# Beginnings

## A conversation with Professor Ian McDonald

Ian McDonald<sup>1</sup> kindly agreed to write the foreword for the first edition of this book. Sadly, he died shortly before it was completed. We met one sunny morning in 2004 and talked, sitting together on a bench in Queen Square.

I explained what I had in mind: an integrated, practical textbook from the National Hospital and the Institute of Neurology. ‘That is quite splendid’, Ian responded, in his inimitable way. ‘Of course’, he continued: ‘a book like this has never been produced and I think no one has been able to draw together the different personalities here – and that will not be at all easy ...’. Ian went on: ‘Charlie Symonds<sup>2</sup> once told me that he had suggested a similar project to the National Hospital Medical Committee in the 1930s’. Dr Charles Symonds, who had been recently appointed to the staff had received an immediate veto from his senior colleague Dr Samuel Kinnier Wilson.<sup>3</sup> ‘Symonds, there is no place for *that*. I have already written the definitive book, and there is no need for another,’ Kinnier Wilson is said to have responded, acidly.

During the last five decades, neurology has progressed immeasurably. Queen Square has become a truly international centre.

The editors integrated this international dimension, drawing on clinical experience and perspectives for the first edition from Australia, Canada, China, Europe, India and the United States. We thank our international editors for their comments and guidance.

This book came to fruition slowly and was quite a challenge. The authors are busy, distinguished in specialist fields, but they came together to produce the first edition, and now the second. The editors are most grateful to them all.

We hope *Neurology: A Queen Square Textbook* in this second edition continues to achieve its object – to reflect the clinical practice of neurology as we know it and to illustrate the approach we teach and follow at the National Hospital for Neurology & Neurosurgery and the Institute of Neurology, Queen Square.

We all valued Ian McDonald’s encouragement and hope that if he were still with us, he would feel the finished product was worthy of the institutions and teachers that have guided our thoughts and practice over the years.

Charles Clarke  
Queen Square  
London WC1

---

1. Ian McDonald (1933–2006) was Professor of Neurology at Queen Square from 1978 to 1998, and was well known for his work on multiple sclerosis.

2. Sir Charles Symonds, KBE, CB (1890–1978) was appointed physician to The National in 1926. A selection of his many papers entitled *Studies in Neurology* was published in 1970.

3. Dr Samuel Kinnier Wilson (1878–1937) was appointed physician to The National in 1912. He had written the seminal paper on progressive hepatolenticular degeneration shortly before this. *Neurology*, his well-known textbook, was published posthumously in 1940.

# Foreword to the First Edition

Queen Square in Bloomsbury, London, is known the world over as a centre for neurology and clinical neuroscience. Like many institutions, The National, initially The National Hospital for the Relief and Cure of the Paralysed and Epileptic, was founded through the hard work and generosity of people with a broad sense of charitable intent, especially the Chandler family – Johanna Chandler, her sister Louisa and their brother Edward. The doors of the original building opened in Queen Square in 1860. Dr Jabez Spence Ramskill was the first physician appointed, followed shortly by Dr Charles Brown-Séquard. Since 1860 there has been an unbroken record of progress across the clinical neurosciences. The names of all those who contributed in those early years are too numerous to mention, but amongst those who stand out today in an historical perspective are Dr Charles Brown-Séquard, Dr John Hughlings Jackson, Sir William Gowers, Sir David Ferrier, Sir Victor Horsley, Sir Gordon Holmes, Dr Samuel Kinnier Wilson, Sir Francis Walshe, Sir Charles Symonds and Dr Macdonald Critchley.

The National Hospital has undergone many changes and revolutionised its approach, for example towards neurological rehabilitation and brain injury, and has developed close and inseparable links with the UCL Institute of Neurology, which has helped to promote research at Queen Square in both basic and clinical sciences. Both Hospital and Institute are now involved in advancing an extensive range of developments in translational medicine that are transforming the treatment of neurological diseases. These developments are reflected in this book.

## The UCL Institute of Neurology

The UCL Institute of Neurology was established in 1950 and has been part of University College London since 1997. The Institute provides research and teaching of the highest quality in neurosciences, and professional training for clinical careers in neurology, neurosurgery, neuropsychiatry, neuroradiology, neuropathology and clinical neurophysiology. With its concentration of clinical and applied scientific activity, the Institute provides a unique national resource for both postgraduate training and research in the basic

neurosciences and its associated clinical disciplines. The Institute currently holds active grants for research into the causes and treatment of a wide range of neurological diseases, including movement disorders, multiple sclerosis, epilepsy, brain cancer, stroke and brain injury, muscle and nerve disorders, cognitive dysfunction and dementia; the work of the Institute's clinical academic staff remains closely integrated with The National Hospital.

## The National Hospital for Neurology & Neurosurgery today

The National, now part of University College London Hospitals NHS Foundation Trust, is a thriving hospital, largely refurbished behind the 1890 façade. The hospital receives over 1000 new outpatient referrals each month and has over 200 beds, a dedicated ITU, extensive rehabilitation services and all ancillary departments in the most substantial specialist neurological hospital within the UK. The hospital provides the surrounding district general hospitals with specialist services. Many of the consultant staff continue to hold appointments that are linked to both general hospitals, the UCL Institute of Neurology and The National itself. This maintains unique contact between the disciplines of research and clinical practice.

## Neurology: A Queen Square Textbook

This book, the first of its kind to come from these two institutions, has a distinctly clinical flavour. It has been written very largely by clinicians, each in the forefront of their field, and focuses on the practical aspects of diagnosis, treatment and patient care. The book also provides an introduction to the basic sciences of neurology, of increasing importance in medical practice. It has been a pleasure to be one of the contributing authors.

Professor Roger Lemon PhD FMedSci  
*Sobell Chair of Neurophysiology & Director, UCL Institute of Neurology*  
(2002–2008)

# Foreword to the Second Edition

I am delighted to be asked to celebrate the publication of this second edition of *Neurology: A Queen Square Textbook*. When I first learnt about this project some 10 years ago I had some misgivings – it seemed to me that neurology had become so specialised that it would be difficult to assemble a coherent book that spanned the whole of the field. I am glad to have been proved wrong, for this work really does encompass the scope of neurology in the twenty-first century.

In the past, neurologists by and large dealt with *all* neurological conditions; today specialisation has taken over and to be a neurologist without a special interest is a rarity. It is thus fitting that the four editors combine vast and broad clinical experience with specialist academic expertise. From the National Hospital for Neurology & Neurosurgery, Charles Clarke, who was the driving force behind the initiation of the project over 10 years ago, is a general neurologist, much of whose work has been in UK district general hospitals. He prides himself on being a ‘general practitioner of practical neurology’. His colleague Robin Howard, who works jointly at St Thomas’ Hospital in London and the National, is also a highly experienced general neurologist; his specialist interests are intensive care neurology and neuromuscular disease.

From the UCL Institute of Neurology, Martin Rossor has developed his interests in cognitive impairment to establish a unit in Queen Square specialising in dementia, a subject of major importance, long neglected. Simon Shorvon has been consultant neurologist at the hospital since 1983; his specialist expertise is in epilepsy, a field in which he has an international reputation.

This book epitomises this combination of practical experience and academic specialisation, and collaboration between institute and hospital, where as part of our daily workload we continue the tradition of teaching, both as a national centre and internationally to Queen Square postgraduate students from all over the world.

The editors and the authors are experienced and distinguished writers who have devoted time to draw together their practical experience. Each chapter has been carefully edited, so essential for a good finished product. I know that this book has been produced within an atmosphere of cordiality and friendship. The text reflects this.

Here, even at a glance, the reader can understand how large a subject neurology has become and how scientific advances, many pioneered within the UCL Institute of Neurology, have become translated into clinical practice. One can find here well-illustrated neuroanatomy, detailed assessments of common conditions such as stroke and dementia, up-to-date aspects of neurogenetics and ion channels, the philosophy and practicalities of rehabilitation, and rarities such as metabolic disorders of copper, unusual muscle diseases or little-known varieties of headache.

As a measure of its authority, *Neurology: A Queen Square Textbook* has become a standard text for the UK neurologists-in-training exit examination. It is already over 5 years since the first edition was published and while neurology and neuroscience continue to advance, I fully endorse the move to complete this new edition without delay.

A man would do nothing if he waited until he could do it so well that no one could find fault in what he had done.<sup>1</sup>

This book to my mind really does achieve its purpose and, like my predecessor Roger Lemon, I am delighted to be a contributing author.

Professor Michael Hanna MD FRCP  
*Professor of Clinical Neurology*  
*Director, UCL Institute of Neurology*

---

1. John Henry Newman, a nineteenth-century English clergyman.

# Preface

All Editors, Authors and Specialist Advisory Editors of *Neurology: A Queen Square Textbook* hold or recently held consultant or equivalent posts at the National Hospital for Neurology & Neurosurgery and/or the UCL Institute of Neurology, Queen Square.

The National Hospital is part of University College London Hospitals NHS Foundation Trust, and the Institute of Neurology part of University College London.

Twenty-three Co-ordinating Authors organised individual chapters, encouraged and liaised with over 70 contributors and with them wrote this book.

The Specialist Advisory Editors gave invaluable advice and guidance in their respective fields. To ensure a worldwide perspective, for the first edition our International Regional Editors, all of whom had close connections with Queen Square, provided guidance and comment.

This book is an attempt to provide a fresh and up-to-date approach to the fascinating subject of neurology. We encouraged each author to relate their own clinical experience but, in order to achieve a degree of consistency, we took a robust overview of the important specialities within neurology and their relevance. Each chapter has been coordinated by an expert in the field, to give the reader an overall grasp of each major subject, indicating where developments within neurosciences fit into a broader picture.

On spelling and use of the English language, whilst appreciating that as a living, multicultural tongue there are wide varieties, we have opted for British English – the sort of way we write our letters, and continue to spell ‘neurone’ with its terminal -e. On medical conditions named after famous figures, we appreciate that many publishers no longer use the apostrophe to describe the disease named after Alzheimer, Wilson, Parkinson and so on. Our authors by and large did not follow this; thus we have left matters much as they signed off their chapters.

The limited size of this book means that it has not been possible to provide references for all material. With the growth of information technology, a wealth of detailed sources is readily available.

We are most grateful to all those who have helped in this joint venture.

# Acknowledgements

We know that the skills of clinical practice are handed down, both by teachers and role models. The editors wish to thank all those who have taught, advised and inspired them in many aspects of neurology and its related disciplines, in neuroscience and in research. When we came to list these many individuals, we soon realised we would be unable to mention each by name. Instead, we trust that all who read this book will understand how much the editors and authors owe to others. We hope we can pass on that knowledge and experience.

We thank those who contributed to the first edition and have moved on, reflecting for most retirement, promotion or in the case of Philip Lee, his death at an early age. Those contributing to the first edition were Peter Brown, Adrian Casey, Sohier Elneil, Clare Fowler, Richard Frackowiak, Peter Goadsby, Andrew Lees, Giovanna Mallucci, Jon Marsden, Geoffrey Raisman, Mary Robertson, Geoffrey Schott, Anette Schrag, Susan Short, Shelagh Smith, David Thomas, Emma Townsley, Michael Trimble and Gelareh Zadeh. Each made a valued contribution.

We thank our publishers, Wiley Blackwell, and especially Rob Blundell, Claire Bonnett and Nick Morgan, as well as Kathy Syplwczak and Jan East for their unstinting patience.

The authors have worked hard and provided the substance of the book, for no personal reward and, despite numerous requests for text, diagrams and amendments, have remained firmly behind this project. We are most grateful to all who have contributed.

Secretarial help has been invaluable, and amongst those who have contributed over and above their normal duties, we thank especially Claire Bloomfield and Wyn Jagger.

The Rockefeller Library provided its valuable resources, both historical and current. The Audio Visual Services Unit was most helpful with the sourcing of some figures and photographs.

Royalties from *Neurology: A Queen Square Textbook* pass directly to The National Brain Appeal (National Hospital Development Foundation), the registered UK charity (No. 290173) that supports projects at Queen Square.

## CHAPTER 1

# Neurology Worldwide: The Epidemiology and Burden of Neurological Disease

Simon Shorvon

UCL Institute of Neurology

Neurological disease casts a heavy shadow over the lives of the patient, their family and friends and over society. In a recent survey, in Europe about one-third of all burden of disease was caused by brain disease – 23% of the years of healthy life is lost (YLL), 50% of years lived with disability (YLD) and 35% of disability-adjusted life years (DALYs). The aim of all neurological services must be to alleviate the suffering associated with the disease, and to realise this aim the rational planning of such health services requires epidemiological knowledge in five broad areas:

- 1 Epidemiology of the condition – its frequency and distribution within a population, its causation, mortality and co-morbidity.
- 2 Broad impact of the disease (the ‘burden of illness’) on individuals, families, health services and societies and also its financial cost.
- 3 Effectiveness and cost-effectiveness of diagnosis, investigation and treatment.
- 4 Existing health care resources – their distribution and priorities, and the potential for prevention.
- 5 Prognosis and outcome, via cohort studies and case-control studies.

The last three areas are outside the scope of this chapter; here an overview of selected issues related to the epidemiology and burden of neurological illness is given and, as this book is based on practice at Queen Square, here too I emphasise studies from the National Hospital for Neurology and Neurosurgery and the UCL Institute of Neurology. These set the scene for the more detailed consideration of neurological disease contained in the rest of the volume.

## Epidemiology of neurological disease

It is self-evident that knowledge of epidemiology is important to underpin any decision about the provision of health care resources. It is also clear that epidemiological data (on frequency, distribution, mortality, etc.) are of little practical value unless related to an intervention or therapeutic advance. Sadly, however, in practice, even where reliable data exist, these are used only inconsistently in planning health care. Neurological disease is one example of this depressing fact, for the amount of education and expenditure is far below its estimated impact. In many, indeed perhaps most, health care settings, the provision of facilities for neurological care is

often surprisingly fragmented and inappropriately targeted, even where, as in the United Kingdom, there is a nationwide health service.

## Frequency and distribution of neurological disease

Incidence and prevalence rates are the most common measures of frequency used in medicine.

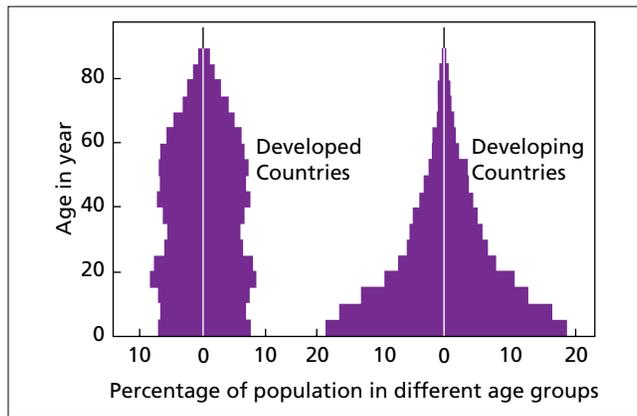

Incidence is a measure of the rate at which new cases occur in a specified population during a specified period. The incidence rate is usually calculated as the number of new cases occurring per 100 000 of the general population per year.

Prevalence is defined as proportion of a population that are cases at a point in time. The prevalence rate is usually calculated as the number of existing cases per 1000 of the general population. Point prevalence is calculated as the number on a particular day (prevalence day) and period prevalence is calculated as the number in a population over a specified period of time. Lifetime prevalence is defined as the risk of acquiring the condition at any time during life and is another important figure.

For many neurological diseases, information on even these basic measures is incomplete. Furthermore, the frequency of many neurological disorders varies markedly in different geographical regions, differs in urban when compared with rural settings, may differ with ethnicity, and is often linked to lifestyle and socio-economic factors.

In most neurological illnesses there are also striking differences in frequency at different ages, and so the age distribution of the population will affect the frequency, and some diseases have marked gender differences. For these reasons, age-specific or sex-specific rates, or frequency estimates in restricted age ranges, are generally more informative than crude rates. For instance, the annual incidence of stroke in a general population is about 190/100 000/year, but in the population over 65 years the rate is 1100/100 000/year. Similarly, the incidence and prevalence of Parkinson's disease in the general population are 20/100 000/year and 2/1000, and in those over 65 years are 160/100 000/year and 10/1000.

Changes in age structure in populations will impact on the number of patients with neurological diseases that have age-specificity. In most developing countries, the population has a far greater proportion of children and young adults than in developed countries. Figure 1.1 shows age structures in a typical developed (Sweden) and

**Figure 1.1** Age structure in developed and developing countries.

developing country (Costa Rica). However, globally, the number of people over the age of 65 years is estimated to double by 2030 and so the number of people with degenerative neurological disease is rapidly increasing. It is also important to recognise that although worldwide human populations are growing in an exponential fashion, growth rates vary widely among different countries and regions and the concept of 'doubling time' is a useful way of quantifying this. Doubling time – the time it is predicted to take for a population to double in size – depends not only on population size and mortality rates, but also on the number of children per woman (Table 1.1) and other social and health care parameters.

The approximate non-standardised figures for the prevalence and incidence of neurological disorders in a developed country are shown in Table 1.2. This table illustrates another important point – that for chronic diseases, as are many neurological diseases, the incidence rates may be low but the prevalence rates are high. This is important for health service planning, as the facilities required for incident cases are very different from prevalent cases. The former require provision for investigation and acute therapy and the latter largely for follow-up, social care, long-term therapy and rehabilitation.

The results of age-adjusted incidence and prevalence figures in a population of 100 230 persons in a selection of general practices served by the National Hospital for Neurology and Neurosurgery, London, from a research project published by the author in 2000 are shown in Tables 1.3 and 1.4. The incidence rates of 625 neurological disorders during a single year of observation were reported. Six per cent of the population in whom lifetime prevalence was surveyed had had a neurological disorder. In the United Kingdom, diseases of the nervous system accounted for 7.6% of all GP consultations between 1981 and 1982. The frequency of disability in private households amongst those over 16 years of age in the United Kingdom in 1971 was comprehensively delineated in the Harris Report in 1971. Disabilities relevant to neurology – CNS disorders, muscular dystrophies, congenital malformations of the spine and hydrocephalus, cerebral birth injury, senility as a cause of cognitive disability – occurred with a prevalence of 78/1000. The UK Office for Population Censuses and Surveys (OPCS) survey of disability 16 years later graded disability according to severity as well as overall frequency. The prevalence of complaints relevant to neurology was 13% for 'CNS disorders', 2% each for dementia and mental retardation, and 6% for back complaints. In a later study, 'CNS complaints' accounted for 7% of disability overall but for 16% of conditions with

**Table 1.1** Population size in selected developing and developed countries – doubling time.

Country	Approximate population size (millions)	Fertility (mean number of children per woman)	Doubling time* (years)
Yemen	15	7.2	20
Nigeria	107	6.2	23
Pakistan	138	5.6	25
Iran	68	4.7	26
Philippines	73	4.1	30
Mexico	95	3.1	32
Bangladesh	122	3.6	35
India	970	3.5	36
Brazil	160	2.5	48
China	1236	1.8	67
USA	268	2.0	116
France	59	1.7	204
Japan	126	1.5	289
UK	60	1.7	433
Italy	57	1.2	NPG
Germany	82	1.3	NPG
Russia	147	1.3	NPG

NPG, no population growth.

\*Doubling time is the predicted time it will take for the population to double in size. The doubling time depends on population size, age structure, number of children per woman and mortality rates. These figures were taken from the Population Reference Bureau, and predate improvements in child health, reductions in mortality rates amongst children and young adults and the HIV epidemic.

a high severity score. Roughly similar figures are found elsewhere. Population-based estimates from the United States, for instance, report point prevalence rates of neurological conditions (excluding headache, back pain and discs, mental retardation, psychosis, non-neurological visual and hearing loss and nervous system trauma) of 36/1000.

Ethnic differences in disease were shown by Stewart *et al.* in 1999 who studied stroke in a multi-ethnic region of London. A stroke register was used with 12 sources of case ascertainment. The population size was 234 533 with 72% Caucasian, 21% black (11% Afro-Caribbean, 7.5% West African and 2.5% mixed) and 3% South Asian. Incidence rates were standardised for age and sex. The crude annual

**Table 1.2** Annual incidence and point prevalence figures of common neurological disorders. The table includes only those conditions with an incidence above 1/100 000/year; whole populations considered, without age standardisation, and excludes shingles.

Disorder	Incidence (per 100 000 persons/year)	Point prevalence (per 100 000 persons)
Migraine	370	12 100
Acute stroke	190	900
Epilepsy	50	710
Febrile convulsions	50	
Dementia	50	250
Chronic polyneuropathy (all types)	40	24
Transient ischaemic attacks	30	
Bell's palsy	25	
Parkinson's disease	20	200
Meningitis	15	
Subarachnoid haemorrhage	15

Primary brain tumour	5	6
Trigeminal neuralgia	4	1
Multiple sclerosis	4	90
Motor neurone disease	2	4
Acute post-infectious polyneuropathy	2	1
All muscular dystrophies	1	6

Source: data derived from Kurtzke 1982; Hopkins 1993; Zakrzewska and Hamlyn 1999; Hughes 2002; Hirtz *et al.* 2007.

incidence rate of stroke was 130 (120–141)/100 000/year and the age-adjusted rate (to a standard European population) was 125 (115–135)/100 000/year. The rate in the black population was significantly higher with an incidence rate of 221 (177–276)/100 000/year. The rate, not surprisingly, increased with age. The study also looked at social class and found higher rates in those less than 64 years in lower social classes. This sort of study generates hypotheses about causation (as yet not explained) and provides data for rational health care planning (partially implemented).

**Table 1.3** The National Hospital for Neurology and Neurosurgery (NHNN) record linkage study: age- and sex-adjusted incidence rates for neurological conditions (MacDonald *et al.* 2000) compared with previously reported rates.

Conditions	NHNN linkage study: age- and sex-adjusted rate (95% CI)/100 000/year	Previously reported incidence rates/100 000/year
<b>Stroke</b>		
First cerebrovascular episode	205 (183–230)	200
Second cerebrovascular episode	42 (33–55)	28–35
Intracranial haemorrhage	10 (5–17)	5% of stroke, i.e. 10
<b>Seizure disorders</b>		
Epilepsy	46 (36–60)	24–53
Single seizures	11 (7–18)	20
<b>Tumours</b>		
Primary CNS tumours (benign and malignant)	10 (5–18)	7; 15
Parkinson's disease	19 (12–27)	12–20
Compressive mononeuropathies – all except carpal tunnel syndrome (CTS)	49 (39–61)	40
Arm – all excluding CTS	24 (17–33)	
Leg – all	20 (14–29)	
<b>Polyneuropathies</b>		
Diabetic polyneuropathy	54 (33–83)	40
All excluding diabetic and alcoholic	15 (9–23)	11
Shingles	140 (104–184)	71; 131; 400; 480
<b>Other conditions</b>		
Post-herpetic neuralgia	11 (6, 17)	13; 34; 9% of shingles
Bacterial CNS infection (overall)	7 (4–13)	10; 11
Essential tremor	8 (4–14)	24
Trigeminal neuralgia	8 (4–13)	2; 4

(continued)

Table 1.3 (continued)

Conditions	NHNN linkage study: age- and sex-adjusted rate (95% CI)/100 000/year	Previously reported incidence rates/100 000/year
Benign CNS tumour	7 (3–13)	10
Multiple sclerosis	7 (4–11)	2–8
Traumatic brain injury	7 (3–12)	4–6
Subarachnoid haemorrhage	7 (3–12)	10–15
Subdural haematoma	6 (3–12)	
Cluster headache	6 (3–10)	6–14
Cranial nerve disorder (excluding II, III, IV, VI, Bell's palsy or trigeminal neuralgia)	6 (2–10)	

Note: Other conditions that were encountered in the study, but which occurred with an incidence of 1–5/100 000: aseptic meningitis, metastatic CNS tumour, presenile dementia, neonatal encephalopathy, other congenital CNS abnormalities, brachial neuritis, Guillain–Barré syndrome, myasthenia gravis, primary malignant CNS tumour, transient global amnesia, spinal cord injury, acute cervical myelopathy, cranial nerve injury, demyelinating conditions (excluding MS), HIV encephalopathy, idiopathic myelopathy, motor neurone disease, spondylitic myelopathy, truncal mononeuropathy, diabetic amyotrophy, focal dystonia, non-cervical disc or cada equina damage, optic neuritis, spinal malformation.

In addition, a small number of cases of the following diseases were also found in this study: cerebellar degeneration, dementia of uncertain cause, frontal dementia with anterior horn cell disease, neurosarcoid with cord involvement, neurofibromatosis, tuberous sclerosis, communicating hydrocephalus, aqueduct stenosis, cerebral cyst, tonsillar herniation with Chiari malformation, syringomyelia, myotonic dystrophy, myositis, idiopathic neurogenic bladder, tubercular meningitis, meningococcal meningitis, syphilis, streptococcal meningitis, *Streptococcus pneumoniae* brain abscess, *Listeria* meningitis, cryptococcal meningitis, and an unidentified ventriculitis.

The collection of epidemiological statistics relating to neurological disorders is difficult; existing figures are probably underestimates and most biases lead to under-ascertainment. Such issues apply to epidemiological studies in all areas, but in addition to the varied general issues there is a particular problem for neurology that requires mention. This is the difficulty of 'case definition' (and thus case ascertainment). Many neurological disorders are defined on clinical criteria, with the inevitable subjectivity this entails. Thus, boundaries exist in which symptoms are occurring without formal diagnosis – for instance, the boundaries between ageing and Alzheimer's disease and between chronic headache and migraine. Similarly, in epilepsy, the inclusion of febrile seizures, single seizures and acute symptomatic seizures within a definition of epilepsy will more than double the apparent incidence rates. In neurological disorders that are only mildly symptomatic in their early stages, such as migraine, some neuropathies, some dementing illnesses and Parkinson's disease, only 'the tip of the iceberg' cases are known to health care professionals.

Severity also varies markedly in many neurological conditions, and the inclusion of mild cases will lead to high prevalence rates with relative little impact on burden of illness. Studies of epilepsy from the National Hospital provide examples of this – with over 60% of patients with epilepsy entering long-term remission and thus having only a minor impact on health services. However, any method using hospital statistics will greatly underestimate the true number of cases as many minor or static neurological conditions are cared for outside the hospital setting. Case finding methods also need to be tailored to the disease's spectrum of severity and frequency.

Similar considerations apply when considering rarer conditions, especially those requiring complex medical care where a sound estimate of frequency is important. A study of the prevalence and causation of dementia in those under 65 years, carried out by Harvey *et al.* in 2003 in West London, is one example. In this population of 567 500 people, the prevalence of dementia in those aged 30–64 years was 0.54/1000 (0.45–0.64). For those aged 45–64 years, the prevalence was 0.98/1000 (0.81–1.18). From the age of 35 onwards, the prevalence of dementia was found to approximately double with each 5-year increase in age. On the basis of these figures, it was estimated that in 2003, there were 18 319 (15 296–21 758) people with dementia under the age of 65 in the United Kingdom. Using diagnostic algorithms, 34% had Alzheimer's disease, 18% vascular dementia, 12% frontotemporal dementia, 7% dementia with Lewy bodies and 19% had other causes which included Huntington's disease, multiple sclerosis, corticobasal dementia, prion disease, Down's syndrome (probably underestimated), Parkinson's disease and others.

Neurology is also distinguished from other areas of medicine by the large number of uncommon conditions within its purview (neurology has the highest number of conditions listed in the International Classification of Diseases), and therefore large populations must be studied to obtain accurate population-based data with appropriate statistical reliability. Sampling error increases with rarer events and for many of the uncommon neurological diseases there are few reliable data.

From the perspective of health services, figures of prevalence and incidence of the cases receiving treatment are important, as it is these cases that consume resources, not untreated (usually mild) or cases before diagnosis. In 1998, a large study of epilepsy was published by Wallace *et al.* amongst a population of 2 052 922 persons in England and Wales of the numbers with epilepsy receiving anti-epileptic drugs. This provided accurate age-specific rates shown in Figure 1.2.

### Causation

Epidemiological studies are also vital for studying the causes of disease. The attribution of causation to neurological disease is rarely a simple matter. Most neurological diseases are multifactorial in nature, being the result of complex interactions between genetic and environmental influences. The balance between the two varies. The genetic influences can be very strong – for instance, in single gene disorders with high penetrance (e.g. Huntington's disease). In others the genetic influence is the result of more complex epigenetic and epistatic interactions (e.g. epilepsy), and in other diseases identifiable Mendelian genetic influences do exist but are seen in some families cases only (Alzheimer's disease for instance is familial in about 10% of cases). The environmental influences are predominant in many diseases, for instance head injury or cerebrovascular disease. An interaction between genetic and environmental factors occurs in other diseases, for instance

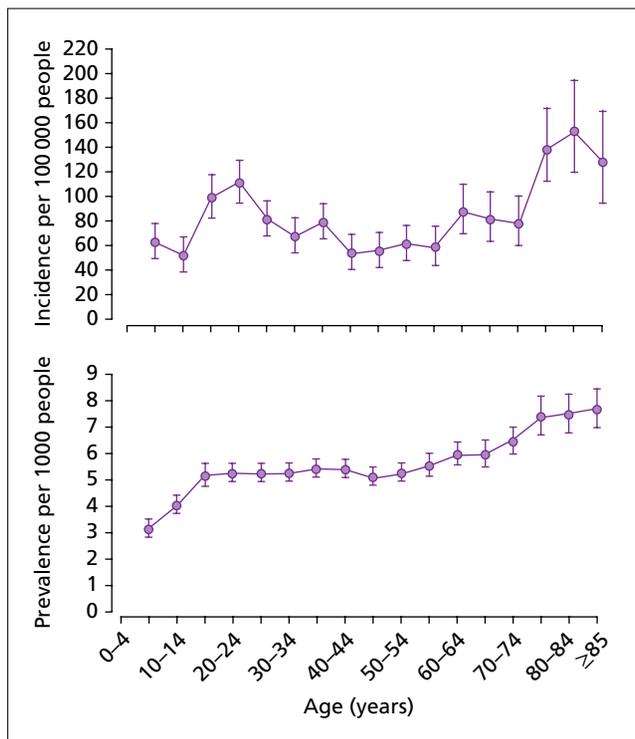

**Table 1.4** The National Hospital for Neurology and Neurosurgery record linkage study: 'lifetime prevalence' of neurological conditions (MacDonald et al. 2000) compared with previously reported rates.

Conditions	'Lifetime prevalence'/1000 population (95% CI)	Previously reported point prevalence (PP) rates/1000
Stroke	9 (8–11)	5
Transient ischaemia	5 (4–6)	2; 6
Epilepsy	4 (4–5)	5
Congenital neurological deficit	3 (3–4)	3, 2/1000 between 7 and 10 years; CNS malformation 0.7, Down's syndrome 0.5
Parkinson's disease	2 (1–3)	1; 2 (1); 2
Multiple sclerosis	2 (2–3)	1; 2
Diabetic polyneuropathy	2 (1–3)	3
Compressive mononeuropathies (except CTS)	2 (2–3)	0.4
Subarachnoid haemorrhage	1 (0.8–2)	0.5
Polyneuropathy (excluding diabetic and alcoholic)	1 (0.8–2)	0.4
Single seizures	1 (0.9–2)	
Bacterial meningitis	1 (0.8–2)	Abscess 0.02, meningitis 0.05
Other meningitis or encephalitis	1 (1–1)	
Aseptic meningitis	0.9 (0.6–1)	
Essential tremor	0.8 (0.5–1)	3 (1)
Polio	0.7 (0.4–1)	
Severe head injury	0.6 (0.4–1)	1
Optic neuritis	0.6 (0.3–1)	0.1
Benign CNS tumours	0.5 (0.3–1)	0.6 in brain, 0.1 in cord
Intracranial haemorrhage	0.5 (0.2–0.8)	

CTS, carpal tunnel syndrome; HTLV 1, human T-lymphotrophic virus type 1; MS, multiple sclerosis; PN, peripheral nerve.

'Lifetime prevalence' was here defined as a history of the condition at any point up until the survey in this population.

Note: Other prevalent conditions encountered in the study, which occurred with a prevalence of less than 0.5/1000 were: other movement disorders, viral encephalitis, spondylitic and compressive myelopathy, cluster headache, subdural haemorrhage, malignant CNS tumours, peripheral nerve or plexus injury, demyelinating conditions other than MS, cauda equina lesions, dystonia, benign intracranial hypertension, myelopathy, spinal cord injury, narcolepsy, motor neurone disease, aqueduct stenosis and hydrocephalus in adults, HTLV myelopathy, transient global amnesia, mononeuropathy (excluding carpal tunnel syndrome), trigeminal neuralgia, post-herpetic neuralgia, muscular dystrophies, myasthenia gravis, eye-movement disorders, brachial neuritis, Guillain-Barré syndrome, Horner's syndrome, pupillary abnormalities, sacral plexitis/plexopathy.

**Figure 1.2** Standardised prevalence and incidence rates of treated epilepsy in a population of 2 052 922 persons in England and Wales in 1995. (Bars indicate 95% CI.) Prevalence of treated epilepsy: overall 5.15/1000 people (95% confidence interval [CI] 5.05–5.25) Source: Wallace *et al.* 1998. Reproduced with permission of Elsevier.

the interaction of smoking and genetic susceptibility in Parkinson's disease, or geographic location and genetic susceptibility in multiple sclerosis. The latter is an interesting example as there are often unexplained geographical variations which may reflect either environmental or genetic influences or both. In most neurological diseases, even the common diseases, the primary causes are not clearly understood. Factors which play a part in causation can be divided into the following:

- Predisposing factors (e.g. age, sex, genetic susceptibility);
- Enabling factors (e.g. poor nutrition, housing, inadequate medical care);
- Precipitating factors (e.g. exposure to infectious or noxious agent);
- Reinforcing factors (e.g. repeated or prolonged exposure).

It should be noted that the epidemiological approach to causation is very different from the laboratory approach which studies mechanisms. Cause and mechanism of disease are not necessarily the same (this was a distinction which Hughlings Jackson recognised in relation to epilepsy).

Most neurological diseases are the result of multifactorial causal influences, each of which on their own would not result in the disease, but together have resulted in the disease. In such multifactorial disease, it is often helpful to define 'risk factors' which can be defined as factors that are positively associated with the development of a disease but which on their own are not sufficient to cause the disease. Risk factor studies rely in particular on case-control methodologies, and these can give important clues as to relative importance of different risk factors. The use of hazard

ratio (HR) and odds ratio (OR) calculations allow meaningful comparative statistics to be drawn up.

The value of risk factor analysis can be demonstrated by the example of epilepsy resulting from cerebrovascular disease. In one study, a history of stroke has been found to be associated with an increased lifetime occurrence of epilepsy (OR 3.3; 95% confidence interval (CI) 1.3–8.5). Among the other vascular determinants, only a history of hypertension was associated with the occurrence of unprovoked seizures (OR 1.6; 95% CI 1.0–2.4). The risk of unprovoked seizures rises to 4.1 (95% CI 1.5–11.0) in subjects having a history of both stroke and hypertension. Haemorrhagic stroke (subarachnoid haemorrhage and, to a lesser extent, primary intracerebral haemorrhage) are followed by a higher risk of seizures. The cumulative probability of developing seizures after a first stroke is about 6% after 1 year and rises to 11% at 5 years, with significant differences across stroke subtypes. A study by Cleary *et al.* in 2004 compared the frequency of stroke after the development of late-onset seizures, and found late-onset seizures to be a risk factor for stroke as important as high cholesterol or blood pressure. A total of 4709 individuals who had seizures beginning at or after the age of 60 years were compared with 4709 randomly selected matched controls with no history of seizures. Log-rank testing, adjusted for matching, showed a highly significant difference in stroke-free survival between the two groups ( $P < 0.0001$ ) and the relative hazard of stroke at any point for people with seizures compared with the control group was 2.89 (95% CI 2.45–3.41).

The Human Genome project also has added a new dimension to the study of causation of neurological illness, and will in the future also influence studies of the burden of disease. Over 200 Mendelian neurological conditions have been identified and here genomics has had a major impact in understanding the epidemiology and causal mechanisms of disease. Most such diseases are rare and it is clear that the genetic influence on the common neurological diseases is complex and may vary from population to population. To date, around 100 genome-wide association studies of common neurological diseases have been initiated. Eventually, it is to be hoped that such studies will provide estimates of disease heritability, provide unbiased populations for conventional disease-burden studies, and help define the clinical and therapeutic relevance of genetic variants.

The co-morbidities of neurological disease are another area in which risk factor analysis is revealing, but the nature of the association can be complex and not necessarily causal. Some of the causal influences on a disease may also be causal influences on co-morbidity – for instance, smoking resulting in vascular disease causing stroke also increases the risk of renal disease, and thus results in a non-causal association between renal disease and stroke. The treatments of some diseases also result in co-morbidities (e.g. behavioural effects caused by antiepileptic drugs) as does the social handicap of some neurological disorders. The psychiatric co-morbidity of cerebral neurological disorders is particularly complex with genetic, environmental, shared underlying causes and also treatment and direct cerebral damage all potentially contributing. Psychosis, depression and anxiety for instance occur much more frequently in patients with epilepsy than in matched non-epileptic persons, and the relationship of psychiatric disease and epilepsy has been shown to be 'bidirectional'. One explanation of such a bidirectional relationship is that both conditions share risk factors, and particularly genetic risk factors, and several recent studies have found the same copy number variations (CNVs) in epilepsy, autism, schizophrenia, mental retardation and attention deficit hyperactivity disorder.

## Mortality

The mortality rate of any condition is defined as the number of persons with that condition dying during a specified period divided by the number of persons in the same population. This information is of limited value, particularly in chronic neurological disease, without a knowledge of the underlying rate of death in patients without the condition or of age distribution. Therefore, mortality is often expressed as the ratio between the observed and expected numbers of death – this measure is known as the standardised mortality ratio (SMR). Expected deaths are calculated by measuring the death rates of a reference population with an age distribution that is similar to the study population. When there is no difference in mortality between the study and reference population the SMR is 1. The 95% CI provides an estimate of the significance of the calculated SMR. Another useful measure is the proportional mortality ratio, which is the percentage of deaths that are due to any one cause. Life expectancy, defined as the median survival, is linked to age and is often lowered in neurological disease when compared with a healthy population, but statistics are complex to derive and there are few studies of this in neurological disease.

Taking epilepsy as an example, in a UK cohort study, reported by Gaitatzis *et al.* in 2006, we followed a cohort of 564 newly diagnosed cases of epilepsy for 11–14 years and found an overall SMR of 2.1 (95% CI 1.8–2.4). The study also calculated the hazard ratio (HR), or risk of mortality in a particular group with a particular risk factor compared with another group without that particular risk factor. For epilepsy overall, it was 6.2 (95% CI 1.4–27.7;  $P = 0.049$ ). Rates varied with the cause of epilepsy: cerebrovascular disease (HR 2.4; 95% CI 1.7–3.4;  $P < 0.0001$ ), CNS tumour (HR 12.0; 95% CI 7.9–18.2;  $P < 0.0001$ ), alcohol (HR 2.9; 95% CI 1.5–5.7;  $P = 0.004$ ) and congenital neurological deficits (HR 10.9; 95% CI 3.2–36.1;  $P = 0.003$ ). An older age at the time of diagnosis was also associated with significantly increased mortality rates (HR 1.9; 95% CI 1.7–2.0;  $P < 0.0001$ ). Life expectancy has also been calculated in the same population based on the Weibull distribution. This depends on age at time of diagnosis and aetiological group, and of course reductions in life expectancy diminish over time. In our study of epilepsy, overall reduction in life expectancy, at the time of diagnosis, was found to be up to 2 years for people with a diagnosis of idiopathic or cryptogenic epilepsy, and up to 10 years in people with symptomatic epilepsy.

Mortality rates can be a useful way of quantifying treatment, but it is equally important in some neurological conditions to consider quality of life. This was well shown in a study of survival after radiotherapy in patients with glioma by Davies *et al.* in 1996. Radiotherapy is known to prolong life if only to a modest extent (in one trial to 38 weeks with radiotherapy compared to 14 weeks with steroids alone). However, the side effects of radiotherapy can be severe, and the trade off between survival and quality of life is important to consider. It was found that the clinical status before radiotherapy was a good indicator of the duration of disability-free life after radiotherapy. The authors showed clearly that for those already disabled by the tumour, radiotherapy offered little physical gain and even if not severely disabled the treatment could cause severe adverse effects.

## Other measures and rates

Other epidemiological measures and rates can be derived, for instance related to childbirth or co-morbidity, and are of importance in certain health care areas:

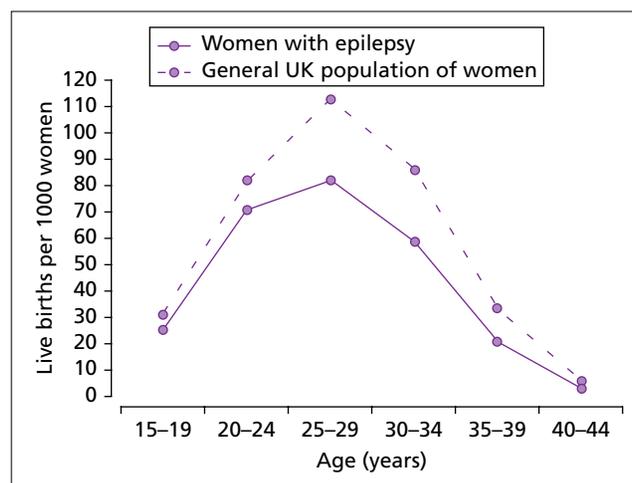

- *Birth rate* is usually defined as the number of live births per mid-year population;

- *Fertility rate* is usually defined as the number of live births per number of women aged 15–44 years;
- *Infant mortality rate* is defined as the number of infant (<1 year) deaths per number of live births;
- *Stillbirth rate* is defined as the number of intrauterine deaths after 28 weeks per total births;
- *Perinatal mortality rate* is the number of stillbirths + deaths in first week of life per total number of births.

Such epidemiological data can be used to investigate causation and assist prevention, but the issues are often complex.

