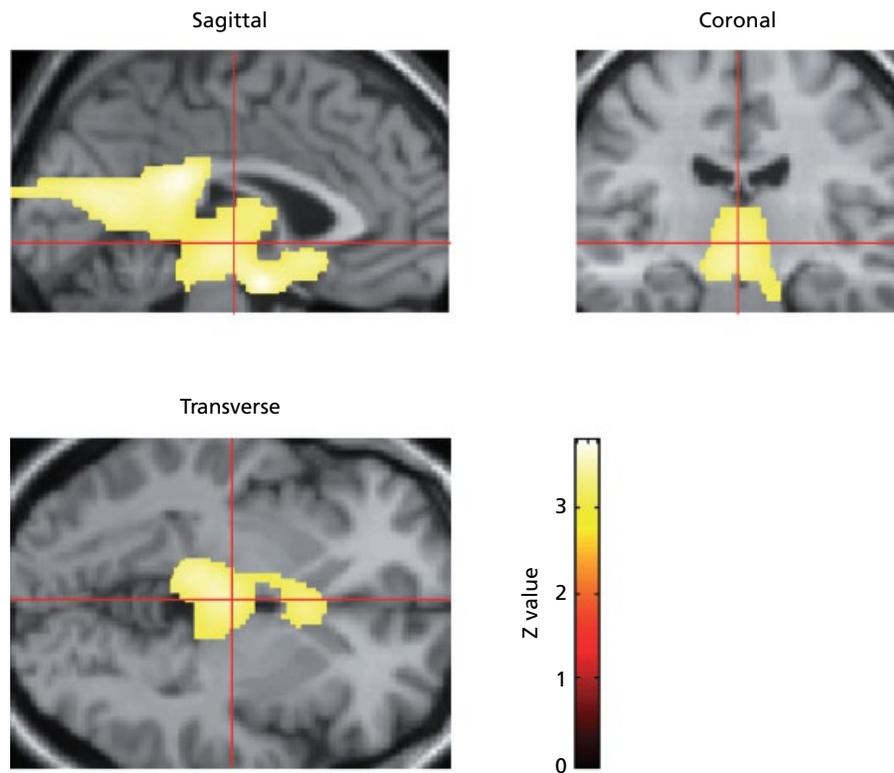

### Cerebellar ataxia

Chronic alcohol abuse is the most common cause of acquired cerebellar atrophy and is often associated with alcohol polyneuropathy. The ataxia usually affects men and can be so severe that the patient is unable to stand without support. Patients walk with a broad-based gait with slow short steps but limb ataxia and speech disturbance are minimal although cerebellar abnormalities of

**Figure 19.16** Korsakoff's syndrome. T2-weighted axial MRI showing thalamic infarct. Courtesy of Professor M. Kopelman, St. Thomas' Hospital.

ocular movement are often present. Progressive unsteadiness evolves over several months with truncal ataxia and mild gait disturbance. Abstinence from alcohol leads to a slow and incomplete improvement. Pathological examination shows selective atrophy

**Figure 19.17** FDG PET scan showing hypometabolism in patients with Korsakoff's syndrome with significant reduction of signal in thalamus, ventro-medial cortex and retrosplenium. Source: Reed *et al.* 2003. Reproduced with permission of Elsevier.

of the anterior and superior part of the cerebellar vermis with cell loss particularly involving the Purkinje cells. Cerebellar ataxia can be associated with Wernicke's encephalopathy or occur in isolation.

#### Confusional state and dementia

Cortical atrophy and ventricular dilatation occur with prolonged alcohol intake. This is associated with a global confusional state characterised by progressive indifference to surroundings and abulia. Patients are easily aroused but are disorientated with cognitive deficits which can worsen and become fixed, interfering with activities of daily living, before evolving into frank dementia which may persist even after discontinuation of alcohol.

#### Alcoholic peripheral neuropathy

Sensorimotor axonal peripheral neuropathy is a characteristic feature of alcohol abuse, occurring as a consequence of thiamine deficiency in Wernicke's encephalopathy or because of direct alcohol toxicity. The neuropathy is usually insidious in onset, often mild and predominantly sensory. However, rapid progression may occur with motor impairment severe enough to affect gait. Painful symmetrical sensory loss occurs to all modalities, particularly affecting the lower limbs; it is characterised by distal tingling, burning and lancinating pain. Autonomic involvement is manifest as impotence, sweating, pupillary abnormalities and postural hypotension. Investigation shows a macrocytosis and elevation of hepatic enzymes. There may be an elevated CSF protein and nerve conduction studies show an axonal polyneuropathy predominantly affecting sensory and motor action potential with slowing of conduction velocity. Management is discontinuation of alcohol consumption

and ensuring adequate nutritional intake with thiamine and vitamin B supplements. However, recovery is generally incomplete and there is often considerable residual weakness and paraesthesiae.

#### Alcoholic myopathy

Acute myopathy can occur with chronic alcohol abuse but may also follow binge intake. It is secondary to the direct toxic effects of alcohol although other factors including muscle crush, seizures and electrolyte disturbances can contribute. The onset is with acute and severe muscle pain, cramp, swelling and a rise in the creatine kinase level, evolving rapidly into focal or generalised myopathic weakness often with selective involvement of the calves. A cardiomyopathy can coexist. Although recovery usually occurs within days or weeks, rhabdomyolysis and myoglobinuria may occur, leading to hyperkalaemia and renal failure. A more chronic myopathy is associated with prolonged consistent alcohol abuse, characterised by slowly developing, painful proximal myopathy particularly affecting the shoulder and hip girdle muscles. This myopathy can be asymptomatic and noted because of an isolated elevation in creatine kinase levels. EMG shows myopathic features and there can also be a coexisting neuropathy. Biopsy of chronic alcohol myopathy shows no significant muscle fibre necrosis but atrophy affecting type II (especially type IIB) fibres. In the acute form there is scattered muscle fibre necrosis with regeneration. The myopathy can be reversible with many months of abstinence and good nutrition. Recovery is often incomplete.

#### Other neurological complications of alcohol abuse

##### Marchiafava–Bignami syndrome

This is a condition associated with drinking strong red wine, usually Chianti, that affects severe and chronic alcoholics in middle or

late life. The aetiology is unknown and presentation is variable with a slowly progressive disturbance of cognitive function, personality and behaviour. There is progressive motor slowing with incontinence, frontal release signs and a broad-based gait. There can be cognitive impairment, dysarthria, hemiparesis, apraxia, aphasia and seizures and occasionally a patient can present in stupor or coma. There is selective demyelination of the central portion of the corpus callosum with sparing of the anterior and posterior portions, other white matter tracts are also affected. Treatment is with nutritional support and rehabilitation but recovery is variable. Imaging shows high signal lesions on T2 MRI in the corpus callosum and anterior commissure.

### Fetal alcohol syndrome

Prenatal exposure to ethanol impairs fetal growth and neurodevelopment. There may be dysmorphic facial features and microcephaly, mental retardation and learning difficulties including speech delay and hyperactivity.

### Psychiatric sequelae

In chronic alcohol abuse depressive illness is common, particularly on withdrawal, and up to one-quarter of patients fulfil the criteria for a major depressive disorder; however, it often remits after several months and rarely requires antidepressant medication. Some patients also have an anxiety disorder which may develop into frank psychotic symptoms during withdrawal.

### Traumatic injury

Traumatic injuries to the head may occur during intoxication causing parenchymal contusions, subdural or extradural haematoma, subarachnoid haemorrhage and lead to post-traumatic epilepsy.

### Compressive neuropathies (see Chapter 10)

The most common neuropathies occurring in alcohol abuse include compression of the radial nerve at the spiral groove causing 'Saturday night palsy'. Compression of the peroneal nerve at the fibula head can lead to foot drop as can compression of the sciatic nerve in the gluteal region.

### Amblyopia (see Chapter 14)

Amblyopia occurs as a consequence of chronic alcoholism and is associated with poor dietary and heavy tobacco use and weight loss. Progressive optic nerve involvement leads to painless visual loss affecting both eyes with diminished visual acuity, a centrocaecal scotoma and mild disc pallor. The treatment is to maintain adequate diet and B vitamins which generally leads to visual recovery.

### Alcoholic cirrhosis

It must be emphasised that neurological effects of alcohol abuse run in parallel with systemic factors. Alcohol-related cirrhosis is the most common and serious manifestation. Patients may develop porto-systemic encephalopathy, tremor, myoclonus and asterixis.

### Strachan's syndrome

This is a severe painful ataxic sensorimotor neuropathy associated with visual loss resulting from amblyopia, tinnitus, gastritis and stomatitis. The condition is related to nutritional deficits. There have been outbreaks of the condition in Cuba associated with retrobulbar optic neuropathy, peripheral neuropathy, sensori-neural hearing loss and myelopathy with spastic paraparesis and dysphonia.

The aetiology remains unclear but a relationship to poor nutrition, heavy alcohol and tobacco exposure has been noted.

## Other deficiency states associated with neurological manifestations

### Copper deficiency

Copper deficiency is rare because of the low daily requirement and its ubiquitous distribution. This occurs following gastrointestinal disturbance, in particular after gastrectomy but excessive zinc (e.g. dental cream and during chronic haemodialysis) can also cause copper deficiency by chelating free copper. It also occurs in enteropathy and as a complication of total parenteral nutrition. Copper is essential to the nervous system and bone marrow and functions as a prosthetic group in key enzymes involved in catecholamine synthesis, the respiratory chain, folate metabolism and antioxidant function. The most common neurological manifestation of acquired copper deficiency is a myeloneuropathy with sensory ataxia. The MRI shows increased T2 signal in the dorsal columns, particularly in the cervical region. The condition appears clinically and radiologically identical to subacute combined degeneration of the cord associated with B<sub>12</sub> deficiency or nitrous oxide intoxication.

### Magnesium deficiency

This can also occur after gastrointestinal surgery or with chronic use of diuretics. It is an essential co-enzyme involved in the metabolism of thiamine and its deficiency can lead to an impaired response to thiamine in Wernicke's encephalopathy resulting from alcohol or hyperemesis gravidarum.

## Drugs of abuse

### Epidemiology

The clinical assessment of drug abuse is difficult because addicts may use several drugs at one time, or abuse alcohol concurrently. Furthermore, the drug can be contaminated either at source or at the time of administration and the metabolism of drugs of abuse is unpredictable depending on dosage, mode of administration and the ability of the body to metabolise the drug.

Drug dependence is both psychological when drug use is compulsive because of pleasurable or dysphoric effects and physical if discontinuation of the drug will lead to serious and painful symptoms. Drug users develop tolerance and require larger doses to maintain the effects of the drug and to prevent the development of withdrawal symptoms.

There are five major groups of drugs of abuse (Table 19.6):

- 1 Stimulants
- 2 Sedatives
- 3 Hallucinogens
- 4 Organic solvents, and
- 5 Drugs used to enhance athletic performance.

### Stimulants

Stimulants share the ability to enhance transmission at the catecholaminergic synapse and therefore have common pharmacological and toxic effects and also develop cross-tolerance. Stimulants are abused because they cause elation, increased alertness and enhance stamina and motor activity. Prolonged excessive use is associated with motor manifestations including tics, tremor, myoclonus and an acute dystonic reaction.

**Table 19.6** Drugs of abuse that affect the nervous system.

<b>Stimulants</b>
<i>Sympathomimetics</i>
Amphetamines, methamphetamine, dexamphetamine
Crack/cocaine
Methylphenidate (Ritalin)
Ephedrine
<i>Serotonergic</i>
MDMA and derivatives (Ecstasy, MDMA, MDEA, PMA)
<i>Others</i>
Modafinil, caffeine, nicotine, methcathinone
<b>Sedatives and tranquilisers</b>
<i>Opiates and opioids</i>
Morphine
Heroin
Opium
Codeine
Hydromorphone
Fentanyl
Pethidine
Tramadol
Naloxone
<i>Barbiturates</i>
<i>Benzodiazepines</i>
<i>Others</i>
Methaqualone, GHB, ethanol
<b>Hallucinogens</b>
<i>Psychedelics</i>
Phenylethylamine – MDMA, mescaline
Tryptamins – LSD, psilocybin
<i>Dissociatives</i>
Dextromethorphan
Ketamine
Methoxetamine
Phencyclidine
<i>Deliriant</i>
Atropine
Scopolamine
<i>Cannabinoids</i>
Marijuana
(GHB and solvents are also hallucinogens)
<b>Organic solvents</b>
<i>Solvents</i>
Propane
Butane
Toluene
<i>Fuels</i>
Gasoline
Kerosene
<i>Propellant gases</i>
Freon
<i>Nitrous oxide</i>
<b>Drugs used to enhance athletic performance</b>
Steroids
Erythropoietin (EPO)
Diuretics
$\beta$ -blockers

**Amphetamines**

Dexamphetamine, the dextro-isomer of amphetamine, is used in clinical practice. Metamphetamine ('crystal meth' or 'ice') is widely abused. Acute intoxication is characterised by increased alertness, a sense of self-confidence and well-being, euphoria and extrovert behaviour, loss of appetite and the desire to sleep, tremor, dilated pupils, tachycardia and hypertension. In extreme cases this results in paranoid delusions, hallucinations and violence. Intoxication can lead to convulsions, hyperthermia, rhabdomyolysis and intracerebral haemorrhage. Stroke resulting from stimulant abuse is discussed later (see Conditions caused by stimulant abuse).

**Designer drugs**

Designer drugs are synthetic derivatives, usually amphetamine analogues. Ecstasy (MDMA) is a synthetic compound that is a derivative of a stimulant (methamphetamine) and a hallucinogen (mescaline). It is widely abused by the young because of its capacity to induce euphoria, wakefulness, intimacy, sexual arousal and disinhibition. It is erroneously believed to provide a 'safe' high but its unique adverse effects are caused by both the release and uptake block of endogenous catecholamines and serotonergic toxicity. In high doses it has an amphetamine-like stimulant effect and unpredictable toxicity, exacerbated by dehydration. It may cause an acute toxic reaction with headache, hypertension, hyperpyrexia, seizures, rhabdomyolysis and the development of hyponatraemia leading to confusion, seizures, cerebral oedema, coma, cerebral herniation and death. A hypertonic state may develop causing hepatotoxicity, coagulopathy, cerebral infarction or haemorrhage. MDMA causes a massive central serotonergic discharge which accounts for its psychic effects which can be clinically indistinguishable from schizophrenia. There can be permanent impairment of memory. Many substances have been combined with Ecstasy as adulterants: toxic MDMA and piperazine analogues, dextrometamphetamine, ketamine, paracetamol and other non-psychoactive adulterants. Several other amphetamine-derived drugs are widely used, and all have similar effects following acute and prolonged intoxication. Other sympathomimetic drugs of abuse such as cocaine, amphetamine and methamphetamine present with a clinical syndrome that is indistinguishable from that of MDMA.

**Methylphenidate (Ritalin)**

This can rarely cause an amphetamine-like syndrome with behavioural disturbances, seizures and intracerebral haemorrhage.

**Methcathinone analogues – khat**

Khat is a flowering plant native to East Africa and the Arabian Peninsula. The leaves contain the alkaloid cathinone, an amphetamine-like stimulant. For many years the leaves have been chewed as a recreational drug within the region where it naturally grows because only fresh leaves are strongly psychoactive. Its stimulatory effects include a feeling of euphoria, excitement, increased alertness and sexual arousal. Toxic effects include anorexia, tremor, tachycardia, arrhythmia, hypotension and respiratory arrest. Increased air transport has led to extensive smuggling of the drug, with a global distribution. Cathinone breaks down to cathine and norephedrine. This occurs after khat has been ingested or if the leaves are left to dry for more than 48 hours.

Methcathinone ('cat' or 'jeff') is a derivative of cathinone. It is inexpensively and easily manufactured as a designer drug from its precursor, ephedrine. It has a similar amphetamine-like stimulant and euphoric effect when snorted, ingested or injected.

Mephedrone is a synthetic stimulant drug of the cathinone and amphetamine class which has received considerable publicity as a 'legal high'. The neurotoxicity remains uncertain but a number of deaths have been reported

### MPTP

Methylphenyltetrahydropyridine (MPTP) was developed in the United States as a designer drug with close clinical similarities to amphetamine. The effects of abuse were similar but some abusers developed a moderate to severe parkinsonian syndrome with bradykinesia, freezing, rigidity, instability, dysarthria and a symmetrical parkinsonian tremor. There was a variable response to levodopa with the development of typical motor fluctuations and dyskinesias. Pathological features include moderate to severe neuronal loss and gliosis in the substantia nigra without Lewy bodies.

### Cocaine

Cocaine is the most commonly abused psychomotor stimulant and is administered intranasally, parenterally or smoked as crack. Moderate doses are associated with mood elevation, increased alertness, reduced fatigue and enhanced performance but psychiatric effects develop rapidly including paranoia, delusions, hallucinations, seizures, choreo-athetoid movements and agitation. Chronic abuse can lead to progressive neuropsychiatric features including restlessness, irritability and psychotic, aggressive, paranoid states. These are associated with visual and auditory hallucinations with amphetamine abuse and violent behaviour with the cocaine alkaloid, crack. Long-term abuse of stimulants can lead to toxic encephalopathy or a fixed cognitive dysfunction with cerebral atrophy.