This is well illustrated in a study of fertility in epilepsy amongst a general population of 2 052 922 persons in England and Wales, carried out from Queen Square and reported by Wallace *et al.* in 1998. Age-specific fertility rates were defined as the number of live births per 1000 women-years at risk, in each age category. Fertility was about 30% lower among women with treated epilepsy, with an overall rate of 47.1 live births per 1000 women aged 15–44 per year (42.3–52.2), compared with a national rate of 62.6 in the same age group. The standardised fertility ratios were significantly lower between the ages of 25 and 39 years in women with epilepsy ( $P < 0.001$ ; Figure 1.3). The reasons for these lower rates are complicated. There are undoubtedly social effects: women with epilepsy have low rates of marriage, marry later, experience social isolation and stigmatisation. Some avoid having children because of the risk of epilepsy in the offspring, and some because of the teratogenic potential of antiepileptic drugs. Other patients have impaired personality or cognitive development. However, there are other biological factors that could lead to reduced fecundity. These include genetic factors and adverse antiepileptic drug effects. The lowering of fertility is a worrying finding which is another and important source of disadvantage for women with epilepsy. If there are potentially preventable causes, these should be sought.

Many neurological conditions take a chronic course, so long-term follow-up is important to our understanding of their prognosis and resource implications. Epidemiologically based prospective cohort studies are the optimal method of study to assess the full impact of the disease.

**Figure 1.3** Comparison of age-specific fertility rates in women with treated epilepsy and general UK population of women in 1993 (study of a population of 2 052 922 persons). Source: Wallace *et al.* 1998. Reproduced with permission of Elsevier.

## Burden of illness

Although the study of the epidemiology of disease provides figures on incidence, prevalence, risk factors and distribution within a population, such information is of limited practical value in terms of population health unless linked to a treatment (or prevention) programme and resource utilisation. A problem that lies at the heart of care provision is the need to focus interventions where needed.

### Definitions

The words 'burden of illness' in their widest sense incorporate all negative impacts of illness, although they are often used to denote only the financial costs of illness where costs are understood to encompass the full social costs, both subjective hard to quantify elements as well as objective more easy to quantify measures. These cost of illness studies have the advantage of attempting to quantify a range of negative effects in monetary terms and thus allow comparisons to be drawn. Their disadvantages are obvious – notably the inherent inaccuracies and absurdities of trying to define quality of life issues in terms of monetary loss. Utility measures (e.g. quality-adjusted life years, QALYs, and disability-adjusted life years, DALYs) have also been derived to try to quantify burden more widely, and a particularly important project has been the Global Burden of Disease project sponsored by the World Health Organization (WHO) and World Bank. The burden of illness on individuals and on carers are not comprehensively accounted for in such studies which focus on broad categories biased towards societal and economic considerations.

### Cost of illness studies

The principal concern of physicians is to provide individual care, but as health care costs are rising so fast, and even the richest economies are seeking to limit expenditure, clinicians are necessarily now involved in factoring in economic considerations when making therapeutic decisions. This has led to cost of illness studies, which although important are bedevilled with methodological problems that limit their usefulness and validity.

The perspective taken in the analysis is of primary importance in any study of cost of illness. The cost (and burden) for individuals has quite different parameters to the burden for families, for health services or for society in general. Most cost of illness studies are carried out from the point of view of society, with social costs estimated in terms of lost employment, lost productivity and premature death.

Costs are usually divided into two types: direct and indirect. In outline, the direct costs are defined as any resource utilisation required in the care of the illness. These include medical costs such as primary care, hospital outpatient, hospital inpatient, investigation, drugs and non-medical costs such as residential care, community care, training and rehabilitation. Indirect costs are defined as the costs resulting from lost economic production and include premature mortality, dependency, unemployment and underemployment. There are various categories of cost, and any comprehensive analysis should include opportunity costs and transfer payments. Estimation of indirect costs may use the 'human capital' approach which ascribes a monetary value to a person in terms of their potential productivity. In health economic analysis the willingness to pay approach has become popular, which defines costs in terms of how much a person would be willing to spend. This has the advantage of accounting for intangible as well as tangible effects. Both methods are difficult to carry out and both are open to a wide variety of biases and criticisms. With all neurological disorders, the

indirect costs are greatly in excess of the direct costs. In one study of epilepsy in 1994, for instance, direct costs accounted for only 13% of all costs in spite of relatively narrow definition of cost.

There are four common methodologies for carrying out economic appraisal:

- 1 Cost minimisation analysis, which compares interventions where the outcomes are the same;
- 2 Cost-effectiveness analysis, where outcomes are compared using a single natural measure (e.g. in epilepsy, cost per 50% reduction in seizure frequency);
- 3 Cost-utility analysis, which is particularly useful for comparing costs between diseases, in which different outcomes can be accounted for and costs are compared in terms of their effects on a utility measure (e.g. the effect on QALYs);
- 4 Cost-benefit analysis, which measures outcome in terms of economic benefit – accounting for both direct and indirect costs. The latter analysis is the most comprehensive, but in neurology there have been few examples of robust cost-benefit studies. With the increasing availability of expensive therapies and investigations, however, there is a pressing need for good economic appraisal.

Ethical issues relate also to cost-effectiveness. The primary responsibility of a doctor is to the individual patient and not to society. Therapies which are not 'cost-effective' from the epidemiological or societal point of view, may be nevertheless beneficial in an individual – and here the societal and clinical perspectives may clash (indeed, many cultures that purport to put society before the individual usually apply hypocritically different standards to the rulers and the ruled). The impact of social policy, for instance in relation to financial benefits and social support, on the burden of illness is another area that can greatly influence the individual burden.

### WHO burden of illness studies

In recent years, the WHO and World Bank have evolved a more comprehensive series of measures of the impact of disease. The best known are the QALY and DALY. The DALY uses a methodology that focuses on disability whereas the QALY focuses on quality of life. These were formidable efforts, involving the WHO in 40 person-years of effort and the collection of data on 483 separate sequelae in 107 diseases and 14 million death certificates. It has to be said, as will be quite obvious to all, that reducing the impact of illness into a one-dimensional measure presents as many methodological difficulties as do studies quantifying illness in monetary terms. The Global Burden of Disease study provides comparative statistics on the impact of disease from 107 countries. To what extent this effort is worthwhile, finally, in helping set priorities has been seriously questioned.

The DALY is an indicator that is most useful in making comparisons between diseases and between regions, and in Table 1.5 some comparative figures are shown for neurological and psychiatric disease. On the basis of this analysis, neuropsychiatric disease accounted for about 15% of the global burden of disease (and 34% of the global burden of disability). For instance, cerebrovascular disease accounts for about 10% of the global burden of neuropsychiatric disease, dementia 2% and epilepsy 1%.

A recent study of disease burden focusing on Europe showed that three of the five highest DALY scoring medical conditions were psychiatric or neurological (stroke, unipolar depression and dementias) and, furthermore, the greatest proportion of DALYs caused by neuropsychiatric diseases were in the highest income group of European countries.

**Table 1.5** Disability-adjusted life year (DALY; in thousands) calculations for year 2000 for neurological and psychiatric conditions. Disability-adjusted life year is an indicator of the time lived with a disability and the time lost due to premature mortality. The figures for Europe were separately calculated (Olesen and Leonardi 2003).

Condition	DALYs				
	Europe	Developed countries*	India	Sub-Saharan Africa	World
Neurological and psychiatric conditions (all) <sup>†</sup>	53 009	24 682	23 949	15 788	165 082
Cerebrovascular disease	10 316	5166	5223	5487	45 770
Unipolar depression	4091	6721	10 064	6193	60 166
Bipolar disease	1541	1673	2867	1785	16 722

### The personal burden of neurological disease – stigma

The burden of illness of any neurological disease includes aspects that are less directly related to economic factors. Psychological, social, educational, employment and legislative aspects can have a major impact. Some of these are proportionate and rational (e.g. driving restrictions in epilepsy or stroke) but others are not, and a particular issue for patients with neurological disease is the stigma attached to the disease.

Stigma deserves special mention, for it is important in many neurological disorders and yet its consequences are overlooked in burden of illness studies. It is often divided into three categories: enacted (actual experience of discrimination), felt (the fear of discrimination) and self (for instance, devaluation or shame or withdrawal as a personal response to perceived discrimination). There are complex interactions and society will often construct a 'stigma theory' about a disease – to explain the dangers the person represents and which imputes a wide range of imperfections on the basis of the disease. The impact of stigma in neurological disease and epilepsy provides an example. The fact of 'being epileptic' is often more devastating than the simple occurrence of occasional epileptic seizures. In 1989, in Britain, the felt stigma of epilepsy was found to be nine times less common than enacted stigma. The stigma is reflected in the belief that sufferers are retarded, weak, slow, antisocial, physically unattractive or aggressive. Such beliefs are most prevalent in developing societies, and in the United States, for instance, in a number of states, up until 1956, people with epilepsy were prohibited from marrying and could be sterilised, and until the 1970s were excluded from restaurants and

theatres. In a large study published in 1999 and 2000, amongst more than 5000 persons with epilepsy in Europe, 51% reported feeling stigmatised and 18% highly stigmatised.

The impact of even non-serious illness can be significant. A study from Dunedin, New Zealand, of tension headache and migraine showed significantly poorer social, mental, physical and emotional functioning than matched non-headache controls. Although equal numbers of those with and without migraine were in employment, 80% of women with migraine were earning £30 000 or less compared with 67% of controls. Nearly half of those with migraine reported that their headaches impaired their social activities. The burden of disease resulting from migraine was considered equal to that of asthma.

### Relative costs – developing countries

Ill health has an economic burden that can impose high and regressive cost burdens on the patient and family in all countries. However, in poorer countries the proportion of family income spent on health may be particularly high, not least as ill health results also in unemployment and underemployment. In Sri Lanka, for instance, where health services are free at the point of delivery, it has nevertheless been estimated that the total cost of all illness amounts to 10% of household incomes, and it is likely that neurological illnesses, because of their generally chronic and disabling nature, are particularly onerous. Tuberculosis (TB) is a serious chronic illness which has been well studied from the health economic point of view. In Thailand, it has been reported that TB results in 15% of poor households having to sell material property

and 10% taking out loans. In India, amongst patients with TB, 67% of rural patients and 75% of urban patients incurred TB-related debts. Eleven per cent of school children with parents with TB had to discontinue their studies and another 8% had to take up employment. What applies to TB will no doubt also apply to chronic neurological diseases. The impact of diseases depends primarily on the economic position of the family (the lower the economic status, the greater the impact) and the social or family networks and community support available.

### Treatment gap

It is also largely economic factors that lie at the heart of failure of treatment. Taking the example of epilepsy again, the concept of the 'epilepsy treatment gap' was devised to provide a numerical measure of the extent of failure of therapy by Farmer and Shorvon in 1989. The treatment gap was defined as the percentage of patients with active epilepsy in a population who do not receive antiepileptic drugs and was an estimate based on prevalence and drug supply figures for that country. Surprising and disturbing results were obtained – in Pakistan, the Philippines and Ecuador treatment gaps of 94%, 94% and 80%, respectively, were ascertained in this study (and considered to be underestimates if anything, resulting from low estimates of prevalence and assumptions of low drug dosages). Since then, prospective population-based studies have largely confirmed similar large treatment gaps in epilepsy in different countries, for instance 62% in China and 73–78% in India. Another study has shown that 41% of people with epilepsy in China have never received antiepileptic drugs. A similar methodology has been widely applied to other countries, for instance recent studies from Georgia and Brazil found about two-thirds of people with active epilepsy had not received appropriate antiepileptic treatment in the month prior to the survey. There are various reasons for these deficiencies of treatment including cost, availability (not least the availability of drugs in pharmacies), cultural factors, lack of medical facilities, and lack of understanding of the potential and role of therapy. Closing the 'treatment gap' has become a priority for health services in many countries, and these findings were a primary stimulus for the highly successful joint WHO and the International League Against Epilepsy (ILAE) campaign to improve epilepsy care – the Global Campaign Against Epilepsy. One intervention study carried out in China 6 months after a Global Campaign survey and found that treatment gap could be reduced by about 20% with relatively simple measures. The campaign is an example of how epidemiological data can be translated into societal action.

## CHAPTER 2

# Nervous System Structure and Function

Charles Clarke<sup>1</sup> and Roger Lemon<sup>2</sup>

<sup>1</sup>National Hospital for Neurology & Neurosurgery

<sup>2</sup>UCL Institute of Neurology

## BASIC NEUROSCIENCE

### Introduction

The complexity of the nervous system must have posed daunting challenges for clinical neurology as our discipline began to develop in the late nineteenth century. However, despite the truly remarkable descriptions of the intricacies of axonal and dendritic networks by Santiago Ramón y Cajal in Spain in the 1890s, using light microscopes (Figures 2.1 and 2.2), the cortical mapping by Korbinian Brodmann in Berlin in the early twentieth century and later the fine detail of neuro-anatomical pathways by Alf Brodal in Oslo and many others in the 1940s, it remained evident that a rudimentary knowledge of neuro-anatomy, and little of neuroscience could provide a robust basis for most day-to-day neurological practice. Many neurologists in the past have had a sketchy knowledge of pathways and disease mechanisms, an indication of the reliability of simple observation of symptoms and signs. It is something of an enigma that trainees in the twenty-first century, alongside the explosion in scientific knowledge still need to know how to use the basic clinical tools developed over 100 years ago – but they can no longer practice neurology with these alone.

Knowledge is increasing rapidly: advances in imaging, neurogenetics, neurochemistry, neurotransmitter technology, immunology and molecular biology have added new dimensions to clinical practice, to the relevance of neuronal and glial ultrastructure and function and complexities of neuro-anatomy. By looking at ultrastructure, imaging, genetics, chemistry and neuronal activity we begin to understand conditions as diverse as Alzheimer's disease, Parkinson's disease, myasthenia gravis, polyneuropathies and headache – itself the most common neurological complaint the world over. This chapter provides a brief overview of how the nervous system is organised and, where appropriate, how abnormalities found on examination are explained.

### The functional unit: the neurone

The neurone (>100 billion within the human brain) is the functional unit of the nervous system. Neuronal specificity, size and cell type vary greatly. One  $\alpha$ -motor neurone of the lower thoracic cord has an axon over 1 m in length and innervates between several hundred and 2000 muscle fibres, to form a motor unit.

By comparison, some spinal or intracerebral interneurons have axons under 100  $\mu$ m long which terminate on a single neuronal cell body. A summary of neuronal ultrastructure follows.

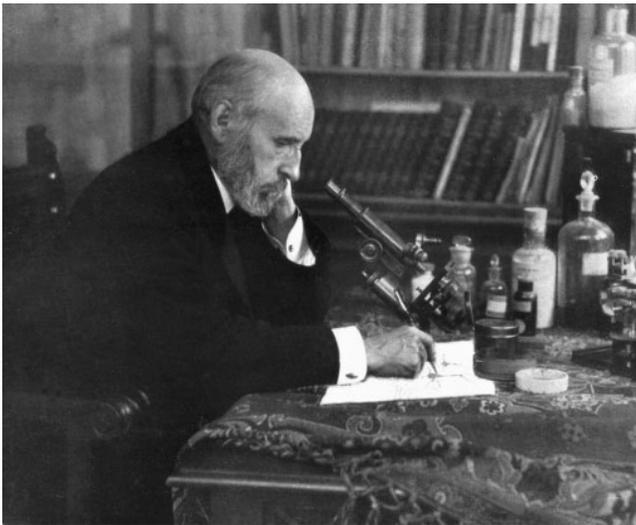

The neurone is constituted by its nucleus, cytoplasm, neuronal membrane and cytoskeleton (Figure 2.3). Neurotransmission and intrinsic modification of the neurone itself are its functions, to facilitate transfer of information, and to adapt to and record change. The combination of axonal electrical activity and synaptic neurotransmitter release provides the basis for most interneuronal transmission; the release of neuromodulators is also an important role. The integrity of intraneuronal and glial structure and function is also essential; glia play a part in synaptic transmission, re-uptake of neurotransmitters and the general control of the extracellular environment in which the neurones are located. Neuronal plasticity means the ability of neurones to adapt, to change, singly, in sequence and/or in groups and is a particularly well-developed aspect of the mammalian nervous system. Plasticity has a pivotal role in both learning and recovery from injury.

From the neurone cell body (soma, perikaryon) extend neurites (i.e. axons, up to 1 m long), and dendrites that are rarely longer than a few millimetres. Most axons branch repeatedly to establish synaptic connections with other neuronal cell bodies. In this way one neurone is able to make divergent connections with many other neurones within the central nervous system (CNS).

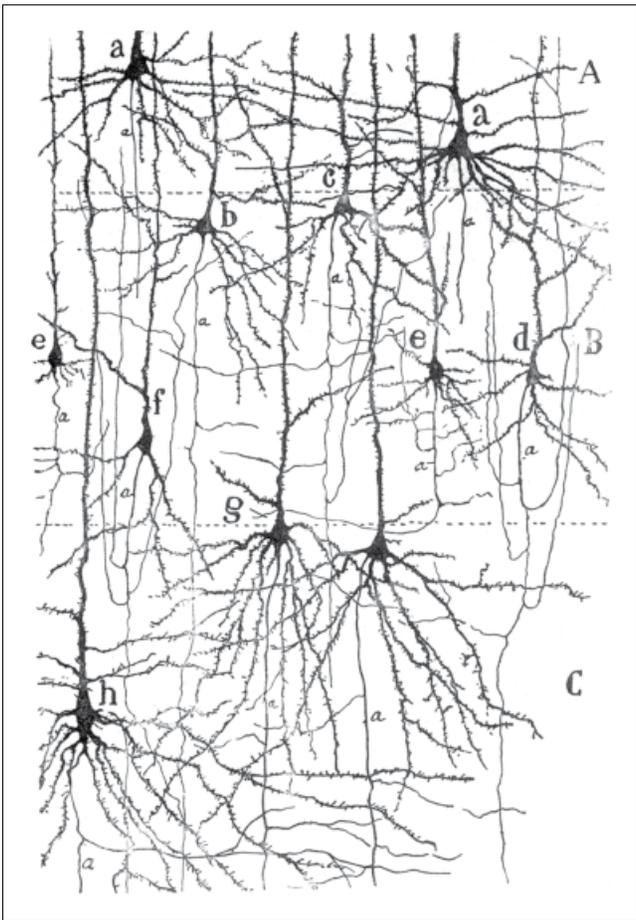

The dendritic and soma membrane represents the main region through which the neurone receives its synaptic input. Some neurones receive many thousands or even hundreds of thousands of such inputs. The neuronal membrane is the 5-nm thick barrier enclosing cytoplasm, excluding substances bathing the neurone. This membrane, a bi-layer of phospholipid has typically a polar hydrophilic head and an insoluble non-polar hydrophobic tail. Neuronal membrane proteins are responsible for the interaction between the neurone and its environment. These proteins are:

- Ion channels, usually either ligand-gated or transmitter-gated
- Receptors, and
- Cell adhesion molecules.

The cytoskeleton consists of microtubules, neurofilaments and microfilaments. Microtubules are some 20 nm diameter, hollow-walled strands of  $\alpha$  and  $\beta$  tubulin – polymers of globular microtubule associated proteins (MAPs). For example, tau is an axonal MAP; dynein and kinesin are motor proteins (also known as

**Figure 2.1** Professor Santiago Ramón y Cajal (1852–1934) working at his light microscope in 1915. (With kind permission of the Instituto Cajal, Madrid.)

**Figure 2.2** Fine detail of neo-cortical pyramidal neurones (Cajal). (a,b,c) Small pyramids; (d,e) medium neurones; (f), bitufted neurones; (g,h) large neurones. (With kind permission of the Instituto Cajal, Madrid.)

molecular motor or motor molecules) that convert chemical energy in adenosine triphosphate (ATP) into mechanical energy (movement).

Neurofilaments are 10 nm thick (intermediate filaments of all other cells), braided, tight, physically strong protein strands. They form a peri-nuclear network and provide structural integrity. Microfilaments are 5 nm thick, braided duplexes of actin (42–44 kDa). They are critically involved in neurone shape.

Neuronal replication is the exception, although neurogenesis has been clearly shown to take place in the olfactory neuro-epithelium, hippocampus and hypothalamus. However, studies of neuronal dynamics show that in all neurones the intraneuronal contents are continually being reformed and degraded. For example, the cofactor ubiquitin molecule interacts with degraded proteins via hydrophobic residues – complexes of more than five ubiquitin molecules are broken down by an ATP-dependent multi-enzyme system, the 26S proteasome. Failure to remove degraded proteins is of signal importance in many neurodegenerative diseases (e.g. Alzheimer's disease; Chapter 8), and myopathies such as inclusion body myopathy (see Inclusion body myopathy, Chapter 10).

### Amyloid and tau in Alzheimer's disease

As an example of a disease mechanism, still to be fully unravelled, in Alzheimer's neurofibrillary tangles develop; these are filamentous inclusions within the soma and dendrites adjacent to it. Paired helical and 15-nm straight insoluble protein filaments become visible. These are isoforms of tau, the microtubule binding protein that in health is soluble. This structural change in the cytoskeleton is likely to impair axonal transport, neurotransmission and eventually viability of the neurone.

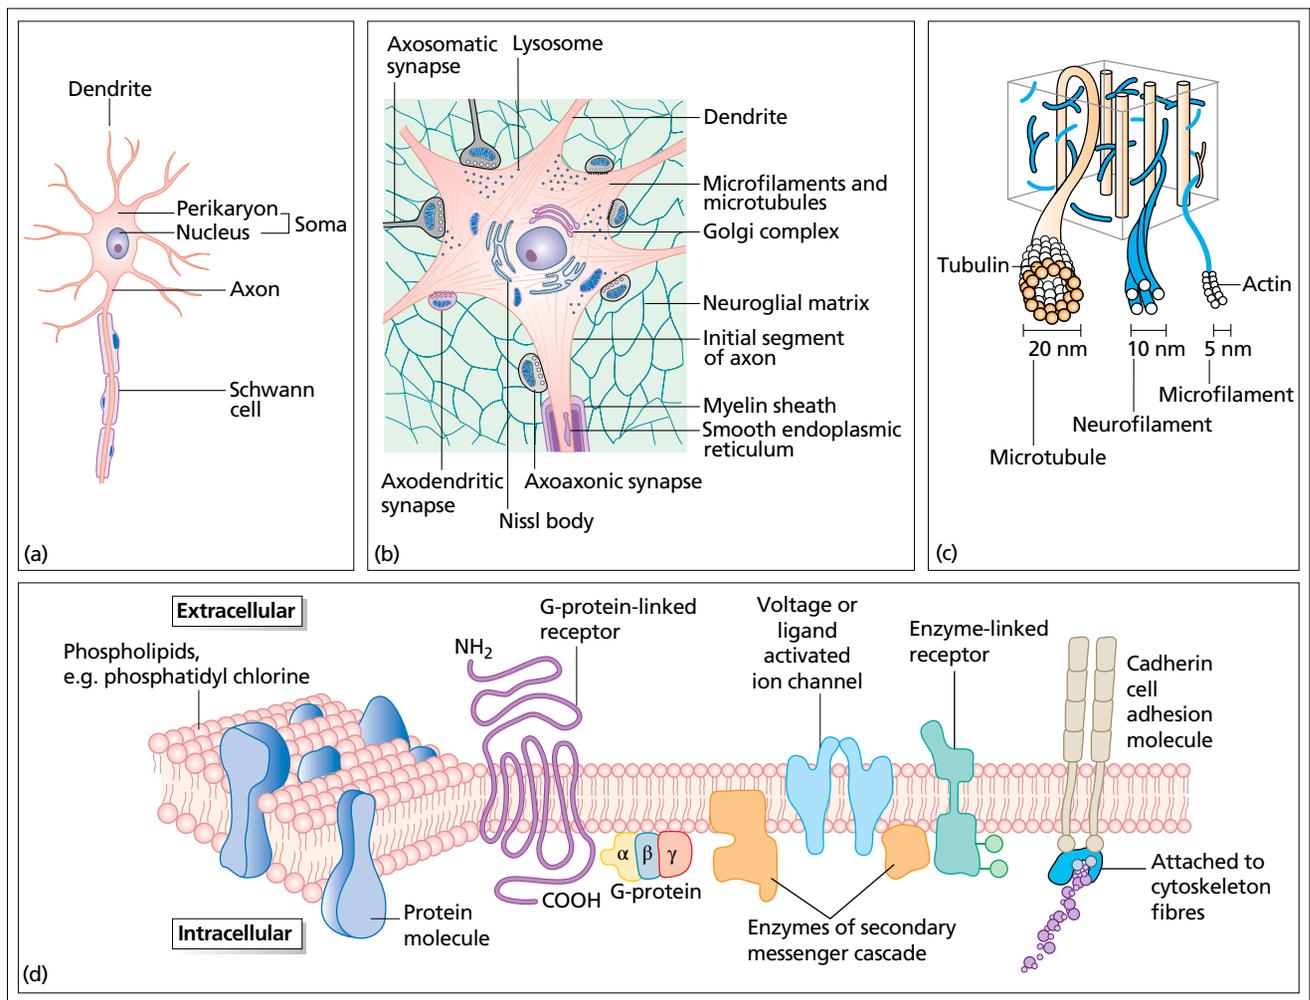

In the second pathological hallmark of Alzheimer's, the extracellular senile plaque, deposits of amyloid are surrounded by dystrophic neuronal elements. Amyloid is the name given to pathological  $\beta$ -pleated sheets of aggregates of fibrillar peptides that stain with Congo red and are doubly refractive in polarized light.  $A\beta$  amyloid, a 4-kDa peptide cleaved from amyloid precursor protein (APP) is the main constituent of histological amyloid.

APP is one member of a larger family of amyloid precursor-like proteins, APLP1 and APLP2. APP is encoded by a gene in the long arm of chromosome 21; it exists in three main isoforms of 695–770 aminoacids. Neuronal APP is the source of most extracellular  $A\beta$  amyloid in Alzheimer's disease. APP synthesis takes place in the rough endoplasmic reticulum. It is glycosylated in the Golgi apparatus and offered to the internal surface of the neurone as an integrated membrane protein. A fraction of APP within the plasma-membrane remains within the neurone from which are generated various forms of  $A\beta$  ( $A\beta_{1-40}$ ,  $A\beta_{1-42}$ , truncated  $A\beta_{17-40}$  peptides). Putative mechanisms of neurotoxicity of  $A\beta$  fragments and the genetics of Alzheimer-APP gene mutations (chromosome 21), presenilin 1 and 2 (chromosomes 14 and 1), and allelic forms of ApoE (chromosome 19) are discussed in Chapter 8 (see Alzheimer's disease).

## Neurotransmission

### Electrical synapses

Between mammalian neurones, the electrical synapses, found, for example, in the giant squid, have largely been replaced by chemical transmission systems. Electrical synapses do, however, persist in the human CNS and are found at gap junctions, where the synaptic cleft is some 3 nm wide. Connexin protein complexes (see Myelin) span these narrow gaps, coupling adjacent cells electrotonically with pores

**Figure 2.3** Motor neurone. (a) Soma, axon and Schwann cell; (b) ultrastructure; (c) cytoskeleton; (d) neuronal membrane.

some 2 nm in diameter. These pores are large enough for the passage of all major cellular ions and many organic molecules. Electrical transmission is bi-directional, and slow. Gap junctions occur between glial cells, epithelial cells, smooth and cardiac muscle cells, and in some nuclei in the brain (e.g. the inferior olivary nucleus). During brain development, transmission via gap junctions between neighbouring neurones coordinates growth and maturation.

### Chemical synapses

In a chemical synapse, the synaptic cleft is some 20–50 nm wide and filled with an adherent matrix, ensuring its stability. The presynaptic element, usually an axon terminal, houses mitochondria, synaptic vesicles and larger secretory granules – the dense-core vesicles seen on electron microscopy. Either side of the synaptic cleft specialised areas of accumulated protein comprise membrane differentiations, with an active zone on the presynaptic side opposite the postsynaptic density. The postsynaptic density houses receptors. Receptors make possible intracellular events, changes in membrane potential or secondary chemical events and are sensitive to interactions with neurotransmitters and neuromodulatory agents released by the presynaptic neurone.

### Types of CNS synapse

CNS synapses are classified as axodendritic (axon → dendrite), axosomatic (axon → cell body), axo-axonic and dendro-dendritic (Figure 2.3). Gray's type I and II synapses are terms also used (Figure 2.4):

- *Gray's type I* usually excitatory. Asymmetrical membrane differentiation, with postsynaptic membrane thicker and more complex than presynaptic.
- *Gray's type II* usually inhibitory. Symmetrical membrane differentiation.

### Peripheral nervous system synapses

Synaptic transmission is also involved throughout the peripheral nervous system, from autonomic nerve fibres to smooth and cardiac muscle and transmission from motor nerves to striated skeletal muscle fibres via neuromuscular junctions, the specialised cholinergic synapses facilitating fast reliable neuromuscular transmission. Their peripheral site and accessible micro-anatomy have made possible the detailed study of neuromuscular transmission.

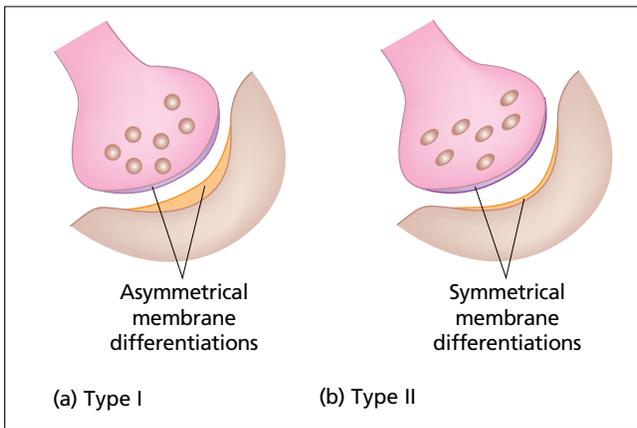

Figure 2.4 Gray's type I and II synapses.

### Neuromuscular junction

At the motor end-plate presynaptic active zones are closely aligned to the postsynaptic membrane densely packed with acetylcholine receptor sites (Figure 2.5). Acetylcholine, liberated by an action potential leads to acetylcholine release from synaptic vesicles into the synaptic cleft. Depolarisation of the motor end-plate follows.

### Neurotransmitters

Effective chemically mediated synaptic transmission requires transmitters to be synthesised, transported, liberated appropriately, metabolised and/or recycled. Neurotransmitters fall into one of four categories (Table 2.1).

Neurotransmitters are synthesised in several ways. Glutamate and glycine are ubiquitous amino acids, abundant in all cells including neurones. Gamma-aminobutyric acid (GABA) and amine neurotransmitters are made only by neurones that release them, via

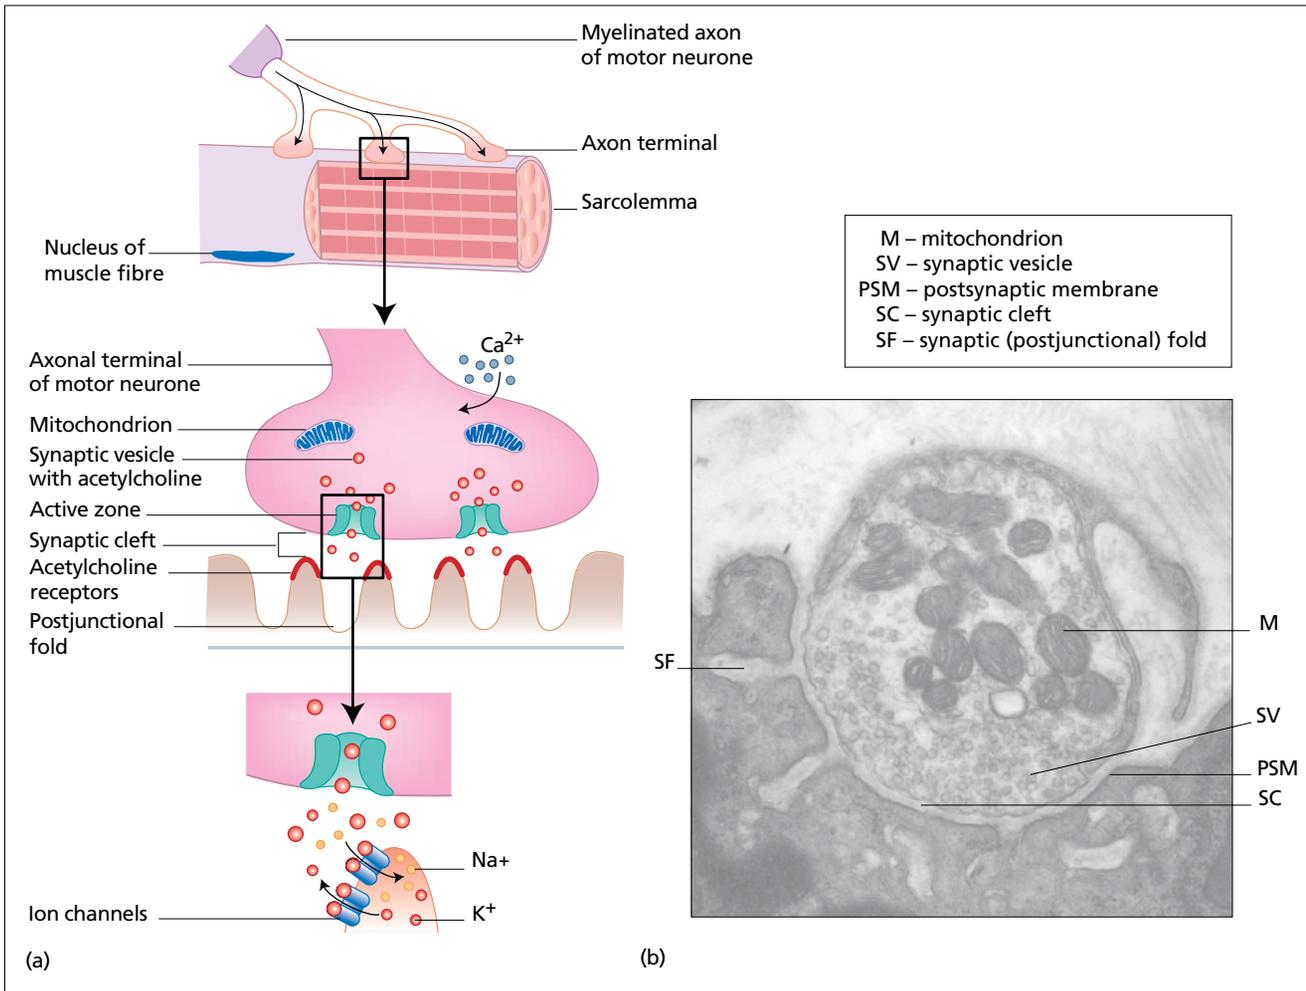

Figure 2.5 Neuromuscular junction. (a) General arrangement and detail. (b) Electron micrograph of neuromuscular junction from mouse flexor digitorum brevis. **Table 2.1** Principal neurotransmitters.

Amino acids	Amines	Peptides (many others)	Gases
$\gamma$ -Amino-butyric acid (GABA)	Acetylcholine (ACh)	Cholecystikinin (CCK)	Nitric oxide (NO)
Glutamate (Glu)	Dopamine (DA)	Dynorphin	Carbon monoxide (CO)
Glycine (Gly)	Adrenaline (epinephrine)	Enkephalins (Enk)	
	Noradrenaline (norepinephrine)	<i>N</i> -acetyl-aspartyl-glutamate (NAAG)	
	Histamine	Neuropeptide Y	
	Serotonin (5-HT)	Somatostatin	
		Substance P	
		Thyrotropin-releasing hormone (TRH)	
		Vasoactive intestinal peptide (VIP) and vascular endothelial growth factor (VEGF)	

Purines, ATP and adenosine are also neurotransmitters.

specific enzymes and precursors. Synthesising enzymes for both amino acid and amine neurotransmitters are transported to the axon terminal where they direct transmitter synthesis, locally and promptly. Once synthesised, transporter proteins concentrate amino acid and amine transmitters within synaptic vesicles.

Peptide neurotransmitters are strung together by ribosomes within the rough endoplasmic reticulum (ER) and cleaved to form active molecules in the Golgi apparatus (GA). Secretory granules bud off the GA and are carried to the axon terminal by axoplasmic transport.

Amine and amino acid transmitters are stored in and released from synaptic vesicles. Peptide neurotransmitters are stored in and released from secretory granules. These may coexist in the same neurone, to be released under different conditions.

### Transmitter release

Neurotransmitter release into the synaptic cleft is triggered by the arrival of an action potential at the axon terminal, where depolarisation of the terminal membrane causes voltage-gated calcium channels to open. Vesicles release transmitters by exocytosis at an active zone into the synaptic cleft; the vesicle membrane is recovered by endocytosis.

Secretory granules (dense core vesicles) also release neurotransmitters by exocytosis, but typically not at active zones. Peptide neurotransmitters are not released by every action potential, but typically by high frequency trains of action potentials. Peptide release is typically slow (50 ms), while amino acid and amine release is rapid.

### Transmitter-gated ion channels and G-protein-coupled receptors

Neurotransmitter–receptor binding – the key–lock analogy is simple but valuable – alters the shapes of receptor proteins and hence their function. There are two types of receptor. Transmitter-gated ion channels consist of protein subunits that open an ion pore, and change shape in response to neurotransmitter. For example, the

ACh-gated ion channel at the neuromuscular junction, permeable to both Na<sup>+</sup> and K<sup>+</sup>, is triggered to produce an excitatory post-synaptic potential (EPSP) in response to ACh. Both ACh and glutamate-gated channels trigger EPSPs when activated (i.e. they are excitatory). Glycine-gated and GABA-gated channels, permeable to Cl<sup>-</sup> ions and tending to hyperpolarise the resting membrane potential, are inhibitory, triggering inhibitory post-synaptic potentials (IPSPs). Amino acid and amine neurotransmitters deliver fast synaptic transmission via transmitter-gated ion channels.

G-protein-coupled receptors are involved in a more diverse, slower and longer lasting mechanism of chemical synaptic transmission in response to amino acid, amine and peptide neurotransmitters. Receptor proteins activate G-proteins that travel along the intracellular face of the post-synaptic membrane. These in turn activate effector proteins – membrane-located G-protein-gated ion channels or enzymes that synthesise second messengers. Binding of odorants to receptors within the olfactory system is an example G-protein-gated transmission.

### Glia

Within the CNS, four types of glial cells support neuronal activity: astrocytes, oligodendrocytes, microglia and ependymal cells. Schwann cells are the neuroglia of the peripheral nervous system, investing some peripheral axons with myelin. Neurones and glia are biologically interdependent.

### Astrocytes

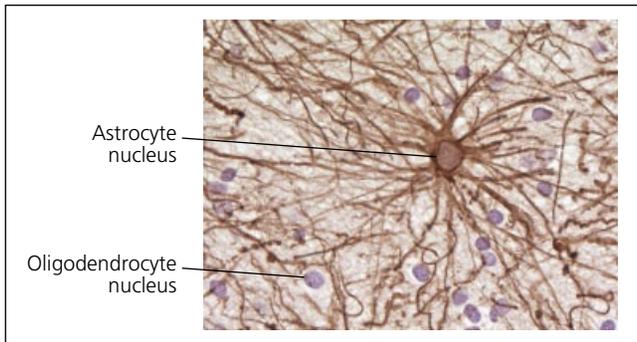

These are microscopically star-shaped shaggy cells from which protrude several dozen, fine astroglial processes that make intimate contact with neurones (Figure 2.6). Intermediate filaments within astrocyte cytoplasm lend tensile strength to the brain and cord. Glycogen granules within astrocyte cytoplasm provide intermediate

energy (glucose) to surrounding neurones. Astrocytes are engaged in recycling glutamate and GABA and scavenging potassium ions following neurotransmission; they have an essential role in controlling the composition of the extracellular fluid. Glial limiting membranes – from astrocytic processes – cover the pial surface of the brain and with ependyma line the ventricles. Vascular processes of astrocytes are in intimate contact with CNS capillaries. Astrocytes retain the capacity to multiply, and do so following neuronal injury to form glial scars (gliosis). Neoplastic proliferation leads to astrocytomas (see Astrocytomas, Chapter 21).

**Oligodendrocytes (oligodendroglia)**

One oligodendrocyte lays the myelin sheaths of 30–40 CNS axons, the inner and outer surfaces forming the spiral sheaths seen as minor and major dense lines on extracellular matrix. The axon is exposed between oligodendroglial segments at each node of Ranvier. Paranodal pockets – collections of cytoplasm – are visible at each end of each myelin lamination (see Schwann cells).

CNS myelination commences *in utero* and continues for some 20 years in humans. The effect of the ensheathing myelin lamellar spiral is to facilitate both saltatory conduction and axonal integrity.

**Figure 2.6** Astrocytes. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

The nature of CNS demyelination (i.e. the breakdown of normal rapid axonal saltatory conduction), seen typically in multiple sclerosis, is discussed in Chapter 11 (see Mechanisms). Neoplastic proliferation leads to oligodendrogliomas (see Oligodendrogliomas, Chapter 21). Within grey matter, modified oligodendroglia are seen as satellite cells – involved in interneuronal ion transfer. Many CNS axons remain unmyelinated – typically small <0.2-µm diameter fibres.

**Microglia**

Some cells of neuro-epithelial lineage develop into phagocytes, known as microglia. When stimulated by neuronal injury, demyelination or vascular CNS damage, these motile scavengers increase in size and number.

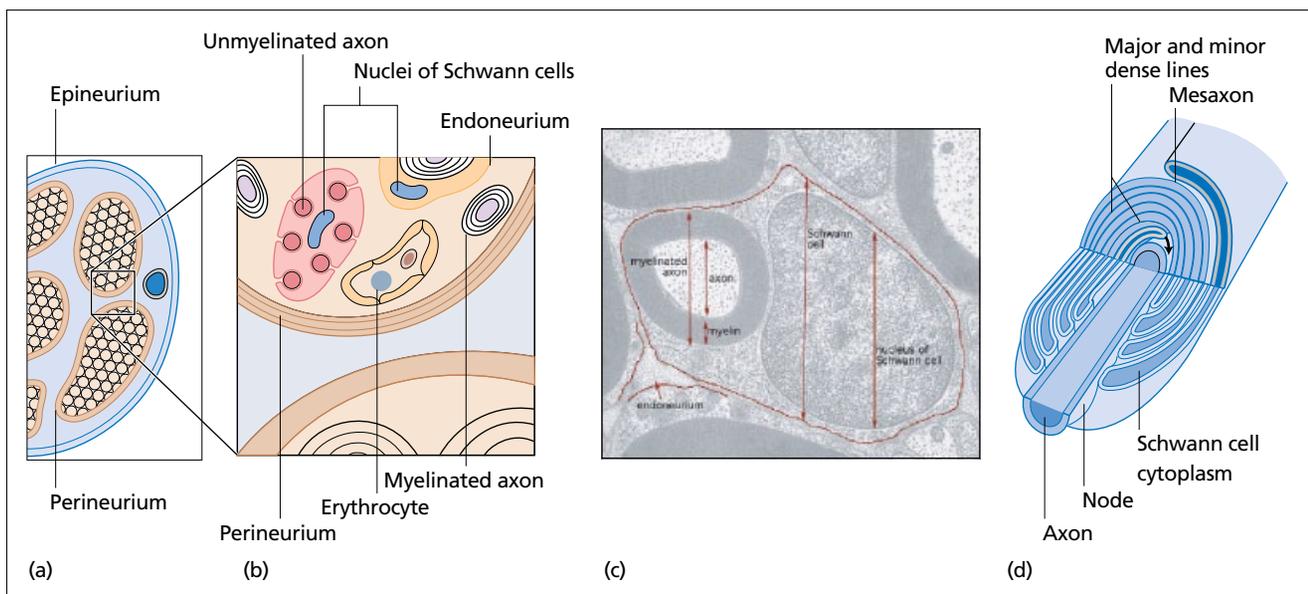

**Ependyma**

Ependyma are ciliated cells that line the cerebral ventricles and central cavity of the cord, together with astrocytic glial limiting membrane. Their function is to define the integrity of the parenchyma–CSF interface. Ependymal cilia are involved in CSF propulsion. Neoplastic proliferation produces ependymomas (Chapter 21).

**Schwann cells**

A sequence of Schwann cells ensheaths each myelinated axon of a peripheral neurone. Like CNS oligodendroglial sheaths, ultrastructural major and minor dense lines are seen, and paranodal sockets of cytoplasm at the end of each Schwann cell, recognised by Ranvier in the 1880s. The mesaxon is the mesenteric membrane, displaced centrifugally as the spiral layering of the Schwann cell develops (Figure 2.7). One main function of the Schwann cell is to make possible saltatory conduction. Modified Schwann cells, known as satellite cells, are found within posterior root ganglia and others known as teloglia at enclosed peripheral sensory nerve endings.

Myelination is an active lifelong process. Remyelination is the response to peripheral nerve injury. The effects and mechanisms of peripheral nerve demyelination are discussed further in Chapter 10.

**Table 2.2** Fibre types within peripheral nerves from various mammalian data.

Fibre type	Diameter (mm)	Conduction velocity (m/s)	Function
A $\alpha$ (mixed)	13–22	17–120	$\alpha$ -motor neurones, muscle spindle primary endings, Golgi tendon organs, touch
A $\beta$ (mixed)	8–13	40–70	Touch, muscle spindle secondary endings, joint position
A $\gamma$ (mixed)	4–8	15–40	Touch, pressure, $\gamma$ -motor neurones
A $\delta$ (mixed)	1–4	5–15	Pain, crude touch, pressure, temperature
B (mixed)	1–3	3–14	Preganglionic autonomic
C (mixed)	0.1–1	0.2–3	Pain, touch, pressure, temperature, post-ganglionic autonomic
Ia (afferent)	12–20	70–120	Muscle spindle primary endings
Ib (afferent)	11–19	66–120	Golgi tendon organs
II (afferent)	5–12	2–50	Touch, muscle spindle secondary endings
III (afferent)	1–5	4–20	Pain, pressure, temperature, crude touch
IV (afferent)	0.1–2	0.2–3	Pain, touch, pressure, temperature

### Peripheral nerve fibre types

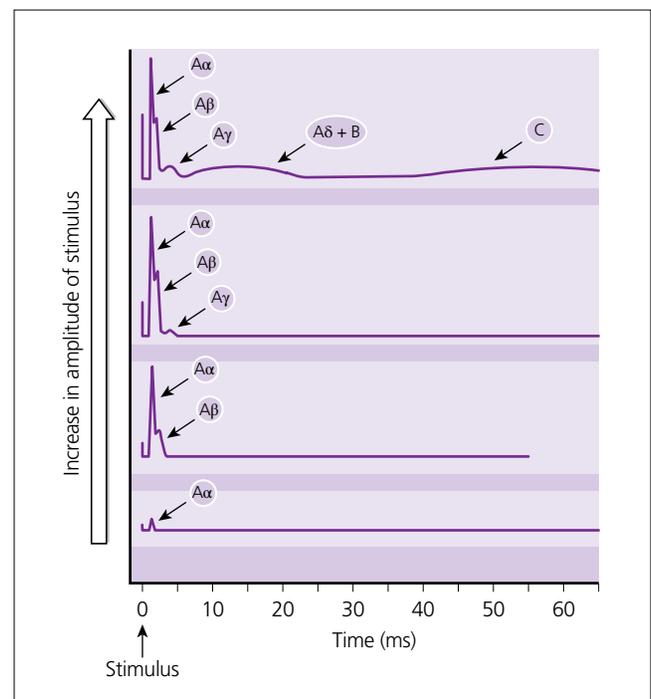

The complex classification (Table 2.2) of fibre types, assembled largely from mammalian data, is seldom used in clinical practice, but it is of value when a particular fibre type is studied. In the cat, conduction velocity up to 15 m/s is achieved in unmyelinated fibres and up to about 120 m/s in myelinated fibres; there is much variation between species. Afferent fibres are classified on a numerical system I–IV, while the A–C classification includes mixed nerves. Peripheral nerve ultrastructure is outlined in Figure 2.7; pathological features are discussed in Chapter 10.

### Myelin and saltatory conduction

The degree of myelination and fibre diameter are the principal factors determining conduction velocity. The contribution of each nerve fibre type to a compound action potential has been outlined earlier (Figure 2.8). In disease, mechanisms that alter nerve function are divided broadly into axonal (i.e. those that affect the axon itself), and demyelinating, where the integrity of myelin is compromised.

Myelin was a word coined by Virchow, simply for a fatty substance obtained from various tissues; it was adopted by Schwann to describe the ‘white substance’ of peripheral nerves. CNS myelin provides similar conduction properties, but there are specific neurochemical characteristics that differentiate it from peripheral nerve myelin. Some functional features of peripheral nerve myelin are outlined here:

- Rapid conduction along both peripheral nerves and within the CNS is achieved by saltatory conduction.
- In the myelinated nerve fibre the axonal membrane is adapted at regular sites. Of note, at each node of Ranvier voltage-gated sodium channels are concentrated; these are involved in action potential propagation. Fast and slow potassium channels are involved in membrane repolarisation.

**Figure 2.8** Recruitment of nerve fibre types with increasing stimuli. Responses from a typical mixed (motor and sensory) nerve (e.g. sciatic).

- Depolarization of the axonal membrane at each node of Ranvier is induced by an initial influx of sodium ions, leading to a voltage-dependent massive influx of more sodium ions, and a new wave of depolarisation to be propagated in saltatory fashion (i.e. jumping) to the next node of Ranvier.
- Depolarisation is also achieved in unmyelinated fibres, but by sodium channels distributed along the whole length of the axon.

**Table 2.3** Myelin protein characteristics.

	Approximate percentage*	Mass (kDa)	Chromosome†
<b>Glycoproteins</b>			
P0	65	28	1
PMP22	4	22	17
MAG	1	100	19
Periaxin	5	170	7 (mouse)
E-cadherin	<0.5	130	16
<b>Basic proteins</b>			
MBP	10	14–21.5	18
P2	5	14.8	8
<b>Other proteins</b>			
CNP	<0.5	46/48	17
PLP/DM20	<0.5	30/25	X
Cx32	<0.5	32	X

\*Of myelin proteins.

†In humans.

Myelin saves space and conserves energy – to achieve a given mean conduction velocity an unmyelinated axon would require a diameter some 40 times greater than a myelinated one and would consume 5000 times more energy.

### Composition of the myelin sheath

Peripheral myelin is the differentiated plasma membrane of a Schwann cell. It is a lipid-rich, tightly packed spiral surrounding the axon (Figure 2.7) penetrated by cytoplasmic channels (Schmidt–Lanterman incisures).

Gene cloning of the principal myelin proteins and their association with specific neuropathies has thrown light on their role in myelin formation, their function and maintenance. Some features of these proteins are outlined in Table 2.3.

### Glycoproteins

**Protein zero (P0)** P0, a major protein of peripheral nervous system myelin is expressed in all myelinating Schwann cells. The role of the P0 molecule is cell adhesion, promoting and maintaining tight compaction of myelin. One of its domains contributes to the intraperiod line.

**Peripheral myelin protein 22 (PMP22)** This is also concerned with adhesion between lipid and protein molecules. PMP22 is also found widely outside the peripheral nervous system.

**Myelin associated glycoprotein (MAG)** MAG is believed to participate in signal transduction during glial differentiation, axonal recognition, adhesion and neurite outgrowth. MAG is located in the Schmidt–Lanterman incisures, paranodal loops at nodes of Ranvier, in external and internal mesaxons and the peri-axonal Schwann cell membrane itself.

**Periaxin** The primary localisation of this peripheral nervous system-specific myelin protein is close to the peri-axonal membrane (rather than an integral membrane protein; cf. P0, MAG and PMP22).

**Epithelial cadherin (E-cadherin)** Cadherins are calcium-dependent adhesion proteins. In Schwann cells, E-cadherin is the major adhesive glycoprotein in non-compacted regions of the myelin sheath.

### Basic proteins

**Myelin basic proteins** Both central and peripheral nervous systems contain peripheral membrane polypeptides known as myelin basic proteins (MBPs). MBPs are believed to participate with P0 in the major dense line and compaction.

**Protein P2** P2 is a fatty acid-binding protein, with postulated roles in the assembly, maintenance and remodelling of myelin.

### Other proteins

Cyclic nucleotide phosphodiesterases (CNPs) are concentrated in the outer perimeter of the myelin sheath, the outer mesaxon, Schwann cell surface membrane and peri-axonal region. Proteolipid proteins (PLPs) are localised in compact myelin and thought to have a structural role in the intraperiod line. Connexin 32 (Cx32) is a component of gap junction channels. It is found at paranodal regions and at Schmidt–Lanterman incisures.

### Myelination and axon–Schwann cell interactions

In a developing nerve, a bundle of naked axons is surrounded by a single Schwann cell layer. Schwann cell–axon contact triggers Schwann cell proliferation. The axons become segregated and as maturation continues a one-to-one relationship develops – each Schwann cell investing a single axonal segment. The Schwann cell elongates and rotates as myelin develops about the axis of the axon, to form the nodal spiral structure seen on microscopy.

The precise nature of the axonal signal for myelination remains obscure. However, when Schwann cells receive the signal to myelinate, various transcription factors (Oct-6, Krox-20, Sox-10) participate in gene expression to ensure the particular myelinating phenotype of the individual Schwann cell.

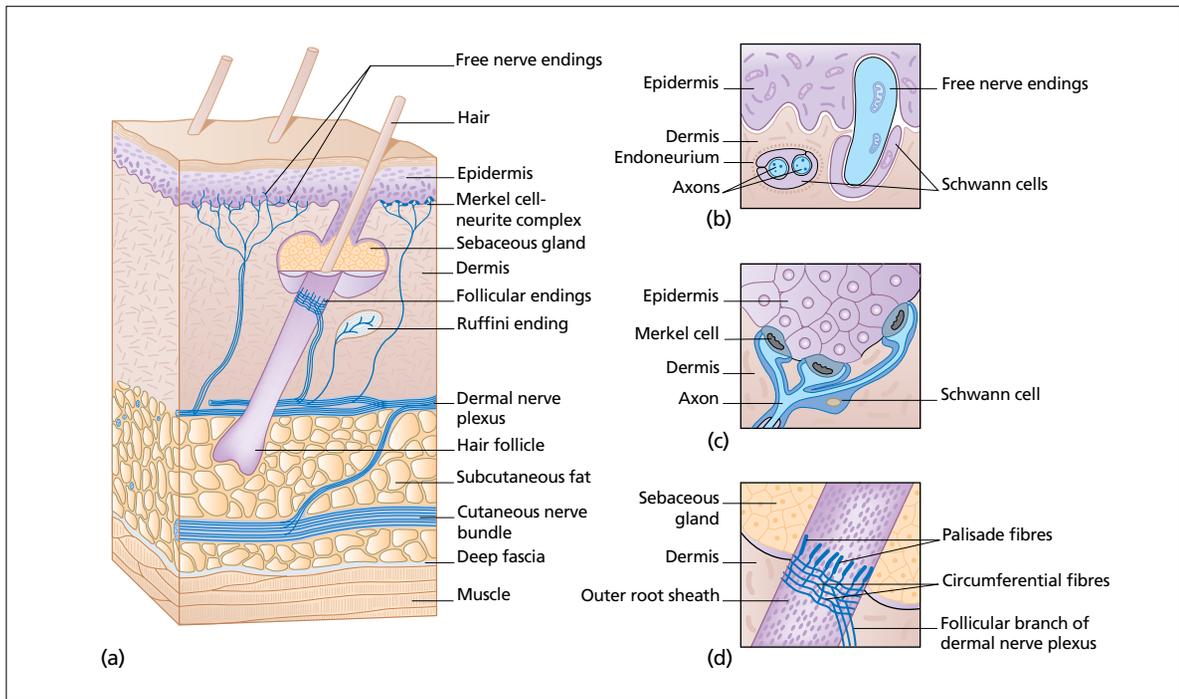

### Sensory nerve endings

A single nerve fibre has the same type of endings on each of its terminals, comprising a physiological sensory unit that receives information from a receptive field. In the skin, each receptive field covers some 5 mm<sup>2</sup> on a finger tip and 2 cm<sup>2</sup> on the upper arm. Sensory units of different modalities frequently supply the same patch of skin (Figures 2.9 and 2.10).

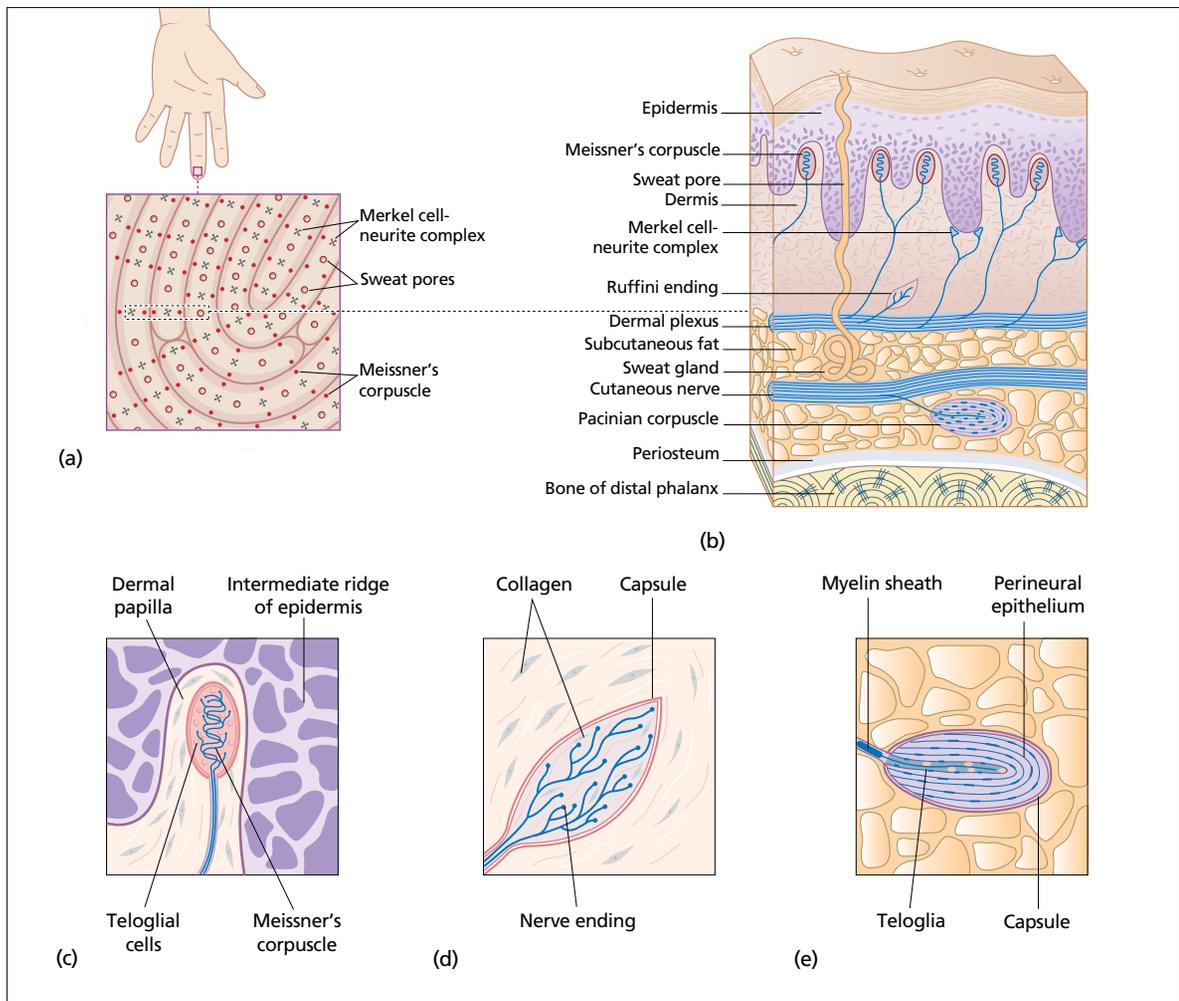

Nerve endings are:

- Free
- Follicular
- Encapsulated, or
- Merkel–neurite complexes
- Muscle spindle flower spray and annulospiral endings.

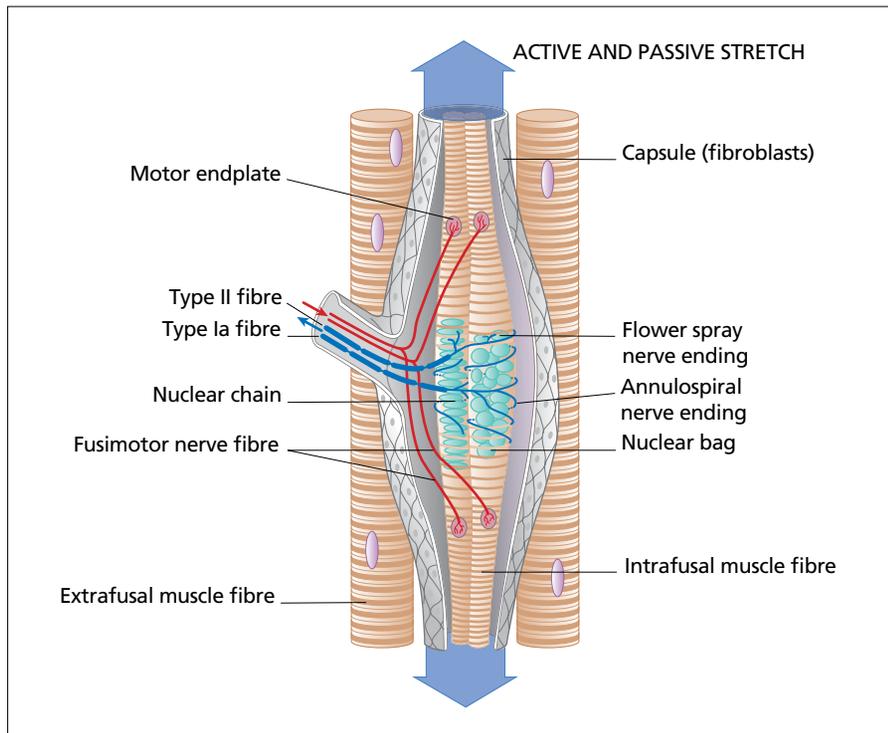

Free nerve endings (naked axons) that have lost both perineurial and myelin sheaths form a dermal and subepidermal network and innervate joints, ligaments and capsules. Some are thermoreceptors, others nociceptors. Some nociceptors (from finely myelinated A $\delta$  fibres) respond fast to severely painful stimuli (e.g. pinching). Others, from slowly conducting C fibres, are

**Figure 2.9** Examples of nerve endings in hairy skin. (a) General arrangement. (b) Free nerve endings. (c) Merkel cell–neurite complex. (d) Palisade and circumferential nerve endings. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

(d) Ruffini ending. (e) Pacinian corpuscle. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

**Figure 2.11** The muscle spindle. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

polymodal nociceptors, capable of sensing mechanical stimuli, heat, cold and chemical irritants. The axon reflex is mediated by C fibres.

Follicular nerve endings fire when a hair is being bent. A circumferential rim of nerve terminals surround an inner palisade, adjacent to each follicle.

Meissner's and Pacinian corpuscles and Ruffini endings are encapsulated by an inner membrane of modified Schwann cells (teloglia), a middle perineural layer and an outer coat of connective tissue. These mechanoreceptors are separated into four subtypes (Johansson-Vallbo classification):

- Meissner's corpuscles, most numerous on finger pads, detect delicate changes in texture (to 20  $\mu\text{m}$  in elevation) and are rapidly adapting.
- Pacinian corpuscles are subcutaneous, 2–3 mm in diameter and are plentiful (approximately 300) in each hand and foot and also embedded in the periosteum in the limbs. They are exquisitely sensitive to vibration, object detection and release.
- Ruffini endings in the skin respond to shearing stress (skin movement).
- Merkel–neurite complexes are expanded nerve terminals applied to Merkel cells (tactile menisci) within skin basal epithelium that respond to sustained pressure.

The pathophysiology of individual types of sensory nerve terminal is in its infancy, but presumably changes within these sensitive structures cause sensory symptoms that will in due course be recognised clinically.

### Muscle spindle motor supply, annulospiral and flower spray endings

Primary type Ia sensory fibres with annulospiral endings surround each intrafusal muscle fibre. Secondary type II fibres (flower spray endings) lie beside each annulospiral ending. Fusimotor fibres

are A $\gamma$  calibre and innervate contractile intrafusal fibres of the muscle spindle, whereas A $\alpha$  extrafusal fibres innervate skeletal muscle (Figure 2.11).

### Golgi tendon organs

Type Ib afferents form an entwining network around tendons. Golgi tendon organs signal force of contraction and effect negative feedback on agonist–antagonist muscle groups. An important function is to restrict joint oscillation.

## THE WORKING BRAIN

### Introduction

Neurons and glia are the structural and functional units of all parts of the nervous system. The remainder of this chapter outlines the structure of different regions of the brain and cord, the connections between them and how these operate. Some understanding of neuro-anatomy is assumed, and is readily available from reference texts.

The approach here is to take a typical activity, to trace its origins, describe its features and outline neuro-anatomical pathways and control systems. Movement is discussed first, because it has a pivotal role in clinical assessment.

### Mechanisms of movement

Skilled, coordinated, fast and appropriate movement is highly developed in humans. Almost all parts of the nervous system become involved – alertness, cognition, volition, mood, all special senses, sensory stimuli, the motor cortex and associated cortical motor and sensory areas, the spinal reflex arc, cerebellum, basal ganglia, motor nerves, neuromuscular junction and, obviously, muscles themselves.

The essential objects of movement are feeding, survival and reproduction. In humans, movement assumed signal further importance with the development and progressive use of tools to an extent that far exceeds the capacity of any other species.

### Three central systems of motor control

All movement is the product of activity within a highly interconnected network. Each final motor pathway that generates eye, head, body and limb movement is under the control of three major interrelated systems within the brain:

- Cortical
- Striatal (basal ganglia), and
- Cerebellar.

The major output from these systems is the corticospinal tract. This pathway originates from motor, somatosensory and limbic areas of the cortex; because all its fibres pass through the pyramids in the medulla, it is often referred to as the pyramidal tract. The tract is particularly well-developed in humans. Clinically, interruption of these fibres is recognised by abnormal physical signs – weakness and loss of skilled movement, and abnormal reflex activity, as seen in hemiplegia. The clinical signs associated with malfunction of the basal ganglia and cerebellum are fundamentally different.

These systems can also be thought of as comprising two motor loops: the cortex–basal ganglia–cortex and the cortex–cerebellum–cortex loops, with the corticospinal outflow providing the major conduit for activity that leads to limb movements generated within these two motor loops.

The corticospinal (pyramidal) system originates in the cortex and delivers information to cranial nerve nuclei and all levels of the spinal cord, including anterior horn cells (spinal motor neurones). Defective function is recognised by abnormalities in the patterns of skilled movement and weakness, and by the appearance of spasticity and reflex change.

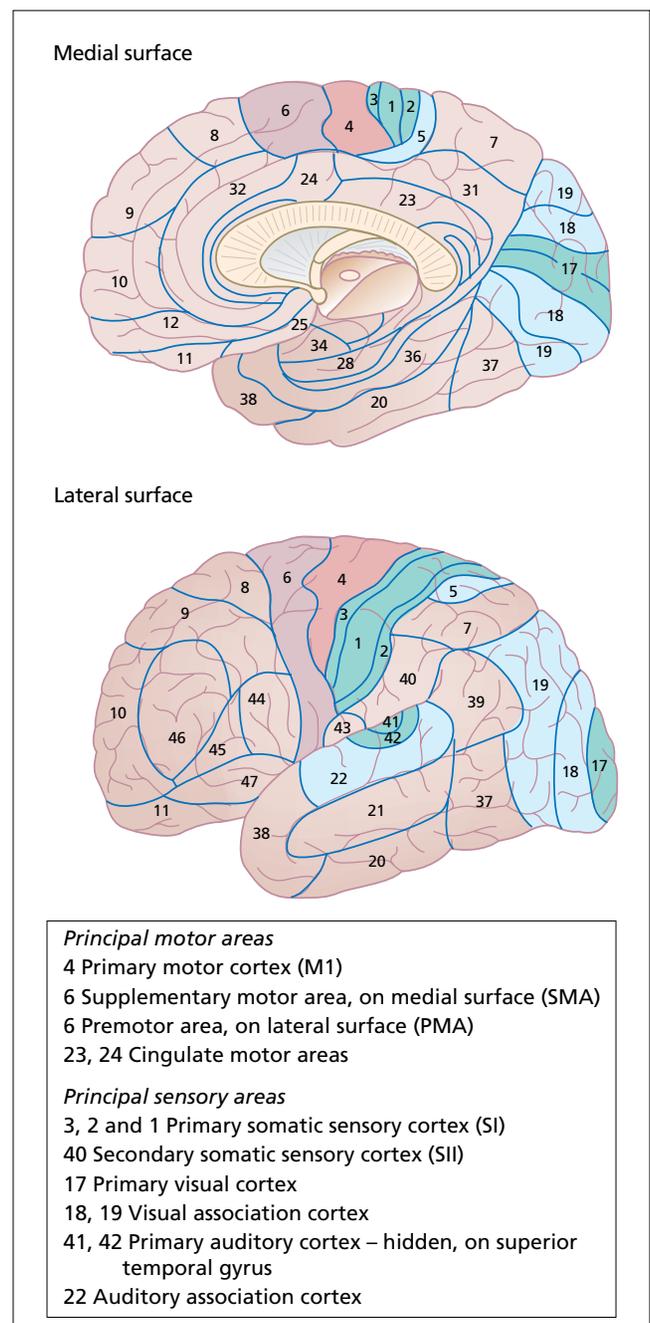

The striatal (extrapyramidal) system facilitates fast fluid movement via servo loops between cortex and basal ganglia. To the clinician, slowness (bradykinesia), stiffness (rigidity, rather than spasticity), rest tremor and various disorders of movement (dyskinesias) are the hallmarks of dysfunction in this system.

The cerebellum and its connections have a role in the coordination of smooth, programmed movement and balance. Ataxia (limb and/or truncal) and action tremor are the cardinal features.

It is reasonable and useful clinically to describe signs and syndromes as ‘extrapyramidal’, meaning slow and parkinsonian, but be wary of the term ‘extrapyramidal pathway’. This is because areas such as the basal ganglia that are involved movement disorders are also closely connected to other motor systems. For example, the main basal ganglia output pathway influencing movement is first via its return projections from thalamus to cortex, but thence through the corticospinal ‘pyramidal’ tract.

### Corticospinal (pyramidal) system

Penfield’s human cortical electrical stimulation experiments in the 1930s explored and mapped areas 4 (primary motor cortex, M1) and 6 (premotor area + supplementary motor area; PMA + SMA), developing the earlier work of Fritsch and Hitzig in the 1870s and individual observations by Ferrier, Sherrington, Campbell and others in the late nineteenth and early twentieth centuries. Brodmann’s cortical areas are shown in Figure 2.12 and the cortical contribution to the corticospinal pathway in Figure 2.13, noting the contributions from primary somatosensory cortical areas 1, 2 and 3 – and all cortical sensory areas concerned with movement towards or away

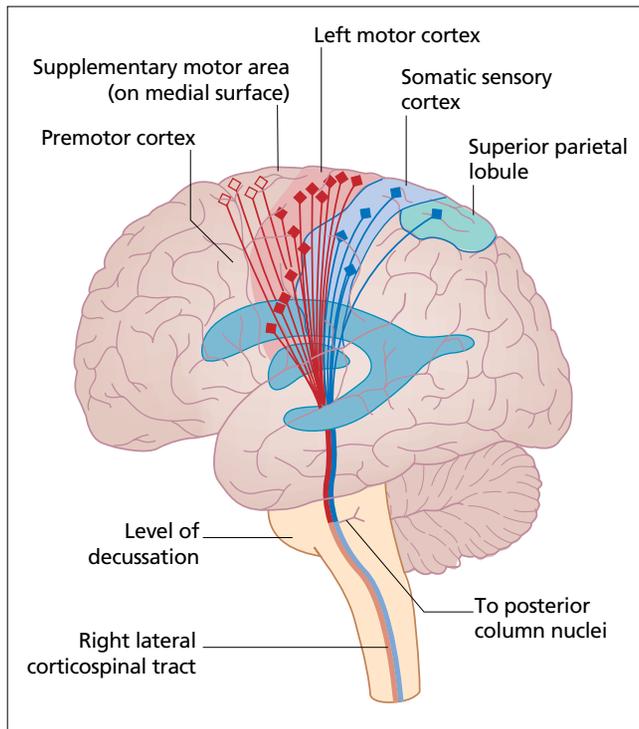

**Figure 2.12** Cortical areas (after Brodmann 1906). Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

from an object. A significant cortico-spinal projection also arises from the cingulate gyrus (areas 23 and 24).

Each corticospinal tract is made up of around  $1.1 \times 10^6$  fibres and is one of the longer and most compact fibre systems in the human CNS. Some two-thirds of these axons originate from cortical areas 4 and 6, where the cell bodies are located in lamina V of the cortex. Most of the remainder derive from parietal areas, including the somatosensory cortex, posterior parietal cortex and area SII. The course of the fibres through the internal capsule, cerebral peduncle, pons and medulla is shown in Figure 2.14.

The term corona radiata describes the radially arranged fan-like sheet of nerve fibres that continues caudally as the internal capsule.

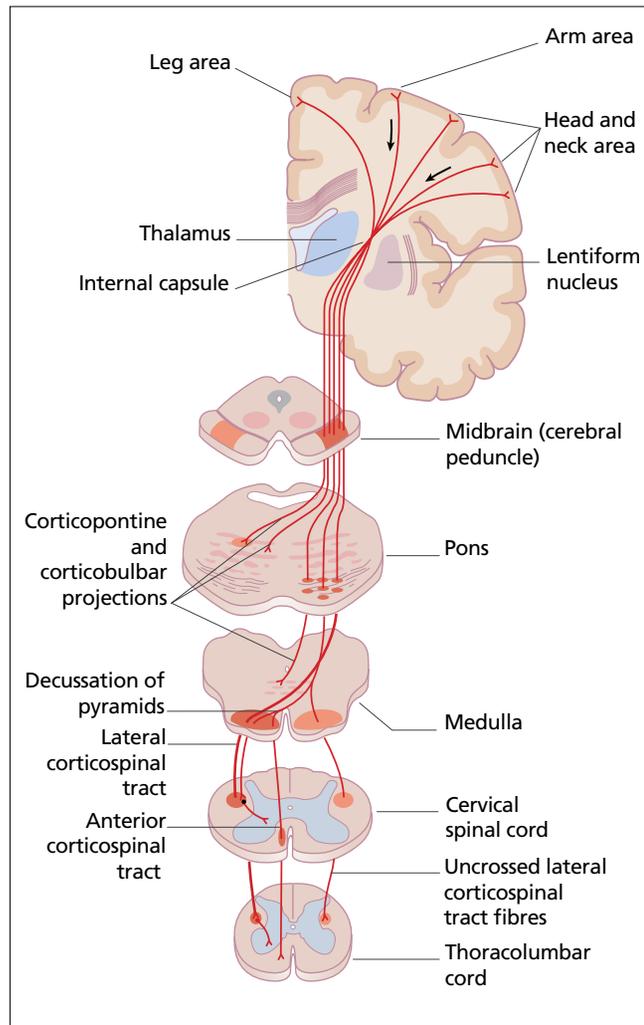

**Figure 2.13** Left hemisphere: cortical contributions to pyramidal tract. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

The area dorsal to the corona radiata, deep to the cortical mantle is known as the centrum semiovale. Pyramidal describes the roughly triangular cross-section of this tract in the medulla but, as discussed earlier, has come to be used functionally (and interchangeably) with corticospinal to describe the pattern of physical signs with disease of this pathway. The majority but not all (around 75%) pyramidal fibres continue into the spinal cord. After decussation, fibres congregate within the cord in the lateral corticospinal tract and terminate along the whole length of the cord, and in all layers of the spinal grey matter, including synapses on motor neurones in the anterior horn. Of corticospinal fibres, 10% remain uncrossed, their neurones of origin outlining an ipsilateral somatotopic map, but of little apparent clinical significance.

The comparative anatomy of the motor pathways indicates that in humans the corticospinal system, as the major descending pathway, has to some extent replaced other descending systems. For example, the rubrospinal tract, which arises from the magnocellular divisions of the red nucleus, is vestigial in humans.

**Movement direction and movement synergy** Neurones in area 4 are known to show patterns of activity that implicate them in the control of key parameters of movement, such as force, direction and timing of movements. The motor areas probably function to activate particular synergies of muscular action to bring about highly specific movements such as particular types of grasp. These synergies depend in part on the pattern of innervation by the direct cortico-motoneuronal projections from primary motor cortex to specific groups of motor nuclei at spinal level.

**Plasticity** In all primates, small cortical lesions cause initial paralysis, slowing, or clumsiness depending on lesion size, of a limb,

**Figure 2.14** Motor cortex and corticospinal (pyramidal) pathways. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

or part of a limb, followed by recovery within hours or days. This recovery is explained by changes in neighbouring cortical cell columns (i.e. plasticity). In the cord, local interneuronal mechanisms underpin movement synergies that function to provide individual skilled movements under the influence of different cortical signals. At a clinical level, following a hemiparesis, the early return of some fine finger or toe movement is a pointer to good recovery of function – a signal that a plastic process of compensation for the damage is under way.

#### Afferents to the primary motor cortex

The primary motor cortex does not act in isolation as the generator of fast skilled movement. Substantial afferent connections arrive from:

- 1 The opposite cortex via the corpus callosum. Most prominent are the dense links between cell columns controlling axial muscles, while the least dense are between distal parts of the opposite limbs. This might be expected – head and trunk posture cannot be under unilateral control, whereas the opposite is the case for fine hand movement.

- 2 Somatosensory cortex. Cutaneous cell columns (areas 1, 2 and 3b) pass forward via short association fibres deep to the central sulcus. Typically, the more complex the subserved movement function (e.g. hand movements), the denser the connections. Proprioceptive cell columns in area 3a receive afferents from muscle spindles and synapse via short association fibres with area 4.
- 3 Cerebellum, via contralateral dentate nucleus and motor areas of the thalamus. Cerebellar impulses determine synergy and timing of cortical neuronal discharges. The cerebellum receives a dense multimodal input of all sensory modalities, including vision.
- 4 Supplementary motor area (area 6) on medial surface of hemisphere. This part of area 6 is especially involved in motor planning, motor memory, intention and responds to internal cues. For example, the supplementary motor area is activated via the frontal lobe when a movement is intended. A major function of the supplementary motor area is programming motor sequences already within motor memory via a loop through the basal ganglia and projecting to area 4. Unilateral damage to the supplementary motor area causes contralateral akinesia.
- 5 Premotor cortex (PMC, area 6 on lateral aspect of hemisphere). The PMC, some six times the size of area 4, is in general responsive to external cues, and seen to be active on functional magnetic resonance imaging (fMRI) when motor sequences follow visual or sensory cues (e.g. reaching for an object in view or feeling the tactile shape of an object). The lateral PMC represents one of the major pathways through which vision is able to control fine movements.

### Basal ganglia and 'extrapyramidal' movement disorders

The term basal ganglia describes neighbouring areas within the deep forebrain and midbrain involved in the control of movement. In practical terms this includes:

- The striatum (caudate nucleus, putamen of lentiform nucleus, nucleus accumbens).
- The globus pallidus – lateral and medial parts, divided by the medial medullary lamina. These parts of the globus pallidus are often known as internal (GPi) and external (GPe). The GPi has as an anatomical extension, the pars reticularis of the substantia nigra.
- The subthalamic nucleus.
- The pars compacta of the substantia nigra.

The pathways between these structures are outlined here. The subject is made difficult by many factors: the sheer complexity of the circuitry, difficulty distinguishing differences in ultrastructure between different parts of the basal ganglia and difficulty recognising somatotopic differentiation in these structures, although such organisation exists. It is also frequently impossible to attribute a specific symptom or physical sign to a single structure. In other words (cf. the cerebral cortex), individual diseases do not appear to affect one discrete area, and thus localisation of one function to a particular zone is often not possible.

There was a relative paucity of interest in disorders of movement until the second half of the twentieth century. Advances in knowledge of the functions of neurotransmitters, levodopa therapy, stereotactic surgery, deep brain stimulation and fMRI and have brought a different focus to this field, which continues to expand rapidly.

Extrapyramidal, the term coined by Kinnier Wilson in the 1920s, is a loose but valuable term for the clinical features of these disorders, but it is in theory no more than a clinical pointer towards a motor disorder distinct from one with hallmarks of corticospinal

(pyramidal) or cerebellar disease. The words 'extrapyramidal syndrome' are usually used to describe a condition with slowing, stiffness and/or tremor seen in idiopathic Parkinson's disease and in other akinetic-rigid syndromes. However, extrapyramidal is also used, although less frequently, to include other disorders of movement, such as chorea, hemiballismus or dystonia. As previously noted, 'extrapyramidal syndrome' should not extend to 'extrapyramidal pathway'.

### Basic circuits within the basal ganglia

The clinical focus is upon the complex motor loops, with dysfunction typified by Parkinson's disease.

**Motor loops** Several neuronal servo-loops commence and end in the motor and frontal areas of the cerebral cortex. They all involve cortical projections to the striatum (putamen + caudate nucleus) and return projections to the cortex via the thalamus. Within each loop there exist two interrelated motor pathways: direct and indirect pathways. Transmission through the loops is controlled by activity in the nigrostriatal pathway, from the pars compacta of the substantia nigra to the lateral globus pallidus, where axons make two principal types of synapse, on excitatory D<sub>1</sub> (dopaminergic, direct pathway) and inhibitory D<sub>2</sub> (indirect pathway) receptors. Matters have become more complex with the discovery of several more dopaminergic receptor D subtypes.

In normal subjects, the nigrostriatal tract is tonically active, selecting preferentially the excitatory, direct pathway and leading, via the loop back to the cortex, to activation of the supplementary motor area before a movement. This early activation of the cortex is thought to underlie the electrical readiness potential (*Bereitschaftspotential*). Other projections to the motor cortex interact with those from the cerebellum to modulate motor cortex output to the spinal cord.

Activation of the cortex (i.e. the intention to move):

- Stimulates (glutamatergic) putamen neurones (tonically facilitated by nigrostriatal D<sub>1</sub> input), which
- Inhibit (GABAergic) medial globus pallidus neurones, which
- Release (disinhibit) ventral lateral nucleus (VL) thalamic neurones, which
- Activate the supplementary motor area.

The sequences can be seen in Figure 2.15.

The indirect pathway engages the subthalamic nucleus via:

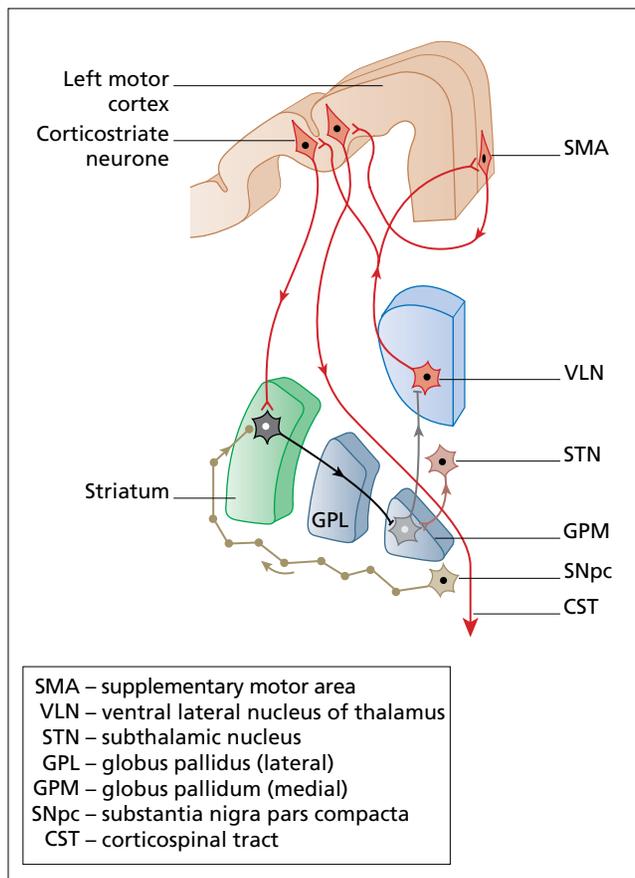

- Striatonigral that inhibit putamen neurones, which
- Inhibit the lateral globus pallidus (GPL), and
- Act on the subthalamic nucleus (STN).

The STN acts on the medial pallidum (somatotopically) to suppress unwanted movement. Destruction of the STN results in uncontrollable movements (see Hemiballismus, Chapter 6). However, high frequency stimulation of the STN relieves tremor and rigidity in Parkinson's disease.

**Normal functions of the motor loop** The basal ganglia do not initiate movement but they are active when action is generated by specific cell assemblies in the motor cortex:

- Scaling strength of muscle contraction and in collaboration with the supplementary motor area
- Programming appropriate movement sequences and suppressing others, and
- Controlling speed of movement.