### Conditions caused by stimulant abuse

**Ischaemic stroke** Ischaemic stroke occurs as a consequence of stimulant abuse for several reasons. It is associated with acute hypertension, vasoconstriction, dissection and haemorrhagic vasculitis occurring with amphetamine or cocaine. Furthermore, cardiac thrombus can embolise to the brain in patients with infective endocarditis or cardiomyopathy caused by arrhythmias or because foreign body material may be injected with the drug. Stroke can also be a consequence of infective endocarditis causing mycotic aneurysms or haemorrhagic transformation in cerebral infarction. Crack cocaine is the most important cause of drug-related stroke accounting for about 50% of all cases and being much more common than amphetamine-related stroke. With crack-cocaine, infarction often affects the cortical or deep penetrating arteries, but anterior spinal artery occlusion also occurs. The onset of stroke following use of amphetamine or crack cocaine is rapid because of blood pressure surges. Approximately 50% occur in the middle cerebral artery territory. Imaging shows asymptomatic subcortical white matter lesions in crack and cocaine users.

**Haemorrhagic stroke** This is particularly associated with cocaine and amphetamine. It seems to occur with intranasal or intravenous usage or smoking crack. Intracerebral haemorrhage is usually in basal ganglia but is occasionally lobar, intraventricular or subarachnoid. Haemorrhage may be associated with hypertension, vasculitis or a pre-existing aneurysm or arteriovenous malformation may rupture.

**Vasculitis** This is seen more commonly with methamphetamine than cocaine. It usually evolves rapidly with headache, progressive encephalopathy and raised erythrocyte sedimentation rate. Diffuse

vasospasm is associated with bleeding or focal narrowing; there can also be a necrotising vasculitis resembling polyarteritis nodosa, involving small calibre vessels and necrosis. Treatment is with high dose steroids.

**Other effects of stimulant abuse** In addition to stroke and epilepsy, systemic complications of stimulants include the development of hyperthermia, dehydration and rhabdomyolysis with an increased risk of myocardial infarction and cardiac arrhythmia. Cocaine and amphetamine also give rise to movement disorders including vocal and motor tics, chorea, and acute dystonic reaction particularly affecting the head and neck and an oromandibular dyskinesia. Treatment is supportive with attempts to cool the patient, reduce blood pressure and maintain oxygenation. Neuroleptics, anxiolytics and sedatives may be necessary and seizures should be treated appropriately. Withdrawal of cocaine can be difficult as the tolerance develops to the euphoric and anorexic effects of the drug and the psychiatric manifestations may worsen.

### Sedatives

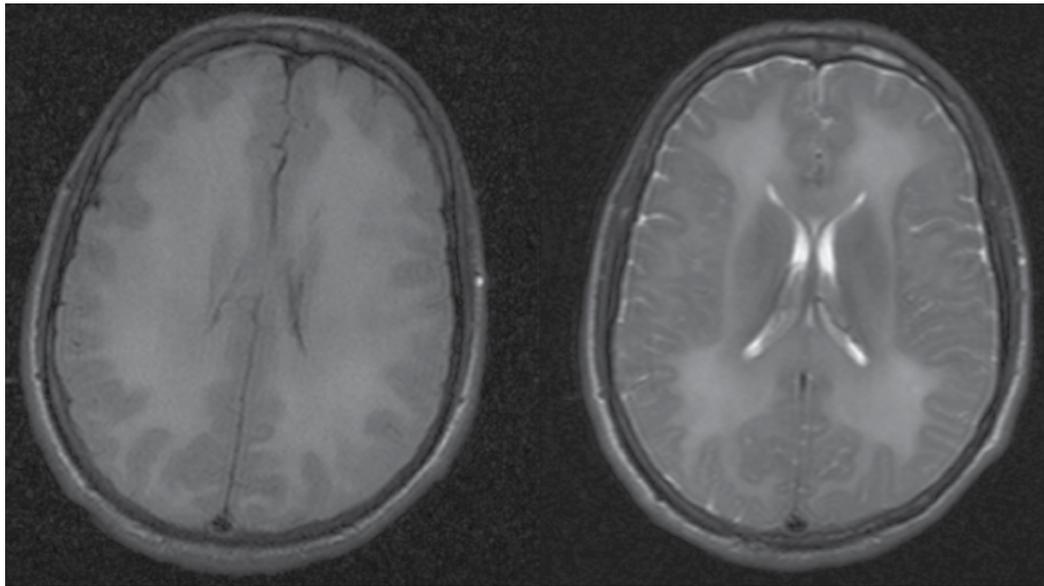

#### Opiates

Heroin and morphine are highly addictive drugs which are usually administered intravenously but can be sniffed, smoked or injected subcutaneously (skin popping). Intravenous administration is often non-sterile and can lead to infective complications (Table 19.7). Fentanyl is an opiate with 100 times the potency of morphine.

The effects of heroin are the same as morphine but more powerful. There is an initial analgesic effect and then a sense of 'rush' with euphoria or dysphoria before drowsiness and hallucinations. Systemic features include pruritus, dry mouth, nausea, vomiting, constipation and urinary retention. There can be severe pupillary constriction before the development of respiratory depression, hypoxic-ischaemic brain injury and post-anoxic encephalopathy. The immediate effects can be reversed with naloxone, a safe and effective antidote which should be given to anyone with a suspected opiate overdose. If the patient has not been discovered for a prolonged period of time there can be extensive

compression and stretching of peripheral nerves and damage to the brachial plexus, common peroneal, ulnar or sciatic nerves with secondary ischaemia. Rhabdomyolysis is caused by a compartment syndrome as a consequence of trauma, hypotension, fever and seizures or brought about by direct opiate toxicity. It occurs after prolonged periods of unconsciousness and leads to myoglobinuria and sometimes renal failure. Repeated intramuscular injections can also lead to focal fibrosis and weakness in injected muscles with contractures. Stroke is secondary to an infective vasculitis or to the development of mycotic aneurysms but infarction can also be a consequence of paradoxical embolism or contaminants. An acute myelopathy can occur with excessive heroin abuse with paraparesis, segmental sensory level, and urinary retention. A distal sensory or sensorimotor neuropathy also occur. Inhalation of heroin pyrolyte, particularly if contaminated by heating the drug on aluminium foil, can cause toxic encephalopathy with extensive white matter change on MRI (Figure 19.18).

The symptoms and signs of withdrawal from opioids appear within hours and include the characteristic syndrome of drug craving, restlessness and irritability, followed by the development of autonomic flu-like symptoms, sweating, lacrimation and rhinorrhoea. There may be piloerection, abdominal cramps, diarrhoea and coughing. The symptoms may develop rapidly following administration of naloxone but controlled withdrawal ought not to be dangerous and treatment of symptoms with oral methadone, a long-acting opiate, may ameliorate the symptoms. Clonidine and  $\alpha_2$ -adrenergic agonists suppress the autonomic disturbances of opioid withdrawal.

### Barbiturates

Barbiturates are abused because of their euphoric and sedative actions which are similar to alcohol. Acute intoxication leads to slurred speech, gait ataxia, coma, hypotension, hypothermia and eventually respiratory depression with apnoea. Treatment is supportive and involves the use of gastric lavage. When barbiturates are

GABA hydroxybutyrate (GHB)
Solvents

withdrawn acutely there may be irritability, tremor, tachycardia and a reduced seizure threshold. It can be necessary to reinstitute the barbiturate before reducing with gradual tapering dosage.

### Benzodiazepines

Benzodiazepines, when used acutely, induce a comfortable sensation of lassitude, but in excessive doses there is progressive drowsiness, confusion, euphoria and impairment of psychomotor function leading to stupor and coma. The effects of acute overdoses can be reversed by flumazenil which is a specific antagonist, but this is short-lived. Chronic use of benzodiazepines leads to tolerance and physical dependence. Withdrawal symptoms develop within 24 hours of cessation of the use of short-acting benzodiazepines leading to irritability, increased sensitivity to light and sound and autonomic disturbance including tremor and tachycardia which can develop into delirium, hallucinosis and seizures.

### Hallucinogens

Hallucinogens are abused because of the heightened and distorted sensory perception with eventual hallucinogenic effects (Table 19.8). The subject experiences perceptual change, decreased pain sensation and autonomic effects which include flushing, sweating, hypertension and tachycardia. Abuse is associated with an acute confusional

state, ataxia, dysarthria and nystagmus. Numbness and perceptual change develop with features of self-mutilation, convulsions, dystonia and coma. LSD and Ecstasy can cause the serotonin syndrome.

### Lysergic acid diethylamide

Lysergic acid diethylamide (LSD) is a hallucinogen that alters perception, mood and thought. Acute effects are associated with dizziness, blurred vision, nausea and weakness. There is often euphoria, depersonalisation, distortion of time and bizarre behavioural effects, including arousal and depression, which can lead to accidents or suicide. Chronic abuse has been associated with cerebral infarction and cognitive deficits.

### Marijuana

Marijuana can be smoked, eaten or taken intravenously. It is widely abused because of its effects on memory, mood, judgement and sense of time. It induces a sense of relaxation with a subjective slowing of time, euphoria and depersonalisation. In high doses there can be a toxic psychosis with hallucination, paranoia and a variable degree of anxiety, aggressiveness or sedation and sleepiness. The long-term consequences of abuse remain uncertain but paranoia and panic reaction do occur. Tolerance leads to a degree of irritability, restlessness and insomnia. Synthetic cannabinoids are analogues of marijuana and have been termed 'legal highs' but many of these are extremely toxic.

### Ketamine

Ketamine is primarily used as an anaesthetic but has hallucinogenic properties. It is a drug of abuse and in large doses can lead to coma in humans while moderate doses can cause euphoria, relaxation and paranoia. Prolonged use leads to a long-term syndrome of psychosis, agitation, bizarre behaviour and catatonia.

### Phencyclidine (angel dust)

This is taken orally, nasally or by inhalation and has a mixture of effects including a euphoric or dysphoric state, which can lead to catatonia and psychosis especially in chronic abuse.

### GABA hydroxybutyrate

GABA hydroxybutyrate (GHB) induces euphoria, disinhibition and loss of short-term memory but its use is associated with sedation, disorientation and vomiting. In higher doses, seizures can develop.

### Anticholinergics

These can also be used as recreational drugs because they can cause hallucinations and delirium. Excessive anticholinergic stimulation is associated with mydriasis, dry flushed skin, tachycardia, urinary retention and fever. In severe overdoses there can be myoclonus, seizures, coma and death.

### Solvents

Lighter fluids, varnishes and paint thinners are frequently abused as inhalants because they are based on organic solvents including toluene, hexane and benzene. Their use is associated with a characteristic rash with inflammation around the mouth and the nose. Inhalation of low doses leads to a feeling of exhilaration, light-headedness and giddiness with auditory and visual hallucinations. With more prolonged or severe usage vomiting, tinnitus, headache occur and eventually the development of seizures. Long-term exposure causes toxic encephalopathy with progressive impairment of coordination and cognition, and the development of diplopia and

ataxia with increasing disorientation, confusion, respiratory depression and coma. Toluene (see Neurological Disorders associated with exposure to toxic substances) particularly can give rise to ataxia, oculomotor and brainstem dysfunction, pyramidal features and dementia. Long-term complications include cardiac arrhythmias, suffocation from the use of plastic bags during inhalation, vomiting, aspiration and peripheral neuropathy. Sudden death can occur. MRI may show widespread white matter abnormalities.

### Athletic performance-enhancing drugs

The neurotoxicity of some of these drugs is uncertain. Anabolic steroids including corticosteroids, insulin and growth hormone have direct physiological effect in building muscle. Stimulants, including amphetamine and cocaine, are also used to heighten alertness, reduce fatigue and prolong endurance. Erythropoietin (EPO) increases haemoglobin and oxygen delivery in endurance sports and  $\beta_2$ -agonists have a fat burning effect. Abuse of these substances is widespread and their effects may be unpredictable.

### Investigation of suspected substance abuse

The first line of investigation is a urine toxicology screen, which can become positive within hours of ingestion and remains positive for variable periods depending on the drug used and the presence of coincidental alcohol use. Positivity for amphetamine, cocaine, barbiturates and morphine is relatively short but benzodiazepines and heroin remain detectable for up to 8 weeks.

### Adverse reactions to drugs

Adverse reactions to drugs are a common cause of neurological morbidity and mortality. Drug reactions commonly lead to a variety of manifestations that can mimic naturally occurring neurological disease. There are many individual anecdotal case reports suggesting drugs are relevant to the aetiology of individual conditions but a clear causal relationship is much more difficult to establish. Throughout this section only the most important or most common forms of neurological drug toxicity are discussed.

### Seizures

Many drugs can cause seizures in healthy individuals or, more commonly, provoke seizures in patients with pre-existing epilepsy or a low seizure threshold (Table 19.9). Iatrogenic seizures can also occur as a consequence of withdrawal of antiepileptic medication or be provoked by other medical procedures such as

**Table 19.9** Drugs that may provoke seizures.

Respiratory agents – theophylline, aminophylline, terbutaline
Psychotropic medication – phenothiazines, clozapine, butyrophenones, lithium
Antimicrobial agents – antibiotics (isoniazide, nalidixic acid), antifungal, antituberculous, antihelminthics
CNS stimulants – caffeine, cocaine, amphetamines, methylphenidate
Antineoplastic agents
Opiates and narcotic agents – pethidine, morphine
Vaccines
Radiological contrast agents

**Table 19.10** Drugs that may cause headache.

Non-steroidal anti-inflammatory drugs	Ibuprofen, diclofenac, celecoxib
Antimicrobial medication	Sulphonamide, cephalosporin, ciprofloxacin, isoniazid, penicillin
Antiviral agents	valaciclovir
Cytotoxic medication	Cytosine arabinoside
Corticosteroids	
Intravenous immunoglobulin (IVIg)	
Intrathecal medication	Contrast material and cytotoxic medication (e.g. methotrexate)
Others	Antimicrobials, steroids, baclofen, spinal anaesthesia

surgery, electroconvulsive therapy, labour and delivery or intrathecal chemotherapy. Other factors predisposing to drug-induced seizures include metabolic abnormalities, organ failure, water intoxication or electrolyte abnormalities, particularly hyponatraemia.

### Headache

Headache can occur either as a direct consequence of medication or because the medication has acted as a trigger in a predisposed individual (Table 19.10). Acute exposure can cause a primary headache often brought about by vasodilatation. The most common drugs causing headaches are non-steroidal anti-inflammatory drugs (indomethacin, diclofenac), nifedipine, cimetidine, ranitidine,  $\beta$ -blockers (atenolol, metoprolol, propranolol) and vasodilator drugs (including glyceryltrinitrate). A number of drugs also cause or exacerbate a tendency to migraine including cimetidine, the oral contraceptive pill, atenolol, indomethacin and nifedipine. Chronic headache is associated with the overuse of medication or by drug withdrawal. Headaches resulting from transient hypertension occur with monoamine oxidase inhibitors (MAOIs), as a reaction to treatment or when sympathomimetic agents are given concurrently. Intravenous immunoglobulin (IVIg) commonly gives rise to headache particularly in known migraine sufferers, this can be caused by aseptic meningitis. Idiopathic intracranial hypertension occurs predominantly in young women who are overweight and is particularly associated with use of the oral contraceptive drug, vitamin A intoxication or a variety of other medications including antibiotics (tetracycline, ampicillin, nitrofurantoin), non-steroidal anti-inflammatory drugs (naproxen, ibuprofen), retinoids, danazole, amiodarone, perhexiline and thyroxine. Headache can also occur as a consequence of drug-induced aseptic meningitis (e.g. NSAIDs, IVIg).

### Confusional states

Drugs are a common cause of a confusional state, manifest as a fluctuating level of consciousness, diminished awareness, impairment of intention and memory, disorientation, hallucination and paranoid delusions. The primary drugs that can be responsible are summarised in Table 19.11.

**Table 19.11** Drugs associated with confusional state.

Tranquilisers and hypnotics – barbiturates
Benzodiazepines
Antiparkinsonian medication
Antidepressants including SSRIs
Abrupt withdrawal of drugs

**Table 19.12** Drugs associated with encephalopathy.

Lithium	Diffuse disturbance of cerebral function associated with tremor, myoclonus, seizures, ataxia and confusion. The cerebellar dysfunction may persist
Psychotropic medication	Impairment of consciousness and memory with psychomotor activity are common, particularly with neuroleptics (haloperidol and antidepressants), tricyclic drugs, fluoxetine, venlafaxine
Anticholinergic medication	Antiparkinsonian, antipsychotics, antihistamines, antiemetics, benzodiazepines
Drugs of abuse	Cocaine, opiates
Histamine (H2) receptor antagonists	Cimetidine
Non-steroidal anti-inflammatory drugs	
Opioid analgesics	Morphine and heroin
Others	Penicillins, cephalosporins, vigabatrin, valproic acid

### Encephalopathy

Clouding of consciousness or delirium is commonly caused by multiple general medical factors but is particularly related to the effects of medication. It can be manifest as a disturbance of consciousness but there can also be changes in cognition or perception. The disturbances develop over a relatively short period of time and fluctuate during the course of the day. A large number of drugs can cause delirium but most reports are anecdotal. The most important medications can have multiple effects (Table 19.12).