The putamen is believed to act as a store of memorised, acquired motor programmes, with an ability to sequence appropriately movements intended and pass information to the supplementary motor area.

### Other basal ganglia circuits

- *Cognitive loop*: motor (volitional) intention
- *Limbic loop*: emotional correlates of movement, and
- *Oculomotor loop*: voluntary saccadic movements.

**Cognitive loop** A large projection of fibres from the prefrontal cortex reaches the head of the caudate nucleus. Increased activity in the head of the caudate, and anterior putamen, globus pallidus and ventral anterior (VA) thalamic nucleus, occurs when new movements are performed by the opposite hand, suggesting a role in motor learning. The VA nucleus projects to:

- The premotor cortex in an ‘open cognitive loop’
- The prefrontal cortex in a ‘closed cognitive loop’.

These connexions with the caudate point to the role of the cortex in forward planning of motor intentions. As a corollary, when a motor task has become automatic (i.e. entirely learnt), the motor loop of the basal ganglia appears to take over.

Parkinson’s patients have particular problems with new fiddly movements; they are unable to sequence and initiate them. Exceptional activity in this cognitive loop perhaps explains rare temporary release phenomena: immobile patients with severe Parkinson’s respond dramatically to great emotional stimulation – ‘they can run down the fire escape’. These ‘paradoxical’ movements may involve cerebellar circuitry.

**Limbic loop** This describes a loop from:

- Inferior prefrontal cortex, via
- Nucleus accumbens

- Ventral pallidum
- Medio-dorsal nucleus of thalamus, to
- Inferior frontal cortex.

This pathway is concerned with the visible expression of emotion – portrayed in facial expression or in more general postures with emotional content such as submission, dominance or aggression.

The stooped (simian) posture and facial masking of Parkinson’s disease can be explained by diminution of activity in this richly dopaminergic pathway – features reversed, at least in part, by levodopa.

**Oculomotor loop** This loop runs from:

- Frontal eye field and posterior parietal cortex (area 7), to
- Caudate nucleus, to
- Pars reticularis of substantia nigra (SNpr), to
- VA nucleus of thalamus, to
- Frontal eye field and prefrontal cortex.

An inhibitory GABAergic projection reaches the superior colliculus from SNpr. These inhibitory synapses are on neurones controlling saccades. Ocular fixation is accompanied by repetitive impulses (tonic activity) in SNpr. In other words, the eyes are held in one position of fixation by this tonic activity.

When a deliberate saccade takes place (‘I want to look right’), the superior colliculus is disinhibited by the activated oculomotor loop. The superior colliculus neurones discharge, reinforcing the direct motor loop and facilitating rapid (almost instantaneous, 70–100 km/hour) conjugate eye movement. Put another way, the sequence is:

- Release of superior colliculus neurones
- Gaze flicks to new target
- SNpr resumes tonic activity
- Gaze vigilance returns.

Slow eye movement (oculomotor hypokinesia) is evident in Parkinson’s disease, although it is a minor clinical issue because axial movement (e.g. head turning) is slow. Ocular hypokinesia is explained by loss of dopamine in SNpr, and faulty disinhibition of superior colliculus neurones.

### Cerebellum

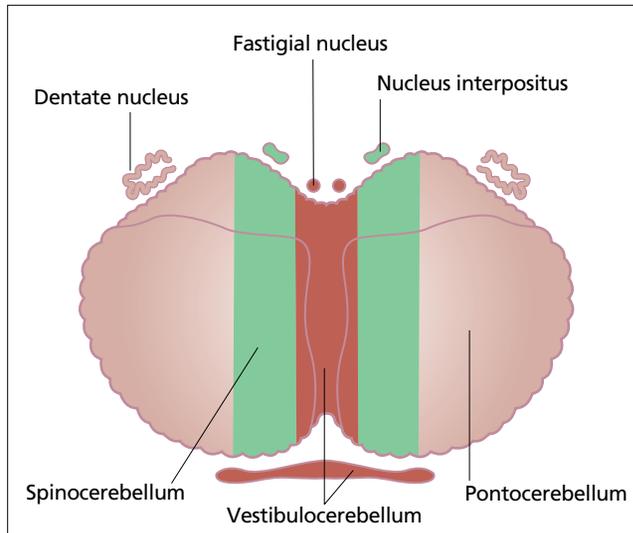

Cerebellar disease is recognised by physical signs of action tremor, nystagmus, truncal and/or gait ataxia and scanning speech (see Physical signs, Chapter 17).

Phylogenetically, functions of the cerebellum in fish were closely allied to the lateral line organs that comprise the fish vestibular system – controlling the fish’s horizontal and vertical posture in water. In quadrupeds, connections with the spinal cord became prominent, facilitating improvement in agility of gait, running and turning. In bipeds, with emerging lateralised skills rich linkages developed between cerebellar lobes and cerebral cortex. These newer cerebellar pathways became intimately concerned with coordination of ipsilateral limbs in addition to the earlier vestibular and spinal connexions.

There are three main zones of the cerebellum (Figure 2.16). Each sends its main output to a distinct nucleus or nuclei:

- 1 Vestibulocerebellum is the central strip (vermis + fastigial nucleus), with primarily sensory afferents from the vestibular system. Output: fastigial nucleus and brainstem vestibular nuclei.
- 2 Spinocerebellum describes regions adjacent to the vermis, with major sensory input from the spinal cord. Output: nucleus interpositus.
- 3 Pontocerebellum (neocerebellum – lateral lobes) receives a massive neuronal input from the contralateral pontine nuclei, the main input of which comes from the cerebral cortex. Output: dentate nucleus. The neocerebellum is most developed and largest in humans.

**Cellular anatomy** The cerebellar cortex has an outer molecular layer, an inner granular layer, with the piriiform layer between the two (Figure 2.17). The granular layer consists of billions of small 6–8  $\mu\text{m}$  diameter neurones (granule cells) with short dendrites. These dendrites receive excitatory synapses from mossy fibres that run to the cerebellar cortex, giving off collateral branches to the deep cerebellar nuclei. Granule cell axons pass to the outer molecular layer, dividing to form parallel fibres, running parallel to the cerebellar folia, to make excitatory synaptic contacts with dendrites of Purkinje cells whose cell bodies lie in the piriiform layer.

**Figure 2.16** Zones of the cerebellum. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

Purkinje cells, large neurones with extensive dendritic trees, are interwoven by numerous parallel fibres. Each parallel fibre makes successive single (one-per-cell) synapses with 300–500 individual Purkinje cells. The action of each parallel fibre is excitatory – although many thousand parallel fibres need to act simultaneously to depolarise a single Purkinje cell.

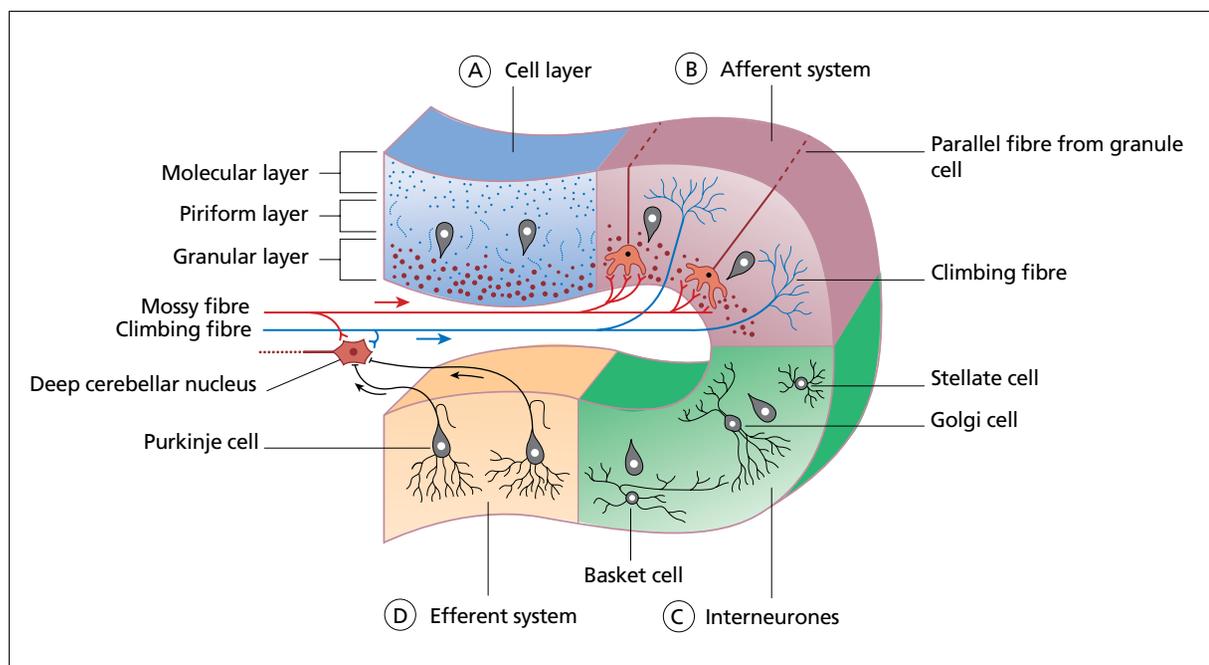

From the contralateral inferior olivary nucleus, each Purkinje cell dendritic tree receives a single climbing fibre. This fibre makes synaptic contact with thousands of dendritic spines of a single Purkinje cell. A single action potential in a climbing fibre triggers a short burst of action potentials from each Purkinje cell, which then becomes temporarily unresponsive to the effects of parallel fibre inputs. Purkinje cell axons leave the cerebellar cortex, the only efferent axons to do so, to reach the deep cerebellar nuclei (dentate, inferior olivary, interpositus), upon which they exert a uniformly inhibitory action.

The molecular layer contains three further, largely inhibitory cell types: basket cells, stellate cells and Golgi cells.

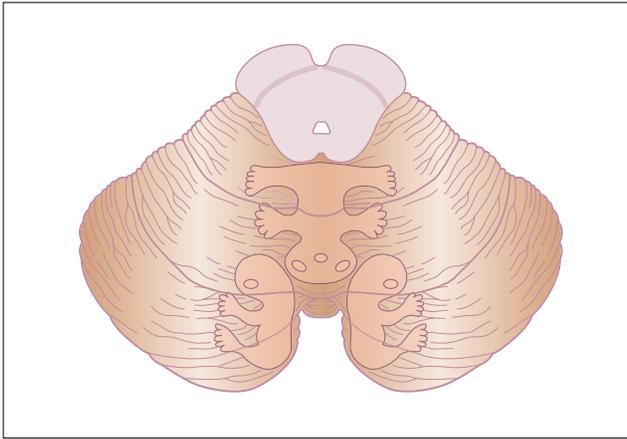

**Somatotopic representation in the cerebellum** Positron emission tomography (PET) and fMRI have confirmed the somatotopic representation deduced from animal studies (Figure 2.18). Corresponding fMRI activity for hand movement in humans is shown in Figure 2.19.

**Afferent cerebellar pathways** The scope and complexity of these pathways is summarised here:

- From muscles and skin (trunk and limbs), information from the posterior spinocerebellar and cuneocerebellar (cuneiform nucleus) tracts enter via each ipsilateral inferior cerebellar peduncle. The massive similar trigeminal input (from the head) enters via all three peduncles.
- Afferents monitoring activity in spinal reflex circuits, in the anterior spinocerebellar tracts loop into each superior peduncle via the pons.

**Figure 2.17** Cerebellar cortex cell systems. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

**Figure 2.19** Cortical and cerebellar fMRI: voluntary activity of left hand. Courtesy of Dr Alex Leff, UCL Institute of Neurology.

- Vestibular, auditory and visual pathways make up the tecto-cerebellar tracts to enter the ipsilateral superior peduncle.
- The pontocerebellar tract, bringing massive mossy fibre input from the cerebral cortex, enters the contralateral middle cerebellar peduncle.

- The olivocerebellar tract enters the contralateral inferior peduncle (climbing fibre input).
- Reticulocerebellar tracts enter via the inferior peduncles.
- Aminergic fibres (serotonin and noradrenaline) enter all three cerebellar peduncles from the brainstem – excitatory transmission in mossy fibres and climbing fibre terminals.

#### *Olivocerebellar tract, learning, the red nucleus and novelty detection*

The inferior and accessory olivary nuclei receive fibres from the ipsilateral sensorimotor (cerebral) cortex. These project as climbing fibres to each contralateral cerebellar cortex in a somatotopic order (accessory nuclei to an anterior cerebellar map, principal nuclei to posterior). When primates are trained to carry out a repetitive motor activity, Purkinje cells show increased simple spike activity – an indication of increased mossy fibre and parallel fibre input. If the task is interrupted (e.g. if activity is physically obstructed), bursts of Purkinje cell complex spikes appear, caused by climbing fibre input. At least, they do so initially. If the obstruction is sustained, these complex spike bursts diminish and eventually disappear. This is one example of the role of the cerebellum in learned movement, for which there is much evidence both in animals and in humans. The system acquires, or adapts to new motor activity. Additional connections to the olivary nuclei come from the visual association cortex and the spino-olivary tract.

Finally, the red nucleus receives collaterals from (cerebral) cortical fibres descending to the olive, and from cerebellar efferents en route to the thalamus. The principal output from the red nucleus is inhibitory to the ipsilateral olive. There is evidence to suggest that if an imbalance occurs between movement intended (cerebral cortex) and movement learned or organised (cerebellum), the red nucleus modulates cell groups within the olive to achieve harmony, and it detects novelty in an organised action. The coarse tremor seen in lesions of the red nucleus can be thought of as a breakdown of this harmonic, over-correcting each part of a movement, and failing to learn to control it.

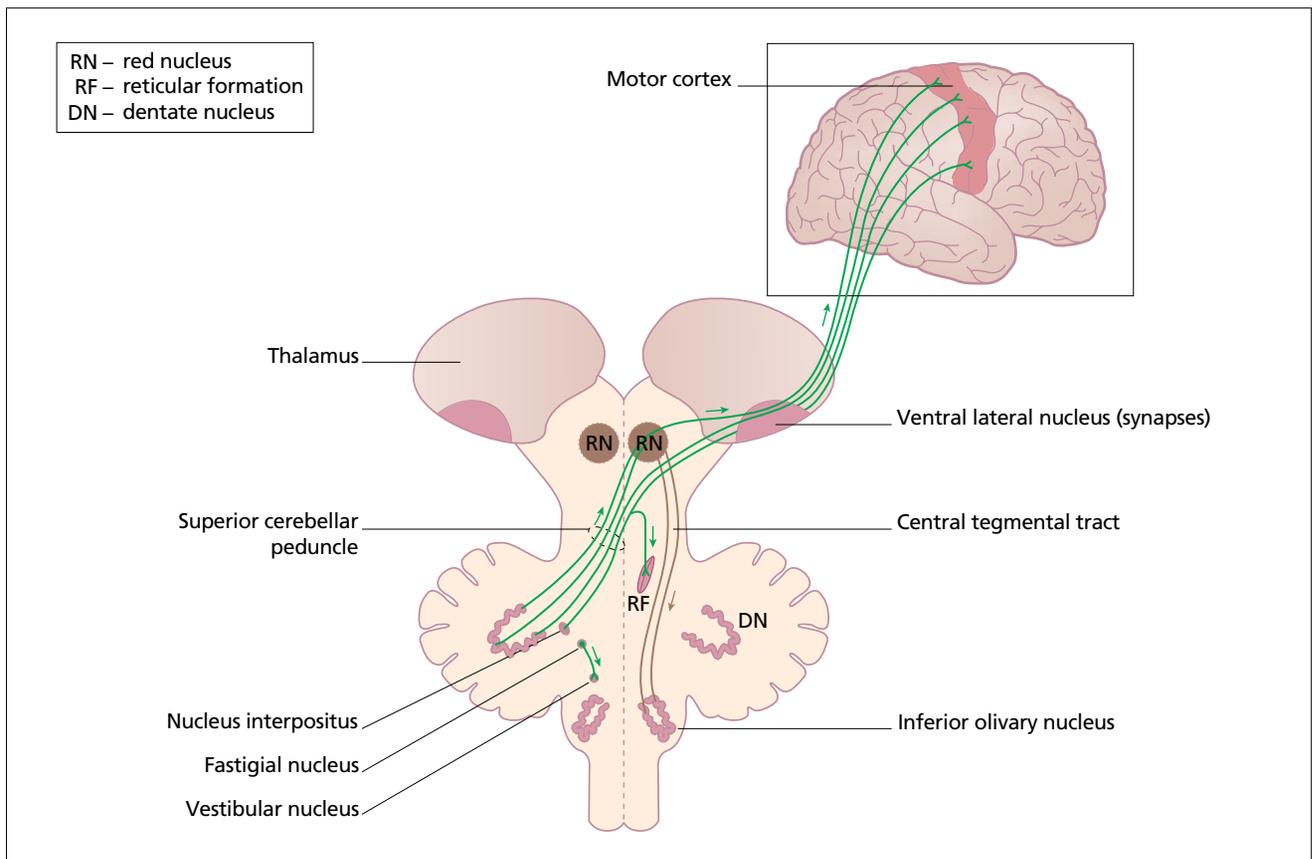

*Efferent pathways* The vestibulocerebellum projects to the vestibular system, the spinocerebellum to the cord and the neocerebellum to the red nucleus, thalamus and motor cortex.

From each fastigial nucleus in the vestibulocerebellum, via the inferior peduncles, axons reach both (right and left) vestibular nuclei (Figure 2.20). Output from the medial and superior vestibular nuclei passes to the medial longitudinal fasciculus, and thus control conjugate lateral gaze. From lateral vestibular nuclei (of Dieter), efferent fibres pass to the vestibulospinal tracts; these help control balance and axial stability. Some fastigial outputs pass directly to the spinal cord, for control of head and neck movements.

From each nucleus interpositus (spinocerebellum) axons travel in the superior peduncle, ending largely in the contralateral reticular formation (posture, gait) and red nucleus (motor learning).

In the neo-cerebellum, outflow from the dentate nucleus makes up the majority of the superior peduncle (dentatorubrothalamic tract), and crosses in the brainstem before reaching both red nucleus and motor thalamus. The latter sends onward projections to the cortex.

*Clinical correlates* In contrast to the complexity of cerebellar micro-anatomy, physical signs of cerebellar disease are distinct, relatively straightforward to recognise but often hard to attribute to individual pathways (Chapters 6 and 17). A lesion of one lateral lobe (e.g. tumour or infarction), causes rebound and past pointing

**Figure 2.20** Cerebellar efferents. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

of the outstretched upper limb – a clinical correlate of the effect of obstruction to a programmed activity described above. Vermis lesions (see Medulloblastoma, Chapter 21) affect primarily vestibular connexions. Truncal ataxia is often an early sign.

Anterior cerebellar lobe lesions (often bilateral, and typically caused by alcohol) cause gait ataxia, often with pronounced head tremor (titubation). In chronic alcohol damage, substantial loss of all major neurone types develops (granular, Purkinje and molecular layer cells). Depression of tendon reflexes – an unusual cerebellar sign, and of little usual clinical value – is explained by loss of tonic stimulation of fusimotor neurones connected via pontine reticulospinal fibres. Nystagmus (coarse, fast phase towards the side of the lesion, and dramatic when it occurs) is an inconstant feature of cerebellar lesions.

Finally, the cognitive affective cerebellar syndrome is of interest, if rarely diagnosed. This syndrome comprises diminished reasoning, inattention, poor memory and flattening of affect, sometimes seen transiently after major cerebellar lesions (e.g. following surgery or massive cerebellar infarction). One explanation, is temporary reduction in blood flow to cerebral cortical association areas, possibly because of diminution of expected impulses of cerebellar origin to the thalamus, and thence to prefrontal cortical areas.

## Sensation and sensory pathways

The neurologist usually deals with sensation in its five clinical modalities: touch, nociception, temperature, joint position and vibration sense. The neuroscientist has a wider perspective, looking at sensation first as conscious or non-conscious. Conscious sensation

is perceived largely at cortical level. Non-conscious sensation is processed within the cortex too, but also within the cerebellum, via the vestibular system, in the reticular formation and widely within the CNS. It is sometimes hard to say precisely whether a sensation is conscious or non-conscious. For example, vertigo, the illusion of movement, is clearly conscious. However, the precise posture of the head in relation to the trunk is usually non-conscious, whereas the position of limb in relation to an object is usually conscious. Partly because of this problem, and in part because of the complexity of the nervous system, it is often hard to say where a particular sensory modality is localised or how it is perceived. Some of the essentials of the sensory pathways are summarised here. Circuitry within the spinal cord is dealt with in more detail in Chapter 16 (see Anatomy and physiology of spinal maldevelopment).

### Conscious and non-conscious sensation

Conscious sensations are exteroceptive and proprioceptive. Exteroceptive sensations stimulate surface somatic receptors (e.g. touch, nociception, temperature) or telereceptors (vision, hearing, olfaction). Proprioceptive (conscious) sensations arise from joints, muscles, bones and the labyrinth (vestibular system). For example, vestibular pathways to the cortex enable us to perceive whether we are stationary or moving, and to discriminate between constant movement, deceleration and acceleration.

Non-conscious sensations are of two kinds:

- Afferent proprioceptive information (e.g. from muscles, joints, tendons, labyrinth) reaching the cerebellum, cortex, reticular formation and elsewhere, and
- Enteroception (e.g. afferents from the gut, heart or blood vessels).

### Somatic sensory pathways in the cord and brain

Two major pathways deliver sensory information to the thalamus and thence to the cortex:

- Spinothalamic pathways (nociceptive);
- Posterior columns → medial lemnisci (touch, position, movement).  
Each system consists of first, second and third order neurones. They have the following features in common:
  - The cell bodies of first order neurones are in the posterior root (dorsal root) ganglia
  - Second order neurones decussate before reaching the thalamus
  - Third order neurones project from thalamus to cortex
  - There is somatotopic organisation throughout the system, and
  - Transmission can be controlled (inhibited/enhanced) between first to second, and second to third order neurones (see Gate control in this chapter, and Neurostimulation procedures: gate theory, Chapter 23).

### Dorsal root ganglia – first order neurones

The arrangement of spinal nerves, dorsal and ventral roots, laminae of the posterior horn and named cell groups are illustrated in Figure 2.21. The complexity of information outlined in the figure is exemplified by the fact that a single nerve root ganglion serving a limb contains around 100 000 neurones, each enshrouded by satellite cells (modified Schwann cells).

### Termination of dorsal root afferents

In the dorsal root entry zone, afferent fibres separate into medial and lateral streams. The lateral stream (A $\delta$  and C fibres) divides into short ascending and descending branches within the posterolateral tract of Lissauer. They then synapse in lamina I (marginal zone), lamina II (substantia gelatinosa) and in III–V.

The medial stream (type I and II mechanoreceptors) divides into ascending and descending branches in the posterior columns. The shorter branches synapse in laminae II, III, IV, V and VI. The longer branches run throughout the posterior columns of the cord to the gracile and cuneate nuclei in the medulla.

### Posterior column → medial lemniscus pathway

The fascicles of the posterior columns of the cord are formed partly by axons of dorsal root ganglia (first order neurones) and partly by axons of second order neurones in the dorsal horn of the spinal grey matter. These axons all project to the gracile and cuneate nuclei in the brainstem, whose axons then decussate in the medulla to form each medial lemniscus (ribbon) that terminates in the lateral part of the ventral posterior nucleus of the thalamus. Thalamo-cortical neurones (third and fourth order) then project to the somatic sensory cortex.

### Spinothalamic pathway

The anterior and lateral spinothalamic tracts consist of second order neurones passing from laminae I, II, III, IV and V of the posterior grey horn to the opposite thalamus. The two tracts merge in the brainstem to form the spinal lemniscus and then enter the ventral posterior nucleus of the thalamus. Third order thalamic neurones project to the somatic sensory cortex (Figure 2.22).

### Other ascending sensory pathways

The two sensory pathways described above dominate the clinical neurology of sensation. Other sensory pathways dealing more with non-conscious sensation are mentioned briefly here.

Spinocerebellar pathways (four on each side) are concerned with non-conscious proprioception and interactions between spinal motor neurones and interneurones (i.e. the excitability of reflex arcs), and movements involving balanced activation of agonist and antagonist muscles:

- Posterior spinocerebellar tract
- Cuneocerebellar tract
- Anterior spinocerebellar tract
- Rostral spinocerebellar tract.

The spinotectal tract passes information from the spinal cord to the superior colliculus, thus relating orientation of the trunk and head towards a visual stimulus. This information is important in orientation reflexes to visual stimuli.

The spino-olivary tract sends tactile information to the inferior olivary nucleus and thence to the opposite cerebellar cortex. This pathway is believed to have a role in motor learning.

Spinoreticular fibres originating in dorsal roots accompany the spinothalamic pathway in the cord. Their functions are arousal and reporting on the content of a stimulus, for example whether it is noxious (pin-prick) or pleasurable (stroking). This is in contrast to the more analytical nature of the spinothalamic pathway which determines the precise nature, intensity and location of a stimulus.

## The brainstem

The brainstem's complexity can be understood by considering first its principal fibre systems, its cell columns (nuclei) and traversing connections:

- Principal efferent (motor) pathways
- Principal afferent (sensory) pathways
- Cranial nerve nuclei
- Reticular formation
- Autonomic, basal ganglia, cerebellar and vestibular traversing connections.

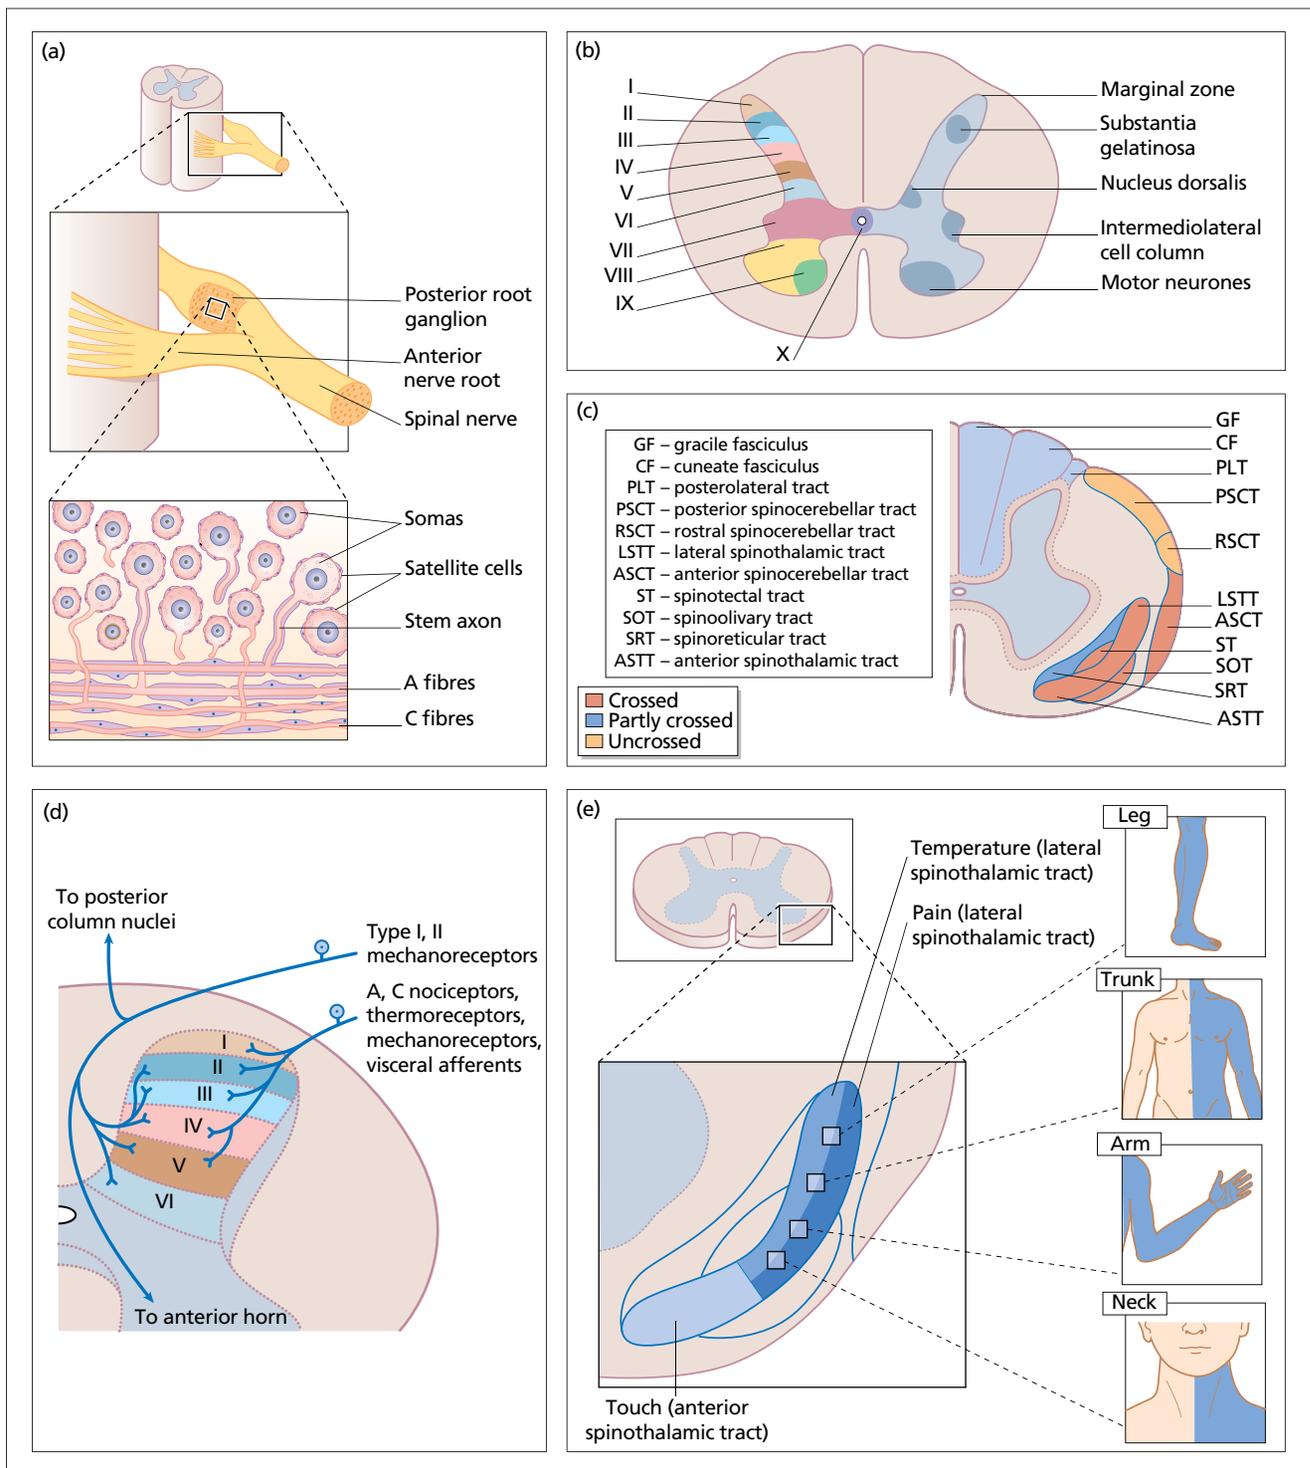

As landmarks, five guidelines are helpful:

- 1 Motor pathways lie in general ventrally.
  - 2 Sensory pathways lie dorsally.
  - 3 Cranial nerve nuclei (two longitudinal columns) denote different levels in the superior–inferior (rostral–caudal) plane.
  - 4 Reticular formation (RF) nuclei tend to lie laterally; some (magnus raphe, median raphe) are midline.
  - 5 Traversing connections are found in all layers of the brainstem.
- See also Chapter 4 (see Figure 4.19).

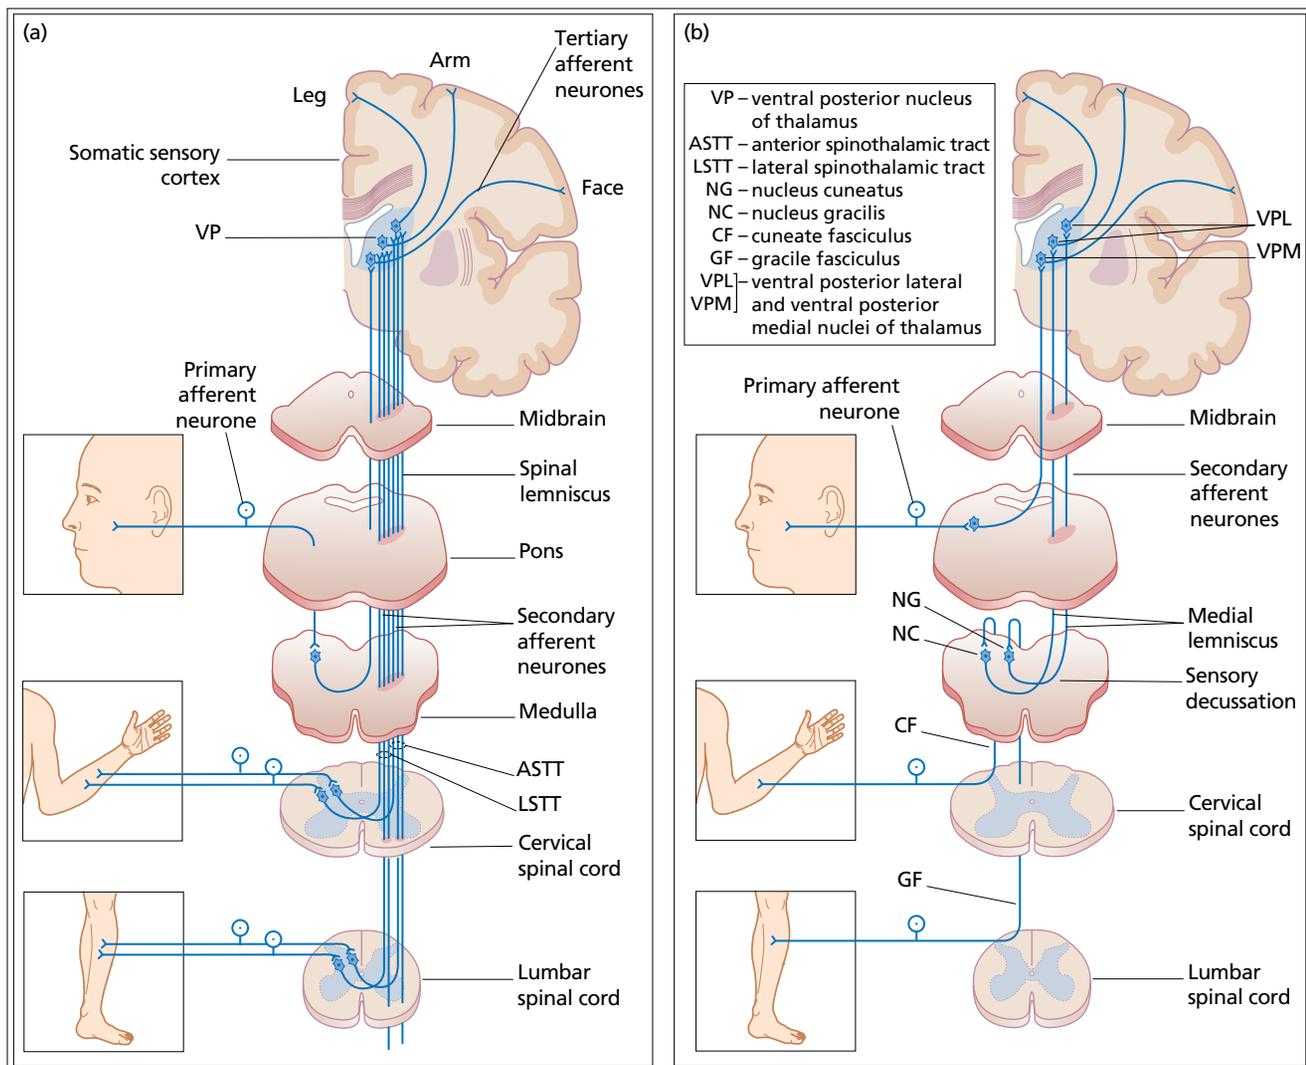

### Brainstem functions

Another approach to the intricacy of the region is to consider that phylogenetically the brainstem was almost the entire brain of distant invertebrate ancestors. For example, the RF connected olfaction to reflex movements associated with alertness, respiration, autonomic function and feeding, and hence survival. As more advanced creatures evolved, cranial nerve nuclei, cortical regions and the cerebellum developed, each to serve specialised functions, such as vision and hearing. The brainstem, in addition to any earlier role became by default the conduit for many pathways to and from those destinations, adding to its complexity.

The reticular formation, a major part of the brainstem, has no single overriding function, in the sense that there is no clinical condition recognisable when it is damaged. However, changes within the RF have prominent effects, principally on respiratory control, sleep and wakefulness, cardiovascular control, patterns of primitive movement, sphincters and mood.

### Motor fibres

The cerebral peduncle carries all cortical efferent fibres to and/or through the brainstem (corticofugal fibres). These tightly packed motor fibres supply, medially to laterally (Figure 2.23a):

- Eye movements
- Face
- Upper limbs
- Trunk, and
- Lower limbs.

Within the ventral pons motor fibres come to lie in separate bundles. Those for eye movements and face leave to reach their nuclei. The remaining bundles then reaggregate in the upper medulla as the pyramidal tract (medullary pyramids). Upper limb (UL) fibres remain medial; lower limb (LL) fibres lateral. A high proportion of these cortico-fugal fibres project to the ipsilateral pontine nuclei; this is the pathway mediating the output of the cerebellar–cortical loop.

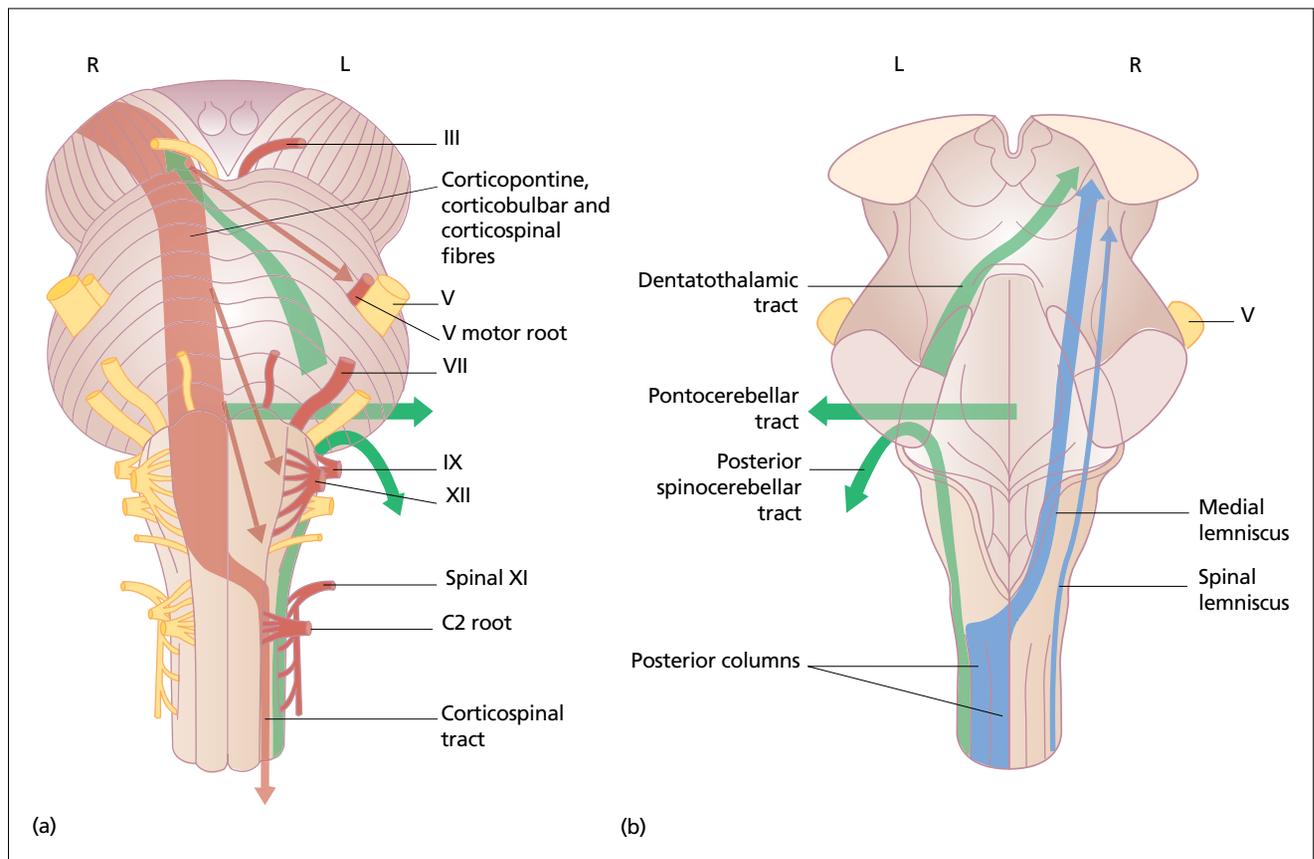

Crossing of motor fibres (pyramidal decussation) takes place below the medullary pyramids, so named because of the triangular cross-section of each. Topographical order is maintained: UL medial and LL lateral. UL fibres cross higher in the medulla than

LL fibres. This makes it possible, though seldom seen, for tiny brainstem lesions to cause bilateral UL weakness (sparing LLs), or even weakness of one UL and the opposite LL. However, paraparesis or tetraparesis is a more common result of a pyramidal tract lesion.

### Motor fibres to cranial nerve nuclei

These corticobulbar motor fibres pass caudally in the genu (knee) of the internal capsule. Depending on the cranial nerve nucleus for which they are destined, a proportion of fibres cross the midline. These proportions vary: some cross completely, some not at all and others in a ratio of about 50 : 50. Understanding these innervation arrangements explains common clinical phenomena.

- Motor nuclei V (mastication muscles) receive 50% of fibres from each cerebral hemisphere. Thus, an internal capsule stroke usually causes no perceptible jaw deviation.
- Nuclei VII are supplied differentially (i.e. upper facial nuclear neurones are supplied 50 : 50 from each hemisphere and lower facial neurones are innervated by crossing fibres). Thus, lesions of the UMN facial motor pathway spare the upper face (i.e. the

**Figure 2.23** Brainstem main efferent (a) and afferent (b) pathways. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

familiar fact that a unilateral stroke causes lower but not upper facial weakness).