### Memory disturbance

Memory impairment is commonly associated with the use of medication. This can cause temporary impairment of anterograde and retrograde memory, a transient global amnesia, fugue-like state or, much less commonly, a fixed and irreversible amnesia (Table 19.13).

### Neuropsychiatric effects

The behavioural effects of medication can be difficult to assess and be non-specific. The development of listlessness, insomnia, drowsiness, restlessness, anxiety, euphoria or depression can be a

**Table 19.13** Drugs that may be associated with memory disturbance.

Chemotherapy (particularly intrathecal methotrexate)
Anticholinergic medication
Antidepressants
Antiepileptic drugs
Analgesic drugs of abuse

manifestation of underlying disease or other metabolic or infective complications but a variety of medications do contribute: tricyclic antidepressants, amphetamines, phenothiazines, barbiturates, hypnotic, anticholinergics, antiepileptic medication and antihistamines. Similar features may be precipitated by acute withdrawal of medication. Affective disorders are less common but may be severe. A depressive reaction can occur during drug treatment. In the past, reserpine and methyl dopa were recognised to cause depression. More commonly now, depression occurs with other antihypertensive medication (clonidine, propranolol and calcium channel blocking drugs) but is also seen with corticosteroids, hypnotic agents, NSAIDs, antituberculous medication, H<sub>2</sub> antagonists, digoxin, baclofen, anabolic steroids, barbiturates and benzodiazepines. Acute manic or hypomanic psychosis is unusual but can be associated with corticosteroids, thyroid replacement or, rarely, captopril, chloroquine and dopaminergic drugs.

### Coma

This usually results from an inadvertent or deliberate overdose with hypnotic sedatives, antidepressants, analgesics or drug combinations. An overdose of insulin will also produce an acute hypoglycaemic coma and other drugs that can be implicated include phenothiazines, salicylates and valproic acid.

### Sleep disorders

Sleep disorders resulting from medication may be manifest by excessive sleepiness, insomnia, sleep-related breathing disorders or parasomnias. Excessive drowsiness is associated with sedative, hypnotic or antidepressive medication and may also occur with antiepileptic drugs. Paradoxically, the same medication may also be associated with insomnia as can respiratory drugs including bronchodilators, cardiovascular drugs (antihypertensive medication, calcium channel blockers, beta-blockers and CNS stimulants). Vivid dreams and nightmares are often associated with drugs affecting noradrenaline, serotonin and dopamine neurotransmitters; these include the CNS stimulants, antipsychotic drugs and antiparkinsonian medication. Parasomnias can be related to the introduction of antipsychotic medication, sedatives, hypnotics or antidepressants.

### Toxic leukoencephalopathy

This is a disorder associated with a structural alteration of white matter caused by a variety of toxic insults usually related to therapeutic agents, illicit drug use and occupational exposure to toxins. The condition involves white matter tracts serving higher cerebral function and therefore presents with neurobehavioural disturbances including inattention, forgetfulness and changes in personality leading to somnolence, apathy, cognitive impairment and ultimately dementia, coma and death. MRI initially shows hyperintensity in the peri-ventricular white matter but this progresses

**Table 19.14** Drugs that may be associated with toxic leukoencephalopathy.

Antineoplastic treatments	Cranial irradiation, methotrexate, cisplatin, cytarabine, levamisole, interleukin 2, interferon
Immunosuppressants	Tacrolimus, ciclosporin
Antimicrobial	Amphotericin B
Drugs of abuse	Toluene, ethanol, cocaine, amphetamine, ecstasy, heroin (IV or inhaled), psilocybin
Environmental toxins	Carbon monoxide, arsenic, carbon tetrachloride

to a severe hyperintensity involving widespread white matter with necrotic areas. These changes are reflected in the pathology of patchy oedema within myelin which becomes widespread, leading to the destruction of oligodendrocytes, axonal loss and necrosis. The condition is associated with a variety of toxins listed in Table 19.14.

### Cerebrovascular disease

Cerebrovascular disease can be associated with the use of drugs by a large number of potential mechanisms. There is a clear risk of haemorrhage as a complication of anticoagulant and thrombolytic therapies. Cerebral blood flow may be reduced particularly in elderly patients in the presence of cerebrovascular disease by any antihypertensive medication that reduces blood pressure below perfusion pressure. This may predispose to cerebral infarction in watershed territories. Cerebrovascular disease may be caused by direct neurotoxicity or indirect mechanisms such as involvement of other systems including cardiovascular, haematological, respiratory, renal, hepatic and metabolic or the presence of predisposing or coexisting general medical risk factors. A variety of medications can cause transiently elevated blood pressure including sildenafil, amphetamines, ephedrine, heroin and other drugs of abuse. Vasospasm may occur with sympathomimetics, triptans and cerebral vasculitis is particularly associated with amphetamines, Ecstasy, penicillin, tacrolimus and, occasionally, allopurinol. There is a small increased risk of thrombo-embolism, ischaemic arterial or cerebral venous occlusion in women taking the oral contraceptive pill; chemotherapeutic agents including cisplatin can also cause cerebral venous or arterial thrombosis or haemorrhage.

### Impairment of taste and smell

Disturbances of taste (dysgeusia) and smell (dysosmia) are extremely common manifestations of drug toxicity. They are particularly associated with antidiabetic therapy (oral hypoglycaemics), phosphodiesterase inhibitors, theophylline, caffeine, ethambutol, other antibiotics including penicillin, antirheumatic medication (gold, D-penicillamine), angiotensin converting enzyme inhibitors and many cytotoxic agents.

### Drug-induced movement disorders (Chapter 6)

Several movement disorders are caused by commonly prescribed medication (Table 19.15). Acute dystonic and dyskinesic reactions often develop immediately following treatment and can be manifest as oromandibular dystonia, oculogyric crisis and opisthotonus.

**Table 19.15** Drug-induced movement disorders.

Acute dystonia	Neuroleptic medication (phenothiazide and butyrophenones) Tricyclic antidepressants Metoclopramide Antiepileptic drugs (phenytoin, carbamazepine) Others (propranolol, ondansetron and fluoxetine)
Akathisia	Phenothiazines Butyrophenones Benzodiazepines Antidepressants, SSRIs (particularly fluoxetine)
Choreoathetosis	Antiepileptic medication Oral contraceptives Drugs of abuse (e.g. crack cocaine) Lithium
Parkinsonism	Dopamine receptor blocking drugs (particularly phenothiazines, butyrophenones and haloperidol) SSRIs may also induce or exacerbate parkinsonian syndromes
Tremor – essential and action	Sympathomimetics Tricyclic antidepressants Lithium and levodopa Aminophylline, theophylline Caffeine Hypoglycaemics Antiepileptic drugs (valproate, phenytoin, carbamazepine, primidone) Sedatives Barbiturates Benzodiazepines
Tardive dyskinesia	Dopamine antagonists (especially antipsychotics) Metoclopramide Promethazine Prochlorperazine Antihistamines Tricyclic antidepressants Levodopa Monoamine oxidase inhibitors

Dystonia can be more generalised with slow writhing movements of the limbs or prolonged contractions of the axial and limb musculature. The acute dystonias are usually self-limiting once the drug is discontinued. Akathisia is a state of motor restlessness characterised by an inability to keep the legs still and an urge to constantly move, pace or run. Akathisia usually remits within days or weeks following withdrawal of the neuroleptic drug but can occasionally persist or be permanent. Choreoathetosis is manifest as irregular multifocal non-stereotyped semi-purposeful jerky movements often associated with slower dystonic movements. Drug-induced tics are associated with amphetamine-like drugs, methylphenidate, haloperidol and other antipsychotic medication. Drug-induced

parkinsonism is the most common form of iatrogenic movement disorder and can be extremely difficult to distinguish from idiopathic Parkinson's disease. The onset tends to be slow, with bradykinesia being the most prominent feature characterised by variable rigidity, tremor and gait disturbance. The condition is usually reversible after drug withdrawal or dosage reduction over the course of several weeks but drugs may unmask latent idiopathic Parkinson's disease. A number of drugs may aggravate an essential or physiological tremor. Tardive dyskinesia usually develops after more than 12 months of continuous therapy but may evolve over a much shorter period, occasionally developing after cessation of therapy. It is characterised by orofaciobuccal dyskinesia with lip-smacking and pursing, jaw opening, closing and protrusion of the face with writhing movements of the tongue and facial grimacing. The movements tend to be stereotyped and may interfere with speech or swallowing. There can be associated choreoathetotic movements of the limbs and trunk with repetitive foot tapping. Tardive forms of tic, myoclonus and tremor are also described. A variety of dopamine receptor blocking drugs can cause tardive dyskinesia; the newer atypical dopamine receptor blocking drugs, including clozapine, appear to carry less risk.

All the major classes of conventional neuroleptic drugs (phenothiazines, butyrophenones, thioxanthenes) and the atypical antipsychotic drugs including clozapine, olanzapine, quetiapine and risperidone have been reported to cause extrapyramidal syndromes. All these side effects are idiosyncratic and patients vary greatly in their susceptibility and in the dose necessary to precipitate the side effects; patients with dementia with Lewy bodies are particularly vulnerable.

### Ototoxicity

Drug-induced damage to the cochlear and vestibular function is common. The former is manifest as tinnitus and hearing loss and the latter as vertigo, oscillopsia and imbalance. Both are characteristically associated with aminoglycoside antibiotics, gentamicin and streptomycin. Balance is usually preferentially affected. Loop diuretics, salicylates, antimalarials (quinine, chloroquine) and cytotoxic agents including cisplatin and vincristine can be associated with hearing loss (Chapter 15).

### Cerebellar disorders

Cerebellar disorders are usually dose-related and reversible but can become fixed deficits after antiepileptic drugs, phenothiazides, lithium or ciclosporin.

### Visual disorders

Drug-induced visual disorders can be brought about by a variety of different mechanisms and visual disorders.

- *Pupillary*: miosis is produced by parasympathetic drugs which include cholinergic agents (neostigmine, pyridostigmine) and opiates (morphine) but mydriasis, which may occur with anticholinergic agents (atropine, hyoscine), tricyclic antidepressants and phenothiazines (MAIOs, tricyclics), is a more serious drug effect because of the risk of precipitating closed angle glaucoma.
- *Distortion of the lens* can cause refractory changes because of fluid shifts with diuretics and antidiabetic therapy (insulin, oral hypoglycaemics) and corticosteroids.
- *Drug-induced retinopathy* can be caused by the development of pigmentary change (as occurs with chloroquine-like drugs and cardiac glycosides).

- *Macular oedema* (oral contraceptive) or visual field loss (e.g. ethambutol, indomethacin, vigabatrin) may occur and optic neuropathy has been associated with some antibiotics (e.g. chloramphenicol, isoniazide, ethambutol, cytotoxic medication, opiates and NSAIDs).
- *Nystagmus* is the most common drug-related eye movement disorder and is caused by antiepileptic drugs, tricyclic antidepressants, ototoxic medication, salicylates and MAOIs.

### Autonomic effects

Disturbances of autonomic function are commonly caused by drug toxicity. Drug-induced syncope may occur as a consequence of vasovagal disturbances, postural hypotension or cardiac disease. Postural hypotension occurs with a variety of antihypertensive medication (particularly  $\beta$ -blockers, vasodilators and diuretics), antidepressants and levodopa. In the elderly, syncope is particularly associated with fluoxetine, haloperidol and levodopa. Bladder disturbance occurs with anticholinergic medication (atropine, hyoscine), particularly with pre-existing prostatic outflow tract obstruction. Medication can cause sexual dysfunction at any level of function. Antihypertensive medication ( $\beta$ -blockers) is particularly associated with impotence or impairment of ejaculation, while antidepressant medication can affect libido or cause orgasmic dysfunction. Spinal toxicity can follow intrathecal injection of steroids, cytotoxic medication or contrast material leading to an infective or aseptic meningitis, adhesive arachnoiditis or direct toxic effects on the spinal cord or nerve roots. Epidural injection is not associated with these problems unless there is penetration of the dura.

### Neuromuscular drug effects

There are many drugs that can cause non-specific fatigability but peripheral neuropathy is an extremely common manifestation of drug toxicity (Chapter 10).

### Peripheral neuropathy

Most drug-related neuropathies are predominantly axonal although demyelination and conduction block can occur. Both motor and sensory patterns are seen. The major categories of drug-induced peripheral neuropathy are summarised in Table 19.16.

### Drugs interfering with neuromuscular transmission

These can cause a myasthenic-like syndrome, uncover latent myasthenia or exacerbate the existing disease. These are discussed in Chapter 10; only the most important drugs are listed in Table 19.17.

A large variety of muscle diseases can be caused by drugs (Table 19.18).

### Myalgia, stiffness and cramp

Many drugs cause myalgia, stiffness and cramp, often in association with a transiently elevated creatinine kinase level. Drug-induced myopathy may be associated with myotonia, pain or myokymia and may be focal or generalised. The most important drugs causing the different forms of myopathy are listed in Table 19.18.

### Malignant hyperthermia

This condition occurs in susceptible individuals following anaesthesia using a halogenated inhaled anaesthetics (including halothane, enflurane and isoflurane) and/or a depolarising muscle relaxant such as succinylcholine. The condition is characterised by the sudden onset of fever and rigidity associated with a high

**Table 19.16** Drugs causing peripheral neuropathy.

Antibiotics		Neuropathy
Metronidazole	A/D	Sensory
Nitrofurantoin	A	Sensorimotor or motor
Isoniazide	A	Sensorimotor or sensory
Ethambutol	A	Sensorimotor or motor
Dapsone	A	Motor
Antiviral nucleoside analogues	A	Sensory
<b>Chemotherapeutic agents</b>		
Cisplatin	A	Sensory
Vinca alkaloids	A	Sensorimotor $\pm$ autonomic
Cytarabine (high dose)	D	Sensory
Thalidomide	A	Sensory
<b>Cardiovascular drugs</b>		
Statins	A	Sensory > sensory motor
Amiodarone	D/A	Sensorimotor > motor
Enalapril	A	Sensorimotor > sensory
Hydralazine	A	Sensorimotor > sensory
Streptokinase	A	GBS-like syndrome
<b>Antirheumatic drugs</b>		
Gold	A/D	Motor > GBS-like
Chloroquine	D/A	Sensorimotor
Colchicine	A	Sensorimotor
Allopurinol	A/D	Sensorimotor
<b>Others</b>		
Tacrolimus	D	GBS-like
Ciclosporin	A	Sensory
Disulfiram	A	Sensorimotor
Lithium overdose	A/D	GBS-like (sensorimotor)
Phenytoin	A/D	Sensory and motor

A, axonal; D, demyelinating.

**Table 19.17** Drugs that may cause disorders of the neuromuscular junction.

Antibiotics – aminoglycosides, tetracycline, ciprofloxacin
Antiarrhythmics – quinidine, procainamide
Antimalarials – chloroquine
Antirheumatics – penicillamine D
Beta-blockers – propranolol, atenolol, metoprolol, sotalol
Antiepileptics – phenytoin
Neuroleptics – chlorpromazine, clozapine, flupenthixol, lithium, MAOIs
Neuromuscular junction blocking agents

MAOI, monoamine oxidase inhibitor.

**Table 19.18** Drugs that may cause muscle disease.**Subacute necrotising myopathy**

Symmetrical proximal weakness with myalgia and elevated CK

- Amiodarone
- Chloroquine
- Lipid-lowering medication – simvastatin, pravastatin, atorvastatin
- Colchicine
- Corticosteroids
- Zidovudine
- Heroin

**Myositis**

Inflammatory myopathy indistinguishable from polymyositis with elevated CK

- Chloroquine
- Corticosteroids
- D-penicillamine
- Lipid-lowering drugs – simvastatin, pravastatin
- Others – phenytoin, levodopa, cimetidine

**Myotonia**

Drug either causing the myotonia or unmasking latent myotonic disorders

- Propofol
- Depolarising muscle relaxants – suxamethonium
- Diuretics – frusemide, acetazolamide
- Vincristine
- Lipid-lowering drugs – simvastatin, pravastatin
- Beta-blockers – propranolol, pindolol

**Focal fibrous myopathy following intramuscular drug injection**

Caused by needle trauma and local effects of agent injected leading to severe muscle fibrosis and contractures

- Antibiotics
- Chloroquine
- Drug abuse

**Myopathy resulting from hypokalaemia**

- Diuretics
- Purgative abuse
- Licorice
- Amphotericin B

**Mitochondrial myopathy**

Characterised by myalgia, proximal weakness and elevated CK

- Zidovudine

**Rhabdomyolysis**

Acute and severe necrotising myopathy characterised by severe muscle pain, swelling and weakness leading to myoglobinuria and renal failure

- Anaesthetics
- Lipid lowering drugs – simvastatin, pravastatin
- Diuretics
- Barbiturates
- Opiates – morphine, heroin
- Alcohol
- Other drugs of abuse – amphetamines, LSD

creatine kinase level with metabolic acidosis and myoglobinuria. Liability to malignant hyperthermia is transmitted in an autosomal dominant fashion and occurs in genetically predisposed individuals who have an intrinsic abnormality of the excitation–contraction coupling mechanism in skeletal muscle. This leads to an excessive release of  $\text{Ca}^{2+}$  from the sarcoplasmic reticulum resulting in myofibrillar contraction. The condition seems to be caused by a defect in the calcium release channel (RYR1) and the genetic basis is a mutation in the *RYR1* gene on chromosome 19q or in other calcium channel genes.

The onset of the condition is variable. In the most florid forms acidosis, rigidity and hyperpyrexia may develop within 30 minutes of anaesthesia but in some patients the onset is slower with the condition developing over several hours with only mild signs. The initial features are tachycardia, raised end tidal carbon dioxide, metabolic acidosis and progressive muscular rigidity. The hyperthermia develops later but can be severe. In its most severe form the condition progresses to rhabdomyolysis and myoglobinuria, disseminated intravascular coagulation (DIC), cardiovascular collapse or hyperpyrexia leading to multi-system failure. There seems to be similar sensitivity to anaesthetic agents in patients with other neuromuscular diseases, in particular Duchenne muscular dystrophy, myotonia congenita, myotonic dystrophy, central core disease, congenital myopathy and osteogenesis imperfecta.

Vulnerability to this syndrome is suggested by a positive family history or previous difficulties during anaesthesia. It can be tested *in vitro* using biopsied muscle and observing a hypercontractile response to caffeine or halothane. Management involves the immediate discontinuation of the triggering anaesthesia and hyperventilation with 100% oxygen at high flow. Dantrolene is recommended as specific therapy in a dose of 2.5 mg/kg IV repeated as necessary. Supportive care of heart rate, temperature and oxygenation are essential. Core temperature can be reduced by ice lavage. Hyperkalaemia is managed by the use of bicarbonate, glucose, insulin and calcium but it is essential to be aware of rebound hypokalaemia which may precipitate further episodes. Myoglobinuria is treated with diuretics, fluid support and bicarbonate as necessary. With rapid and appropriate management the prognosis in an acute episode is good and the syndrome resolves rapidly. It is clearly essential to be aware of any susceptibility to this condition in planning anaesthesia. Complete recovery occurs in general but weakness may last for months after an acute episode.

**Neuroleptic malignant syndrome**

This is a serious and potentially fatal complication of treatment with antipsychotic agents. The condition is characterised by onset within 2 weeks of initiating or increasing neuroleptic therapy although, rarely, it can develop after months or years of stable treatment. The signs evolve over up to 72 hours although the onset can be more acute and it usually resolves within 2 weeks. The presentation is usually with progressive and severe pyrexia ( $>40^{\circ}\text{C}$  in 40% of patients) although a more insidious prodrome with a modest pyrexia can occur. There is progressive encephalopathy and impairment of conscious state ranging from lethargy to delirium, confusion, agitation and coma. Severe 'lead pipe' rigidity with other extrapyramidal features including bradykinesia, rest tremor and dystonia develop. There is autonomic instability including tachycardia, tachypnoea, diaphoresis, labile blood pressure, skin pallor or flushing, sialorrhoea and urinary disturbance including incontinence. The condition is characterised by grossly elevated creatine

kinase level and there is also usually a leukocytosis, metabolic acidosis and elevated CSF protein but muscle biopsy is non-specific.

The most common drugs causing this condition are haloperidol, fluphenazine and chlorpromazine but other phenothiazines, lithium, metoclopramide, tricyclic antidepressants or atypical antidepressants (clozapine, risperidone, olanzapine) can also be responsible. Other risk factors seem to include the use of depot injections, rapid dose increase and the presence of dehydration or agitation. There can also be a genetic predisposition to the condition. Despite treatment, neuroleptic malignant syndrome can progress to the development of rhabdomyolysis leading to myoglobinuria and renal failure, coagulation defects from DIC, respiratory failure, shock, seizures and coma. In some series mortality has been up to 20%, with persisting neurological sequelae in 10% of survivors.

The management is both supportive and specific. The neuroleptic must be immediately discontinued and the core temperature normalised. There must be close attention to hydration, blood pressure, cardiac, respiratory and renal function with adequate anticoagulation. Specific management remains controversial. Dantrolene is a muscle relaxant that inhibits excitation contraction mechanisms and may influence central dopaminergic mechanisms in the active phase of neuroleptic malignant syndrome. It has been reported to be effective but there is a risk of hepatic toxicity. Bromocriptine is a dopamine agonist that works by acting centrally to counter the neuroleptic effects. It has been given in divided doses for up to 10 days after resolution of symptoms but its use is limited by side effects of nausea, hypertension and worsening mental state. Electroconvulsive therapy has been advocated because of its efficacy in treating malignant catatonia but there is little evidence to support its use.

Neuroleptic malignant syndrome probably results from a sudden decrease in central dopaminergic function resulting from profound dopamine receptor blockade at multiple sites including the corpus striatum and thermoregulatory and vasomotor centres in the hypothalamus. However, while the condition usually occurs with dopamine receptor blocking drugs it may also be seen with dopamine depleting drugs or even without exposure to neuroleptics.

### Serotonin syndrome

Serotonin syndrome is a variable but potentially life-threatening drug reaction caused by excessive serotonin stimulation of the central and peripheral nervous systems. It results from therapeutic use, intentional self-poisoning or inadvertent interaction between drugs. Clinical manifestations are variable. There is a characteristic triad of mental state change, neuromuscular abnormalities and autonomic hyper-reactivity. The condition is probably more common than was previously thought particularly with increasing use of selective serotonin re-uptake inhibitors (SSRIs).

Presentation can be with mild tachycardia and minor autonomic features including shivering, diaphoresis and mydriasis. These can be considered to be simple drug reactions and the medication is often discontinued. However, in more severe forms the condition may progress to an intermittent tremor or myoclonus with hyper-reflexia. There can be severe hyperthermia, tachycardia and hypertension. Progressive encephalopathy with clouding of consciousness, confusion and hypomania may develop. Autonomic features that may evolve include mydriasis, hyperactive bowel sounds, diaphoresis and neurological involvement including the development of lead pipe rigidity, myoclonus, tremor, incoordination, clonus and hyper-reflexia. The condition usually develops

within 24 hours of the initiation of causative medication but the onset can be within minutes or come on after several weeks at stable dosage.

Laboratory investigation may show metabolic acidosis, rhabdomyolysis, abnormalities of liver function and there may be features of DIC or renal failure but most cases are relatively minor and resolve over 12–24 hours. The condition occurs with monotherapy using SSRIs or when there is an interaction between two drugs from this class. These include SSRIs (citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine and sertraline) or other antidepressant drugs that inhibit the re-uptake of serotonin by other mechanisms including duloxetine, olanzapine, mirtazapine and venlafaxine.

Serotonin syndrome can also be associated with other drugs that inhibit the re-uptake of serotonin and these are listed here. The condition has been reported to follow administration of a serotonergic agent up to 5 weeks after discontinuation of fluoxetine.

Drugs that can cause serotonin syndrome either in isolation or when combined include:

- SSRIs
- Atypical antidepressants
- MAOIs – phenelzine and selegiline
- Tricyclic antidepressants
- Dopaminergic agents
- Antiepileptic drugs – sodium valproate, carbamazepine
- Lithium
- Anaesthetics
- Opiate analgesics – tramadol, meperidine, pentazocine
- Risperidone
- Over-the-counter cold remedies containing ephedrine and dextromethorphan
- Antiemetics – ondansetron, metoclopramide
- Antimigraine – sumatriptan and other triptans
- Drugs of abuse – Ecstasy, opioids, LSD
- Herbal products – St John's wort
- Withdrawal of medication.

The condition can be transient and not require treatment other than the discontinuation of the relevant medication. However, if the symptoms are severe, management is both supportive and specific. Following discontinuation of the serotonergic medication it is necessary to control agitation, monitor the level of consciousness, respiratory and cardiac function and to control hyperthermia and autonomic instability. Sedation, neuromuscular paralysis and orotracheal intubation with ventilation can be necessary.

There remains controversy about specific treatment using 5-HT antagonists. A variety of treatments have been used but none is proven. The present recommendations are for the administration of cyproheptadine as it binds to 5-HT receptors. Chlorpromazine has also been used but there is no benefit from other 5-HT antagonists including lorazepam, methysergide and propranolol.

It is important to distinguish this condition from neuroleptic malignant syndrome, malignant hyperthermia, anticholinergic syndrome and the tyramine cheese reaction and this differential diagnosis is summarised in Table 19.19.

### Tyramine cheese reaction

The tyramine cheese reaction usually occurs in patients taking non-selective MAOIs. Ingestion of tyramine-containing substances (usually cheese or red wine) or sympathomimetic agents can lead to an acute hypertensive crisis, headache, nausea and vomiting culminating in hyperthermia and rarely DIC, renal

**Table 19.19** Comparison of clinical features of serotonin syndrome, neuroleptic malignant syndrome (NMS), malignant hyperpyrexia, tyramine and anticholinergic syndrome.

		Serotonin syndrome	NMS	Malignant hyperpyrexia	Tyramine	Anticholinergic
Medication		Serotonergic drugs	Dopamine agonists	Inhalation anaesthetic or succinylcholine	MAOI	Anticholinergic
Onset		<12 hours	1–3 days	30 min – 24 hours	<12 hours	<12 hours
Vital signs	T <sup>o</sup>	++	+	++	0	+

MAOI, monoamine oxidase inhibitor.

failure and cardiopulmonary arrest. The condition is caused by excessive tyramine that has not been deaminated, leading to the release of catecholamines in nerve endings and the adrenal medulla. There may be progressive confusion and delirium which may evolve into coma. The patient appears flushed and may be pyrexial but there are no extrapyramidal features. Management is by withdrawal of the precipitating medication and supportive care.

#### Anticholinergic syndrome caused by medication toxicity

In this condition, mental state changes are common, usually beginning as a mild encephalopathy with disorientation but progression to profound clouding of consciousness and coma may occur. Anticholinergic features include mydriasis, dry oral mucosa and hot erythematous skin. In contrast to the serotonin syndrome there are reduced or absent bowel sounds and no extrapyramidal features. There is a tachycardia, increased respiratory rate and occasionally urinary retention. Management is with discontinuation of the causative drugs.

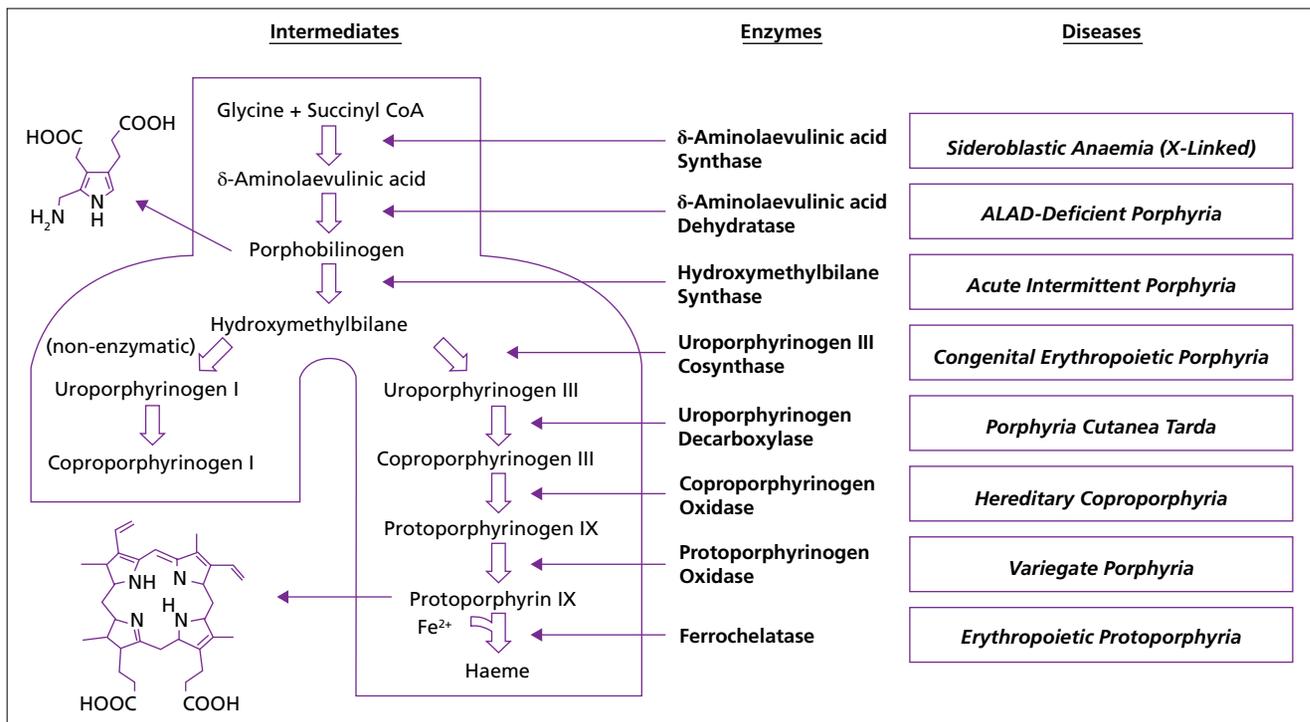

### Inherited disorders of metabolism

This section deals with neurological disease seen in adult patients with inherited disorders of metabolism. The clinical presentation, differential diagnosis, investigation and management of adult onset leukodystrophy is also discussed. The conditions described do not make up a fully comprehensive or exhaustive list of all the inherited metabolic defects that can lead to neurological abnormalities in adults, but rather represent the conditions that are more frequently encountered in a large adult metabolic clinic.

### Porphyria

The porphyrias are a group of rare conditions caused by abnormal biosynthesis of haem, which is a precursor of haemoglobin and cytochrome P450 enzymes. Most, apart from X-linked protoporphyria, are inherited in an autosomal dominant manner.

Classification is based on the tissue where metabolic intermediates accumulate (hepatic or erythrocytic) or on the clinical

**Figure 19.19** Metabolic pathway for the formation of haem.

presentation (neurovisceral or cutaneous). The most common of the acute porphyrias (acute intermittent porphyria; AIP) is caused by deficiency of the enzyme hydroxymethylbilane synthase leading to the overproduction and accumulation of the porphyrin precursors ALA ( $\delta$ -aminolevulinic acid) and PBG (porphobilinogen) which are neurotoxic. Other forms of porphyria are caused by enzyme defects at other points in the synthetic pathway (Figure 19.19).

### Acute intermittent porphyria

Most heterozygotes with this autosomal dominant condition remain asymptomatic throughout life. However, certain precipitants including drugs, a calorie deficient diet, intercurrent infection, surgery or the luteal phase of the menstrual cycle, can trigger an attack.

AIP is characterised by recurrent attacks of acute abdominal pain and neuropsychiatric manifestations, generally from the teenage years onwards. There can be an acute or subacute, predominantly motor, polyneuropathy but no skin photosensitivity. It is characterised by symptom-free periods interrupted by acute neurovisceral attacks occurring with varying frequency. Neurovisceral attacks are characterised by the acute onset of severe abdominal pain which is usually poorly localised and associated with nausea, vomiting, diarrhoea or constipation and features of an ileus. There is a secondary dysautonomia with hypertension, tachycardia, tremor, hyperhidrosis and urinary retention. Neuropsychiatric manifestations include anxiety, confusion, restlessness, agitation, insomnia and psychosis. There can be generalised seizures, sometimes in association with hyponatraemia. The polyneuropathy often follows neurovisceral attacks, but also occurs independently, and can be associated with

back pain, prominent wasting and involvement of the proximal and cranial musculature. There can be occasional mild sensory features, but profound muscle weakness sometimes progresses to involve respiratory muscles, particularly the diaphragm.

### Diagnosis

The finding of elevated urine porphobilinogen during an attack is a sensitive and specific indicator of an acute porphyria. This usually remains elevated between attacks of acute intermittent porphyria, unless there have been no symptoms for a prolonged period.

For confirmation of the diagnosis, determination of the specific enzyme deficiency, and finding of asymptomatic carriers then total urinary porphyrins, plasma porphyrins, faecal porphyrins, measurement of erythrocyte hydroxymethylbilane synthase activity and/or mutation analysis are useful. To determine the most appropriate samples for investigation discuss with a local specialist porphyria service (contact details available on [www.porphyrria-europe.org](http://www.porphyrria-europe.org)).