- IX, X, XI, XII motor nuclear neurones (in nucleus ambiguus and hypoglossal nucleus) are supplied variably by corticobulbar fibres in different individuals (i.e. sometimes 50 : 50, but sometimes less symmetrically). Thus, following an internal capsule stroke, usually there is usually no unilateral palate, tongue or vocal cord weakness (i.e. innervation is 50 : 50 from each side). However, on occasions when unilateral deviation of the tongue is seen in a hemiparesis, it is because the supranuclear innervation of the XIIth nucleus is largely contralateral – there is no need to consider an additional lower motor neurone (nuclear) brainstem lesion (see Pseudobulbar palsy, Chapter 13). The hypoglossal nuclei also receive projections from the RF (see Motor nuclei of V and supratrigeminal nuclei), cortical speech areas and cerebellum.
- For the XIth motor nucleus, uncrossed supranuclear fibres innervate the XIth nuclear neurones for sternomastoid of the same side. Crossed fibres innervate the XIth nuclear neurones for trapezius on the opposite side. In the normal situation as the left hand reaches out to the left (right motor cortex, left anterior horn cells), the head follows, turned to the left, by the right sternomastoid, with left scapula supported and controlled by the left trapezius. With a left hemiparesis the right sternomastoid and the left trapezius become weak.

### Sensory pathways within the brainstem

The two sensory systems traverse the brainstem, to merge just before entering the thalamus (Figure 2.23b):

- Spinothalamic tracts*: pain and temperature sensation (spinal lemniscus)
  - Posterior (dorsal) columns*: light touch, two-point discrimination, light touch, kinesthesia (medial lemniscus).
- Matters are complicated by the massive Vth nuclei and their connections.

### Spinothalamic tracts

The cell bodies giving rise to the spinothalamic tract are in the dorsal horn and receive ipsilateral primary afferents. The axons of these spinothalamic tract cells cross the midline in the cord (within one to three segments of their point of entry) to form each spinothalamic tract. This ascends from the cord and comes to lie laterally in the medulla (with LL fibres lateral to UL fibres) until it merges with the medial lemniscus in the upper midbrain.

The descending sympathetic pathways lie close to the spinothalamic tracts in the brainstem.

*Clinical correlate* When a spinothalamic lesion in the brainstem causes loss of pain and temperature in the opposite limbs, an ipsilateral Horner's syndrome is also frequently present.

### Posterior column → medial lemniscus

Cell bodies lie in the cuneate (UL) and gracile (LL) nuclei in the medulla. Axons decussate there and form the medial lemniscus. This ribbon-like structure ascends and rotates in the brainstem, maintaining LL fibres laterally and UL fibres medially, to coalesce with the spinothalamic tract.

**Vth nerve central pathways**

The massive Vth nerve input enters the brainstem in the mid pons. Touch sensation and the corneal reflex afferents pass to the pontine Vth nucleus, and decussate to the opposite Vth pontine nucleus. Pain and temperature afferents enter the pons, but not the pontine Vth nucleus itself. They descend alongside the spinal Vth nucleus, enter the nucleus when they reach the medulla and upper cord and then decussate, to synapse on the opposite Vth spinal nucleus. The quintothalamic tract (or secondary, ascending tract of the Vth nerve) completes the route to the thalamus for nociceptive and temperature information as the trigeminal lemniscus, the tract lying lateral to the medial lemniscus.

**Clinical correlates**

- The corneal reflex is the most subtle sign of an emerging Vth nerve lesion (see Trigeminal nerve sensory and motor examination, Chapter 4).
- Peripheral Vth nerve lesions are usually recognisable from sensory loss, numbness and/or pain within the cutaneous distribution of V<sub>1</sub>, V<sub>2</sub> and V<sub>3</sub>.
- Central lesions affecting the spinal nucleus of V produce circumoral sensory loss (onion skin distribution, see Figure 2.54, and Trigeminal nerve lesions, Chapter 13).

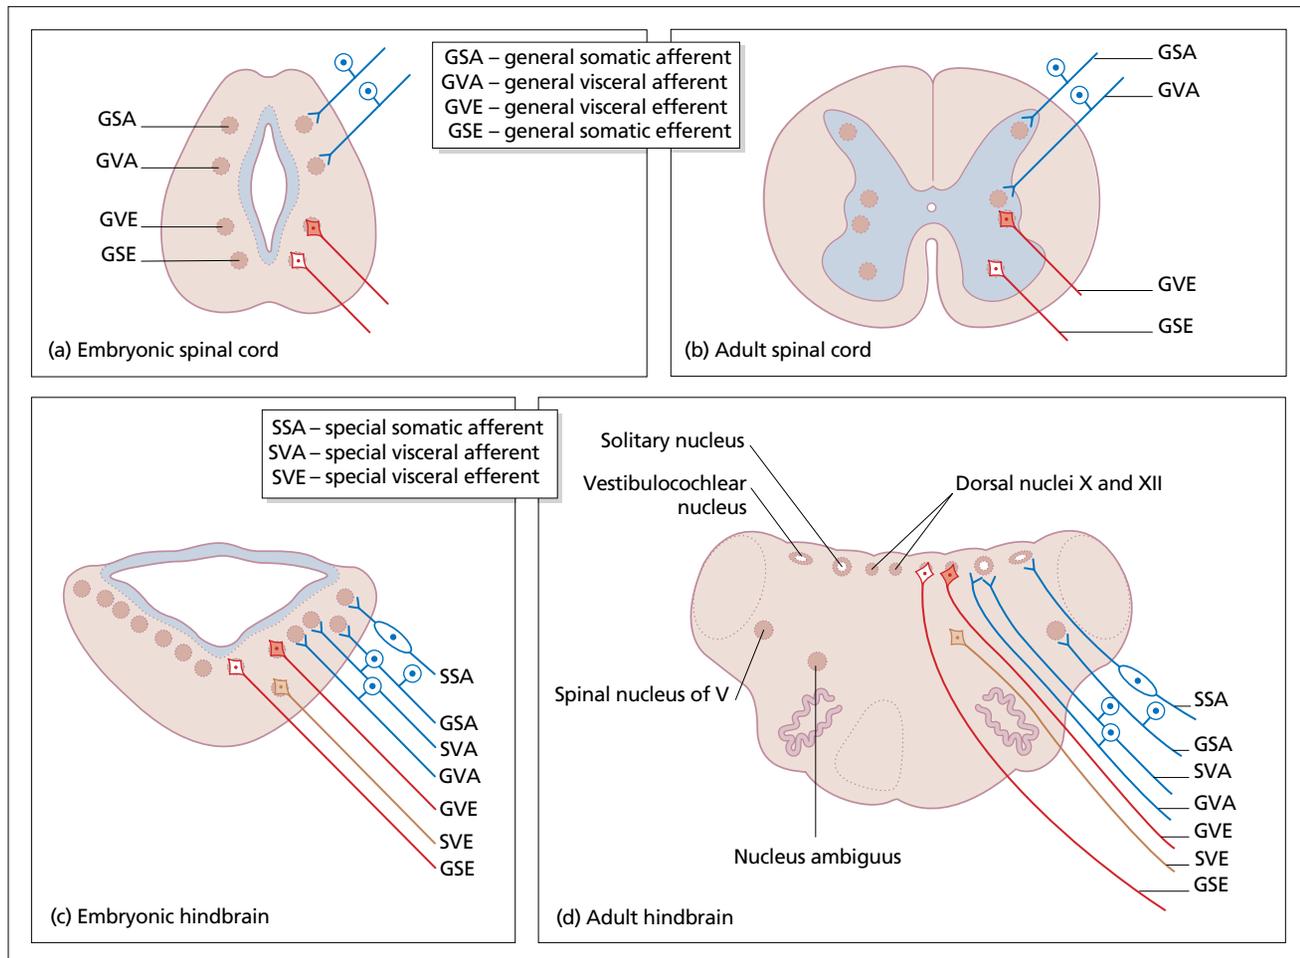

- Facial numbness on one side with spinothalamic sensory loss in the contralateral limbs is diagnostic of a dorsolateral brainstem lesion. This crossed sensory loss can occur with a lesion anywhere between upper cervical cord and mid pons.
- When a cavity develops within the medulla (syringobulbia), bizarre patterns of facial and upper cervical sensory loss can be seen when the crossing central fibres of the spinal nucleus of V and quintothalamic tract are damaged. These are often dismissed initially as non-organic.

At a more general level, with such a magnitude of afferent information, the face is highly sensitive. Trigeminal-mediated pain is exquisitely painful, such as toothache and trigeminal neuralgia. The importance of the trigeminovascular system in headaches is considered in Chapter 12 (see Anatomy and physiology of headache).

**Cranial nerve nuclear columns**

A summary of the embryological development begins to explain the layout (Figure 2.24). Seven nuclear columns (four afferent, three efferent) contribute to the nuclear masses of the brainstem and cord. Motor cranial nerve nuclei are derived from two of these columns:

- III, IV, VI and XII arise from a paramedian nuclear mass known as the general somatic efferent (GSE) column.

**Figure 2.24** Seven nuclear columns: embryonic and adult cord and hindbrain. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

- V (motor), VII, IX and X (nucleus ambiguus) and XI (spinal accessory nucleus) arise from ventrolateral cells known as the special visceral efferent (SVE) column.

As the fetus develops, GSE column nuclei III, IV, VI and XII remain close to the midline. The SVE nuclei move laterally along the lateral margin of the fourth ventricle.

Of the main afferent nuclei:

- The Vth nerve nuclei are described later (see Cranial nerves and VIII: vestibulocochlear nerve).
- The vestibular nuclei (SSA) occupy a wide area in the pons, extending through the medulla to upper cervical cord (see Cranial nerves and V: trigeminal nerve).
- The nucleus of the tractus solitarius (SVA) receives taste fibres and relays gustatory reflexes.

## Reticular formation

The biological role of the RF can be understood from its origins as a polysynaptic, slow conducting, central pathway that:

- Linked olfactory and limbic systems, and
- Coordinated autonomic and reflex activity.

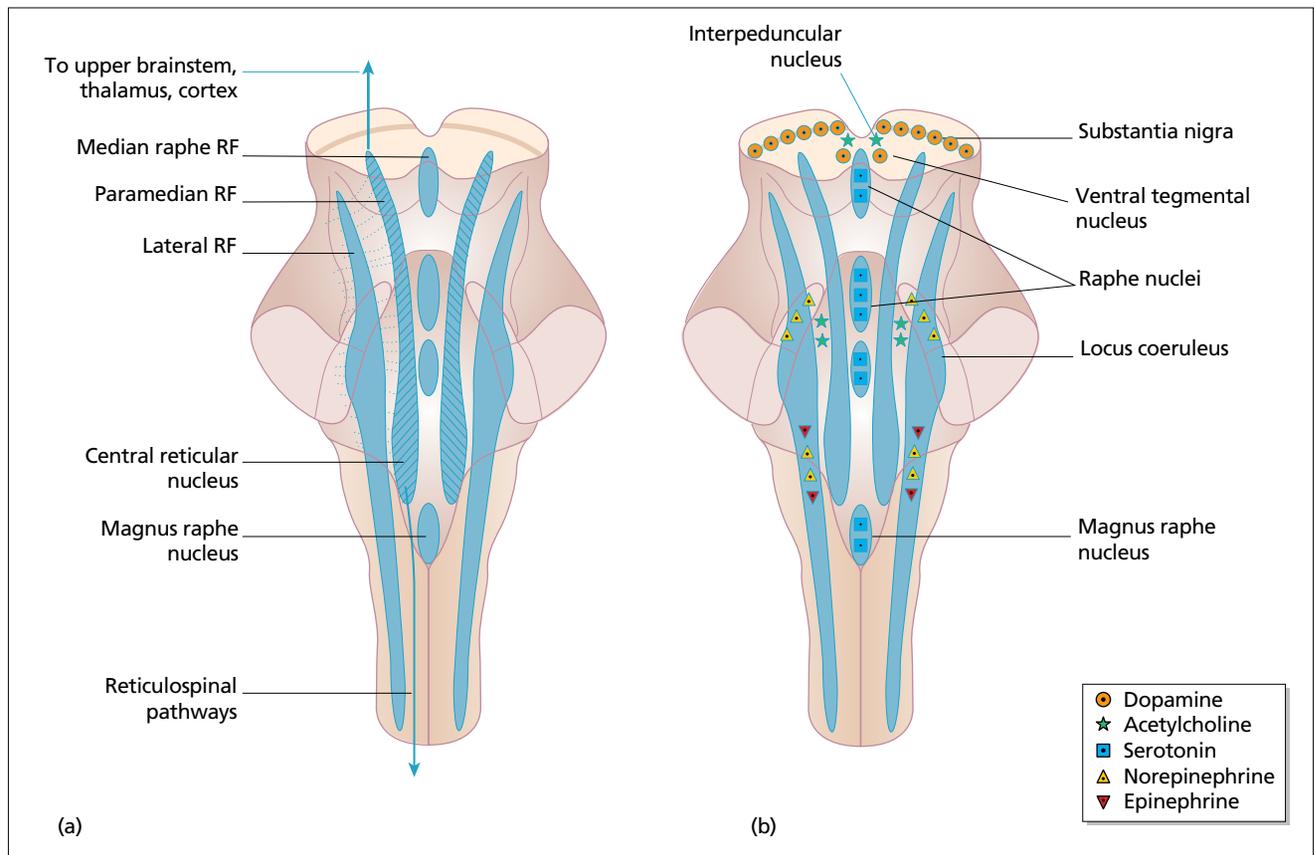

Phylogenetically, as vision and hearing assumed important roles together with olfaction, direct lateralised pathways of these special senses bypassed the RF. In mammals, the older pathways were superseded by fast direct linkages between cortex and sensorimotor systems. In humans, the RF means the polysynaptic, modulating, neuronal network within the brainstem, although the system

extends further – caudally into the cord and rostrally to thalamus and hypothalamus. It is of importance in:

- Respiratory control
  - Sleep, wakefulness, arousal and mood
  - Cardiovascular control
  - Pattern generation of some reflex motor activities (e.g. chewing, swallowing, conjugate gaze)
  - Micturition, bowel and sexual function
  - Sensory modulation (see Neuro-stimulation procedures: gate theory, Chapter 23), and
  - Autonomic and reflex activity generally.
- Aminergic neurones are prominent in the RF:
- Serotonergic RF neurones form a ubiquitous network throughout the raphe nuclei
  - Dopaminergic neurones occupy substantia nigra and ventral tegmental nuclei
  - Noradrenergic neurones are congregated in the locus coeruleus (floor of 4th ventricle) and through the pons, medulla and midbrain
  - Adrenergic neurones occupy principally the medulla, and
  - Enkephalins are also involved (peri-aqueductal grey matter).

## Essential anatomy

This is outlined in Figure 2.25. The raphe nuclei (raphe, pronounced 'raffay'; Greek: a seam) are the major source of serotonergic neurones in the neuraxis.

**Figure 2.25** Reticular formation: (a) subdivisions (nuclei); (b) principal neurotransmitter cell groups. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

Alongside the median raphe nuclei lie the paramedian RF (magnocellular and gigantocellular neurones) on each side. Each paramedian network blends into the lateral RF (parvocellular neurones).

The lateral RF is largely afferent, receiving input from all sensory pathways, especially:

- Olfactory system (via median forebrain bundle, next to the hypothalamus)
- Visual pathways (via superior colliculus)
- Auditory pathways (via superior olivary nucleus)
- Vestibular pathways (via medial vestibular nucleus), and
- Somatic sensory and trigeminal system (spinoreticular tracts, pontine Vth nuclei).

The paramedian RF is a smaller efferent polysynaptic distributive pathway to:

- Thalamus
- Spinal cord (via pontine and medullary reticulospinal tracts), and
- Cardiovascular and respiratory regulators.

### Respiratory control

This is achieved via:

- Dorsal and ventral respiratory nuclei
- Medullary chemosensitive area, and
- Carotid chemoreceptors.

Cyclical respiration is modulated by the dorsal and ventral respiratory nuclei in the medulla. The dorsal nucleus is mainly inspiratory (efferent connections to respiratory muscles) and the ventral, expiratory. A third medial paracentral nucleus adjacent to the locus coeruleus is involved in initiating and driving respiratory rhythms. The dorsal respiratory nucleus receives excitatory impulses from the medullary chemosensitive area. These cells in the lateral RF at the level of the IXth nerve nucleus and 4th ventricle choroid plexus are exquisitely sensitive to hydrogen ion concentration: any increase in hydrogen ion concentration stimulates the dorsal respiratory nucleus. Sampling of  $p\text{CO}_2$  also takes place here.

Carotid chemoreceptors (glomus cells at the carotid bifurcation) are exquisitely sensitive to changes in arterial  $p\text{O}_2$ , and/or a rise in arterial  $p\text{CO}_2$ . Impulses pass via the sinus nerve (a branch of IX) to stimulate the dorsal respiratory centre.

The ventral respiratory nucleus is largely expiratory. It acts as an inhibitory oscillator during normal breathing and is engaged via GABAergic internuncials with the dorsal respiratory nucleus. During increased ventilation (e.g. exercise) the ventral respiratory nuclei activate anterior horn cells supplying expiratory accessory and abdominal muscles.

### Sleep, wakefulness and mood

In animal models, destruction of raphe midbrain neurones or depletion of serotonin results in prolonged insomnia. The ascending reticular activating system is a term that harnesses this concept of cortical activation. Activation is seen on electroencephalogram (EEG) during waking from sleep – high amplitude slow (delta) waves are replaced by fast (alpha) waves. The principal cellular candidates for this role are:

- Cholinergic neurones near the coerulean nuclei, or
- Histaminergic neurones in the tuberomammillary nuclei.

Following arousal the alert state is sustained by continuing activation by these neurones and by activation of the basal nucleus of Meynert in the basal forebrain. Inactivity within the ascending reticular activating system is inherent in the mechanisms of coma.

The limbic system and RF are mentioned in Chapter 22 (see Neuropsychiatric aspects of movement disorders) in the relation to mood and the orexin–hypocretin system in Chapter 20 (see Hypersomnias of central origin).

### Cardiovascular control

The solitary nuclei in the medulla receive afferents from baroreceptors in the carotid sinus and aortic arch. The barovagal and barosympathetic reflexes modulate blood pressure and cardiac output (see Cardiovascular system; Orthostatic hypotension, Chapter 24).

### Patterns of primitive movements

These movements are primitive only in phylogenetic terms:

- Conjugate gaze – pontine centres for lateral and vertical gaze
- Chewing – supratrigeminal premotor pontine nucleus
- Respiration – medullary respiratory nuclei
- Swallowing, coughing, sneezing, vomiting, crying, salivation, and
- Locomotor pattern generators.

### Micturition control

A micturition control centre (MCC or M centre) lies in each paramedian pontine reticular formation (PPRF). Axons from magnocellular neurones pass directly to parasympathetic (motor) neurones at S2–4 in the cord.

The essential anatomy of cortical and subcortical influences on micturition are included here (Figure 2.26). Neurones in lateral peri-aqueductal grey matter (LPAG) receive fibres from the sacral posterior grey horn and project excitatory fibres to the M centre. The ventral posterior nucleus of the thalamus also receives sacral fibres. The LPAG also receives excitatory fibres from the pre-optic nucleus (PON).

### Gate control: Sensory modulation

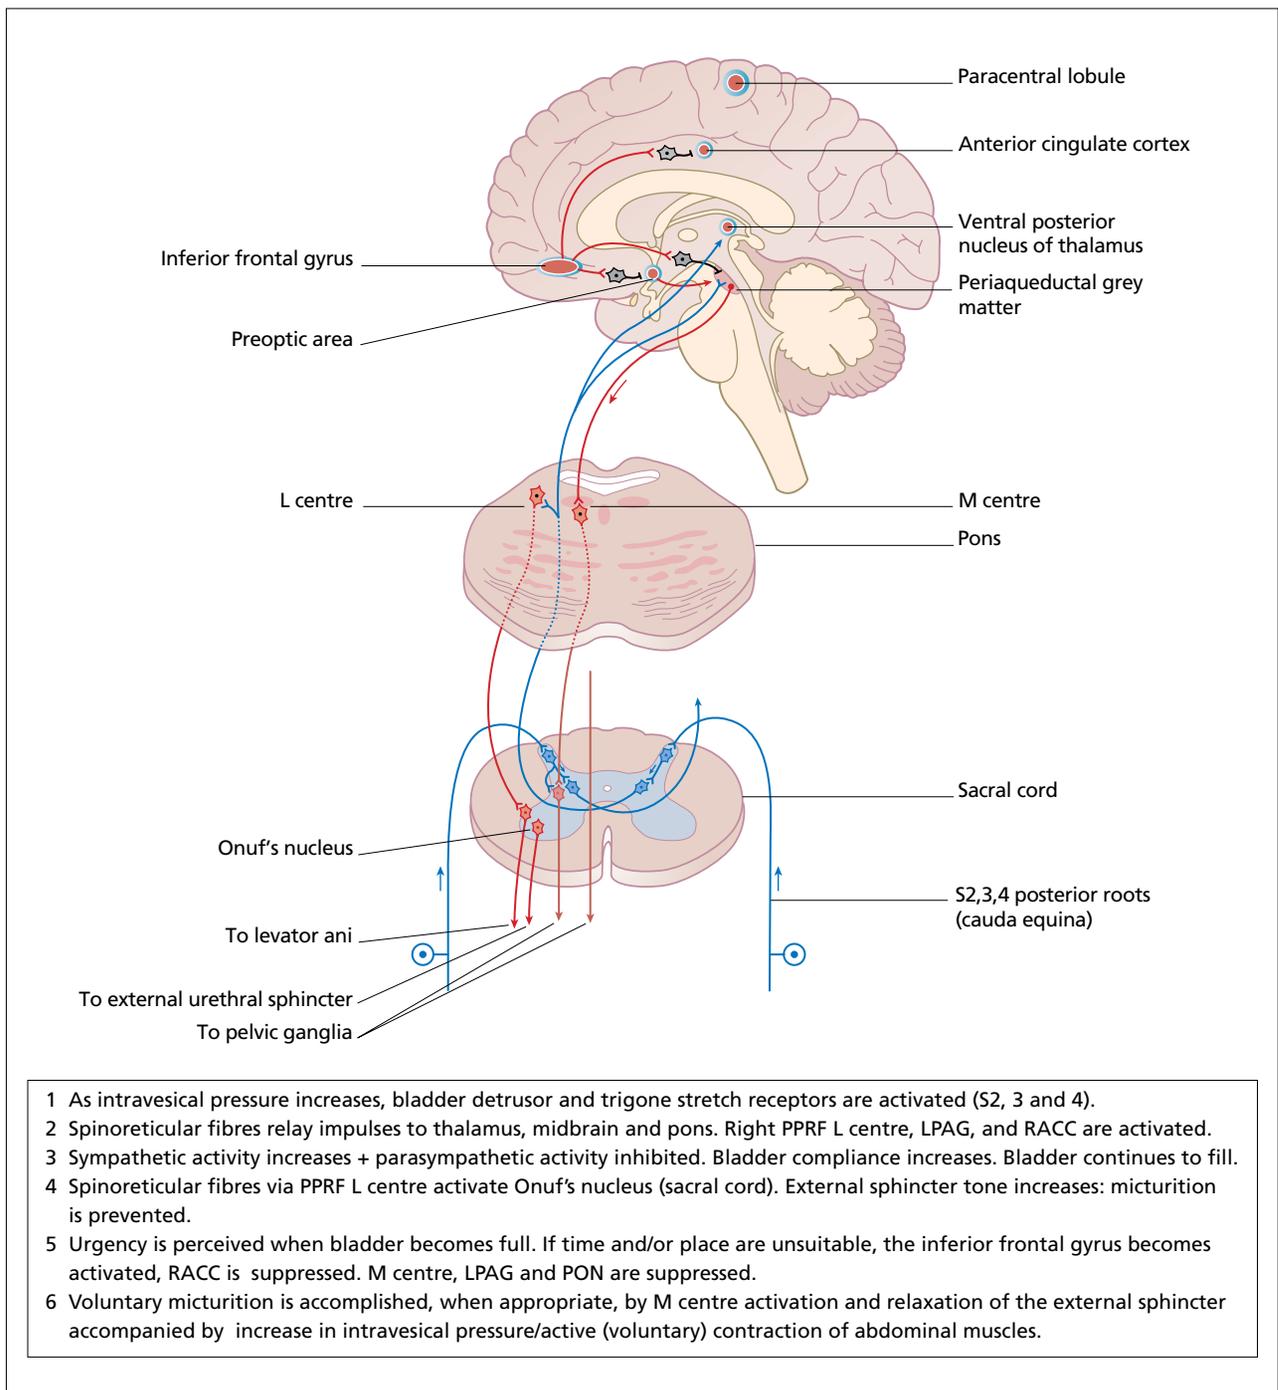

The anatomy and role of the RF in pain control, also known as supraspinal antinociception, is summarised in Figure 2.27. Gating (see Neuro-stimulation procedures: gate theory, Chapter 23) involves control of synaptic transmission between one neurone or set of neurones and the next. While the gate theory of pain is sometimes questioned, it remains a useful model.

Tactile sensory transmission is gated at the posterior column nuclei. Nociceptive transmission from the trunk and limbs is gated in the posterior grey horn of the cord, and from the head and neck in the spinal V nucleus. One crucial structure in the cord is the substantia gelatinosa (Figure 2.21b), rich in excitatory glutaminergic neurones and inhibitory GABAergic and enkephalinergic neurones.

Unmyelinated C fibres mediate dull, intense, prolonged, poorly localised pain, largely via excitatory substantia gelatinosa interneurones and thence via lateral spinothalamic tracts to the thalamus. Short, sharp, well-localised pain is mediated by finely myelinated A $\delta$  fibres. These synapse directly on dendrites of relay neurones of the lateral spinothalamic tract.

Large A (mechanoreceptor) afferents from hair follicles and skin synapse on anterior spinothalamic relay cells and send collaterals to inhibitory (GABAergic) gelatinosa cells. These then synapse on lateral spinothalamic tract relay cells.

Gating of C fibre activity can be enhanced by stimulating A fibre afferents or enhancing RF inhibition from the magnus raphe nucleus (MRN), for example by rubbing, transcutaneous electrical nerve stimulation (TENS), implanted stimulators, inducing sleep and some pain-modulating drugs such as gabapentin. All are believed to increase central gating of pain.

## Limbic system, hippocampus and related structures

The limbic system (Latin: a rim) was coined by Broca in the late nineteenth century to describe cortex bounded by the corpus callosum. The hippocampus takes its name from Greek, originally for a horse + monster (ἵππος + κάρμπος) and later the seahorse, which the hippocampus resembles in coronal cross-section.

The limbic system includes:

- Hippocampi, mamillary bodies and septal area
- Insulae, cingulate and parahippocampal gyri, and

- Amygdala – subcortical nuclear masses adjacent to each temporal pole.

Other subcortical regions nearby are the nucleus accumbens, medial dorsal nucleus of the thalamus, hypothalamus and part of the reticular formation. The orbital cortex (frontal cortex above the orbit), the temporal pole, the corpus callosum, choroid plexus and lateral ventricle are also nearby (Figure 2.28).

The parahippocampal gyri are the main interfaces between hippocampi (known as allocortex) and the cerebral neocortex. The entorhinal cortex is the anterior section – area 28. This is

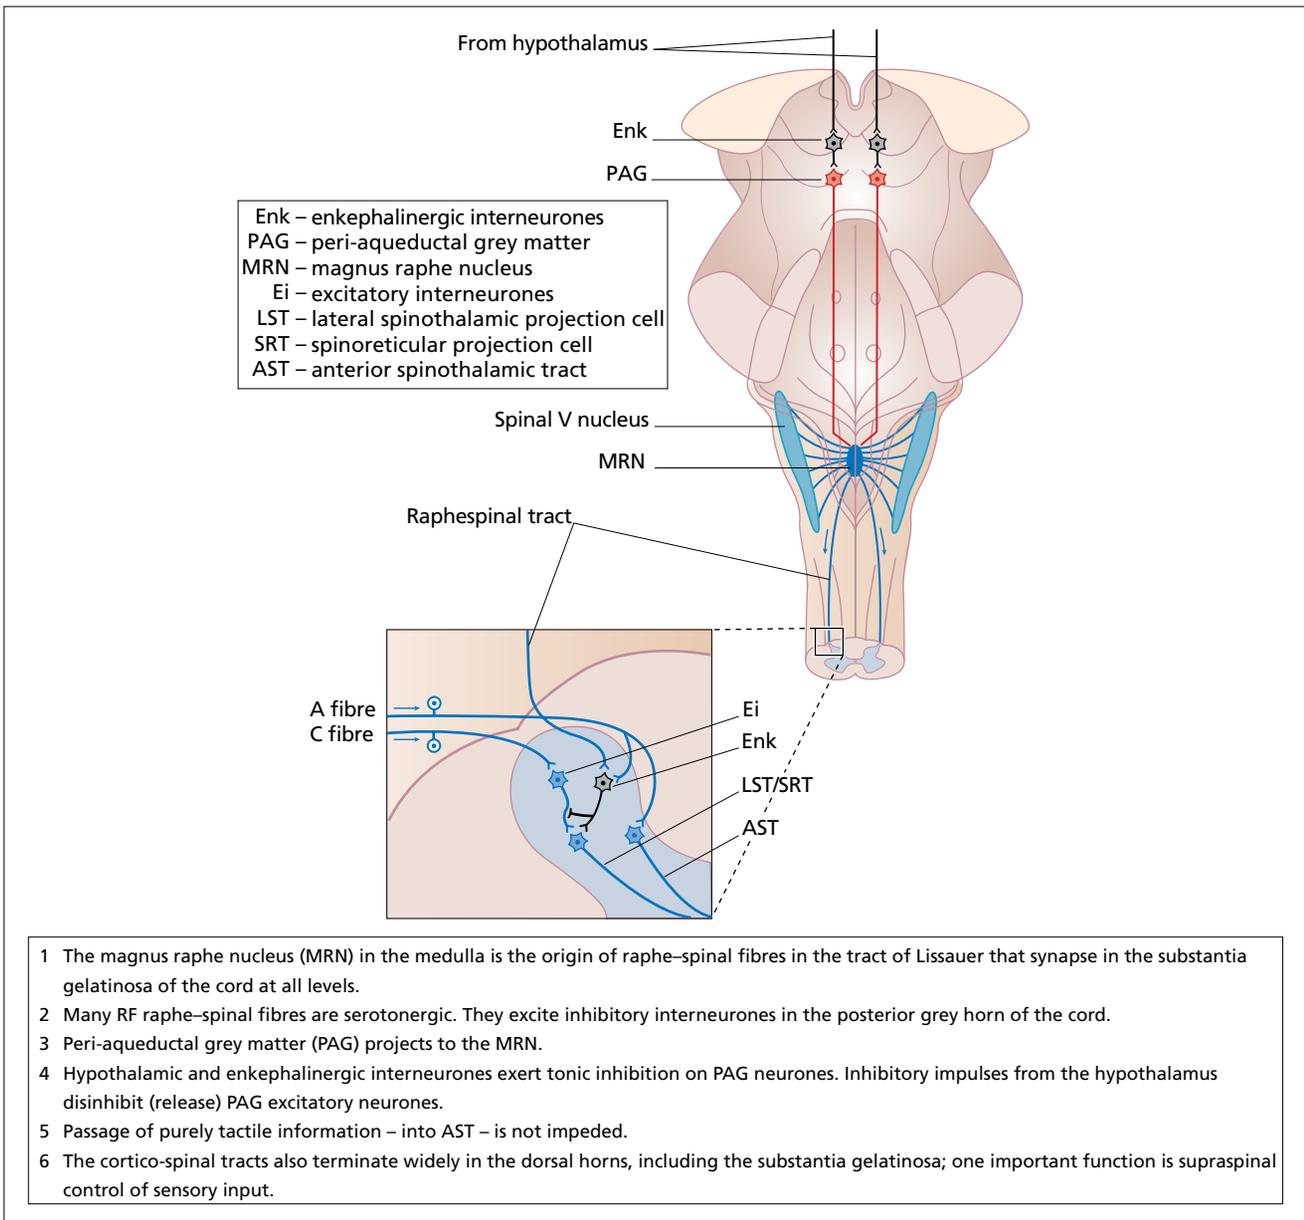

Figure 2.27 Anatomy of sensory modulation.

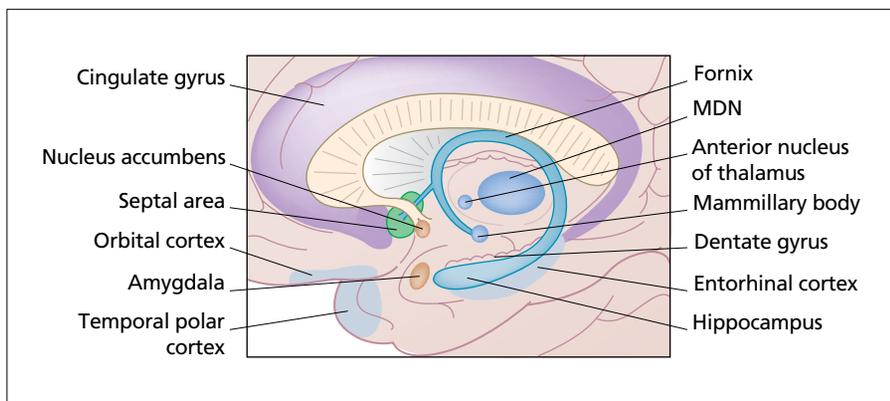

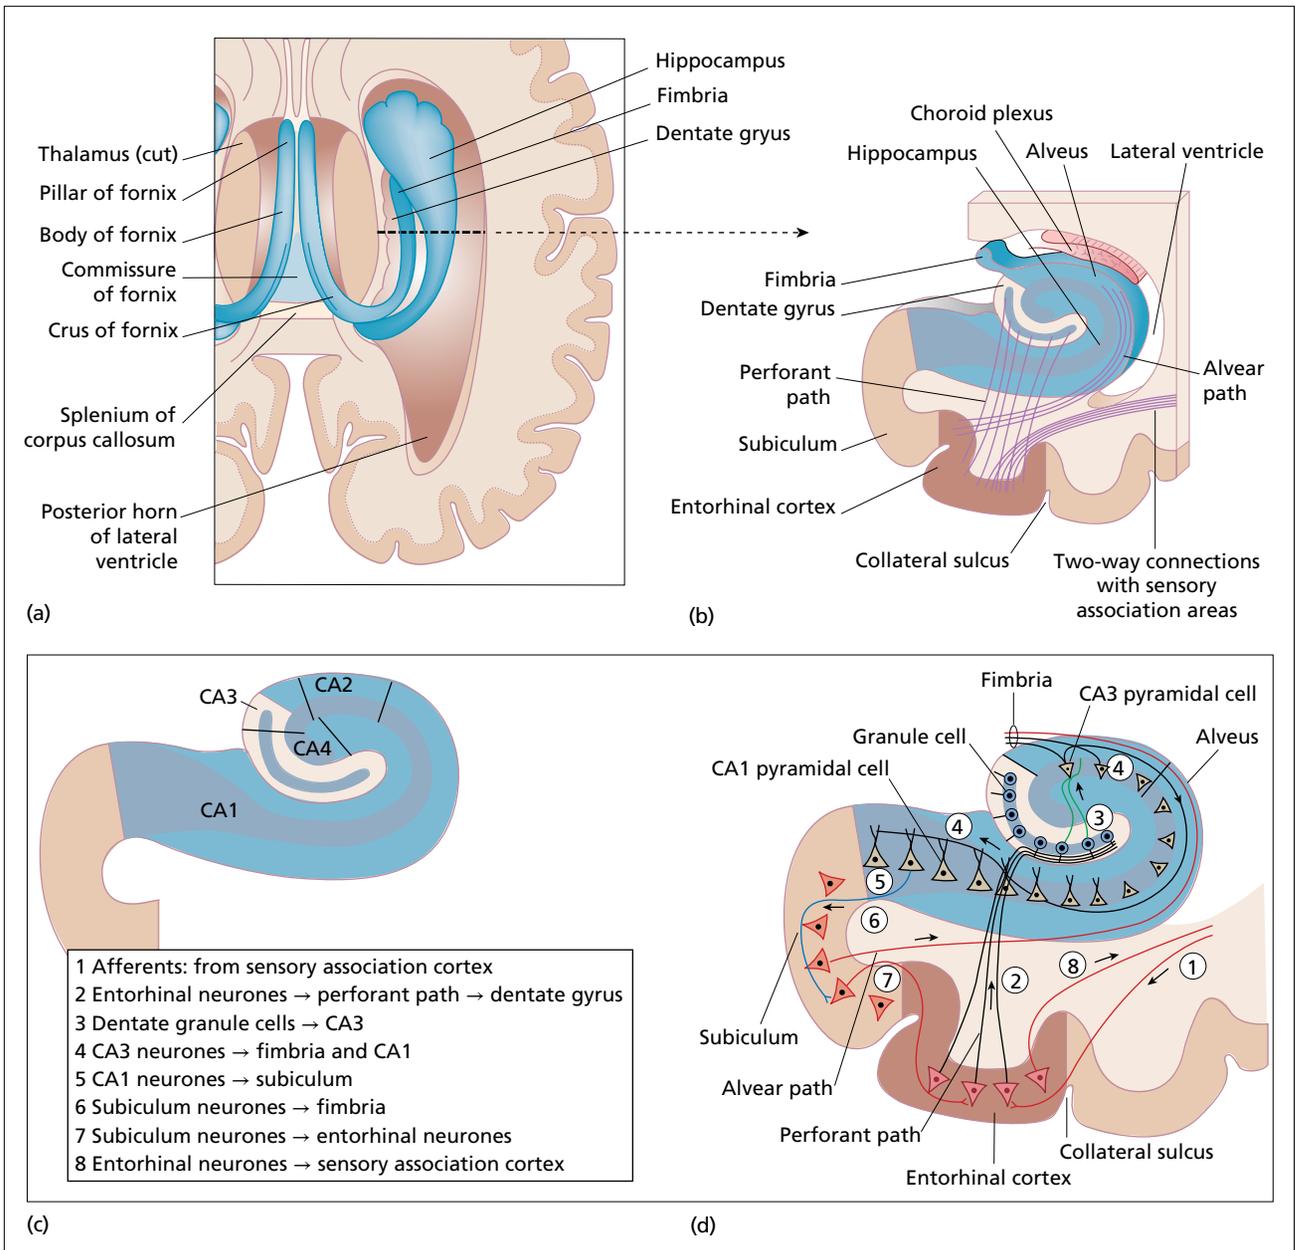

Figure 2.28 Limbic and subcortical areas: medial view. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

six-layered cortex, exchanging fibres between the four neocortical association areas and the hippocampus. Each fornix, looping over the medial dorsal thalamic nucleus into the mamillary body, provides a second route between neocortex and hippocampus.

The planes, contours and nomenclature of the hippocampal formation (subiculum, dentate gyrus, hippocampus) are complex. Looking from above, picture a horseshoe lying tilted in the floor of the lateral ventricle. One (lateral) arm is the hippocampus. The other arm twists into the loop of the fornix to follow the contour of the thalamus (Figure 2.29).

The coronal cross-section of the hippocampus – the seahorse-like outline – has its head in the lateral ventricle and a tail leading to the entorhinal cortex. The dentate gyrus is surrounded by the seahorse’s head.

Additional terminology comes from the ancient descriptive name for the hippocampus, Ammon’s horn (Ammon was the Egyptian ram deity; *cornu* means horn), hence *cornu ammonis* (CA) zones which divide the hippocampus into four (Figure 2.29d). Pyramidal cells are the main cell types seen in the subiculum and hippocampus and granule cells in the dentate nucleus. Inhibitory GABAergic interneurons are present throughout the area.

**Figure 2.29** (a) Hippocampus and surrounding structures (from above). (b) Coronal section from subiculum to lateral ventricle. (c) Ammon’s horn: CA1, CA2, CA3, CA4. (d). Basic hippocampal wiring (1–8). Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

This region is intimately involved in memory, arousal and mood – and in epilepsy (see Hippocampal sclerosis, Chapter 7). This summary outlines majority views in a complex field. Much original work was derived from clinical observation in humans. Extrapolation from primate studies, and more recently fMRI, have added insights into these areas. Their relevance in epilepsy, memory and mood – and in dementia – is dealt with in Chapters 7 (see Hippocampal sclerosis) and 8 (see Memory).

### Afferent hippocampal connections

The perforant path passes from the entorhinal cortex to dendrites of dentate nucleus granule cells. The alvear path passes from the subiculum to the alveus, the ventricular face of the hippocampus. Mossy fibres, the axons of granule cells synapse in CA3 pyramidal cells. CA3 pyramidal cell axons pass into the fimbria, giving rise to Schaffer collaterals between CA3 and CA1. CA1 projects to the entorhinal cortex. Visual, visuo-spatial and auditory afferents also reach the region:

- Auditory fibres from the superior and middle temporal gyri to hippocampus
- Visuospatial data from area 40 (supramarginal gyrus), and
- Visual association data (object shape and colour/facial recognition) from the occipito-temporal region to the perirhinal cortex (adjacent to the entorhinal) and thence to the hippocampus.

Diffuse afferent connections also reach the hippocampus (Table 2.4) largely via the fornix.

### Efferent hippocampal connections

First, the entorhinal cortex projects to neocortical association areas. Secondly, axons in the fornix (Latin: vault or arch) project forwards from the subiculum and hippocampus itself. Components of the fornix are:

- Fimbriae (Latin: thin projections, forming a fringe).
- The crus (cross) arches up below corpus callosum, joins opposite the fornix to form the trunk and hippocampal commissure.
- The trunk divides into the two pillars of the fornix. Each pillar divides around the anterior commissure:
  - Precommissural fibres pass to the septal area
  - Postcommissural fibres pass to the anterior hypothalamus, mamillary body and medial forebrain bundle.

Each mamillary body (Latin: mamilla = nipple) projects to the anterior nucleus of the thalamus, thence to the cingulate cortex.

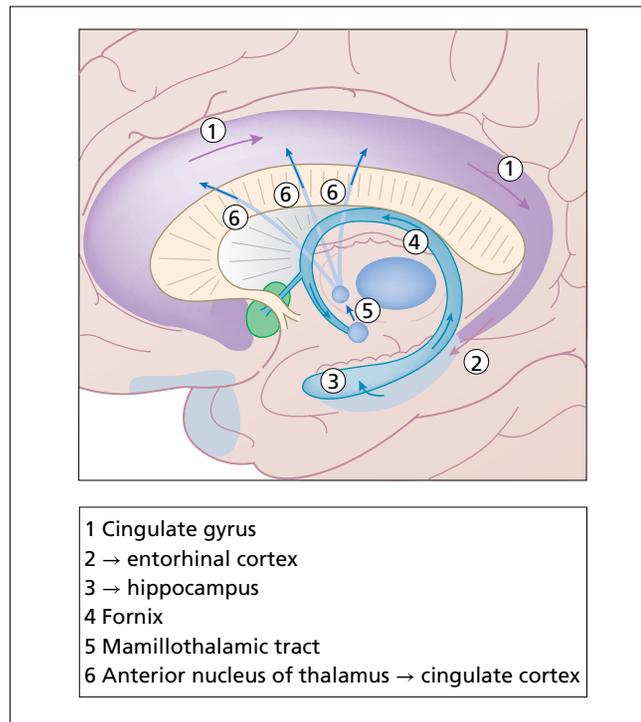

Papez's circuit (1937; Figure 2.30) is the loop:

Hippocampus → fornix → cingulate cortex  
→ entorhinal cortex → hippocampus.

The concept of this circuit has stood the test of time, though with more anatomical than clinical relevance.

**Table 2.4** Diffuse afferents to the hippocampus.

Neurotransmitter	Source	Clinical association
Cholinergic	Septal nuclei	Memory
Noradrenergic	Coerulean nuclei	Arousal
Dopaminergic	Ventral tegmentum	Movement/thought disorder
Serotonergic	Raphe nuclei	Mood

**Figure 2.30** Papez's circuit. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

### Declarative memory and long-term potentiation

Data-based (declarative) memory, the ability to retain and retrieve new facts, is lost when the anterior hippocampus is damaged. Procedural memory is preserved (e.g. thread a needle, assemble a jigsaw, ride a bicycle). The hippocampus is not involved in procedural memory – there is growing evidence that the cerebellum is a principal structure involved in these procedural or motor memories.

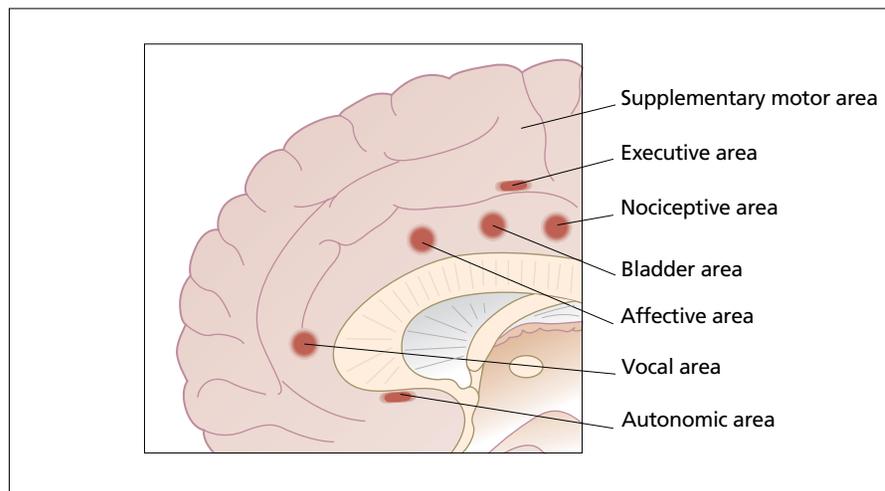

Long-term potentiation (LTP) is a phenomenon seen widely within the nervous system but especially within the dentate gyrus and hippocampus. As its name implies, target cells remain sensitive to a fresh stimulus a long time (hours) after stimulation.

LTP can be demonstrated in animals both in perforant path → dentate granule cells and Schaffer collateral → CA1 connections. A brief, several millisecond stimulus to either Schaffer collaterals or perforant path induces this long-lasting sensitivity in target neurones following GABA receptor activation. New synapses appear within minutes, while existing synapses expand. It is believed that LTP is of fundamental importance in learning. LTP is enhanced by opioid peptides, norepinephrine and dopamine released within the perforant path.

ACh muscarinic activity within the hippocampus is also significant in learning. Hyoscine in small doses blocks memory for lists and numbers. Hyoscine (scopolamine) became known as 'the truth drug' – of 007 James Bond, CIA and KGB repute. Hyoscine frequently distorts recall and has hallucinogenic effects – making it of no value for extracting secrets from detainees. Physostigmine blocks the effect of hyoscine. This was the original basis for development of anticholinergic therapy in Alzheimer's disease.

### Insula, cingulate cortex and parahippocampal gyrus

The insula can conveniently be divided into three:

**Figure 2.31** Anterior cingulate cortex (medial view): six functional zones. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

- 1 *Anterior*: a cortical centre for pain
- 2 *Posterior*: connects with the amygdala and entorhinal cortex (emotional responses to and memories of pain), and
- 3 *Central*: language functions.

The cingulate cortex, part of Papez's circuit merges into the posterior parahippocampal gyrus behind the splenium. The anterior cingulate (part of the rostral limbic system – amygdala, ventral striatum and anterior insula) has six functional zones (Figure 2.31):

- 1 *Executive*: connected to dorsolateral prefrontal cortex (DLPFC) and supplementary motor area.
- 2 *Nociceptive*: afferents from thalamus (medial dorsal nucleus).
- 3 *Affective* (emotional): happy thoughts activate this area on fMRI – and the amygdala switches off. Anterior cingulectomy was once performed for aggressive psychopathic behaviour.
- 4 *Micturition*: activity seen on bladder filling.
- 5 *Vocalisation*: active during decisions about syntactic construction. Reduced regional blood flow is seen in some cases of stammering.
- 6 *Autonomic*: respiratory and cardiac – responses to emotion, sweating and blushing.

### Amygdala

Amygdala is Greek for an almond. This is a substantial nuclear group anterior to the caudate nucleus tail. Fear and anxiety are mediated via the amygdala – a glance at afferent and efferent pathways of Tables 2.5 and 2.6 indicates widespread connections and potential pathways for everyday experiences (e.g. feeling unwell, hypotensive and sweaty at the sight of blood).

Kindling is a term used, often conjecturally to describe development of seizure activity in an area of brain contralateral to or distant from an epileptic focus. At a neurophysiological level, it means a group response within neurones that increases following a uniform strength stimulus. This phenomenon is unique and, as far as is known, confined to the amygdala and hippocampus.

### Nucleus accumbens

Stimulation of these areas of the ventral striatum (nucleus accumbens, ventral olfactory tubercle, ventral caudate and putamen) leads typically to a sense of well-being akin to a shot of heroin, attributed to excessive dopamine release flooding the

prefrontal cortex and nucleus itself. Most stimulant drugs increase dopamine levels in these areas. Ninety-five per cent of nucleus accumbens neurones are spiny GABAergic projection neurones; 5% are cholinergic neurones (non-spiny, also known as aspiny neurones).

### Septal region

Afferents to the septal nuclei come from:

- Hippocampus (via fornix)
- Brainstem, via medial forebrain bundle (monoaminergic neurones)
- Amygdala, via the diagonal band of Broca, and
- Olfactory tract, via medial olfactory striae.

Efferents travel in two principal pathways:

- 1 Striae medullaris → habenula nucleus → habenulo-interpeduncular tract → interpeduncular nucleus, and
- 2 Septohippocampal tract.

The interpeduncular nucleus participates in sleep–wake cycles (with the locus coeruleus).

The septohippocampal tract is believed to have a role in generating temporal cortex theta EEG activity, by synchronous discharge of hippocampal pyramidal neurones.

Stimulation of the septal region in humans produces pleasurable sexual sensations and/or orgasm. In animals, destructive lesions cause extreme anger – known as septal rage.

### Basal forebrain

This region lies between the olfactory tracts and infundibulum (caudally) and the amygdala. The magnocellular basal nucleus of Meynert is the largest single nuclear group here, its cholinergic neurones extending throughout the cortex (Figure 2.32). These magnocellular basal nuclei, septal nuclei and neurones in the diagonal band of Broca are known as basal forebrain nuclei. The floor of the basal forebrain, the anterior perforated substance, is traversed by branches of the anterior cerebral arteries. The basal forebrain nuclei exert tonic cholinergic activity within the cortex, thus maintaining wakefulness, and facilitating perceptive activity. Cholinergic activity is believed to enhance LTP in pyramidal cells of the cortex.

**Table 2.5** Amygdala afferents – to the lateral nucleus.

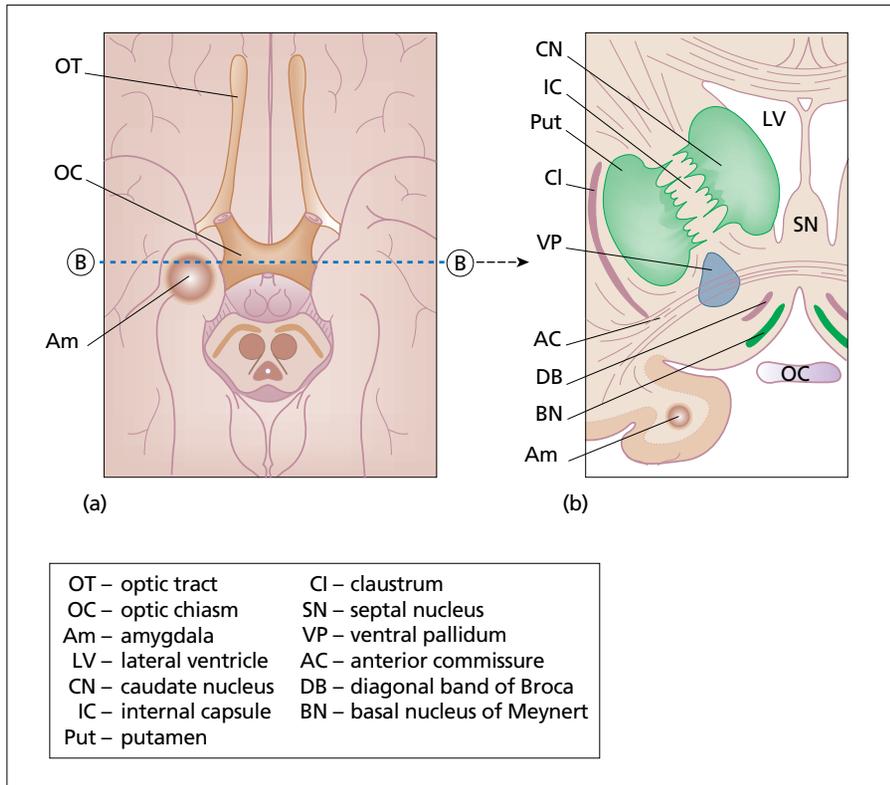

Type	Subcortical origin	Cortical origin
Touch	VP nucleus of thalamus	Parietal cortex
Hearing	MGB	Superior temporal gyrus
Vision	LGB	Occipital cortex
Smell		Piriform lobe
Memory		Hippocampus/ entorhinal cortex
Cardiac	Hypothalamus	
Pain	RF	Insula
Cognitive		Orbital (frontal) cortex
Attention/anxiety	Locus coeruleus	Basal nucleus of Meynert

LGB, lateral geniculate body; MGB, medial geniculate body; RF, reticular formation; VP, ventral posterior (nucleus).

**Table 2.6** Amygdala efferents – from the central nucleus.

Pathway/distant target nucleus	Effect
PAG	Pain suppression (antinociception)
PAG	Freezing with fear
Locus coeruleus	Wakefulness/arousal
Medullary norepinephric neurones (to lateral grey horn)	Increase in pulse and blood pressure
Hypothalamus/dorsal nucleus of vagus	Slowing of pulse/syncope
Hypothalamus (corticotrophin RF)	→Cortisol secretion
Parabrachial (thence to respiratory) nuclei	Hyperventilation/apnoea

PAG, peri-aqueductal grey matter; RF, reticular formation.

## The thalamus

The paired conjoined thalami are among the larger nuclear masses of the brain. They are complex relay stations. In contrast to this complexity, the clinical neurology is relatively sparse, but of increasing relevance with the development of stereotactic surgery and neurostimulation.

Divisions and connections are shown in Figure 2.33. It can be simplified by noting the large 'Y', of thalamic white matter – the internal medullary lamina – that divides the nuclei into three cell groups:

- 1 Anterior (within the 'Y')
- 2 Medial dorsal, and
- 3 Lateral nuclei.

Lateral nuclei are divided into ventral and dorsal tiers. The medial and lateral geniculate bodies lie posteriorly. The reticular nucleus surrounds each thalamus laterally, separated by an external medullary lamina traversed by thalamocortical fibres. The three groups of thalamic nuclei, somewhat uninformatively named are:

- 1 Relay (specific) nuclei
- 2 Association nuclei, and
- 3 Non-specific nuclei.

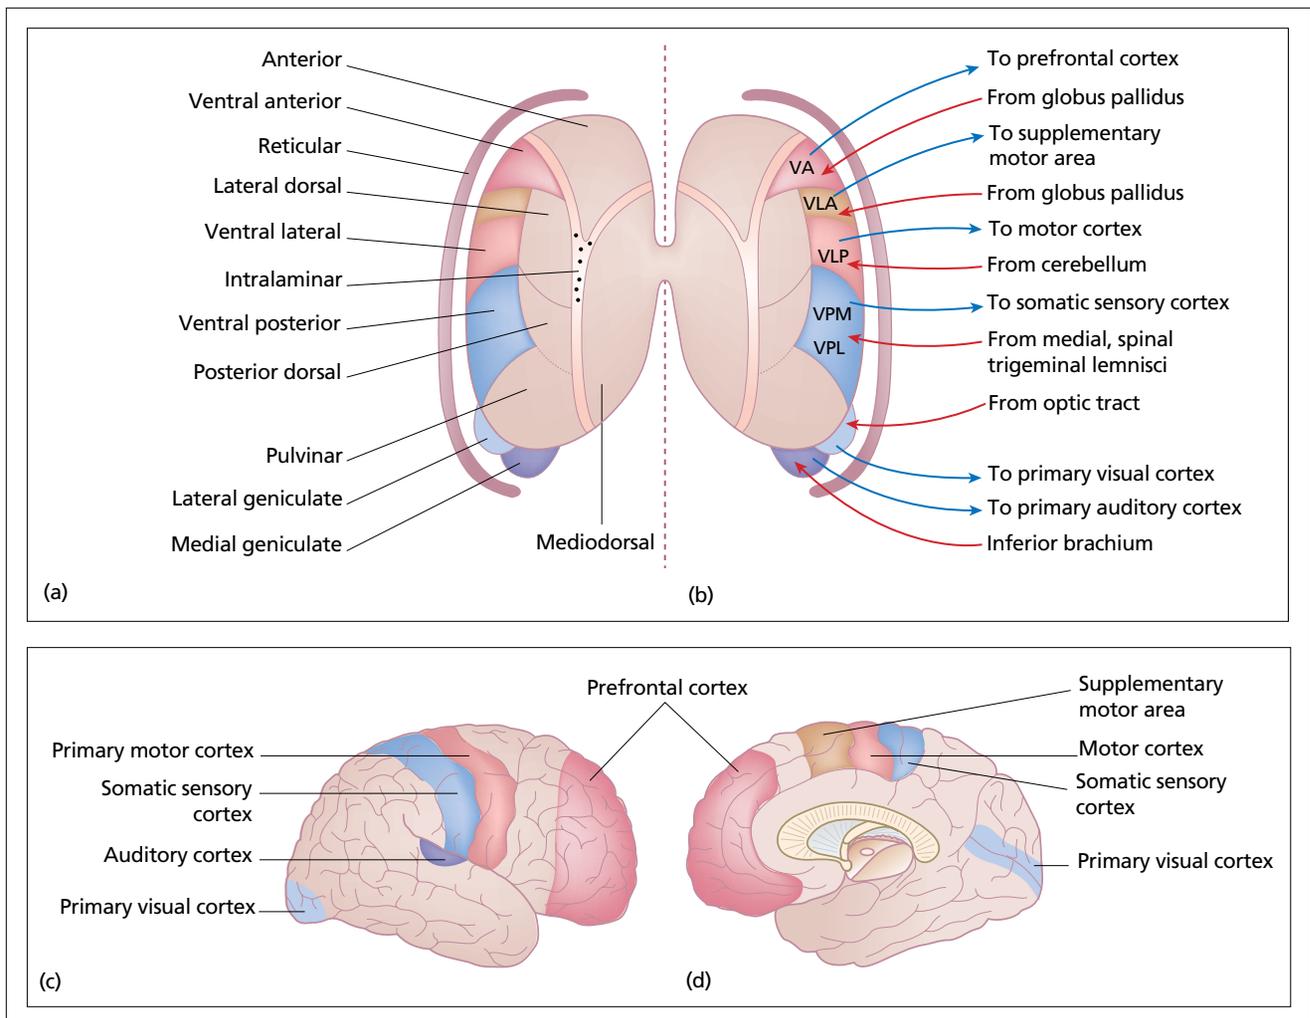

Principal connections are shown in Table 2.7.

### Cortical connections

Four, largely afferent connections from thalamus to cortex run in the anterior, posterior, inferior and superior thalamic peduncles in a cruciform arrangement:

- 1 Anterior thalamic peduncle → cingulate gyrus and prefrontal cortex via internal capsule (anterior limb).
- 2 Superior thalamic peduncle → motor, premotor and sensory cortex via internal capsule (posterior limb).
- 3 Posterior thalamic peduncle → occipital, posterior parietal and posterior temporal cortex via internal capsule.
- 4 Inferior thalamic peduncle → anterior temporal and orbital cortex.

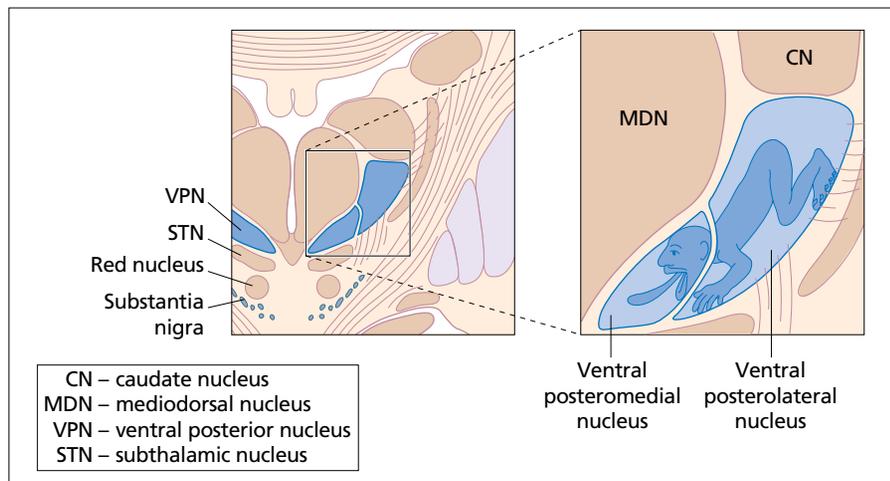

Each fan of these sensory fibres forms part of the corona radiata between internal capsule and cortex.

**Figure 2.33** Thalamic nuclei and connections (from above). (a) nuclei; (b) connections of relay nuclei; (c) hemisphere – lateral view; (d) hemisphere – medial view. **Table 2.7** Thalamic nuclei: sources and destinations of principal pathways.

Source	Thalamic nucleus	Destination
Mamillary body, hippocampus	Anterior	Cingulate gyrus
Globus pallidus	VA	Prefrontal cortex
Globus pallidus	VLA	Supplementary motor area
Cerebellum (dentate nucleus)	VLP	Motor cortex
Head somatic afferents	VPM	Somatic sensory cortex (S1)
Trunk + limb somatic afferents	VPL	Somatic sensory cortex (S1)
Inferior colliculus (auditory)	Medial geniculate body	Primary auditory cortex
Superior colliculus (vision)	Lateral geniculate body	Primary visual cortex
Parietal lobe	Lateral dorsal	Cingulate cortex
Superior colliculus + parietal lobe	Pulvinar + lateral dorsal	Visual association cortex
Reticular formation, basal ganglia	Intralaminar	Cortex, basal ganglia
Thalamus, cortex	Reticular nucleus	Thalamus

**Figure 2.34** Thalamus (coronal section): ventral posteromedial and ventral posterolateral (VPM/VPL) nuclei – somatotopic projection. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

### Specific (relay) thalamic nuclei

These nuclei of the ventral tier are connected to distinct motor and sensory areas of the cortex:

- Anterior and VA nucleus (Table 2.7).
- The anterior part of the VL receives fibres from the pallidum and relays them to the supplementary motor area.
- The posterior part of VL receives fibres from the opposite superior cerebellar peduncle (from the dentate nucleus) and relays to the motor cortex.
- Ventral posterior nucleus (VP). This receives all axons of the medial, spinal and trigeminal lemnisci and projects to the somatosensory cortex. The somatotopic arrangement is shown

in Figure 2.34. The medial part (VPM) deals with the head; the lateral (VPL) with the limbs and trunk. Within each part of the VP there is segregation of sensory modalities – proprioception at the front, nociception at the back, with touch in the middle.

- The ventral intermediate nucleus (VIM), located between VL and VPL provides a direct route for somatosensory input to the motor cortex. VIM is of significant importance in the functional neurosurgical treatment of tremor (see Surgery for Parkinson's disease, Chapter 6).
- Within the VP there is no evidence of gating (cf. the substantia gelatinosa) or modulation – the system is either off (no pain) or on

(intense pain). This may explain the persistent and untreatable pain of the thalamic syndrome, when a stroke disconnects VP from the sensory cortex (see Central post-stroke pain, Chapter 23).

- The medial geniculate body is an auditory system nucleus.
- The lateral geniculate body is a nucleus of the visual system.

### Association thalamic nuclei

These are connected to association areas of the cortex:

- The lateral dorsal nucleus is connected to the cingulate cortex (memory).
- The medial dorsal nucleus is connected to entire prefrontal cortex, olfactory and limbic systems (mood, executive function, cognition, memory, associations of smells).
- The pulvinar and lateral posterior nucleus project to the visual and parietal association cortices, having received fibres from the lateral geniculate. Also, a direct pathway, from optic tract via superior colliculus reaches the visual cortex, without relaying through the lateral geniculate – involved in attention within the visual field, but outside conscious perception.

### Non-specific thalamic nuclei

These nuclei are non-specific in the sense that they are not directly involved with individual sensory modalities. The intralaminar nuclei are the rostral termination of the reticular formation. Aminergic afferents reach the region from the midbrain raphe nuclei and the locus coeruleus. Prolongation of such excitatory aminergic activity in thalamocortical fibres is one effect of tricyclic drugs, and a possible mode of their action in chronic pain. There is widespread onward connection from intralaminar nuclei to the cortex.

The shield-shaped reticular nucleus connects to all thalamic nuclei. Each thalamocortical fibre connects to a reticular nucleus neurone via a collateral. Reticular nucleus cells respond by a GABAergic inhibitory response to the corresponding thalamic nucleus – terminating a sensory stimulus (Figure 2.35). During sleep–wake cycles, thalamocortical neurones are constantly

inhibited during sleep and constantly active (disinhibited) during wakefulness. This inhibition may explain the effect of sleep and sedation on pain.

## Hypothalamus and pituitary gland

The multiple paired nuclei of each hypothalamus (about 4 g apiece in humans) lie each side of the 3rd ventricle. They are involved in two allied neuro-effector control systems:

- 1 Autonomic nervous system, and
- 2 Pituitary axis.

The hypothalamus is a central neural effector of basic survival, with roles in:

- Temperature homeostasis
- Regulation of food and water intake
- Defence, arousal and sleep–wake cycles, and
- Sexual activity.

The hypothalamus mediates control of all endocrine and all autonomic activity.

The essential nuclear anatomy and blood supply are outlined in Figure 2.36 and the three groups of nuclei are listed in Table 2.8. The median forebrain bundle (aminergic fibres) merges with and lies lateral to the lateral nucleus of the hypothalamus on each side.

### Arterial and capillary supply

Delicate perforating branches of the anterior communicating artery supply the hypothalamic region. Hypophyseal branches of the internal carotid artery supply the pituitary itself:

- *Superior hypophyseal artery*: anterior pituitary.
- *Inferior hypophyseal artery*: posterior pituitary.

Each hypophyseal arterial system forms a second capillary portal system that surrounds the neuroendocrine cells. Hormones are liberated into venous blood, draining into the cavernous sinus. These fenestrated portal capillaries are outside the blood–brain barrier.

### Neuroendocrine cells

These neurones, specific to the region, both conduct action potentials and also liberate into the bloodstream peptide and other hormones, the latter having been synthesised in the endoplasmic reticulum and stored in Golgi complexes. The peptides are attached to long-chain polypeptides – neurophysins. Cell bodies of neuroendocrine cells lie in the region of the pre-optic nuclei and tuber cinereum. The principal nuclei that also contribute to this system are:

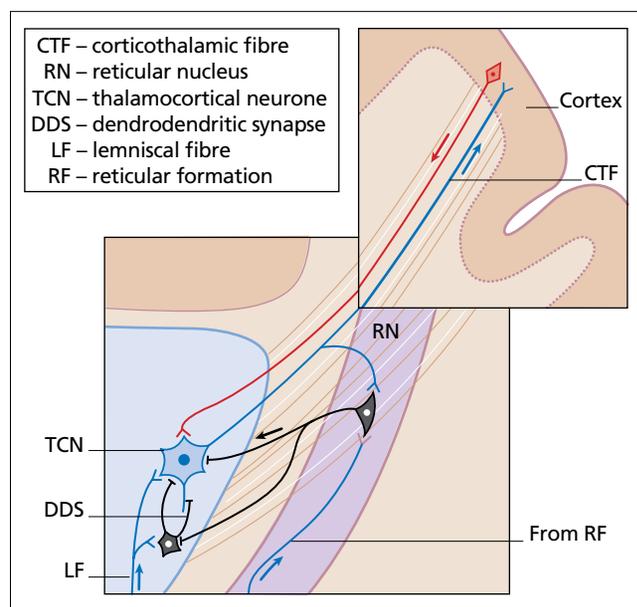

- Supra-optic
- Paraventricular
- Ventromedial, and
- Arcuate nuclei.

Small neurone (parvocellular) axons in the tubero-infundibular tract reach the median eminence, where releasing (RH) and inhibiting hormones (IH) are liberated. Large neurone (magnocellular) axons form the hypothalamo-hypophysial tract that passes to the posterior pituitary.

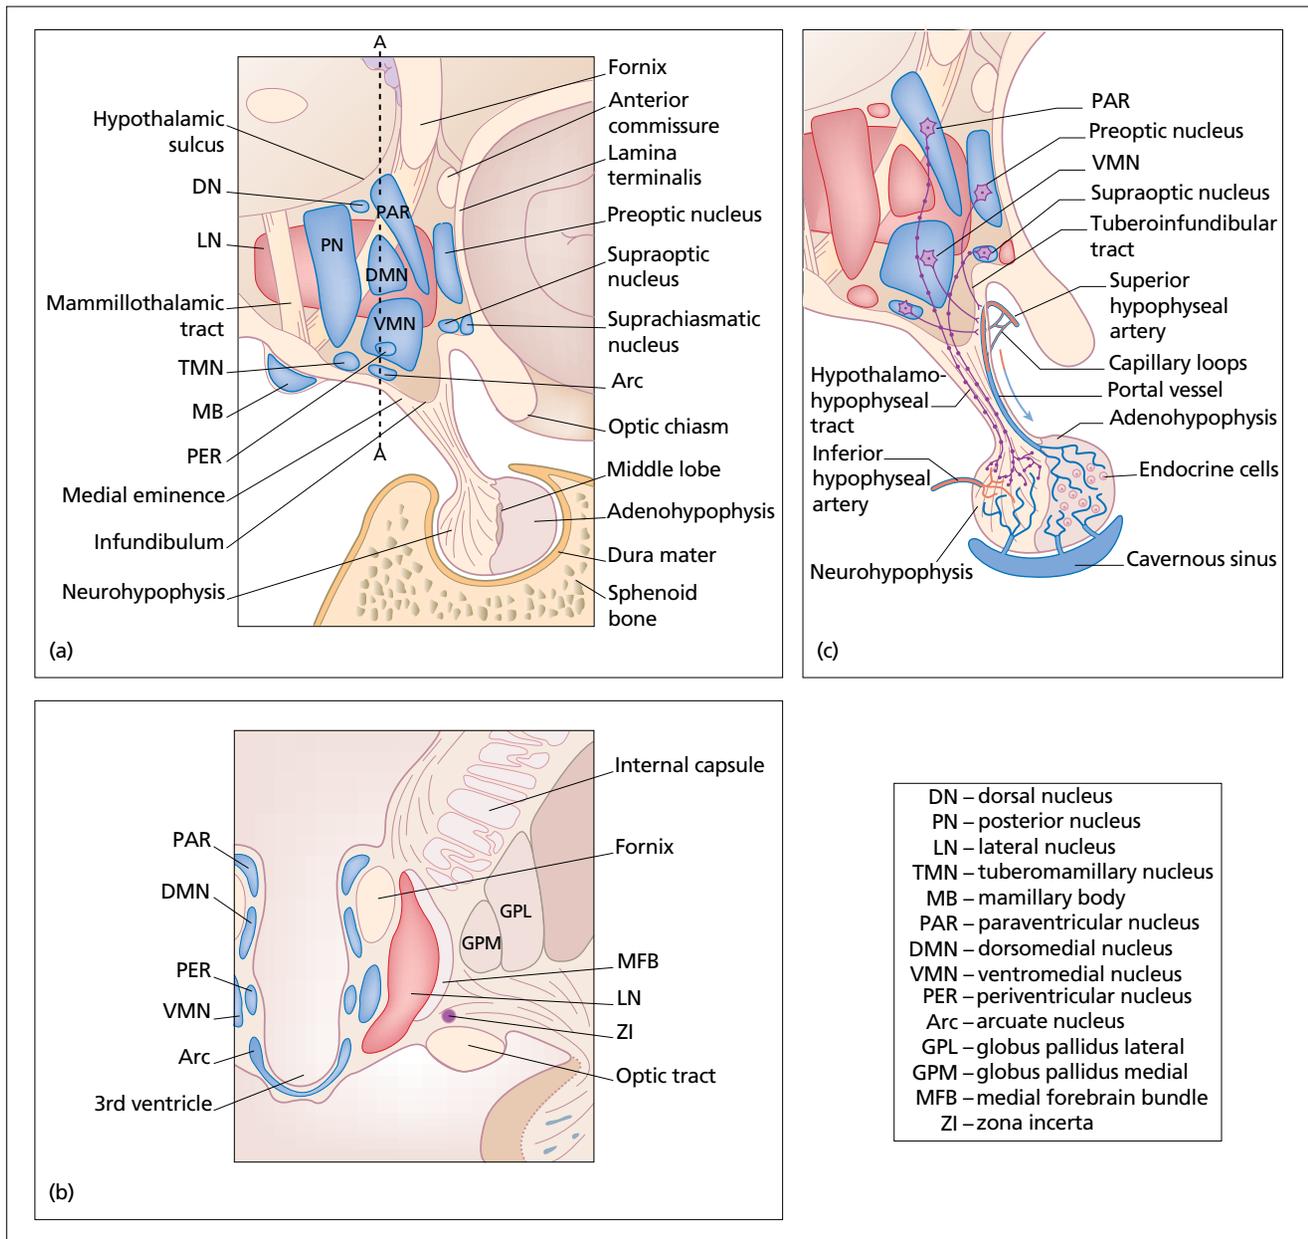

### Anterior pituitary axis

The anterior pituitary axis hormones are listed in Table 2.9. All RH/IHs, with the exception of prolactin IH, are peptides. Prolactin IH is dopamine. The complex control systems for these hormones, include:

- Traditional feedback loops
- Depolarisation by action potentials entering from the limbic system and reticular formation (e.g. arousal effects)

**Figure 2.35** Reticular nucleus: connections between cortex and specific thalamic nuclei. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

**Figure 2.36** (a) Hypothalamic nuclei and pituitary, viewed from right. (b) Coronal section through A–A. (c) Blood supply to pituitary. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

**Table 2.8** Hypothalamic nuclei.

Anterior	Middle	Posterior
Pre-optic	Paraventricular	Posterior
Supra-optic	Peri-ventricular	Mammillary body
Suprachiasmatic	Dorsomedial	Tuberomammillary
	Lateral	Dorsal
	Ventromedial	
	Arcuate	

**Table 2.9** Pituitary and hypothalamic releasing/inhibiting hormones (RH/IH).

Anterior lobe hormone	RH/IH
ACTH	Corticotrophin RH
FSH/LH	Gonadotrophic hormone RH
Growth hormone	Growth hormone RH and IH
Prolactin	Prolactin RH and IH
Thyrotropin	Thyrotropin RH

ACTH, adrenocorticotrophic hormone; FSH, follicle-stimulating hormone; LH, luteinising hormone.

- Hyperpolarisation by local GABAergic neurones
- Inhibition by opiate-releasing neurones (numerous in the hypothalamus), and
- Activation directly of anterior pituitary endocrine cells by opiates and endorphins.

### Posterior pituitary axis

Each hypothalamo-hypophyseal tract passes from large (magnocellular) neurones of the supra-optic nucleus and paraventricular nucleus to the posterior pituitary (neurohypophysis). There are also contributions from periventricular neurones (opiate and peptide neurotransmission) and brainstem (aminergic) neurones.

Vasopressin (antidiuretic hormone) and oxytocin are secreted by specific neurones in both supra-optic and paraventricular nuclei; these hormones are housed in axonal secretory granules (Herring bodies) before being released into the capillary system within the posterior pituitary itself.

### Circumventricular organs

This term refers to six groups of specialised neurones and glial cells adjacent to the ventricular system that have an intimate relation to fenestrated capillaries:

- 1 Neurohypophysis
- 2 Median eminence
- 3 Vascular organ of the lamina terminalis (VOLT)
- 4 Subfornical organ
- 5 Area postrema
- 6 Pineal gland.

Functions are outlined in Table 2.10.

### Sympathetic and parasympathetic hypothalamic activity

Posterior hypothalamic stimulation produces noradrenergic sympathetic effects:

- Heart rate ↑
- Blood pressure ↑
- Pupil dilatation
- Gut stasis.

**Table 2.10** Circumventricular organs.

Organ	Function	Comment
Neurohypophysis	ADH secretion	See text
Median eminence	Anterior pituitary hormone release and inhibition	
VOLT + SFO	Facilitate ADH secretion	Axons to supra-optic and paraventricular nuclei (feedback loop: low blood volume → kidney → renin → angiotensin II → VOLT/SFO → ADH)
Area postrema	Chemoreceptor (emetic) centre	Reflex vomiting (situated at obex of 4th ventricle)
Pineal gland (body)	Melatonin	Sleep–wake cycles

ADH, antidiuretic hormone; SFO, subfornical organ; VOLT, vascular organ of the lamina terminalis.

Anterior hypothalamic stimulation produces muscarinic parasympathetic effects:

- Heart rate ↓
- Blood pressure ↓
- Pupil constriction
- Peristalsis.

The axonal pathway projects from anterior and posterior hypothalamus to autonomic nuclei in the brainstem and cord – via the dorsal longitudinal fasciculus in the midbrain and pons.

### Temperature regulation

Thermosensitive neurones in the hypothalamus respond to core temperature changes. Spinoreticular tracts also deliver information to these hypothalamic neurones from skin thermal receptors. The autonomic effector sympathetic system alters skin blood flow and sweating via the posterior nucleus of the hypothalamus – axons pass direct to the lateral horn of the cord. Increase in core temperature is achieved by:

- Skin vasoconstriction
- Abolition of sweating
- Shivering/muscular activity, and
- Behavioural responses (e.g. crouching, huddling, extra clothing).

Hypothalamic temperature-sensitive neurones also respond to exogenous pyrogen, setting the central thermostat to a higher level, and are also involved in the production of central pyrexia (see Initial assessment and management of coma, Chapter 20).

### Water intake and thirst

The zona incerta, a strip of cells beside each lateral nucleus of the hypothalamus, controls thirst. Lesions of this region lead to neglect of drinking, and in animals stimulation leads to thirst and excessive water intake. Many other mechanisms also contribute to osmotic homeostasis (e.g. serum sodium and glucose levels and renal function).

### Appetite and satiety

Balance in activity between the lateral and ventromedial hypothalamic nuclei constitutes, in theory at least, a satiety system in humans. In experimental models:

- Lateral hypothalamic (feeding centre) stimulation leads to overeating
- Lateral hypothalamic destruction leads to lack of interest in food
- Ventromedial hypothalamic (satiety centre) stimulation inhibits eating
- Ventromedial hypothalamic destruction (bilateral) leads to gross obesity.

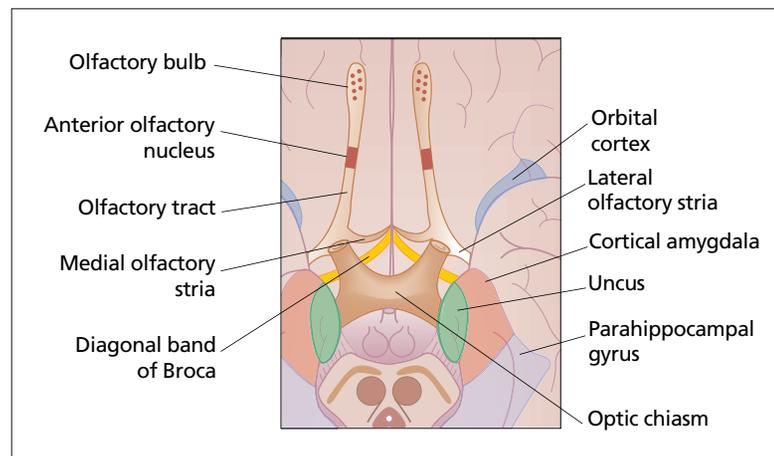

Serotonergic activity down-regulates the appetite set point, and vice versa, selective serotonin re-uptake inhibitors (SSRIs) and other antidepressants tend to increase appetite.

### Mood, sexual arousal, wakefulness and memory

**Mood** Aggression or docility are features of experimental lateral/ventromedial hypothalamic imbalance. Obese animals with ventromedial lesions become aggressively enraged. Underweight, ventromedially stimulated animals are docile. Hunger stimulates arousal. In human behaviour this may explain why some people become angry when they are not fed at the time they expect to be.

**Sexual arousal** Specific neurones (INAH3 cells) in each pre-optic nucleus are more numerous in males than in females. This is an area rich in androgen receptors, activated by testosterone and which when experimentally stimulated induces male sexual activity.

**Figure 2.38** Olfactory tract region, from below. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

- → Membrane depolarisation and an excitatory action potential and propagation along the axon of a bipolar cell.

There are around 1000 odorant receptor genes. These are expressed on individual bipolar cells (i.e. there are around 1000 receptor cell subtypes, a large number, but vastly insufficient to account for the appreciation, in humans of about 100 000 different smells, and for the exceptional sense of smell in some mammals).

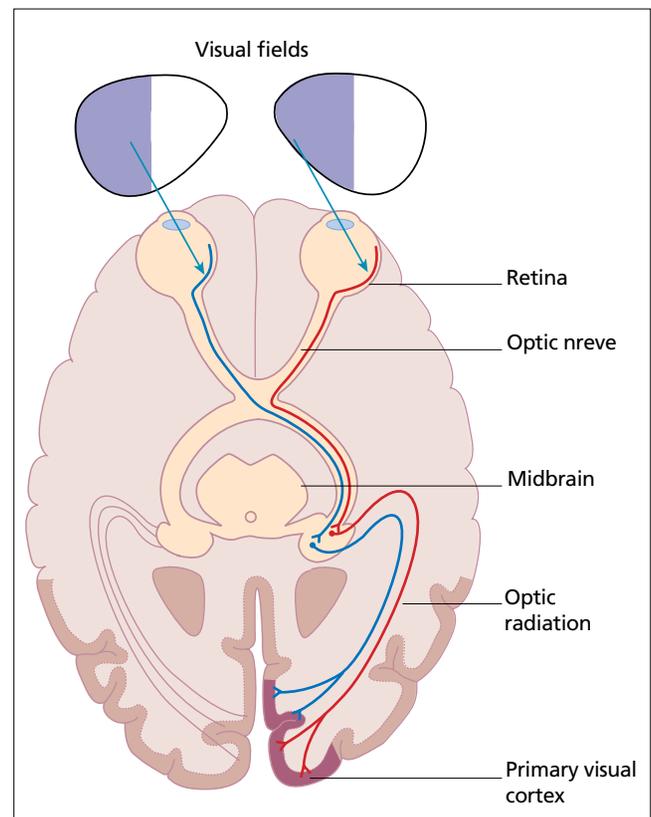

In olfactory neurones, the single second messenger is cAMP (i.e. the channels are cAMP-gated). Each receptor subtype is broadly tuned – each responds to various similar odorants – and, correspondingly, each odorant can stimulate more than one receptor subtype. Thus, each bipolar cell yields potentially ambiguous information. A further selection process takes place at the level of the glomeruli.

Each olfactory bulb contains some 2000 spherical glomeruli 50–200  $\mu\text{m}$  in diameter. The endings of around 25 000 primary olfactory bipolar receptor axons end in the glomeruli, forming synapses with about 100 second order olfactory neurones. The association between individual receptor subtypes and a particular glomerulus is precise. Receptor neurones expressing one gene, although scattered throughout the epithelium, converge on several glomeruli in each olfactory bulb.

Within each glomerulus there is excitation and inhibition (e.g. see Olfactory epithelium) and thence it is the temporal coding of afferent impulses that determines the particular perceived smell by cortical receptive fields. Olfactory cortical neurones recognise a particular ‘tune’ of impulses as an individual smell.

The projection of each afferent olfactory pathway is direct to phylogenetically ancient regions of the cortex, in contrast to most other sensory tracts that passes first to the thalamus before reaching the cortex. From the olfactory cortex, there are projections to areas throughout the brain.