### Management

The greatest period of risk to patients is prior to the diagnosis being made when they and their physicians are unaware of the potential problems. Management includes the prevention of attacks by avoiding precipitating factors. Treatment during an attack is both symptomatic and specific: symptomatic care involves the use of narcotic analgesics for abdominal pain; treatment of nausea, vomiting and agitation; correction of electrolyte disturbances; maintenance of high carbohydrate intake (IV 10% glucose); and treatment of underlying precipitating factors including infection. Specific

---	---

treatment involves the use of intravenous haem arginate which acts by inhibiting aminolaevulinic acid (ALA) synthase, the rate-limiting enzyme, allowing further metabolism along the pathway and leading to rapid resolution of symptoms (though weakness and neuropathy may resolve slowly and incompletely, particularly after a prolonged severe attack).

Medications should be checked before administration to ensure that they are not known to be porphyrinogenic (including hormonal contraception, anaesthetic agents and antiepileptic drugs, particularly carbamazepine, phenytoin, phenobarbital, primidone and topiramate). Liver transplant for severe frequent attacks is effective.

### Disorders of amino acid metabolism

There are many disorders of amino acid metabolism associated with neurological abnormalities, including enzymatic deficiencies within the degradative pathways of specific amino acids (e.g. phenylketonuria, the organic acidemias, classic homocystinuria), as well as within pathways using common products of catabolism, such as the urea cycle disorders (Table 19.20).

### Phenylketonuria

Phenylketonuria (PKU) is one of the most common inherited metabolic disorders, with an incidence of about 1/10 000 live births. For more than 40 years, all newborn babies in the United Kingdom (and other countries) have been screened for PKU, and patients with PKU make up the largest cohort of any adult metabolic clinic. PKU results from a deficiency of phenylalanine hydroxylase, which converts phenylalanine into tyrosine. Hyperphenylalaninaemia can also, rarely, be caused by deficiency of tetrahydrobiopterin (a cofactor of phenylalanine hydroxylase).

The infant brain is sensitive to high phenylalanine levels and, if left untreated, PKU gives rise to severe mental retardation. Microcephaly is common and about 25% of patients with untreated PKU have epilepsy. In older patients, behavioural problems are common and some have psychotic illnesses. A few patients develop movement disorders with pyramidal and extrapyramidal signs. Although most of the pathology is related to brain damage, eczema is also common. Because of a deficiency in melanin formation (secondary to tyrosine deficiency), Caucasian patients tend to be fair-skinned with blond hair and blue eyes.

There is evidence to suggest that phenylalanine itself is toxic to the developing brain. In rare patients who have normal IQ despite very high plasma phenylalanine concentrations, magnetic resonance spectroscopy (MRS) has shown that phenylalanine concentrations in the brain are normal. Like other large neutral amino acids, phenylalanine is actively transported into the brain by the L-type amino acid carrier. It has been suggested that genetic variance in this transport system might account for the phenotypic variability seen between PKU patients with similar plasma concentrations of phenylalanine but, to date, no evidence for this has been found.

There are also secondary deleterious effects of hyperphenylalaninaemia. Because phenylalanine competes with other large neutral amino acids for transport into the brain, high levels of phenylalanine in the CNS are accompanied by low levels of other amino acids such as tyrosine and tryptophan. It has been suggested that this can lead to deficiencies in neurotransmitters, particularly dopamine, which is derived from tyrosine. A relative deficiency of large neutral amino acids can also affect protein synthesis.

MRI studies show signal abnormalities in the periventricular white matter, but these appear to relate directly to the brain concentration of phenylalanine, improving if phenylalanine levels are lowered, and it is questionable whether they have any functional consequences.

**Management** Blood and brain phenylalanine levels can be lowered by restricting dietary protein intake. Provided this dietary therapy is instituted soon after birth, PKU can be effectively treated, with intellectual outcomes similar to those of unaffected siblings. The low protein diet is highly restrictive: patients must avoid high protein foods such as meat, fish and eggs, and are allowed only limited amounts of many other staple foods such as potatoes and cereals. For normal growth and health it is therefore necessary to prescribe synthetic supplements to provide protein requirements, as a phenylalanine-free amino acid mixture, and all the vitamins, minerals and other micronutrients that are usually obtained from meat and dairy products (e.g. vitamin B<sub>12</sub>, calcium and iron). The amount of natural dietary protein allowed is titrated against blood phenylalanine concentrations which vary according to residual PAH enzyme activity which in turn is a function of the genotype. In infancy and early childhood, metabolic control needs to be strict in order to protect the developing brain and, in the United Kingdom, practice is to keep the phenylalanine level 360–480 μmol/L (normal range 33–81 μmol/L).

There is evidence that after 10 years of age the IQ of children with PKU is fixed, whether or not they remain on a strict low protein diet, implying that the brain becomes resistant to the toxic effects of phenylalanine as it matures. However, other studies have shown more subtle, reversible cognitive deficits in adult patients not on a protein-restricted diet when compared with those who have followed a diet throughout life. Current recommendations in the United Kingdom are to encourage patients to follow a protein-restricted diet with a more relaxed target phenylalanine level of 700 μmol/L in adults.

In practice, however, many adult patients choose to resume a normal diet, and their phenylalanine levels rise accordingly. There is currently no evidence that this poses any risk of irreversible neurological damage, although higher levels can affect executive function and reaction time. The current uncertainty about the effects of high phenylalanine on the adult brain is reflected in the lack of international consensus on what phenylalanine targets should be in adult patients following a protein restricted diet. Some US authors suggest that patients should maintain levels of less than 360 μmol/L throughout life while French guidelines are for adults to maintain levels under 1300 μmol/L. The authors' current practice is to

educate and support patients to achieve the phenylalanine levels where they feel they function best.

There have been some reports of spastic paraparesis developing in untreated patients, but these seem to have been secondary to vitamin B<sub>12</sub> deficiency. These patients are particularly susceptible to nutritional deficiencies as, even when dietary restrictions have been lifted, many still avoid high protein foods and follow a diet of poor nutritional quality. In these cases, it is important to monitor nutritional status carefully and continue with appropriate vitamin supplementation.

**Maternal PKU syndrome** Phenylalanine is teratogenic and high maternal levels of phenylalanine will cross the placenta and cause the maternal PKU syndrome in the fetus (intrauterine growth retardation, developmental delay, microcephaly, congenital cardiac disease and dysmorphic features). This syndrome can be prevented by meticulous maternal control of phenylalanine levels in the pre-conception period and throughout pregnancy.

### Organic acidemias

These are a group of disorders resulting from impaired activity of specific enzymes involved in the catabolism of the branched-chain amino acids – leucine, isoleucine and valine (Figure 19.20). The most common of these conditions that are seen in the adult metabolic and neurology clinic are maple syrup urine disease (MSUD), isovaleric acidemia (IVA), methylmalonic acidemia (MMA) and propionic acidemia (PA). The disorders can have common clinical presentations:

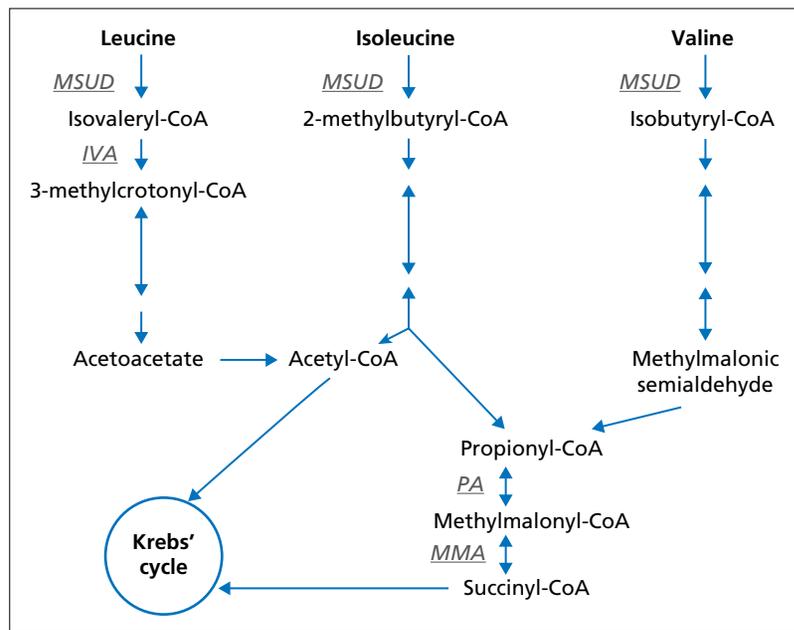

- 1 A severe neonatal metabolic decompensation with neurological impairment
- 2 An acute intermittent form with recurrent episodes of metabolic decompensation
- 3 A chronic progressive form with developmental delay, failure to thrive and neurological involvement.

Diagnosis is based on plasma amino acid analysis (e.g. MSUD), a urine organic acid profile, and confirmed by measurement of specific enzyme activities in cultured fibroblasts and/or genetic testing. Newborn screening, where available, is carried out by blood spot leucine/isoleucine (e.g. MSUD) or acylcarnitine (e.g. IVA, PA, MMA) measurement.

### Maple syrup urine disease

MSUD is caused by a defect in the catabolism of the branched-chain amino acids leucine, isoleucine and valine caused by deficiency of branched-chain α-ketoacid dehydrogenase (BCKD) (Figure 19.20). MSUD derives its name from the aroma of the accumulated ketoacids excreted in urine. Classic untreated MSUD, with complete deficiency of BCKD, usually presents in the first week of life with non-specific symptoms which rapidly progress to encephalopathy and death. Partial enzyme activity results in an intermediate phenotype with intermittent acute encephalopathic episodes, developmental delay and a spastic paraparesis.

Neurotoxicity is directly related to the degree and duration of elevation of the plasma leucine level. Acute leucine intoxication is characterised by confusion, hyperactivity, hallucinations, dystonia, ataxia and eventually coma. There is some evidence to suggest that leucine competitively inhibits transport of other large neutral amino acids (LNAAs), such as tyrosine, across the blood–brain barrier. Low cerebral tyrosine has been implicated in some of the acute symptoms of leucine toxicity. A chronic cerebral protein deficiency, secondary to the effects of leucine on other LNAAs levels and on general protein restriction as part of treatment, may result in

**Figure 19.20** Catabolism of the branched chain amino acids (the organic acidurias). The branched chain amino acids, leucine, isoleucine and valine, are initially catabolised by a common pathway. Subsequently, leucine is catabolised to acetoacetate and acetyl-CoA which enters the Krebs' cycle (tricarboxylic acid, TCA). Acetyl CoA and propionyl-CoA are derived from isoleucine. PropionylCoA also enters the Krebs' cycle via conversion to succinyl-CoA. Valine is also metabolised to propionyl-CoA. Maple syrup urine disease (MSUD) is caused by deficiency of the branched-chain 2-ketoacid dehydrogenase complex; isovaleric acidemia (IVA) by isovaleryl-CoA dehydrogenase deficiency; propionic acidemia (PA) by propionyl-CoA carboxylase deficiency; and methylmalonic acidemia (MMA) by methylmalonyl-CoA mutase deficiency or deficiency of its cofactor adenosylcobalamin (see Figure 19.23).

paucity of dendritic branching and suboptimal myelination and contribute to the developmental delay seen in many patients.

**Management** With timely treatment, death and neurodisability can be avoided even in the severe classic forms of MSUD. In the acute phase, high leucine levels can rapidly be reduced by haemofiltration. Long-term management is dietary. The principles of treatment are to restrict dietary protein to reduce levels of the toxic metabolite, to provide a synthetic amino acid supplement, lacking the toxic metabolite and containing trace elements and vitamins, to replace protein requirements and allow normal growth and development and to prevent protein catabolism at times of fasting or physiological stress using a high carbohydrate emergency regimen. Patients collect regular blood spots at home (using the same Guthrie cards as in newborn screening) so that leucine levels can be monitored and their dietary protein intake adjusted accordingly.

With timely diagnosis and rapid reduction of leucine levels in the newborn period the prognosis can be good. Normal intellectual ability is possible, but is dependent on meticulous long-term dietary treatment with expectant management of intercurrent illnesses. Several countries, including the United Kingdom, now perform newborn screening for MSUD.

### Isovaleric acidemia

Isovaleric acidemia (IVA) is caused by deficiency of isovaleryl-CoA dehydrogenase, a mitochondrial flavoenzyme (Figure 19.20). The severity of its clinical phenotype is variable and asymptomatic patients are known. Management is with a restricted protein diet and supplemental glycine and carnitine. Metabolic crisis in adulthood is unlikely.

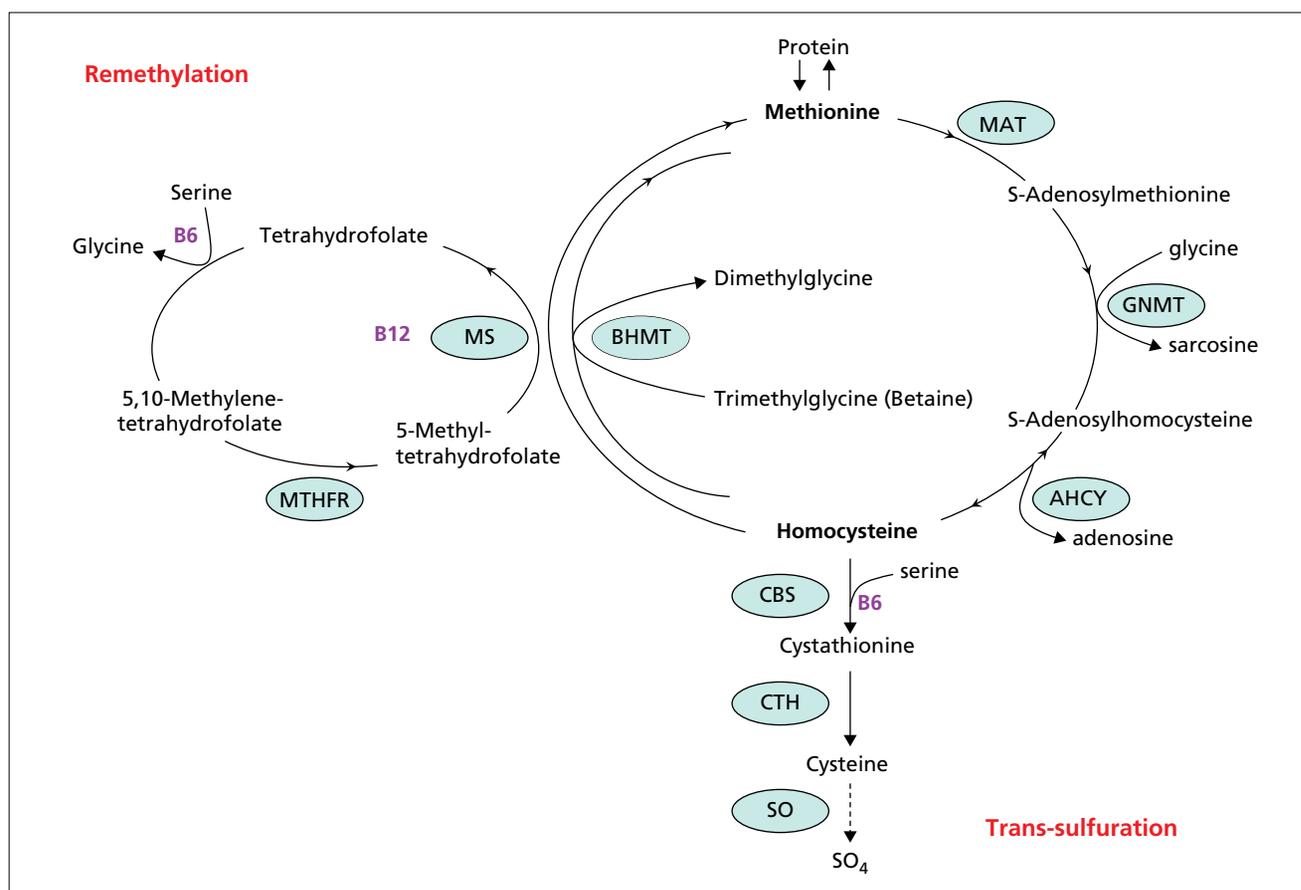

### Propionic acidemia and methylmalonic acidemia

Propionic and methylmalonic acid are biochemical intermediaries of BCAA degradation, and both have fundamental roles in energy production, in the degradation of other amino acids, fatty acid metabolism, the Krebs' cycle, gluconeogenesis and the detoxification of ammonia (Figure 19.20). Complete deficiency of either propionyl CoA carboxylase or methylmalonyl CoA mutase (MUT 0) results in severe neonatal encephalopathy, often fatal. Partial deficiency or defects in the synthesis of a cofactor such as adenosylcobalamin can present either in a similar manner or subacutely, but are more amenable to treatment.

Classic MMA and PA present in the neonatal period with non-specific signs that rapidly progress to lethargy, seizures and coma. Patients typically demonstrate a severe metabolic acidosis with increased anion gap, ketonuria, a variable pancytopenia and hyperammonaemia. Intermediate phenotypes including cofactor defects can present later in life with acute encephalopathy, developmental delay, a movement disorder or behavioural disturbances. Specific insults to the basal ganglia result in choreoathetosis with compatible radiological findings.

**Management** Some patients with MMA respond to intramuscular vitamin B<sub>12</sub> and all patients should be offered a trial of this. Subsequent treatment includes a protein restricted diet, prevention of catabolism, supplementation of vitamins and trace elements, and use of an emergency regimen during periods of acute decompensation.

**Long-term complications** Both PA and MMA require surveillance for long-term problems: acute pancreatitis, cardiomyopathy, osteopenia, an acute and/or chronic extrapyramidal disorder, premature

**Figure 19.21** Methionine is converted to S-adenosylmethionine by the enzyme methionine S-adenosyltransferase (MAT). S-adenosylmethionine is a methyl-group donor for a number of transmethylation reactions. One of these reactions produces S-adenosylhomocysteine, which is cleaved to adenosine and homocysteine by S-adenosylhomocysteine hydrolase (AHCY). Homocysteine is then either recycled back into methionine or condensed with serine to form cystathionine. The condensation reaction is catalysed by cystathionine beta-synthase (CBS). Remethylation is catalysed by cobalamin-requiring methionine synthase (MS), or by betaine-homocysteine methyltransferase (BHMT). The methyl group is transferred to cobalamin from 5,10-methylenetetrahydrofolate which is regenerated in the folate cycle (requires 5,10-Methylenetetrahydrofolate reductase (MTHFR)). Cystathionine is cleaved to cysteine and alpha-ketobutyrate by cystathionine gamma-lyase (CTH). The final step of trans-sulfuration is catalysed by sulfite oxidase (SO) and converts sulfite to sulfate. GNMT Glycine N-methyltransferase.

ovarian insufficiency, optic atrophy and sensorineural hearing loss. Complications can occur even in the presence of apparently good metabolic control. Progressive renal glomerular and tubular disease are specific features of MMA and in some cases can be very aggressive leading to end-stage renal failure.

### Disorders of homocysteine metabolism

The methionine-homocysteine cycle, also known as the single carbon transfer pathway, is found in all tissues and can broadly be divided into transsulfuration and remethylation components (Figure 19.21). The cycle aims to conserve methionine and provide sufficient S-adenosylmethionine for vital transmethylation reactions. Vitamin B<sub>12</sub> (cobalamin, Cbl) is important in the effective metabolism of homocysteine and thus defects of cobalamin absorption, transport and intracellular metabolism have biochemical and clinical consequences, similar to HCU.

### Transsulfuration defects

**Homocystinuria (Table 19.21)** Homocystinuria (HCU) is an autosomal recessive defect caused by deficiency of the enzyme cystathionine β-synthase (CBS), and characterised biochemically by

elevated plasma homocysteine and methionine and decreased cysteine. Classic clinical manifestations involve the eye, skeleton, central nervous and vascular systems, but the age of onset and severity vary widely among affected individuals. Reported neurological involvement includes developmental delay, mental retardation, dystonia, seizures and psychiatric disturbances. As there are effective treatments, neonatal screening is available in some countries.

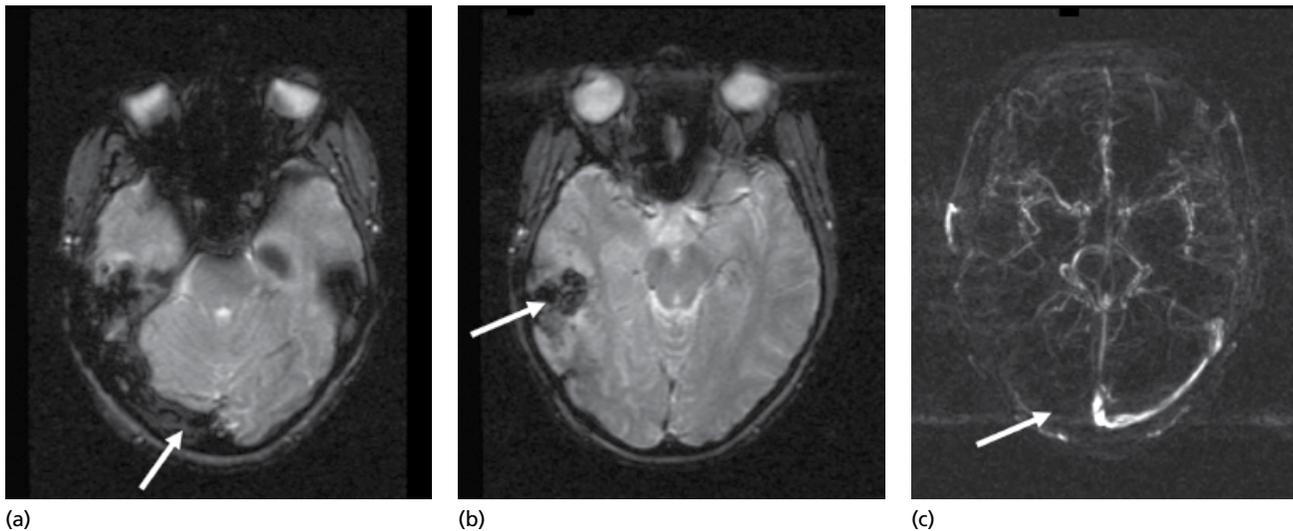

HCU is a cause of stroke in childhood and adulthood (Chapter 5). Cerebral infarction is caused by arterial or venous sinus thrombosis (Figure 19.22). Occlusive vascular disease results in cognitive decline and is associated with significant morbidity and mortality. Without treatment, just over one-third of patients with HCU will have a thromboembolic event, with cerebrovascular accidents accounting for one-third of these. Pregnancy, the combined oral contraceptive pill and other typical risk factors for thrombosis are well-recognised precipitants in patients with HCU. It is important to remember that thrombosis can be the first and *only* manifestation of Homocystinuria. However, there is an 85% risk reduction in vascular events among adequately treated patients.

Approximately 20% of untreated patients will develop seizures. Again, these are largely preventable by early effective treatment.

**Table 19.21** Disorders of homocysteine metabolism.

Disorder		Enzyme/protein deficiency	Gene	EC number/ gene map locus	Cognitive impairment	Other neurological features	Met	tHcy	MMA	B12	Folate	Treatment options

**Figure 19.22** Transverse venous sinus thrombosis presenting in a pregnant women subsequently diagnosed with homocystinuria (HCU). (a) A 33-year-old woman presented at 11 weeks' gestation with a severe headache secondary to a right transverse sinus thrombosis. (b) She also had acute haemorrhage in the right posterior temporal lobe (b). (c) On MR venogram she had a filling defect in the right transverse venous sinus. She was found to have severe hyperhomocystinaemia, tHcy 214  $\mu\text{mol/L}$  (reference range 0–15  $\mu\text{mol/L}$ ), and was subsequently diagnosed with HCU. She had previously had one miscarriage and one normal pregnancy. She was treated with subcutaneous heparin 7500 units twice daily, folic acid 5 mg/day, oral vitamin B<sub>12</sub> 50  $\mu\text{g/day}$  and pyridoxine 300 mg/day. By the third trimester her total homocysteine level had fallen to 6  $\mu\text{mol/L}$ . The remainder of pregnancy was uneventful and she delivered a normal, healthy child. Heparin was continued for 2 months post-partum. In addition post-partum warfarin 3.5 mg/day was continued for 2 years until the venous sinus became patent again 2 years later. Source: Murphy 2010. Reproduced with permission of Oxford University Press, USA.

Psychiatric features are frequently reported in patients with HCU, although the precise prevalence is uncertain. Clinically significant diagnoses have included depression, chronic behavioural abnormalities, obsessive–compulsive disorder and personality disorders.

**Management** The aim of treatment is to reduce total homocysteine levels to at least less than 100  $\mu\text{mol/L}$  and preferably to as close to normal as possible, lifelong. In those patients diagnosed by neonatal screening, the aim is to prevent intellectual impairment, neurological, vascular, ocular and skeletal complications. In later diagnosed patients, the aim is to prevent vascular events and worsening of existing complications.

Adequate B<sub>12</sub> and folate status should be ensured for all patients with HCU. Vitamin B<sub>6</sub> (pyridoxine) is a cofactor for the enzyme CBS. Hence, some patients with homocystinuria are vitamin B<sub>6</sub> (pyridoxine) responsive. A large international natural history survey identified 629 patients, of whom 36% were classed as B<sub>6</sub>-responsive, 36% B<sub>6</sub> non-responsive and the remainder either unclassified or intermediate in response. It is important to ensure adequate folate status before testing for B<sub>6</sub>-responsiveness to prevent masking of potential responsiveness by less than optimal N5-methyltetrahydrofolate-dependent homocysteine remethylation. To test for pyridoxine responsiveness it is recommended to give 500 mg/day, checking homocysteine at baseline and again after 6 weeks. Ideally, once responsiveness has been determined, the dosage should be reduced incrementally until the lowest effective dose for maintenance therapy is reached.

For B<sub>6</sub> non-responsive patients, in those countries where patients are identified by newborn screening, then a natural protein-restricted diet supplemented by a synthetic methionine-free, cystine-supplemented amino acid mixture is introduced. However, starting a low-protein diet is often unpalatable to older children and adults, so that many of these are treated with medications

alone. Betaine is a methyl donor that has been shown to reduce homocysteine and raise methionine concentrations by increasing homocysteine methylation via betaine-homocysteine methyltransferase. Doses of betaine up to 9 g/day in divided doses have been given in adults. Plasma methionine increases on betaine therapy, and the dosage is usually adjusted to maintain plasma methionine levels <1000  $\mu\text{mol/L}$  to reduce the risk of cerebral oedema.

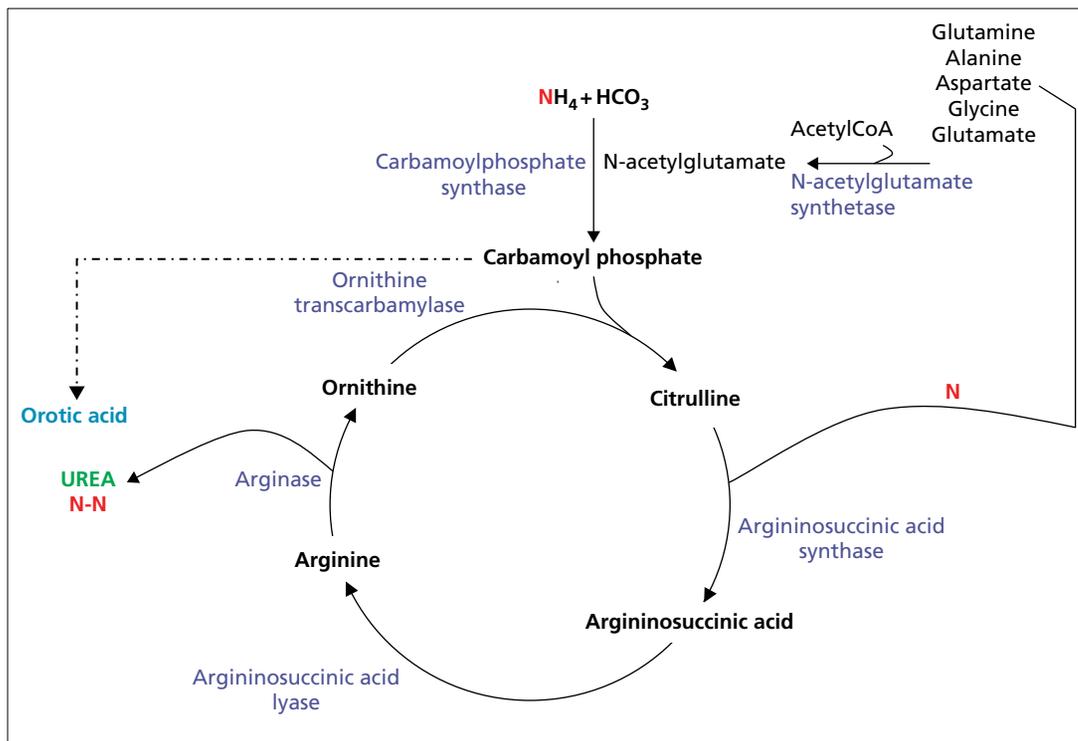

#### Defects in intracellular cobalamin metabolism

Eight distinct defects of the intracellular cobalamin pathway have been identified by fibroblast studies and complementation analysis (Figure 19.23). Dependent on their location in the pathway, these defects can lead to combined hyperhomocystinaemia and methylmalonic acidemia (cblE, cblC, cblD-hyperhomocystinaemia and methylmalonic acadaemia), isolated hyperhomocystinaemia (cblD-hyperhomocystinaemia, cblE, cblG) or isolated methylmalonic aciduria (cblA, cblB, cblD-methylmalonic acidemia, MUT).

**Cobalamin C (CblC) defects** Defects in CblC with combined hyperhomocystinaemia and methylmalonic acidemia are the most common of the disorders of the intracellular cobalamin pathway. Neonatal presentation is associated with progressive neurological deterioration, and ophthalmologic, haematologic and dermatologic abnormalities. Later onset cases have been described with learning difficulties, dementia and gait abnormalities.

**Management** All Cbl defects can be treated with parenteral B<sub>12</sub>, although this does not always reverse or prevent clinical complications. Intravenous therapy may be given for the first days following an acute presentation and then switched to frequent intramuscular hydroxocobalamin (the dose required will vary but may be up to 1 mg/daily, lifelong). Betaine and folic acid can also be useful.

**Figure 19.24** The urea cycle. Ammonia, from amino acid catabolism, is detoxified to urea in the liver. Urea is then excreted in the urine. One turn of the urea cycle results in the disposal of two nitrogen atoms, one from  $\text{NH}_3$  and one from aspartate. The cycle consists of six enzymatic reactions: three in the mitochondrial matrix (carbamoylphosphate synthetase 1 [CPS1], ornithine transcarbamylase [OTC] and N-acetylglutamate synthetase [NAGS]) and three in the cytosol (argininosuccinate synthetase [ASS], argininosuccinate lyase [ASL] and arginase [ARG]). Defects of all six enzymes have been described. X-linked OTC deficiency is the most common. The other disorders are autosomal recessive in inheritance.

Encephalopathy in the context of an adult patient with an inherited metabolic disease, can be intermittent, fluctuating or rapid and fulminant progressing to coma. Patients can present with reduced cognition and concentration, a change in personality (often agitated and/or aggressive), lethargy, vomiting or decreased consciousness and coma. Neurological findings include seizures, abnormal posturing, abnormal gait and poor coordination. Symptoms are often reversible with early treatment and consideration of a metabolic component should be given to any adult who presents with encephalopathy. Late-onset 'milder' inherited metabolic conditions in adults are often unmasked by intercurrent infection, alcohol or drug (mis)use, and so physicians should be wary of attributing all encephalopathic symptoms to these, particularly if patients are not responding as expected to standard treatments. Information about previous unusual behaviours (e.g. protein aversion, unexplained episodes of confusion or agitation) should be sought from family and friends.

All adults who present with acute or acute-on-chronic encephalopathy in whom there is no obvious cause (e.g. recent trauma or hypoxia) should have a plasma ammonia level measured promptly.

By far the most common cause of hyperammonaemia in adults is hepatic failure, often associated with portosystemic shunting. Once this has been excluded as a cause then consideration should be given to other secondary causes, and defects of the urea cycle are important amongst these. Hyperammonaemia can occur secondary to a fatty acid oxidation disorder or an organic acidemia – but is much more frequently a result of these conditions in infancy or childhood than in adulthood. An important secondary cause of

elevated ammonia is valproate therapy, which can precipitate hyperammonaemia, including in individuals with a previously unknown urea cycle defect.

While the precise underlying cause of hyperammonaemia can take some time to elucidate, treatment can be started immediately to avoid death or long-term neurological damage. The aims of treatment are to reduce nitrogenous waste production and lower plasma ammonia before cerebral oedema develops.

### Diagnosis

Definite diagnosis should not delay immediate treatment but appropriate samples (including plasma amino acids, an acylcarnitine profile, urine organic acids) should be taken, preferably during the acute presentation, in order that chronic management can be tailored and genetic counselling can be given to both the index patient and other potentially affected family members.

### Management

In severe hyperammonaemia with marked encephalopathy, seizures or coma, haemodialysis is the most efficient way to reduce plasma ammonia (peritoneal dialysis is not as efficient and should be avoided). Vascular access should be secured and haemodialysis started as soon as possible in the HDU or ITU setting.

Protein intake should be stopped for 24–48 hours, and a hypercaloric solution (intravenous 10% dextrose; intralipid may also be given) started, with insulin if needed to enhance anabolism. Intravenous arginine and alternative pathway therapies (sodium benzoate and sodium phenylbutyrate) will promote the excretion of

nitrogen-containing metabolites in the urine, as an alternative to urea formation.