Finally, not all olfactory perception is at a conscious level. Pheromonal perception in humans undoubtedly exists – probably accounting for part of sexual attraction. For example, pheromones are of critical importance in lepidoptera, enabling attraction to take place over several kilometres in moths between males and females. There is evidence to support the existence of a vomero-nasal receptor organ in humans in the lateral nasal mucosa. Central pathways in humans remain

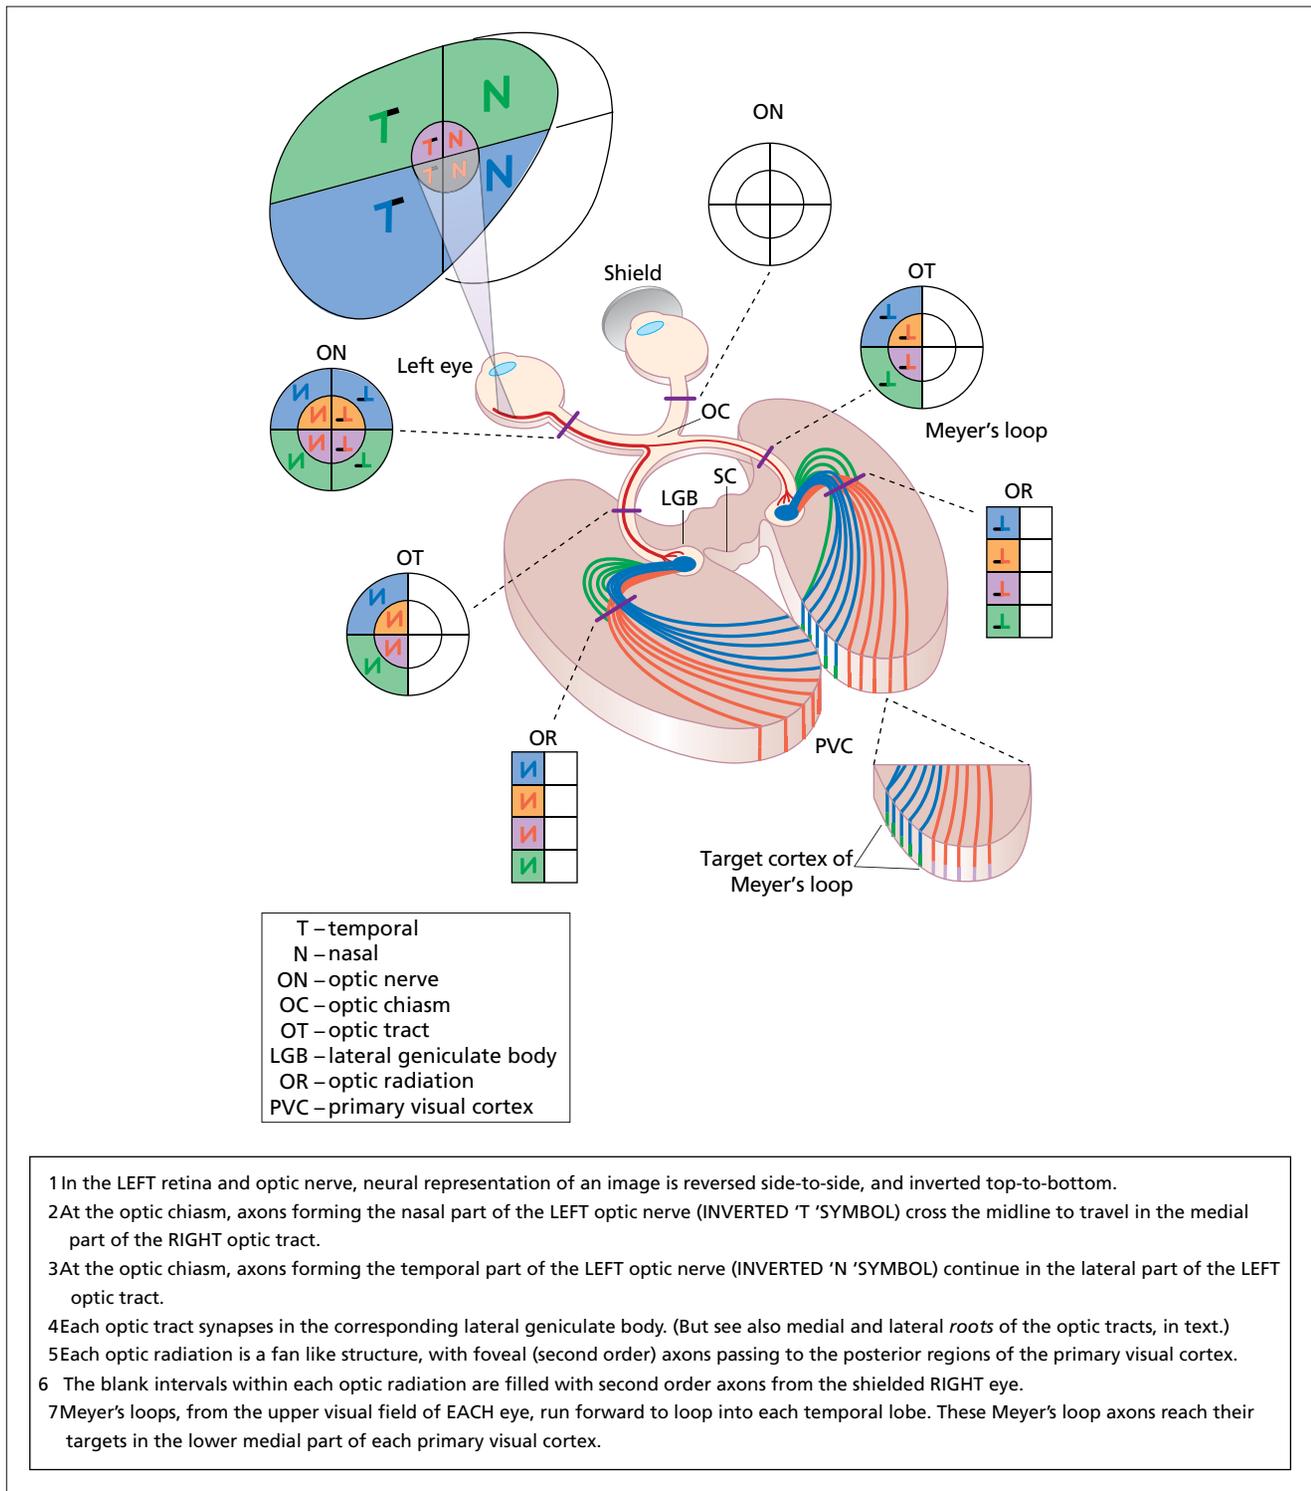

**Figure 2.39** Essential anatomy of visual pathway. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

unknown and the neurochemistry of pheromonal activating systems conjectural.

### Optic nerve and visual system

The visual pathway is summarised in Figures 2.39 and 2.40. Typical field defects are summarised in Figure 2.41 and are discussed further with clinical aspects in Chapter 14 (see Visual field defects).

**Figure 2.40** Detail of visual pathway; RIGHT eye shielded. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

The following sections focus on individual regions and functional aspects of this complex and highly developed special sense.

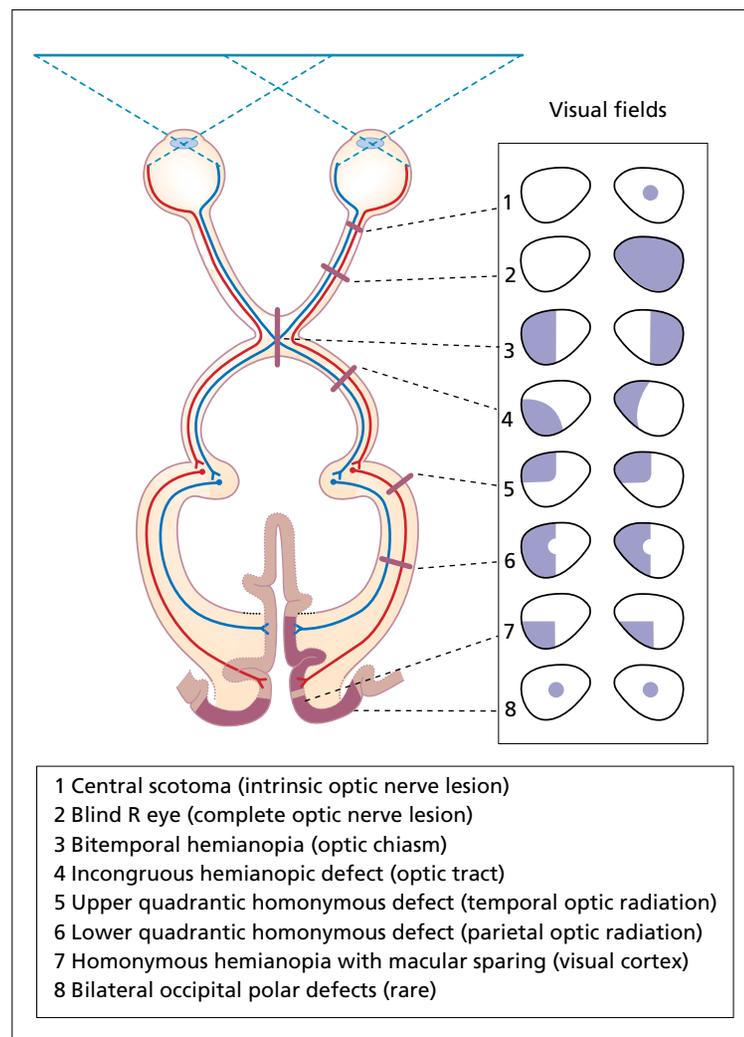

**Retinal structure**

The eight retinal cell and fibre layers are shown in Figure 2.42:

- Photoreceptors (2) – rods and cones – are applied to the pigment epithelium (1), adjacent to the choroid.

- Ganglion cells (7) are the source of action potentials conducted by axons that form the retinal nerve fibre layer (8) and pass into the optic nerve.
  - Two sets of retinal neurones – horizontal cells and amacrine cells – are arranged transversely.
- The essential circuitry is shown in Figure 2.43.

*Photoreceptors and bipolar cells* Cone photoreceptors are sensitive to bright light, colour and shape. They are clustered in and around

**Figure 2.41** Visual field defects: examples of typical lesions.

the fovea. Photoreceptor end-feet synapse with bipolar cells and horizontal cells processes. Cone bipolar cells are either:

- ON bipolars, that is, switched ON (depolarised) by light, or inhibited by neurotransmitters released when light levels fall. They synapse and converge on ON cone ganglion cells.
- OFF bipolars have an opposite response. They synapse and converge on OFF ganglion cells.

Horizontal cells extend dendrites between photoreceptors and bipolar cells with which they make inhibitory contacts. Bipolar cells (and hence retinal ganglion cells) outside the immediate zone of excitation are inhibited. This restricts retinal activity to the area under direct photic stimulation, a feature known as centre-surround antagonism.

Rod photoreceptors are active in conditions of low illumination and are insensitive to colour: dimly lit objects are perceived in shades of grey. Like cones, rods display centre-surround antagonism, between white and black and synapse with ON and OFF bipolar cells.

Rod bipolar cells activate ON and OFF rod ganglion cells via amacrine cells. Amacrine cells have 6–10 dendrites that emerge from one aspect of each cell body. Over one dozen types of amacrine cell are recognised, with different transmitters (e.g. ACh, dopamine, serotonin). Their action is to turn ON or OFF groups of ganglion cells. Functions include enhancement of contrast and detection of subtle movement by retinal rods.

Ganglion cells, of either ON or OFF variety, are activated by bipolar neurones. An ON ganglion cell is activated by a point light source and inhibited via horizontal cells and appropriate bipolars by a surrounding ring of light, known as annular inhibition. An OFF ganglion cell reacts in reverse, being inhibited by a point source and excited by an annulus of light.

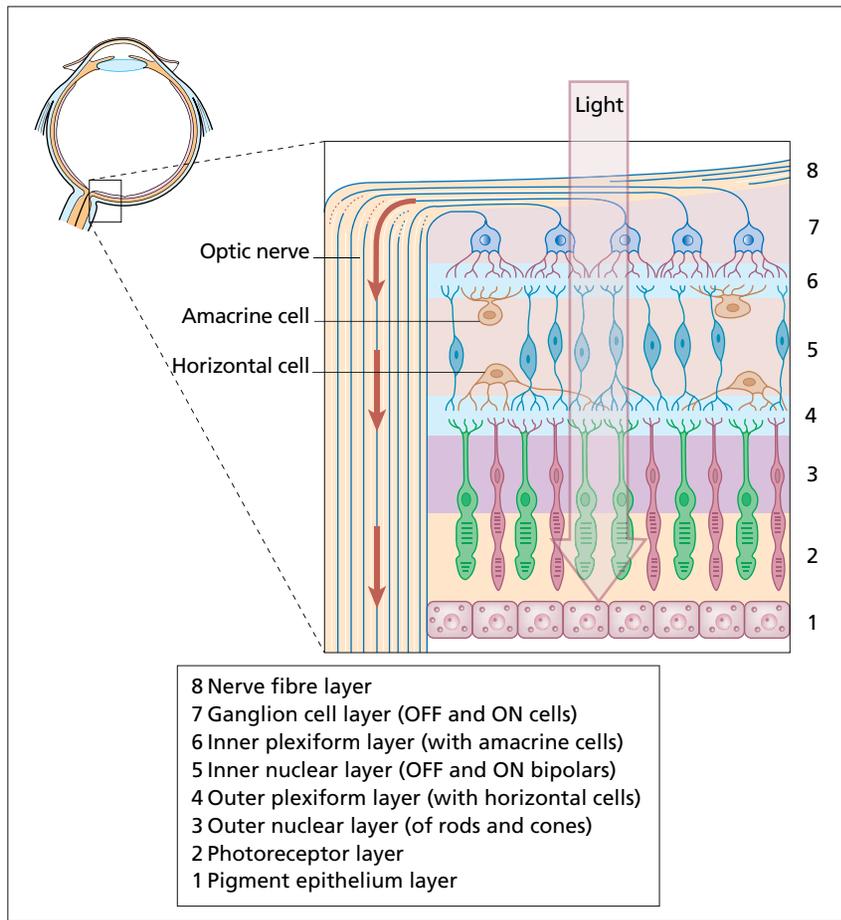

*Colour recognition within the retina – red, green and blue* Colour opponency is the response that characterises specific ganglion cells. Ganglion cells are either:

- ON-line for green + OFF-line for red
- ON-line for red + OFF-line for green
- ON-line for blue + OFF-line for yellow.

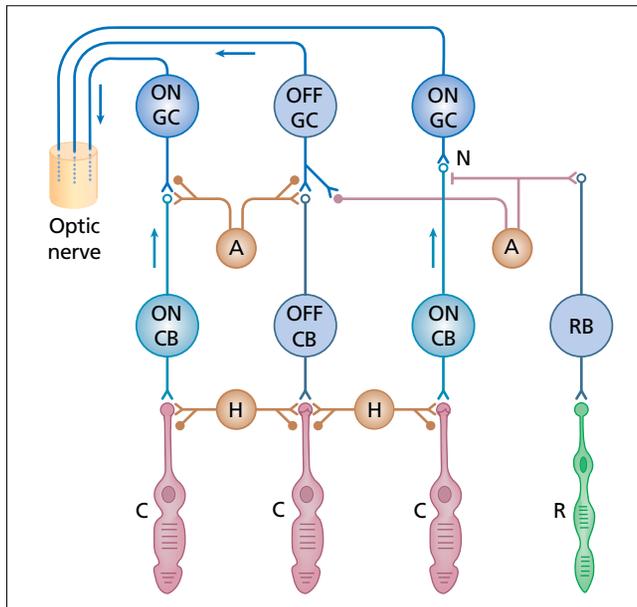

Colour recognition is achieved by individual cones sensitive to specific wavelengths of electromagnetic energy.

*Heterogeneity of rods, cones and ganglion cells* The majority of both rod and cone ganglion cells are parvocellular (small, P cells) – small receptive fields receptive to shape and colour. A minority are magnocellular ganglion cells (large, M cells) – large fields, particularly receptive to moving objects.

The specialised region of cones is the fovea and its central 100 µm, the foveola – the area that has the highest sensitivity for object discrimination and colour appreciation (Figure 2.44). Several anatomical features of the foveola enhance sensitivity:

**Figure 2.42** The eight retinal layers. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

**Figure 2.43** Circuit diagram of retina. A, amacrine cell; C, cone; CB, cone bipolar; GC, ganglion cell; H, horizontal cell; N, nexus (gap junction); R, rod; RB, rod bipolar. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

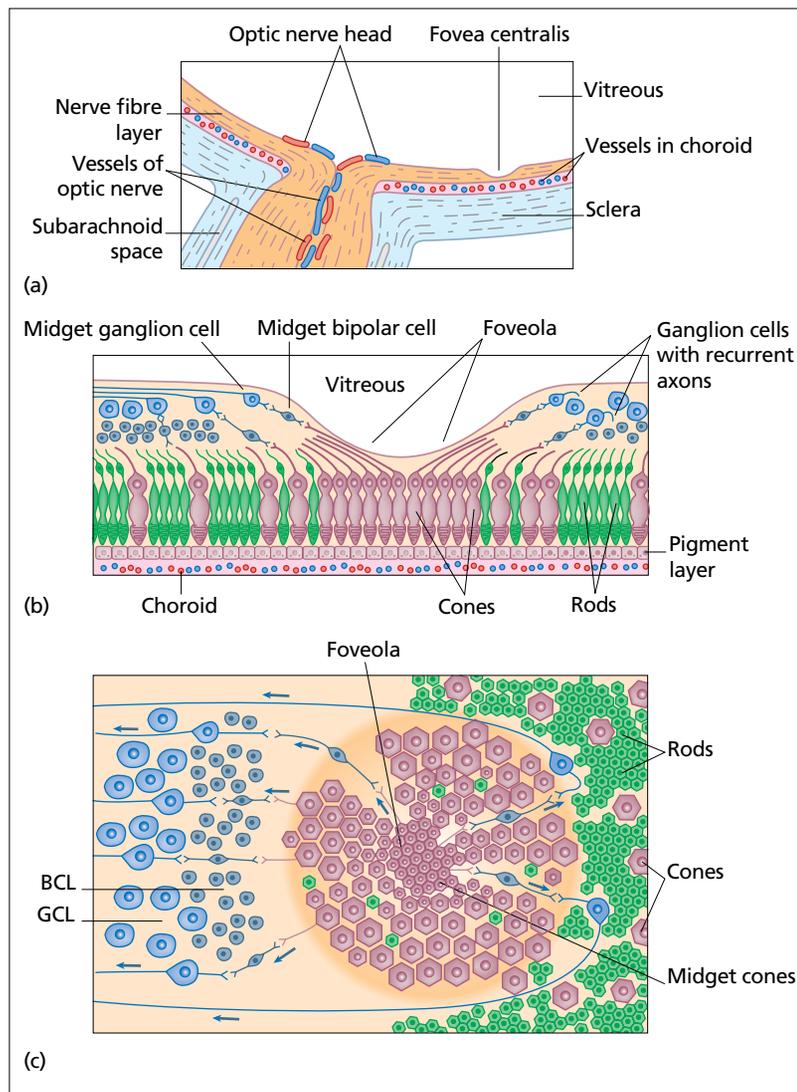

- Midget cones in the foveola have one-to-one synaptic contacts with midget bipolar cells and ganglion cells. Outside the foveola sensitivity is less acute.
- Superficial layers of the retina have long neurites; cell bodies surround the fovea rather than covering the cones. This allows light to strike midget cones directly.

**Optic nerve, chiasm and optic tract**

Each optic nerve (a CNS structure rather than a peripheral nerve) contains between 800 000 and 1.5 million ganglion cell axons, with a supporting infrastructure – astrocytes, oligodendrocytes, blood supply and meningeal sheath. The chiasmal decussation, optic tract and optic radiation are illustrated in Figure 2.40.

Each optic tract (comprised of uncrossed temporal-half and crossed nasal-half retinal axons) divides into a medial and a lateral root. The medial root of each optic tract enters the midbrain. It carries:

- Fibres serving the pupillary light reflex – passing to the pretectal nucleus
- Fibres from retinal M cells – scanning movements – to the superior colliculus
- Fibres to the reticular formation (parvocellular) – arousal function, and
- Fibres relaying from superior colliculus, to pulvinar and visual association cortex – the extrageniculate visual pathway.

**Figure 2.44** (a) Fovea and optic nerve, in section. (b) and (c) Fovea and foveola: section and surface diagram. BCL, bipolar cell layer; GCL, ganglion cell layer. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

The axons of lateral root of the optic tract synapse in the lateral geniculate body (LGB) of the thalamus. The LGB is six-layered:

- Three cellular laminae receive crossed fibres and three uncrossed
- The two deepest laminae (magnocellular) receive axons from retinal M ganglion cells (movement detection)
- The four outer laminae are parvocellular, receive axons from P ganglion cells (detail and colour).

### Optic radiation

The optic radiation (*syn.* geniculocalcarine tract), its ordered somatotopic arrangements and cortical targets are also shown in Figure 2.40. The radiation is the most prominent white matter bundle in the posterior part of the brain. Important features:

- The radiation enters the posterior (retrolentiform) part of the internal capsule, runs beneath the temporal cortex and alongside the posterior horn of the lateral ventricle.
- Meyer's loop – forward-sweeping fibres in the anterior temporal lobe. These are from the upper part of the visual fields and run to the lower half of the occipital cortex.

### Occipital cortex

The optic radiation is seen macroscopically as a pale stripe (stria) of myelinated fibres within the primary visual or striate cortex (Brodmann area 17) before synapsing with spiny stellate cells of cortical layer IV. Francesco Gennari (1752–1797) was a medical student in Padua when he described the occipital striae that bear his name.

The spiny stellate ganglion cells are arranged in alternating ocular dominance columns (alternating inputs between left and right eyes). Thus, impulses from identical points on each retina arrive in the striate cortex in side-by-side columns. Further differentiation is achieved by a hierarchy of cell groups:

- Spiny stellate cells produce simple responses – to fine slits of light in a particular orientation.
- Some pyramidal cells produce complex responses – to broad slits (bars), orientated at a particular angle and either stationary or moving broadside in one direction across the visual field.
- Other pyramidal cells are hypercomplex, responding to L-configurations.

The mechanism of this hierarchy is explained by convergence:

- Several simple cell axons converge on to complex cells, and
- Complex cell axons converge on to hypercomplex cells.

The primary visual cortex can be thought of as a complex pixelated screen, detecting not only position, but shape and movement. Area 17 (V1) does not interpret what we see. For example, area 17 does not itself recognise a face or describe an object. Recognition (i.e. perception) is achieved by connections with the visual association cortex, with the temporal lobes and with memory. The value of vision is also enhanced by eye movement, and by moving the head, limbs and/or trunk in relation to visual stimuli. The cortical eye fields are intimately involved in these processes.

### Visual association cortex and V1–V5 terminology

Brodmann areas 18 and 19, also known as peristriate or extrastriate (*syn.* visual association) cortex contain cortical cell columns concerned with feature extraction. This means that certain cell groups respond to geometry (i.e. shape), some to perception of height/depth (stereopsis) and others to colours with ability to differentiate between many hues. The regions contain cell groups that recognise these particular attributes of objects. Afferents arrive primarily from area 17. There are also direct thalamic projections from the pulvinar.

The V1–V5 nomenclature, based more on functional imaging than the descriptive anatomy of the Brodmann system, is now widely used (Table 2.11). The lateral and medial parts of area 19 (V4, V5) contain specialised connections known as ‘where’ and ‘what’ visual pathways:

- ‘What’ is the ventrally placed, medial stream of object recognition (V4)
- ‘Where’ is the lateral, dorsally situated stream concerned with location (V5), with projections to the posterior parietal lobe.

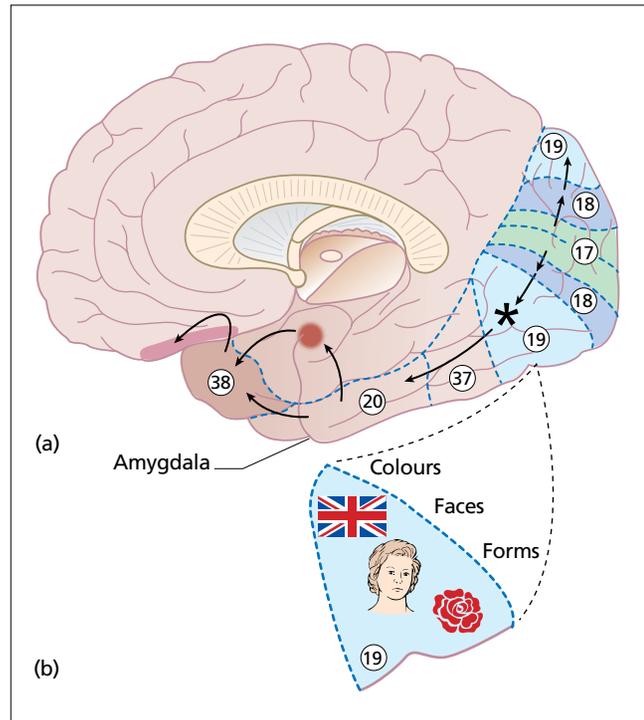

‘What’ Three principal types of visual recognition take place in this region (Figure 2.45):

- 1 Recognition of forms, shapes and categories of objects (generic or canonical identification) takes place in the lateral zone.
- 2 Human face recognition (generic identification – ‘this is a face’) takes place in the mid zone.
- 3 Colour recognition takes place medially.

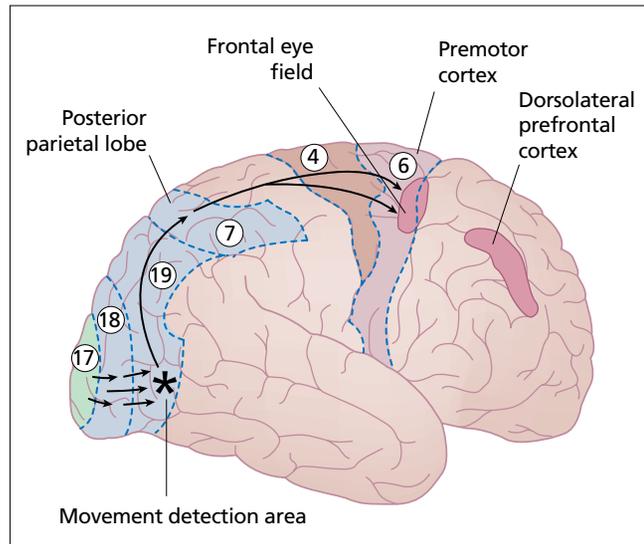

More sophisticated recognition of individual objects and faces involves area 20 (inferotemporal cortex) and area 38 (temporal pole cortex). Objects and faces that are threatening generate activity via areas 20 and 38 in the amygdala and inferofrontal cortex.

**Table 2.11** V1–V5 and Brodmann areas: primary visual and visual association cortex.

V Region	Brodmann area
V1	Brodmann area 17
V2	Brodmann area 18
V3	Brodmann area 19
V4	Identification modules in fusiform gyrus in area 19 (anteromedial)
V5	Movement detection modules in area 19 (anterolateral)

‘Where’ The lateral part of area 19 is particularly responsive to movement in the contralateral hemifield (Figure 2.46). The main projection is to area 7 (posterior parietal cortex), long known as the area affected in disorders of spatial recognition such as astereognosis (see Sensory abnormalities: patterns at different levels, Chapter 4). Area 7 is involved in:

**Figure 2.47** Functional MRI (a) and diagram (b) showing cortical eye fields. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

**Table 2.12** Seven cortical areas involved in saccades: afferents, efferents, functions.

Eye field	Afferents	Efferents	Functions/comments
DLPFC	Visual association cortex	SC, ipsilateral FEF, SEF, CCx	Voluntary saccades, approach and withdraw decisions
CCx	DLPFC, FEF, SEF	SC, ipsilateral FEF	Emotional significance of object; paying attention
SEF	DLPFC, PEF, Area 22	SC, ipsilateral FEF	Motor planning, multiple saccades
FEF	DLPFC, opposite FEF, PEF	SC, opposite PPRF, ipsilateral CCx	Voluntary saccades
Area 22	Auditory association area, PEF	Ipsilateral SC, neck movement	Saccades to sound source
PEF	'Where' pathway, pulvinar, DLPFC	Ipsilateral FEF, SC	Reflex (responsive) saccades
OC	Visual pathway	All cortical eye fields and SC	Interpretation and visual pursuit

CCx, cingulate cortex; DLPFC, dorsolateral prefrontal cortex; FEF, frontal eye field; OC, occipital cortex; PEF, parietal eye field; PPRF, paramedian pontine reticular formation; SC, superior colliculus; SEF, supplementary eye field.

- Movement perception
- Stereopsis (three-dimensional vision)
- Spatial sense (relative position of objects to each other).

Area 7 also receives fibres from the pulvinar known as blindsight fibres. Fibres project to the ipsilateral frontal eye field and premotor cortex. Functional imaging shows increased cortical activity in area 7 in response to a moving object in the contralateral hemifield (covert attention). During saccadic gaze and/or limb movement towards the object, both area 7 and area 5 are activated (overt attention).

### Cortical eye fields

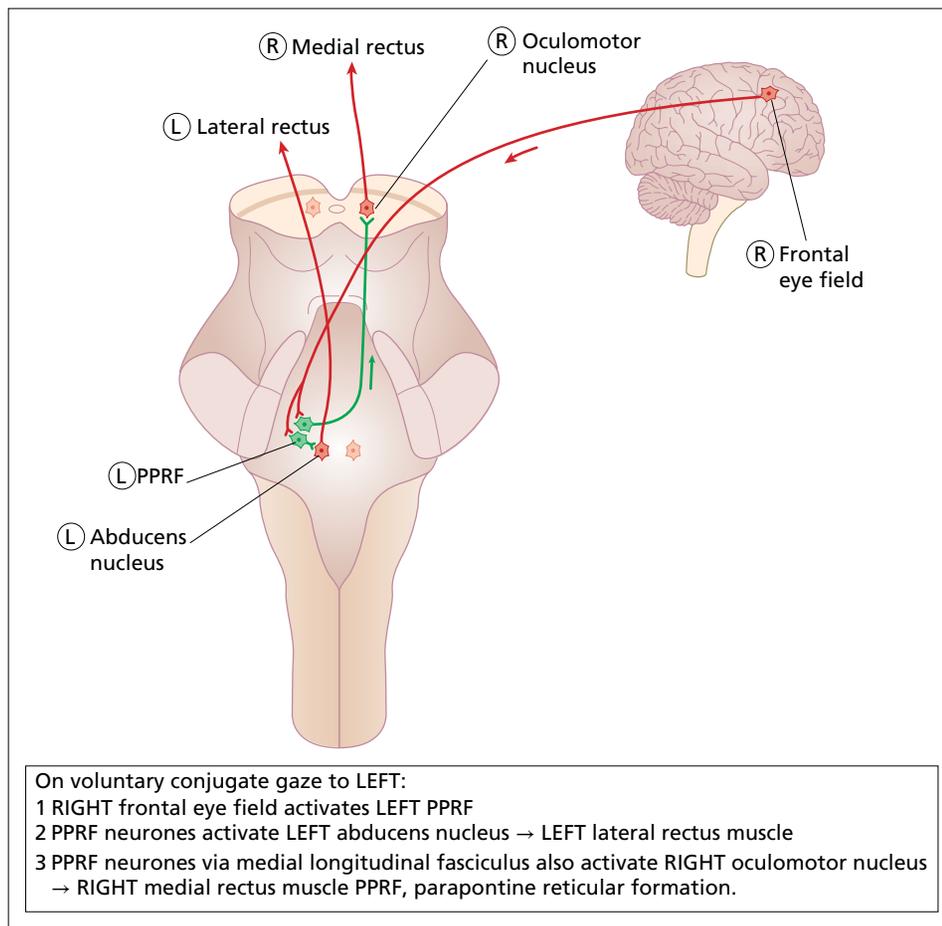

Conjugate eye movement is controlled by discrete regions within the grey matter. These are shown in Figure 2.47, Table 2.12. The complexity is evident. fMRI has been of value here, confirming clinical data, and variability between individuals.

Three different mechanisms are involved in driving conjugate (i.e. yoked) gaze (jugum = Latin: the yoke of a pair of oxen):

- *Scanning*: saccades (i.e. rapid movement from one target to another)
- *Tracking*: smooth pursuit of a target across the visual field
- *Compensation*: maintenance of gaze during head movement via vestibulo-ocular fixation reflex.

Voluntary saccades are initiated in the frontal eye fields. Smooth pursuit movements originate in the occipital and parietal cortices (Table 2.12). Velocity detectors in the upper pons receive information via the medial root of the optic tract. Fixation is achieved by visual pursuit modulated by input from the vestibular system (head and neck movement) and smooth ocular movements by the cerebellar flocculus.

Automatic scanning movements are generated by retinal action potentials in the medial portion of the optic tract, via the pulvinar and area 7. These are also influenced by the cerebellar vermis and

**Figure 2.48** Voluntary conjugate eye movement (midbrain: posterior view) Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

vestibular system. This explains some automatic movements (e.g. hands being in position to catch a rapidly moving ball before it becomes visible).

Eye and pupil movement below the level of the cortical eye fields consists of:

- Conjugate gaze mechanisms within the brainstem
- Pupillary light reflexes
- Individual cranial nerves III, IV and VI and the muscles supplied
- Near and far responses.

### Gaze centres in the brainstem

Horizontal (lateral) gaze centres lie in the right and left PPRF adjacent to each abducens nucleus (Figure 2.48). Upward gaze is controlled by the rostral interstitial nucleus (RiN) close to the pretectal nucleus (IIIrd nucleus level). This lies at the rostral end of the medial longitudinal fasciculus (MLF). This bundle connects each PPRF and abducens nucleus with the portion of the IIIrd nucleus that supplies the medial rectus – thus yoking together abduction in one eye with adduction in the other. The downward gaze centre is ventral to the RiN at the same level

### The light reflex: pupil constriction

The pathway from retinal ganglion cell to post-ganglionic parasympathetic fibres and onwards to the iris (sphincter pupillae) is shown in Figure 2.49. The sympathetic pathway (pupil dilatation) and the near reflex are mentioned in the following section.

### III, IV and VI: third, fourth and sixth nerve nuclei and nerves

Essential anatomy is summarised here (Figure 2.50). Lesions of these nerves and nuclei are discussed in Chapters 4, 14, 15 and 20.

#### Oculomotor nucleus and IIIrd nerve

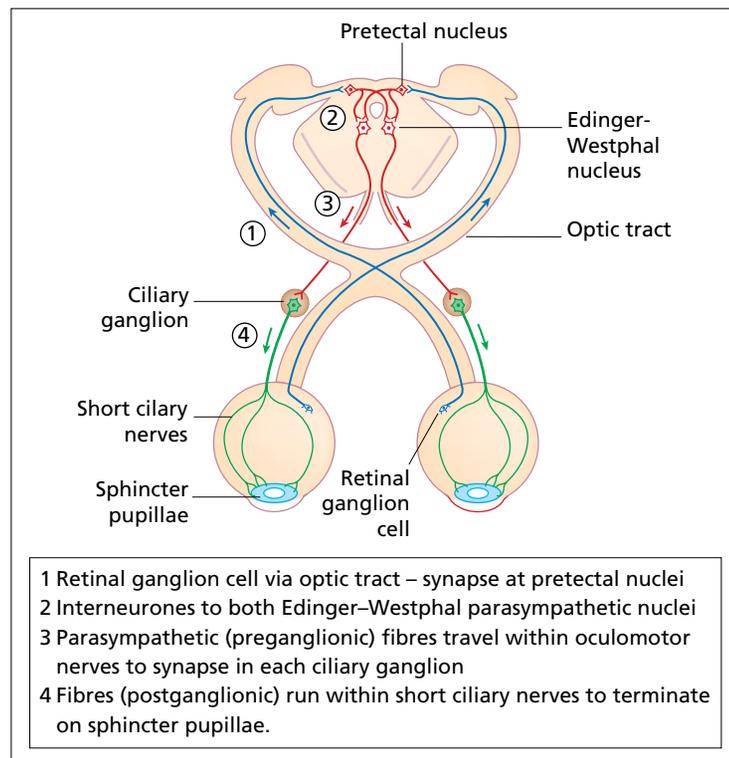

This compound nucleus, adjacent to the peri-aqueductal grey matter at superior colliculus level consists of neurones that supply:

- Five striated muscles: medial, superior, inferior recti, inferior oblique and levator palpebrae superioris
- Muscles supplied by the parasympathetic system: ciliaris (ciliary muscle) and sphincter pupillae, via the Edinger–Westphal nucleus.

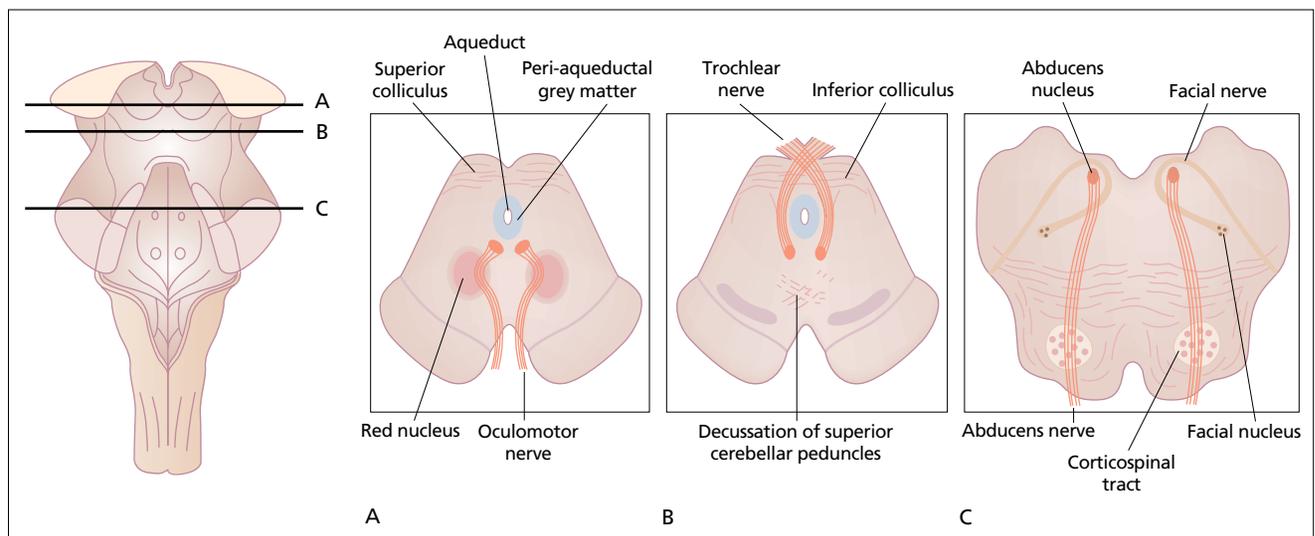

The oculomotor (III) nerve passes through the midbrain tegmentum, emerges into the interpeduncular fossa, crosses the apex of the petrous temporal bone, enters the cavernous sinus and leaves in two divisions within the superior orbital fissure. Parasympathetic fibres travel in the lower division and leave in the branch to the inferior oblique muscle. They synapse in the ciliary ganglion, pierce the sclera and, via the short ciliary nerves, reach ciliaris and sphincter pupillae.

#### Trochlear nucleus and IVth nerve

The nucleus is at the level of the inferior colliculus. Each IVth nerve then decussates, emerges from the back of the brainstem, passes around it and enters the cavernous sinus (just below III), entering the orbit through the superior orbital fissure to reach the superior oblique muscle.

**Figure 2.49** Pupillary constriction to light (midbrain at level of superior colliculus). Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

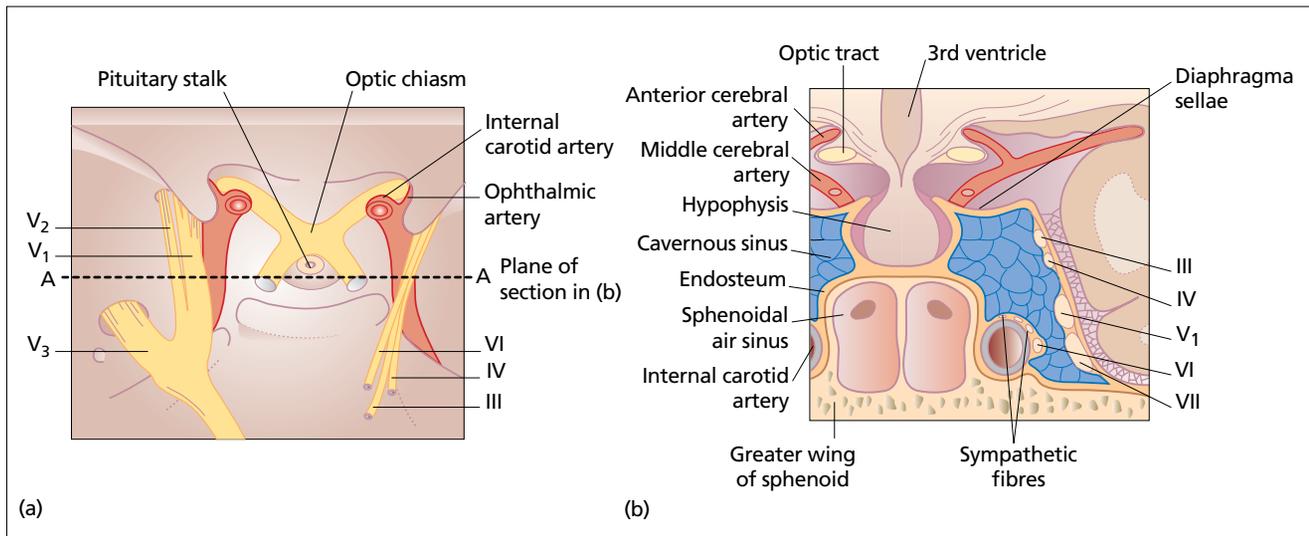

**Figure 2.50** Origins of III, IV and VI: transverse sections of brainstem. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

### Abducens nucleus and VIth nerve

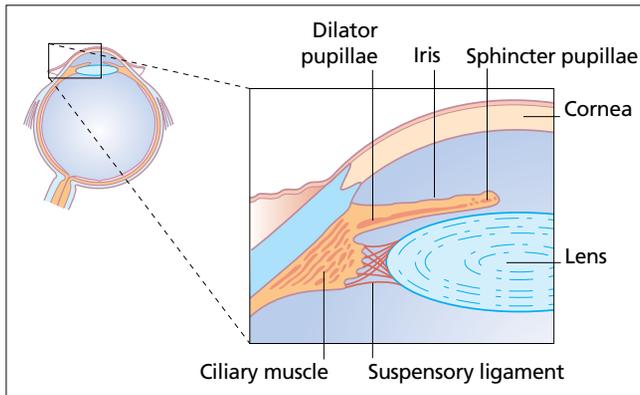

Each VIth nucleus, lower in the brainstem than III and IV, lies in the mid pons at the level of the facial nucleus. The nerve runs a long intracranial course, initially beside the basilar artery, thence over the petrous temporal bone. Within the cavernous sinus it lies beside the internal carotid artery (Figure 2.51). Like III and IV, VI passes through the superior orbital fissure. VI innervates the lateral rectus muscle.