Long-term management will require input from a specialist centre to ensure appropriate dietary advice (including supplementation of vitamins and minerals in those on a restricted diet) and titration of oral medications to ensure optimal metabolic control. Protocols for the management of hyperammonaemic encephalopathy can be found on the British Inherited Metabolic Disease Group website ([www.bimdg.org.uk](http://www.bimdg.org.uk)).

### Arginase deficiency

Arginase deficiency is an atypical UCD in that hyperammonaemia is not generally the presenting feature. Instead, there is failure to thrive and children have developmental delay and a progressive spastic diplegia. Epilepsy can also be a feature. In patients diagnosed by newborn screening, if arginine levels are controlled with the use of a low protein diet and essential amino acid supplements, neurological disease can be slowed. In late diagnosed patients, controlling arginine levels can improve symptoms and slow progression.

## Disorders of carbohydrate metabolism

### Glycogen storage diseases (the GSDs)

Glycogen is a macromolecule composed of up to 60 000 linked glucose molecules. It is the primary energy source between meals, with a series of metabolic reactions releasing stored glucose as needed. Glycogen is found in many tissues, being particularly abundant in liver and muscle. Many disorders of glycogen synthesis or breakdown are described. Clinically, these are broadly divided into those that predominantly affect the liver (e.g. types 0, I, III, VI and IX), those mainly affecting skeletal and/or cardiac muscle (e.g. types II, V, VII, and XV) and those that are associated with neurodegeneration (e.g. Lafora disease and some of the polyglucosan body storage disorders; Table 19.20).

### Hepatic involvement in glycogen storage diseases

The hepatic forms do not generally have specific neurological manifestations apart from the potential consequences of severe prolonged hypoglycaemia which can cause encephalopathy, seizures and even death.

### Skeletal/cardiac muscle involvement in glycogen storage diseases

**Pompe disease/acid maltase deficiency (GSD II)** GSD II is caused by lysosomal acid maltase deficiency and can either cause infantile Pompe disease with a significant cardiomyopathy and generalised myopathy, or late onset disease with a limb girdle dystrophy presenting in later childhood or adulthood. Without specific therapy, infantile Pompe disease is invariably fatal. Late onset acid maltase deficiency causes progressive weakness with diaphragmatic involvement and leads to death following respiratory failure. Since 2006, enzyme replacement therapy, which is modifying the natural history of the disorder, has been available.

**GSD III** GSD type III is caused by glycogen debrancher deficiency. An echocardiographic appearance of hypertrophic cardiomyopathy has been documented in many individuals. Its clinical significance is uncertain, however, as most affected individuals are asymptomatic, though severe cardiac dysfunction, congestive heart failure and sudden death have occasionally been reported. There have also been a few case reports of a diet high in protein and limited in carbohydrate reducing severe cardiac hypertrophy.

Skeletal myopathy often becomes prominent in the third to fourth decade of life. Proximal muscles are primarily affected but involvement of the diaphragm and distal muscles including the calves, peroneal muscles and hands is also described. Exercise intolerance is reported.

**McArdle disease (GSD V) (Chapter 10)** GSD V is characterised by muscle pain that typically comes on within a few minutes of starting exercise. Exercise tolerance (reduction in heart rate) may improve after 7–10 minutes if aerobic exercise (e.g. jogging, cycling) is continued but at a slower, gentler pace – this is called the second-wind phenomenon. Static or isometric exercise (e.g. bench press, shoulder raises, carrying heavy shopping) is poorly tolerated, as is sprinting. Some older patients may have evidence of a fixed proximal myopathy with wasting.

**Diagnosis** Laboratory tests will show elevated creatine kinase, urate and myoglobinuria and, in severe cases, renal impairment. In up to 85% of patients from northern Europe, a common mutation R50X can be detected, and so, in patients with a typical clinical history, genetic mutation analysis can be used as a first line diagnostic test. GSD V can also be confirmed by muscle biopsy which shows an excess of glycogen and absence of muscle phosphorylase. The ischaemic forearm exercise test, with measurement of lactate and ammonia, the traditional screening test for muscle disorders of carbohydrate metabolism, is less often performed now as it is painful for the patient, not specifically diagnostic for GSD V and has been largely superseded by genetic testing.

**Management** Acute severe rhabdomyolysis should be treated with prompt fluid (normal saline) replacement and renal support as required. Intravenous dextrose during acute crises and oral sucrose prior to exercise may also be helpful. Patients should be given advice on safe forms of exercise and how to achieve the second-wind phenomenon.

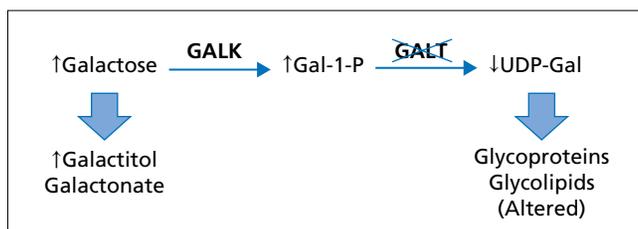

### Central nervous system involvement in glycogen storage diseases

**Lafora disease** Lafora disease is characterised by seizures, often with visual hallucinations that typically start during adolescence, followed by progressive myoclonus, severe dementia with dysarthria and ataxia. Most affected individuals die within 10 years of onset, usually from status epilepticus or from complications related to nervous system degeneration. It is caused by mutations in one of two genes: *EPM2A* (laforin) or *NHLRC1* (malin). Diagnosis is confirmed by mutation analysis. A skin biopsy will show abnormal inclusions – the Lafora bodies.

**Adult polyglucosan body disease (GSD IV)** GSD type IV, caused by glycogen branching enzyme deficiency, can present in various forms including cirrhosis and liver failure, or, in its adult form, with progressive gait disturbance, urinary incontinence, upper and lower motor neurone dysfunction, distal sensory loss and cerebellar dysfunction. Histopathological findings include large polyglucosan bodies which contain abnormally long and poorly branched glucosyl chains.

### Galactosaemia

Classic galactosaemia is an autosomal recessive inborn error of metabolism caused by mutations of the *GALT* gene, resulting in markedly reduced function of the enzyme galactose-1-phosphate

**Figure 19.25** Simplified scheme of disturbance of galactose metabolism in classic galactosaemia.

Deficiency of galactose-1-phosphate uridylyltransferase (GALT, crossed) leads to altered metabolites with increases in galactose, galactitol, galactonate, and Gal-1-P (galactose-1-phosphate), and reduction in UDP-Gal (uridine diphosphate-galactose), a sugar required for normal galactosylation of glycoproteins and glycolipids. GALK (Galactokinase). Source: Rubio-Agusti 2013. Reproduced with permission of John Wiley & Sons.

uridylyltransferase (GALT) and subsequent accumulation of galactose-1-phosphate (Gal-1-P), galactose and derived metabolites, through alternative pathways (Figure 19.25). It has an estimated prevalence of 1/30 000 newborn babies. Diagnosis can be established by demonstrating increased levels of erythrocyte Gal-1-P and decreased activity of erythrocyte GALT (<5%).

Galactosaemia presents almost invariably in the neonatal period with acute multiple organ dysfunction, often involving the liver, after newborn infants are exposed to dietary galactose. Although it can be fatal if untreated, acute symptoms resolve rapidly with galactose restriction. Despite adequate treatment, however, surviving patients can develop long-term complications, such as premature ovarian failure and CNS dysfunction, including cognitive difficulties, psychiatric symptoms, speech and motor problems.

Motor complications have been reported in 18–45% of patients, with the most common features being tremor and cerebellar ataxia. There is a wide spectrum of severity, with some patients showing mild abnormalities on examination and others with disabling symptoms. Following a systematic clinical examination of all patients attending our clinic with galactosaemia, we found a higher proportion of motor dysfunction, reaching 66%, although only 28% of our patients reported symptoms. Mild motor dysfunction might therefore be missed in some patients unless carefully they are carefully examined. Patients with evidence of motor dysfunction also had a higher frequency of other non-motor neurological features, including cognitive impairment, psychiatric problems and speech difficulties, suggesting a common pathogenic mechanism, leading to widespread CNS damage.

**Management** Current recommendations are that dietary restriction of galactose is continued lifelong. However, there are a few reports of adults on unrestricted or more relaxed diets in whom the outcome is similar to that of patients who have continued on dietary galactose restriction. This remains therefore an active area of research.

### Fatty acid oxidation defects

Mitochondrial oxidation of fat is an important energy source for many tissues, especially during fasting or sustained aerobic exercise. At these times, long-chain fatty acids are released from triglyceride stores in adipose tissue and transported to other tissues in the blood. Short- and medium-chain fatty acids can diffuse

across the mitochondrial membrane, but long-chain fatty acids require a specific transport mechanism (Figure 19.26). Long-chain acyl-CoA compounds are conjugated with carnitine to form acyl-carnitines, which are then transported into the mitochondrial matrix by carnitine palmitoyltransferases (CPTs). Once inside the mitochondria, the carnitine is recycled to the cytoplasm and the acyl-CoA esters enter the  $\beta$ -oxidation pathway. Each  $\beta$ -oxidation cycle shortens the acyl chain by two carbon atoms and results in the production of one molecule of acetyl-CoA which can then enter the tricarboxylic acid (TCA) cycle or, in the liver, be used to generate ketone bodies.

About 15 inherited fatty acid oxidation (FAO) disorders have been described (Table 19.20). Many of these are life-threatening diseases of childhood and present with hypoketotic hypoglycaemia, encephalopathy and hepatic dysfunction. Milder phenotypes can present in adulthood, causing exercise intolerance, episodic rhabdomyolysis and neuropathy.

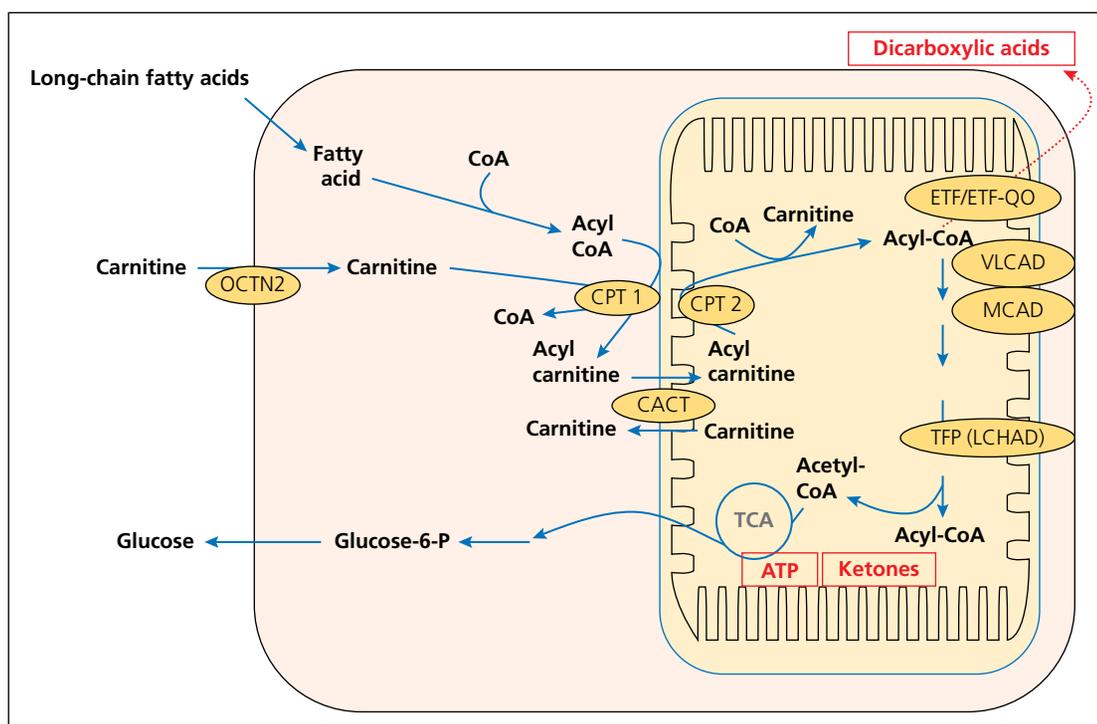

Although resting skeletal muscle relies on low level FAO for energy, during exercise there is a switch to utilising muscle stores of glycogen. Once these have been depleted (after about 5–10 minutes), the main fuels become the muscles' stores of triglycerides and glucose from the circulation. As exercise continues, the supply of free fatty acids becomes more important and, after about an hour, mitochondrial FAO is once again the major source of energy for muscle. In the milder FAO defects, residual FAO is adequate to supply the resting energy requirements of muscle, but is insufficient during extended exercise, resulting in muscle cell death and rhabdomyolysis.

FAO disorders such as carnitine palmitoyltransferase 2 (CPT2) or very long chain acyl-CoA dehydrogenase (VLCAD) deficiencies can present for the first time in adolescence or adulthood. The presentation is typically with symptoms of myalgia, muscle stiffness and/or rhabdomyolysis after more prolonged exercise (e.g. playing football or marathon running). Prolonged fasting, cold exposure, intercurrent infection or even emotional stress are other well-recognised precipitants. Symptoms may last for a number of weeks following an acute attack, but patients may be completely asymptomatic, with normal muscle strength on examination, between attacks.

Medium-chain acyl-CoA dehydrogenase deficiency (MCADD) is the most common FAO defect with an incidence of 1/10 000 live births. Patients usually present with hypoglycaemic hypoketotic encephalopathy towards the end of the first and into the second year of life. Because a significant number of affected infants either die or have significant cerebral damage in this first episode, neonatal screening is now widely available. Rare patients will present for the first time in adulthood with rhabdomyolysis or cardiomyopathy.

Multiple acyl-CoA dehydrogenase deficiency (MADD), also known as glutaric aciduria type II (GA-II), is caused by mutations in a number of different proteins that are involved in the mitochondrial transport of electrons from acyl-CoA to ubiquinone. This results in a functional defect in a number of acyl-CoA dehydrogenases involved both in  $\beta$ -oxidation and in the degradation of branched-chain amino acids. The more severe forms lead to early death with non-ketotic hypoglycaemia and acidosis, but adult onset disease has also been described. This can involve metabolic decompensation, hypotonia, cardiomyopathy and, rarely, leukodystrophy with spastic quadriplegia. In milder cases, there is only a lipid storage myopathy and rhabdomyolysis. Biochemically, organic acids are detectable in the urine and there is a secondary carnitine deficiency.

The final stages of  $\beta$ -oxidation of long-chain fatty acids is catalysed by an enzyme complex termed the mitochondrial trifunctional protein (TFP). Isolated long-chain 3-hydroxyacyl-CoA

**Figure 19.26** Fatty acid oxidation. Fatty acids enter the mitochondria. Medium- and short-chain fatty acids enter independently of carnitine, but long-chain fatty acids need to be activated to coenzyme A and transferred to carnitine (CPT1, carnitine palmitoyltransferase I) in order to cross the inner mitochondrial membrane (CACT, carnitine acylcarnitine translocase). They are then transferred back to CoA esters in the mitochondrial matrix (CPT2, carnitine palmitoyltransferase II). Beta-oxidation is catalyzed by enzymes of different fatty acid chain length specificity (VLCAD, MCAD, TFP(LCHAD)). Electrons are passed to the respiratory chain either directly or via transfer proteins (ETF, ETF-QO). Acetyl-CoA can be oxidized in the tricarboxylic acid (TCA, Krebs) cycle or, in the liver, used to synthesize ketone bodies. ETF: electron transfer flavoprotein; ETF-QO: electron transfer flavoprotein ubiquinone oxidoreductase; MCAD: medium-chain acyl-CoA dehydrogenase; OCTN2: high affinity sodium-dependent carnitine transporter; VLCAD: very-long-chain acyl-CoA dehydrogenase; TFP (LCHAD): mitochondrial trifunctional protein (long chain acyl CoA dehydrogenase).

dehydrogenase deficiency is the most common form of MTP deficiency. Patients present either acutely with hypoglycaemia, liver failure and cardiomyopathy, or more chronically with feeding problems and hypotonia. Long-term complications include retinopathy and peripheral neuropathy. Exercise intolerance and episodic rhabdomyolysis may also occur.

### Diagnosis

If there is a strong suspicion of a fatty acid oxidation disorder, then a muscle biopsy should be avoided. Instead a typical acylcarnitine profile (plasma or blood spot) will suggest the condition which can then be confirmed by measurements of fatty acid oxidation and/or CPT2 enzyme activity in skin fibroblasts (grown from a punch skin biopsy). Genetic testing allows screening of other potentially affected family members.

### Management

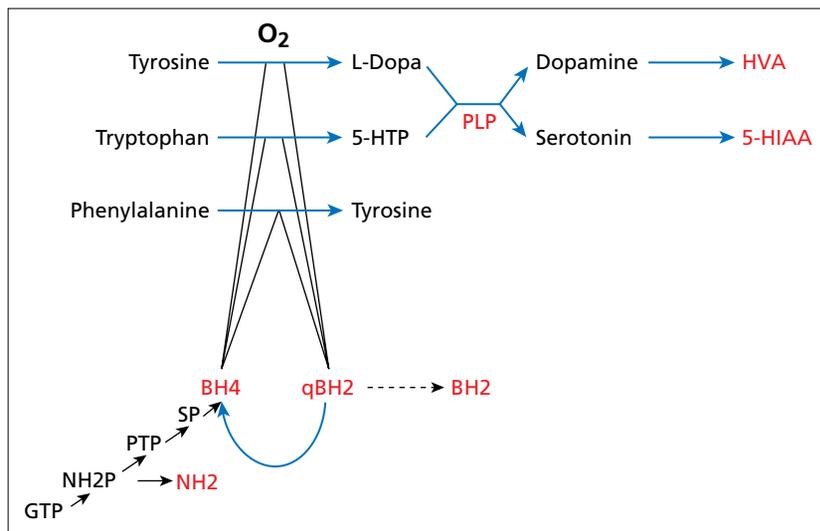

Acute severe rhabdomyolysis (Chapter 10) should be treated with prompt fluid (saline) replacement, intravenous dextrose and renal support as required. Other measures that may be helpful in preventing recurrent symptoms include restriction of dietary long-chain fat, with substitution by medium-chain triglyceride (MCT), carbohydrate or triheptanoin. The lipid lowering agent, bezafibrate (200 mg three times daily) has been shown to increase CPT II enzyme activity in muscle and reduce the number of attacks of

rhabdomyolysis. In some patients with fatty acid oxidation disorders cannot achieve the second-wind phenomenon.

### Neurotransmitter disorders

The term neurotransmitter disorder usually refers to those disorders that can be identified by analysis of CSF. These include the inherited disorders of dopamine and serotonin metabolism along with disorders affecting the availability of the vitamins, pyridoxal phosphate (PLP) and 5-methyltetrahydrofolate (5-MTHF) (Figure 19.27).

Dopamine and serotonin both require the presence of the cofactor tetrahydrobiopterin (BH4) to catalyse the first committed step of their biosynthesis. The initial enzymes in the pathway, tyrosine and tryptophan hydroxylase, work in concert with BH4 and the substrates tyrosine and tryptophan to generate L-dihydroxyphenylalanine and 5-hydroxytryptophan (5-HTP). A single PLP-dependent enzyme, aromatic amino acid decarboxylase (AADC), then catalyses the conversion of L-dihydroxyphenylalanine and 5-HTP to form dopamine and serotonin. These neurotransmitters can be packaged into synaptic vesicles and liberated in response to an action potential. Upon release, the neurotransmitter can be taken back into the presynaptic neurone and repackaged into vesicles or metabolised further. With regards to dopamine, the action of catechol methyl transferase, monoamine oxidase and aldehyde dehydrogenase results in the formation of homovanillic acid (HVA). For serotonin, the action of monoamine oxidase leads to generation of

**Figure 19.27** Dopamine and serotonin metabolism. Dopamine and serotonin are synthesised via tyrosine hydroxylase and tryptophan hydroxylase and aromatic amino acid decarboxylase activity. Molecular oxygen and BH<sub>4</sub> are the obligatory cofactors for these two hydroxylases. BH<sub>4</sub> is synthesised, de novo, from guanosine triphosphate (GTP) via a number of enzymatic steps. GTP cyclohydrolase catalyses the conversion of GTP to dihydroneopterin triphosphate (NH<sub>2</sub>P). 6-pyruvoyal tetrahydropterin (PTP) is formed from NH<sub>2</sub>P via the action of PTP synthase. Aldose reductase generates sepiapterin (SP) from PTP. SP is then transformed to the active BH<sub>4</sub> cofactor as a consequence of sepiapterin reductase activity. When acting as a cofactor, BH<sub>4</sub> is oxidised to quinonoid dihydrobiopterin (qBH<sub>2</sub>). A recycling system, comprising of dihydropteridine reductase plus pterin-4a-carbinolamine dehydratase, regenerates BH<sub>4</sub> from qBH<sub>2</sub>. The concentration of the metabolites in red can be quantified in CSF to provide insight into the integrity of dopamine, serotonin, BH<sub>4</sub> and PLP metabolism. NH<sub>2</sub> is the dephosphorylated form of NH<sub>2</sub>P and BH<sub>2</sub> is the stable rearrangement product of qBH<sub>2</sub>. Note BH<sub>4</sub> is also required for the hepatic metabolism of phenylalanine to tyrosine via phenylalanine hydroxylase.

5-hydroxyindoleacetic acid (5-HIAA). Assessment of HVA and 5-HIAA is used to provide an indication of the integrity of central dopamine and serotonin metabolism, respectively.

### Clinical presentations

Dopa-responsive dystonia (DRD, Segawa syndrome) is classically caused by a dominantly inherited mutation in the GTP cyclohydrolase 1 gene. Patients typically present in childhood with lower limb dystonia, parkinsonism and sometimes a degree of spasticity. Symptoms often show diurnal fluctuation so that they get worse as the day goes on. Not all patients represent with this classic phenotype. Some present in infancy with a more severe phenotype, while others present in late teens or early adult life with asymmetric tremor and bradykinesia mimicking early onset Parkinson's disease. Response to small doses of levodopa is typically very dramatic and this response is sustained in the long-term. For this reason all those with young-onset dystonia in whom there is no known cause should be investigated for DRD or at least have a trial of levodopa (Chapter 6).

Patients with other defects in the pterin pathway (e.g. sepiapterin reductase deficiency, tyrosine hydroxylase deficiency, rare patients with homozygous GTP cyclohydrolase 1 mutations) present with an earlier onset and more severe phenotype characterised by oculogyric crises, severe dystonia, spasticity, parkinsonism, myoclonus and cognitive impairment. A similar phenotype is seen in those with AADC deficiency or central folate disorders. Parkinsonism, dystonia, chorea, oculogyric crises, ptosis, hypersalivation, myoclonic epilepsy, epileptic encephalopathy, cognitive decline, microcephaly, swallowing difficulties, pyramidal tract features, temperature instability and sweating can form part of the clinical picture. Additionally, decreased PLP availability is associated with a neonatal epileptic encephalopathy that can be refractive to antiepileptic drugs. White matter changes may also be

apparent because of the critical involvement of 5-MTHF and one carbon metabolism in myelin formation.

### Laboratory diagnosis

Inherited disorders of dopamine and serotonin metabolism can exhibit a highly informative pattern in CSF. Patients with tyrosine hydroxylase deficiency will have an isolated low CSF HVA concentration while in individuals with AADC deficiency the concentrations of HVA and 5-HIAA will be below the appropriate age-related reference interval. Additionally, for AADC deficiency, elevated levels of 5-hydroxytryptophan and 3-methyl dopa (metabolite of L-dihydroxyphenylalanine) can be demonstrated (i.e. due to substrate accumulation). Patients with disorders of BH<sub>4</sub> metabolism can also have decreased concentrations of HVA and 5-HIAA and a characteristic pterin profile that can reflect the nature of the metabolic block (e.g. failure of the BH<sub>4</sub> recycling system leads to an increase in the CSF concentration of BH<sub>2</sub> while GTP cyclohydrolase 1 deficiency patients have decreased NH<sub>2</sub> and BH<sub>4</sub> concentrations). Hyperphenylalaninaemia is associated with the majority of BH<sub>4</sub> disorders. However, sepiapterin reductase and the autosomal dominant form of GTP cyclohydrolase are not associated with an elevated blood concentration of phenylalanine. These patients will therefore not be identified by a newborn screening programme but can be identified by phenylalanine loading.

Deficiency of PLP, arising from enzyme deficiencies that affect availability of this cofactor (e.g. pyridox(am)ine-5'-oxidase [PNPO] deficiency) can have a low CSF concentration of PLP. As a consequence of this PLP deficiency, dopamine and serotonin metabolism may be compromised, giving a profile comparable to that of AADC deficiency.

5-MTHF is the major transport form of folates and is the species that is quantified in CSF to provide an insight into folate availability and integrity of one carbon metabolism. In addition to the disorders of folate metabolism that directly lead to alterations in

5-MTHF status (e.g. 5,10,-methylene tetrahydrofolate reductase deficiency), other inborn errors of metabolism appear to negatively impact upon 5-MTHF availability: dihydropteridine reductase deficiency and disorders of the mitochondrial electron transport chain. In the latter, the mechanisms responsible for the failure of mitochondrial function leading to a CSF 5-MTHF deficiency have not been fully elucidated but might include a failure of active transport across the blood–brain barrier and an increase of reactive oxygen species generation leading to accelerated 5-MTHF catabolism. A CSF deficiency of 5-MTHF can occur in conjunction with a peripheral folate deficiency (e.g. caused by folate malabsorption and dietary insufficiency) or in isolation. This latter situation is known as cerebral folate deficiency (CFD). An important cause of CFD is mutations affecting the function of folate transporter alpha (FOLR1) which is involved in the transport of 5-MTHF into the CSF compartment. Drugs such as levodopa can also result in a decreased 5-MTHF within CSF. This situation arises as a consequence of excess levodopa being methylated to 3-methyldopa. Consequently, there is a drain on one carbon metabolism resulting in loss, with time, of 5-MTHF.

In addition to the enzyme deficiencies described, perturbation of dopamine metabolism can arise as a result of failure of the dopamine reuptake transporter (SLC6A3). For such patients, a distinctive CSF profile results (i.e. there is a markedly elevated concentration of HVA as a result of the extra-neuronal metabolism of dopamine).

### Management

Once identified, patients with ‘neurotransmitter’ disorders can, in general terms, respond well to appropriate treatment intervention. Knowledge of the biochemical pathways involved coupled with expertise gained in other areas of neurology (e.g. treatment of patients with Parkinson’s disease) can lead to effective and targeted options. With regards to tyrosine hydroxylase deficiency, levodopa (in the presence of a peripheral decarboxylase inhibitor) can correct the central dopamine deficiency and is often associated with marked clinical improvement. Disorders of BH4 metabolism are treated with levodopa plus 5-hydroxytryptophan in order to correct both the dopamine and serotonin deficiency. BH4 can also be included in order to correct peripheral phenylalanine metabolism. Alternatively, a phenylalanine restricted diet can be implemented. Treatment of AADC deficiency can be more challenging because of the nature of the metabolic block. PLP administration can be tried in an attempt to stimulate, by its role as a cofactor, any residual AADC activity. Folinic acid is also given to correct any secondary 5-MTHF deficiency arising from the increased methylation of accumulating levodopa to 3-methyldopa. Dopamine agonists and monoamine oxidase inhibitors are also frequently used.

Patients with a PLP deficiency, arising from impaired PNPO activity, need to be treated with PLP, and not pyridoxine, and can respond well to initiation of such treatment. 5-MTHF deficiency should be addressed by administration of folinic acid. Folic acid should not be given as this can exacerbate a CSF 5-MTHF deficiency state.

Currently, there does not appear to be an effective treatment for patients with mutations affecting the functioning of the dopamine transporter. However, some reports suggest a response from the use of dopamine agonists.

### Lysosomal storage disorders

Lysosomal storage disorders (LSDs) (Table 19.22) are inherited diseases that affect the ability in a cell to recycle macromolecules (complex lipids, glycoproteins and mucopolysaccharides). Deficiency of lysosomal hydrolases or associated proteins leads to the

**Table 19.22** The lysosomal storage disorders that may be associated with neurological problems.

<b>Mucopolysaccharidoses</b>
Type I (Hurler/Scheie)
Type II (Hunter)
Type III (Sanfilippo types A–D)
Type IV (Morquio types A and B)
Type VI (Maroteaux–Lamy)
<b>Glycosphingolipidoses</b>
GM1 Gangliosidosis (neonatal, juvenile and adult forms)
GM2 Gangliosidosis (Tay–Sachs and Sandhoff’s diseases)
Gaucher disease (type I, II and III)
Niemann–Pick disease types A and B
Niemann–Pick disease type C
Fabry disease
Farber disease
Krabbe disease (globoid cell leukodystrophy)
Metachromatic leukodystrophy
Saposin-related disorders (types A, B, C, combined)
<b>Oligosaccharidoses</b>
Fucosidosis
Mannosidosis
(Galacto)sialidosis
<b>Mucopolipidoses</b>
ML II (I-cell disease)
ML III
<b>Neuronal ceroidlipofuscinoses</b>
Adult neuronal ceroid lipofuscinosis (NCL) (Kufs disease)

accumulation of substances proximal to the metabolic block within the lysosomal compartment. This storage leads to ultrastructural changes in the cell and pathological alterations to cell biology. Lysosomal storage disorders are classified according to the type of storage material (e.g. sphingolipidoses, mucopolysaccharidoses, glycoproteinoses). LSDs are a clinically heterogeneous group of conditions, with the phenotype depending on which tissues have the highest turnover of the relevant storage material. For instance, the GM2 gangliosidoses cause storage in neurones and neurodegeneration, while metachromatic leukodystrophy leads to storage in oligodendrocytes and demyelination.

Within each disease there is also marked variability of clinical phenotype. This is thought to relate in large part to the precise nature of the genetic mutation and the degree of residual activity of the affected enzyme. As a rule, the most severe mutations lead to early onset, rapidly progressive disease, while those with residual activity of even a few per cent may have a relatively attenuated, late onset presentation. In mucopolysaccharidoses types I and II (Hurler and Hunter diseases), skeletal involvement with dysostosis multiplex is seen in all patients, but only the most severely affected develop neuronal storage and neurodegeneration.

Many of the lysosomal storage disorders can lead to neurological involvement as summarised in Table 19.23. Some of the more common diseases are discussed in more detail here:

**Table 19.23** Neurological involvement in lysosomal storage disorders, clinical features and current treatment options.

Disease	Inheritance	Gene product	Storage material	Incidence	Clinical features	Options for treatment
MPS I (Hurler Scheie's disease)	AR	Alpha-L-iduronidase	Dermatan sulfate  Heparan sulfate	1/75 000–85 000	Dysostosis multiplex resulting in compression neuropathies and myelopathy  Corneal clouding Hepatosplenomegaly Cardiomyopathy Pneumonia Cognitive impairment	Bone marrow transplantation. ERT for systemic features but does not affect CNS disease
MPS II (Hunter disease)	X-linked	Iduronate-2-sulfatase	Dermatan sulfate  Heparan sulfate	1/92 000–149 000 (males). Symptomatic females also reported	Dysostosis multiplex resulting in compression neuropathies and myelopathy  Hepatosplenomegaly Valvular heart disease Obstructive sleep apnoea Cognitive impairment	Bone marrow transplantation. ERT for systemic features but does not affect CNS disease
MPS III (Sanfilippo disease)	AR	Heparan-N-sulfatase/ Alpha-N-acetylglucosaminidase/ Acetyl-CoA:glucosamine-N-acetyltransferase/ N-acetylglucosamine-6-sulfatase	Heparan sulfate	1/86 000–114 000	Cognitive impairment Behaviour problems	Intrathecal ERT (in clinical trial). Chaperone therapy
Gaucher disease	AR	Beta-glucocerebrosidase	Glucosyl ceramide	1/57 000–86 000	Hypersplenism Hepatomegaly Bone involvement Horizontal supranuclear gaze palsy Dementia Ataxia Spasticity Epilepsy Parkinsonism	ERT for systemic features but does not affect CNS disease. Substrate reduction therapy

Fabry disease	X-linked	Alpha-galactosidase A	Ceramide trihexoside	1/80 000–117 000	Peripheral neuropathy Ischaemic stroke Dolichoectasia (elongation/ fusiform dilatation of intracranial vessels)	ERT: Chaperone therapy (in clinical trial)
GM1-gangliosidosis	AR	Beta-galactosidase	GM1	1/161 000–384 000	Dystonia Pyramidal signs Skeletal disease	Currently supportive
GM2-gangliosidosis (Tay-Sachs, Sandhoff diseases)	AR	Beta-hexosaminidase	GM2	1/32 000–384 000	Ataxia Dysarthria Spasticity Dementia	Chaperone therapy
Niemann-Pick C disease	AR	NP-C1/NP-C2	Cholesterol, GSLs	1/45 000–286 000	Ataxia Dystonia Dysarthria Dementia Psychiatric Vertical supranuclear ophthalmoplegia	Cyclodextrin (in clinical trial)
Krabbe disease	AR	Beta-galactocerebrosidase	Galactosylceramide Psychosine	1/74 000–201 000	Paraplegia or hemiplegia Ataxia Visual loss Peripheral neuropathy Dementia	HSCT if performed early
Metachromatic leukodystrophy	AR	Arylsulfatase A	Metachromatic lipid deposits	Overall 1/40 000. 20% adult onset	Personality change Spasticity Seizures Peripheral neuropathy	Intrathecal ERT (in clinical trial)

ERT, enzyme replacement therapy; HSCT, haematopoietic stem cell transplantation.

### Glycosphingolipidoses

Glycosphingolipids (GSL) are derived from ceramide by sequential addition of sugar molecules. The glycosphingolipidoses are a group of lysosomal storage disorders that result from an inability to degrade these complex lipids. As a group, they are the most common of the lysosomal storage disorders and all can involve the nervous system.