**Ocular muscle motor units and sensory connections** These motor units contain 5–10 muscle fibres (cf. 500 or more in biceps and large striated limb muscles) and comprise A, B and C muscle fibres:

- A fibres (fast twitch) are involved in saccades
- B fibres (slow twitch) are used in smooth pursuit, and
- C fibres are involved in maintaining the visual axes and are tonically active, when awake.

**Figure 2.51** III, IV, VI, and V within cavernous sinus. (a) Middle cranial fossa from above (cavernous sinus removed). Right: relations of V. Left: relations of III, IV and VI. (b) Coronal section through pituitary (AA). Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

**Figure 2.52** Dilator and sphincter pupillae, lens and ciliary muscle. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

Proprioceptive pathways from the extraocular muscles extend widely – to the mesencephalic nucleus of V and to the cuneate nucleus in the medulla. Peripheral afferent projections from the neck muscles and output projections from the vestibulocerebellum to these nuclei assist coordinated simultaneous movements of the neck and head in response to changes in gaze.

### The near response

Three responses combine to enable gaze to focus on a near object:

- 1 Convergence of the ocular axes is brought about by contraction of the medial recti
- 2 The ciliary muscle contracts – the lens bulges passively, the thicker lens shortening its focal length (Figure 2.52), and
- 3 Sphincter pupillae contract – concentrating light through the central part of the lens.

Retinal impulses pass via the lateral geniculate body to the occipital cortex, thence to the visual association cortex which analyses stereoscopically the object in view. Thence, the efferent pathway

reaches the Edinger–Westphal nucleus and vergence cells within the reticular formation.

### The far response

To bring a distant object into focus, the ciliary muscle must be inhibited – allowing the suspensory ligament to become tight and flatten the lens. Sympathetic impulses cause this relaxation of the ciliary muscle via  $\beta_2$  receptors. This dilates the pupil (contraction of dilator pupillae) via  $\alpha_1$  receptors.

### Sympathetic pathway to the eye and face

The sympathetic system originates in the hypothalamus. Central efferents decussate in the midbrain and are joined by ipsilateral fibres running within and from the reticular formation. The pathway descends in the cord, emerges in the first ventral thoracic root and reaches the sympathetic chain. These preganglionic fibres synapse in the superior cervical ganglion. Postganglionic fibres run within adventitia of branches of the internal and external carotid arteries. The internal carotid system is accompanied by two sets of fibres. One joins  $V_1$  in the cavernous sinus, but leaves this nerve in the short and long ciliary nerves to the smooth muscles of the eye (dilator pupillae, ciliaris and levator palpebrae superioris). The second forms a plexus around the internal carotid artery. Branches reach the skin of the forehead and scalp. Horner's syndrome is discussed in Chapter 14 (see Horner's syndrome).

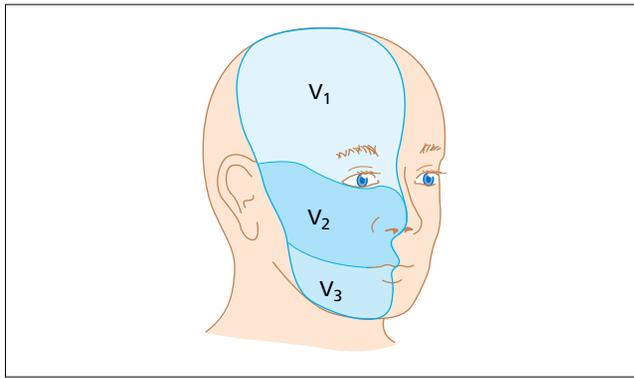

External carotid sympathetic fibres are intimately related to all branches of the external carotid artery: superficial and middle temporal, facial, maxillary, middle meningeal, posterior auricular and lingual arteries.

### V: trigeminal nerve, sensory and motor nuclei

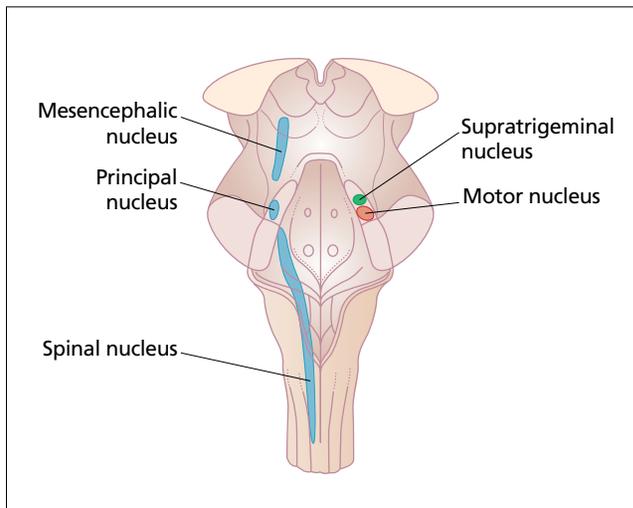

The trigeminal nerve and its nuclei form a massive sensory input via the ophthalmic ( $V_1$ ), maxillary ( $V_2$ ) and mandibular ( $V_3$ ) divisions. The sensory cutaneous distribution is shown in Figure 2.53.

The Vth nerve also carries sensation from:

- The eyes
- Dura mater of anterior and middle cranial fossae
- Adventitia of cerebral and basilar vessels

**Figure 2.53** Cutaneous distribution of the three divisions of Vth nerve. Source: Patten 1996. Reproduced with permission of Springer Science + Business Media.

**Figure 2.54** Trigeminal nuclei within the brainstem. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

- Paranasal sinuses
- Teeth
- Oral and nasal mucous membranes, and
- Facial and masticatory muscles.

#### Motor nucleus of V and supratrigeminal nuclei

Each Vth motor nucleus in the tegmentum of the pons supplies muscles of mandibular arch origin (Figure 2.54). Supranuclear connections run from each motor cortex to both these V motor nuclei, but largely to the contralateral. Within the reticular formation are the supratrigeminal nuclei, lying at the upper poles of the Vth motor nuclei. These generate masticatory rhythms. Muscles supplied via  $V_3$  are:

- Temporalis
- Masseter
- Pterygoids and digastric
- Infrahyoid muscles, and
- Tensor tympani and tensor palati.

Paralysis of one motor root causes deviation of the opening jaw to that side. The motor root is the efferent arc of the jaw jerk, a mono-synaptic reflex.

#### Sensory Vth nuclei

There are three sensory Vth nerve nuclei (Figure 2.54):

- 1 Mesencephalic nucleus
- 2 Principal (pontine), nucleus, and
- 3 Spinal nucleus.

#### Mesencephalic Vth nucleus

Peripheral processes enter the sensory root via the trigeminal mesencephalic tract. The mesencephalic nuclear neurones are unique – they are cell bodies of primary sensory neurones (Figure 2.55). Their peripheral origins are the stretch receptors of masticatory muscle spindles ( $V_3$ ) and stretch receptors of peri-odontal ligaments of the teeth ( $V_2$ ,  $V_3$ ) and some fibres from the eye and eye muscles ( $V_1$ ). Central processes of the mesencephalic afferents descend through the tegmentum of the pons (tract of Probst). Most terminate in the supratrigeminal nucleus; others reach the main part of the motor nucleus, the pontine Vth nucleus and even the dorsal nucleus of the vagus

#### Principal (pontine) Vth nucleus

These paired nuclei are homologues of the spinal gracile and cuneate nuclei. They process touch discrimination from the mouth, nose and face.

#### Spinal Vth nucleus

These paired nuclei extend from the pons to spinal level C3. Each main spinal Vth nucleus (pars caudalis) receives pain and temperature afferents from the entire trigeminal area and beyond.

Each nucleus is microscopically a continuation of the outer laminae (I–III) of the posterior horn of the cord – enkephalinergic and GABAergic connections in the substantia gelatinosa and serotonergic fibres from the reticular formation (magnus raphe nucleus).

Each Vth spinal nucleus receives input from three principal sources:

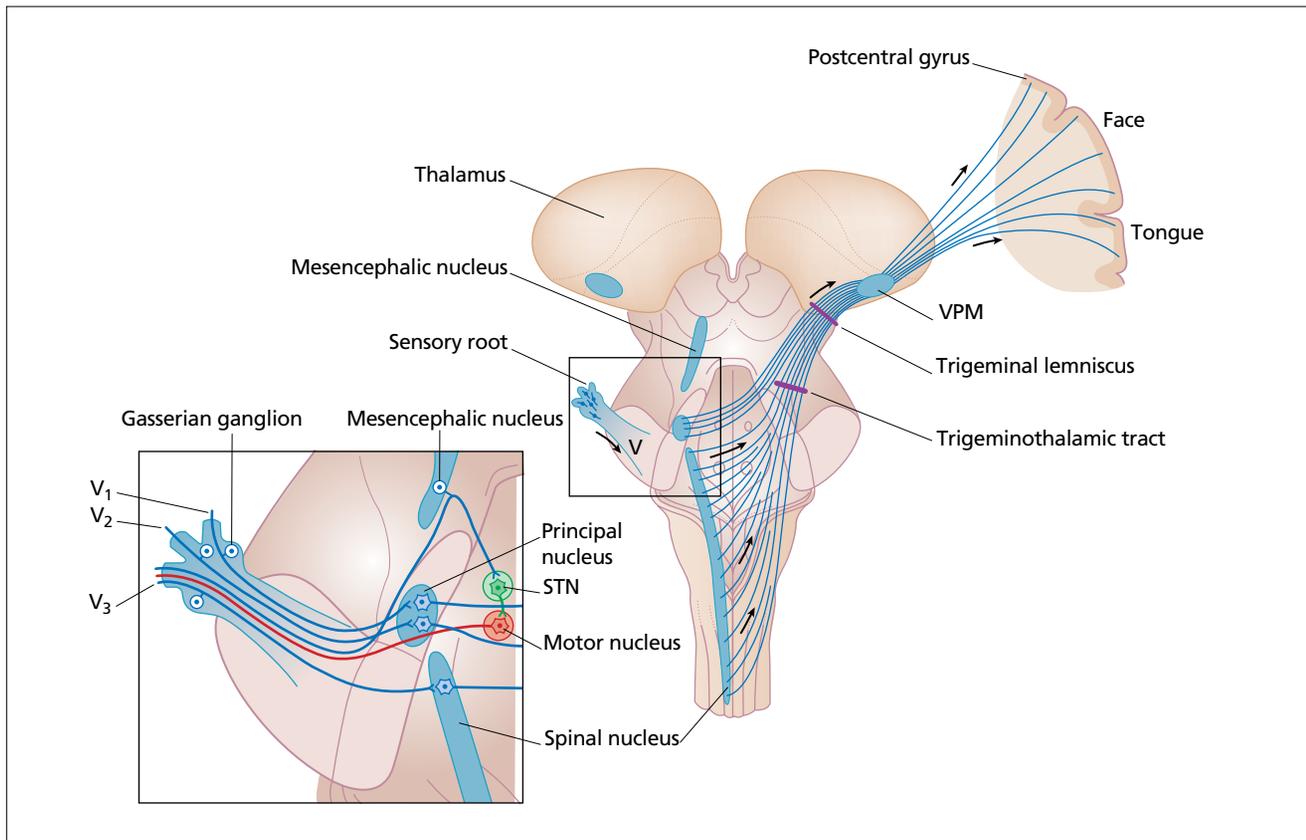

- 1 Gasserian ganglion (trigeminal afferents)
- 2 IX and X, and
- 3 Three (C2–5) cervical posterior roots (C1 is vestigial or absent).

Trigeminal afferents are the central processes of Gasserian ganglion neurones. Topographical representation within the nucleus is linear (mouth rostral) but layered, like an onion centred on the mouth (Figure 2.56). Peripheral fibres carry pain, temperature and touch centrally (facial skin, teeth, sinuses, cornea, temporo-mandibular joints, dura of anterior and middle fossae). Afferents from IX and X (middle ear, Eustachian tube, pharynx, larynx) also reach the spinal fifth nucleus; their cell bodies are within the inferior sensory ganglia of IX and X. Cervical afferents (dura of posterior fossa and cord, cervical joints) ascend through the hypoglossal canal.

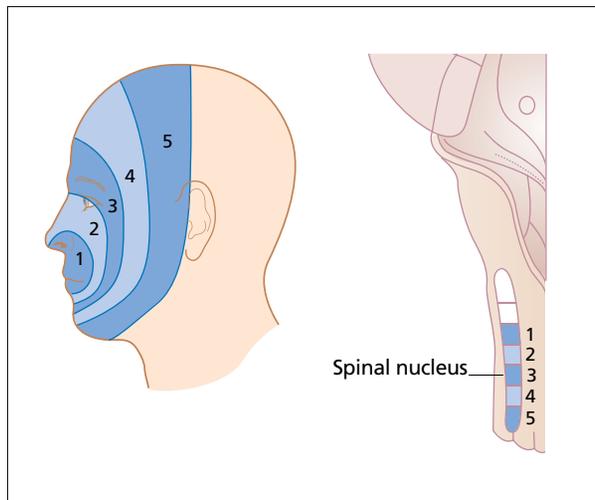

*Trigeminovascular system – innervation of cerebral vessels*  $V_1$  lies close to the internal carotid artery in the cavernous sinus. Afferent  $V_1$  fibres and autonomic fibres accompany the carotid artery, follow its branches and form a network throughout the intracranial vasculature. The role of this important system in the pathogenesis of headache is discussed in Chapter 12.

#### Trigeminothalamic tract, lemniscus, cortical projection and reticular formation

The spinal Vth nucleus gives rise to the lower part of the trigeminothalamic. This crosses the midline, ascends in the pons and carries pain, temperature and touch. Within the pons the tract is joined by fibres from the principal (pontine) Vth nucleus to form the trigeminal lemniscus – the ribbon of

**Figure 2.55** Trigeminal pathways within the brainstem. STN, supratrigeminal nucleus; VPM, ventral posteromedial nucleus of thalamus. Source: Patten 1996. Reproduced with permission of Springer Science + Business Media.

**Figure 2.56** Spinal Vth nucleus: distribution. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

trigeminal fibres that terminates in the ventral posterior medial nucleus of the thalamus (Figure 2.55). Thence, third order afferents pass from the thalamus to the somatic sensory cortex.

Trigeminoreticular fibres synapse in the lateral RF (parvocellular neurones). They are believed to mediate arousal, for example slapping or irritating the face.

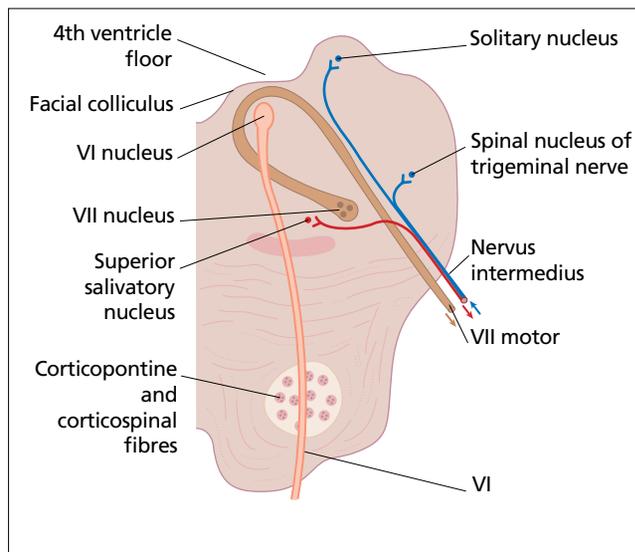

**The jaw jerk and other masticatory reflexes** Spindle afferents from jaw muscles make direct synaptic contact with Vth motor nuclear neurones. Supranuclear lesions of the Vth motor nucleus (see Pseudobulbar palsy, Chapter 13) are accompanied by an exaggerated jaw jerk, a monosynaptic stretch reflex.

Other masticatory muscle reflexes such as jaw closing in response to food in the mouth, jaw opening, chewing, and snapping are mediated via the pattern-generating supratrigeminal motor nuclei. While of no diagnostic significance, they perhaps explain potential hazards of being bitten, by stuporose patients and sleepy animals.

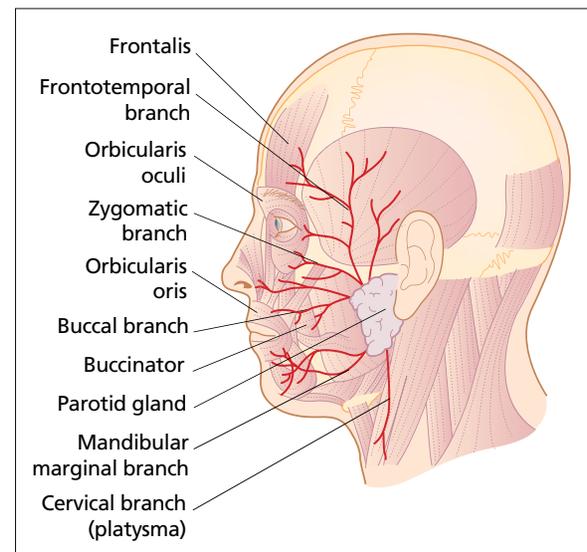

**The corneal reflex** The afferent pathway is via pain fibres in the nasociliary branch of V<sub>1</sub>. The efferent pathway is via VIIth nerve innervated muscles – bilateral blinking (Chapters 4, 13 and 20). The clinical reality is that the patient feels and usually reports the unpleasant stimulus. Visible lacrimation and conjunctival injection follows in a normal eye. All these features diminish when there is a Vth nerve lesion. The upper five-sixths (or so) of the cornea are innervated by the ophthalmic division (V<sub>1</sub>), and the lower sixth, from about 5 to 7 o'clock by the maxillary (V<sub>2</sub>). Depression of the corneal reflex is an early sign of a Vth nerve lesion – of importance in the diagnosis of cerebello-pontine angle lesions before non-invasive imaging.

#### VII: facial nerve

The facial nerve arises from the VIIth nucleus in the pons and before leaving the brainstem loops around the abducens (VI) nucleus, known as the internal genu, creating the facial colliculus

**Figure 2.57** Facial nucleus, facial and abducens nerves (pons – cross-section). Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

in the 4th ventricle floor (Figures 2.57 and 2.58). The nerve leaves the skull via the stylomastoid foramen – its only constituent. Principal motor branches supply muscles of facial expression. A small motor branch supplies the stapedius. VII also carries sensory taste fibres from the anterior two-thirds of the tongue via the chorda tympani.

Supranuclear connections allow the facial muscles to respond both in volitional and emotional activities, and bilaterally in many common habitual situations – smiling, blinking, frowning – and in several reflex actions (Table 2.13). Part of each VIIth nucleus supplying the upper face, principally frontalis, receives supranuclear fibres from each hemisphere. The face muscles are exquisitely responsive to emotional states, and to all sensory input; the limbic contribution is from the nucleus accumbens in the ventral basal ganglia.

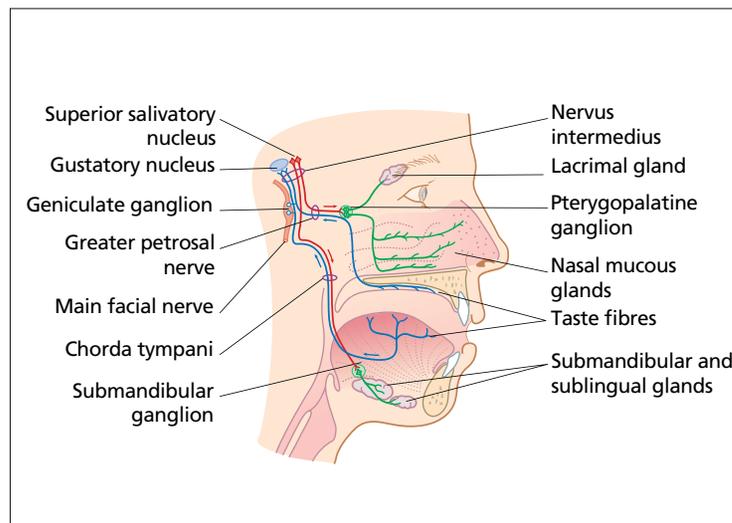

#### Nervus intermedius, greater petrosal nerve and chorda tympani

Distal to the internal genu, the nervus intermedius (part of VII) acts as one stage of a complex conduit, for efferent parasympathetic and afferent special sensory fibres (Figure 2.59):

- The parasympathetic root arises from the superior salivatory nucleus to form motor components of:
  - the greater petrosal nerve → pterygopalatine ganglion → lacrimal and nasal glands, and
  - the chorda tympani → submandibular ganglion → submandibular and sublingual glands.
- The special sensory root consists of cell bodies that lie in the geniculate ganglion. Afferent fibres from taste buds in the anterior two-thirds of tongue travel in the chorda tympani. Those from taste buds in the hard palate travel in the greater petrosal nerve. Central processes enter the gustatory nucleus, part of the nucleus solitarius that also receives fibres from IX. Thence, second order neurones project via the thalamus, to anterior insular and cingulate cortex.
- Some geniculate ganglion cells also receive sensory impulses from skin around external auditory meatus (see Bell's palsy, Chapter 13).

#### VIII: vestibulocochlear nerve

The vestibulocochlear nerve contains primarily afferent axons of bipolar neurones whose cell bodies lie within the petrous temporal bone. Peripheral processes of these neurones are in contact with specialised neuro-epithelium of the labyrinth and cochlea.

**Figure 2.59** Nervus intermedius, greater petrosal nerve and chorda tympani. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

The two components of VIII (vestibular and cochlear) enter the junction between pons and medulla at the cerebellopontine angle.

The neuro-otological system is complex – an entire subspecialty is devoted to it (Chapter 15). Vertigo, meaning the illusion of movement, hearing loss and tinnitus are the prominent symptoms. Essential peripheral neuroanatomy and central connections are shown in Figure 2.60.

### Vestibular system

The dense petrous temporal bony labyrinth contains perilymph, an extracellular fluid that provides a fluid housing for the membranous labyrinth that encloses the organs of balance. These are washed by endolymph – potassium ion rich, sodium ion poor, similar to intracellular fluid.

Each labyrinth (Figure 2.60a) houses five sensory organs within the utricle, saccule and three semicircular canals. Each utricle and each saccule contains a macula. Each canal contains a crista within an ampulla:

- Maculae (two) are sensory organs of static head position
- Cristae (three) are sensory organs of head movement.

The vestibular ganglion lies in the internal auditory meatus. Peripheral processes are applied to the five sensory organs. Central vestibular nerve axons enter the brainstem to synapse at the lateral, medial, superior and inferior vestibular nuclei (VN). Other connections are shown in Figure 2.60d.

*The static labyrinth* In the erect posture:

- The utricular macula is essentially horizontal
- The saccular macula is essentially vertical.

Hair cells in these maculae are in contact with vestibular nerve fibres via ribbon synapses (Figure 2.60b). Stereocilia (about 100/cell) and a longer process, a kinocilium (one/cell) projects into otoconia (ear sand), a gelatinous matrix of calcium carbonate crystals. Each macula has a central groove, a striola. Cilia are arranged either side of each striola. Depolarisation takes place whenever kinocilia are parted from stereocilia.

The maculae respond to:

- Linear acceleration (e.g. walking)
- Vertical acceleration (e.g. falling), and
- Tilting.

The roles of the static labyrinth are to indicate head position in relation to the trunk, and to alter centre of gravity of the body to maintain upright or other postures. The system is adapted to work within and to compensate for the Earth's gravitational field; weightlessness causes problems during space travel.

*The kinetic labyrinth* In the kinetic labyrinth, the ciliated, cellular arrangement of the static labyrinth is replicated in the cristae of the three semicircular canals, their ampullae and each cupula (Figure 2.60c). The cupula is a gelatinous projecting part of each crista within an ampulla – bathed in endolymph. Into each cupula, kinocilia project from hair cells.

The three cupulae are quite exquisitely sensitive to angular acceleration and deceleration. Endolymph remains relatively static. Each crista billows and deflects as this miniature sail-like organ is thrust against endolymph as head velocity changes in a particular plane.

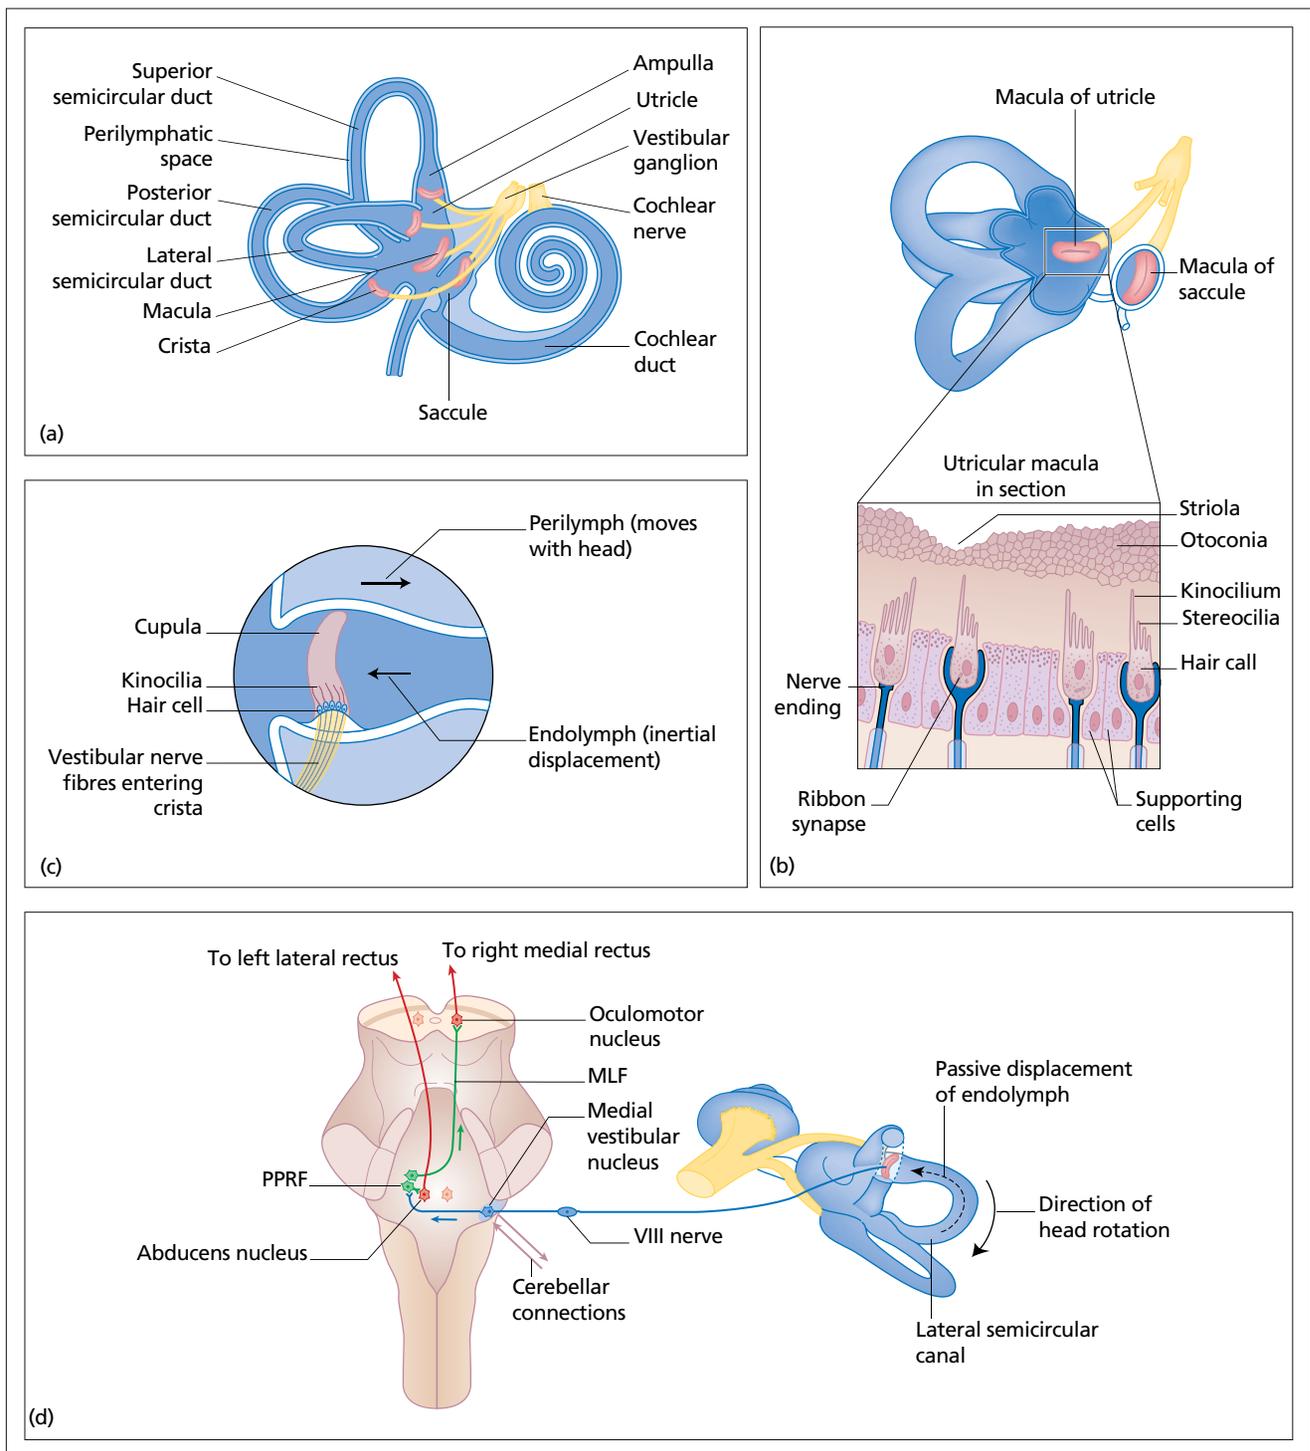

*Vestibular nuclei and central connections* Central axons of each vestibular nerve synapse at the lateral, medial, superior and inferior VN in the brainstem (Figure 2.60d).

The lateral vestibulospinal tract arises from the lateral VN (nucleus of Dieter). Fibres descend in the anterior funiculus of the cord to synapse with a complex variety of limb, neck and trunk  $\alpha$  and  $\gamma$  motor neurones concerned with posture. The flocculonodular lobe of the cerebellum has two-way connections with all vestibular nuclei. There also connections to the vomiting centre in the area postrema in the obex of the 4th ventricle.

The medial vestibulospinal tract arises in the inferior and medial VN, descends in the medial longitudinal fasciculus and ends in the cervical cord. Head and eye-righting reflexes are dealt with by this system; there are connections with the kinetic labyrinth.

Central second order neurones from the VN reach the contralateral VP nucleus of the thalamus. Third order neurones project to the various cortical areas – close to the facial area in the somatosensory cortex, to the insula and temporoparietal cortex.

Vertigo is the illusion of movement characteristic of vestibular pathology. The specific cortical location of this common symptom is unclear. Electrical stimulation of somatosensory cortex sometimes

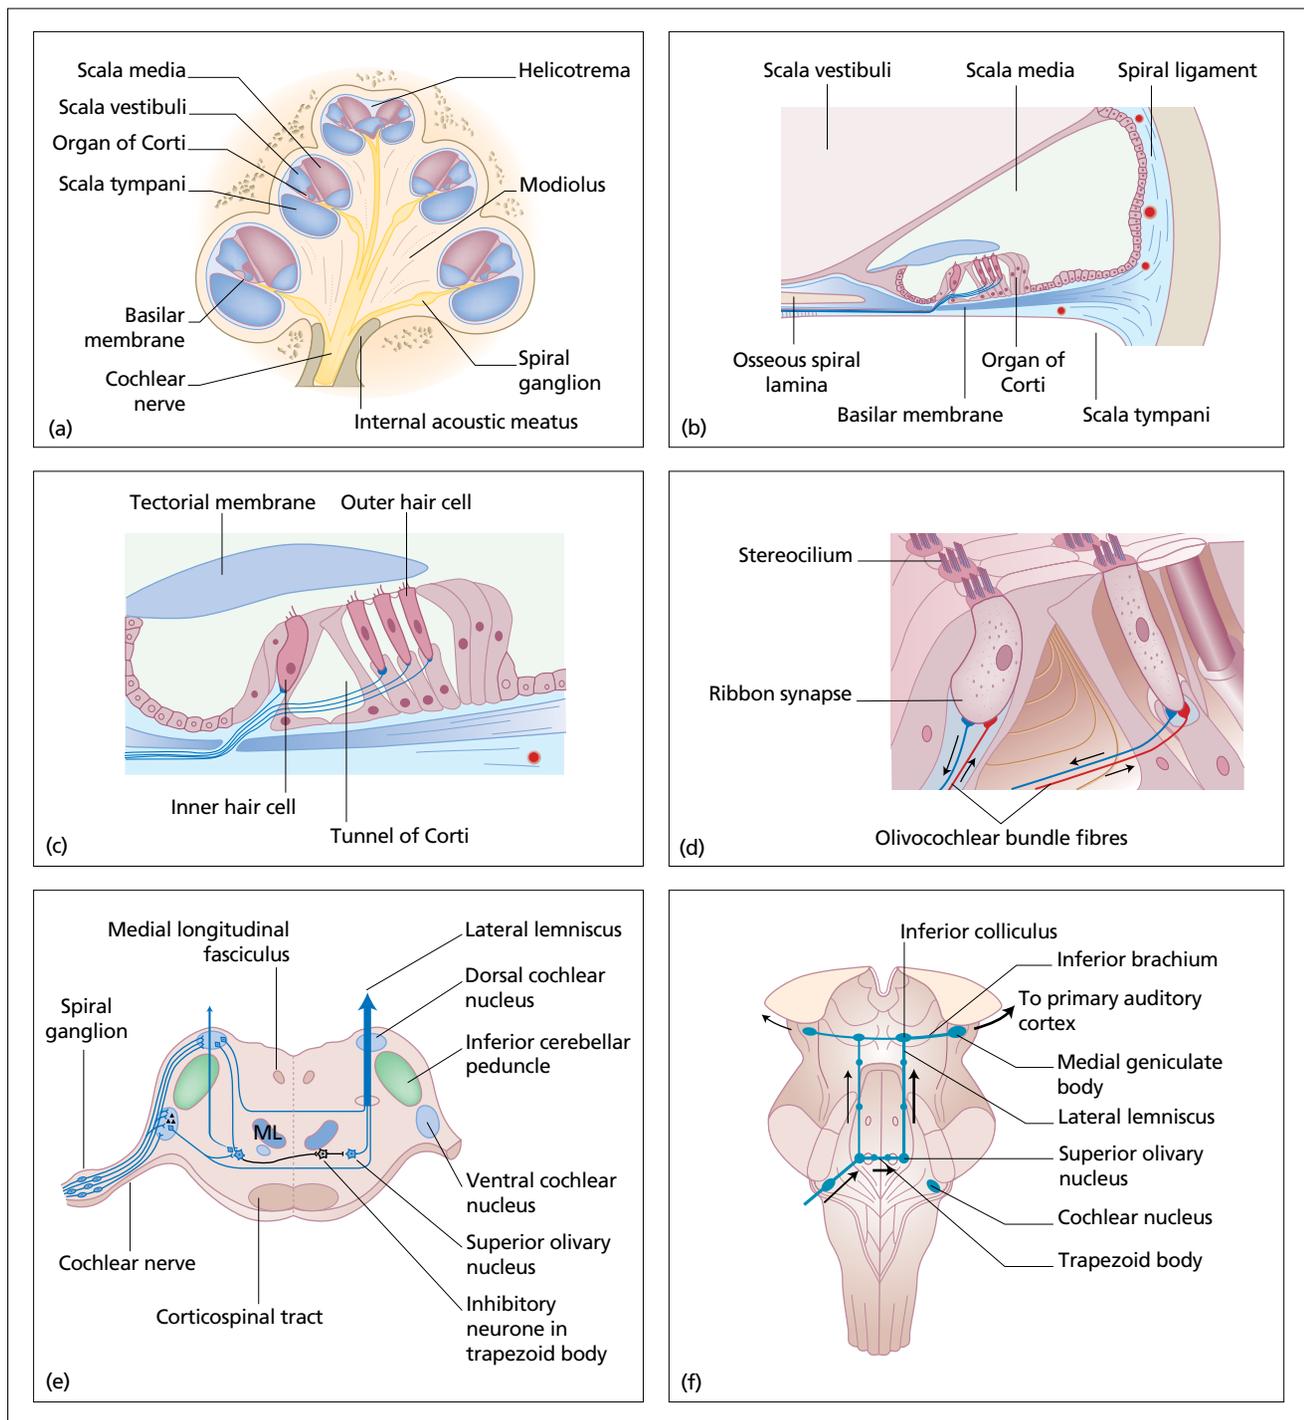

**Figure 2.60** Vestibular system. (a) Five vestibular sense organs. (b) Cells of static labyrinth. (c) Kinetic labyrinth: crista in ampulla of semi-circular canal. induces it, and vertigo can occur with focal seizure activity in the temporoparietal cortex, though it is uncommon as an epileptic event. It is common knowledge that vertigo is sometimes followed by nausea and vomiting. Any prolonged new vestibular imbalance can be followed by intractable vomiting and profound malaise; this happens for example in seasickness. The neuro-anatomical

explanation is vestibular stimulation of the vomiting centre (see Area postrema).

One relevant feature of the vestibular system – and a reason why vertigo, nystagmus and dizziness have relatively poor localising value – is that right–left imbalance in the system, at any level, produces symptoms and/or signs. (Nystagmus is discussed in Chapters 4 and 15.)

### Auditory system

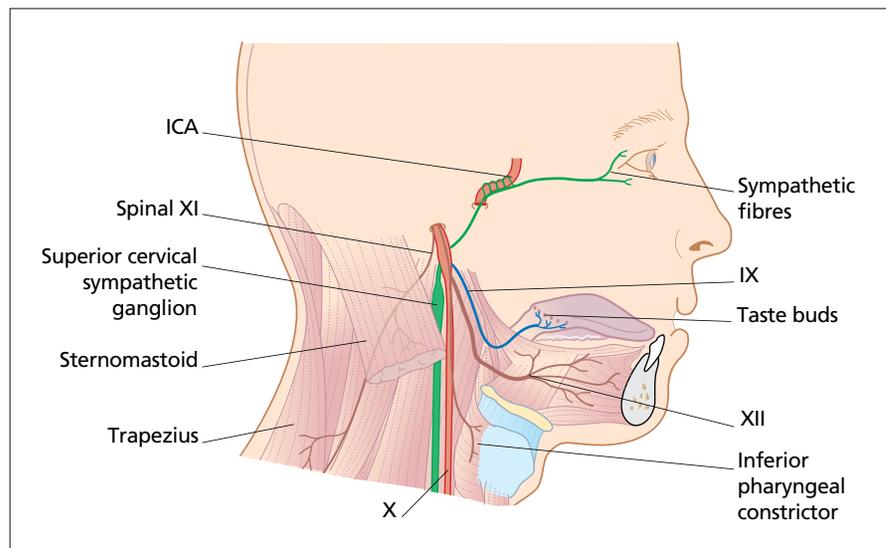

Sound quantity, quality, position, timing and relevance are detected via:

- Cochlea and cochlear nerve
- Cochlear nuclei and central pathways, and
- Auditory cortex.

Secondary projections interpret the emotional content of sound and music and determine actions in response to sounds.

The afferent system is illustrated in Figure 2.61. Auditory efferents are mentioned in Chapter 15.

**Cochlea** Hair cells, from which protrude stereocilia, form the principal auditory neuro-epithelium. They lie within the organ of Corti (spiral organ). The complex terminology is summarised as follows:

**Figure 2.62** Distribution of IX, X, XI, XII and superior cervical ganglion. ICA, internal carotid artery. Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

- The modiolus is the central bony pillar of the cochlea – it is in the line of the internal auditory meatus.
- The osseous spiral lamina projects from the modiolus. The cochlear spiral has two and half turns and is about 1 cm both in height and diameter.
- The basilar membrane is fixed to the tip of the spiral lamina. It extends across the cavity of the bony cochlea and is attached to the spiral ligament.
- The scala vestibuli and the scala tympani are the upper and lower chambers of the cochlea. They are filled with perilymph. They communicate via the helicotrema.
- The scala media lies above the basilar membrane and is filled with endolymph – and separated from the scala vestibuli by the vestibular membrane.
- The organ of Corti lies on the basilar membrane. The organ contains a central tunnel (tunnel of Corti) containing perilymph diffusing through the basilar membrane.

The arrangement of inner and outer hair cells, tectorial membrane and ribbon synapses is shown in Figure 2.61. Their nerve supply (the cochlear nerve) is via bipolar spiral ganglion cells in the osseous spiral lamina. One inner hair cell has some 20 afferent fibres in contact with it.

**Auditory transduction** The snug fit and sensitive articulation of the ossicles – ‘the footplate of the stapes rests on the oval window’ – transmits vibrating pressure waves through the tympanic membrane to the basilar membrane. The basilar membrane is tonotopic:

- Low frequency waves produce resonance where the fibres are longest – at the apical turn of the cochlea
- High frequency waves (high-pitched sounds) cause short fibres in the basal part of the cochlea to resonate.

### Cochlear nerve and central connections

Myelinated axons from some 25 000 large bipolar neurones form the cochlear nerve. The pathways are illustrated in Figure 2.61. The sequence is:

- Inferior and superior cochlear nuclei (termination of first order fibres)

- Trapezoid body (second order fibres), superior olivary nucleus to inferior colliculus, and
- Inferior brachium via medial geniculate body to auditory cortex.

The primary auditory cortex is located in Heschl’s gyrus on the anterior surface of the temporal lobe. In humans, destruction of this region on one side causes no perceptible deafness but an initial inability to localise sound. Hearing loss is produced rarely by central lesions – potential imbalance is compensated by bilateral representation. The usual focus of clinical neurology is the distinction between conductive and sensorineural deafness (Chapters 4 and 15).

**Acoustic reflex pathways** Biologically important auditory automatic pathways include:

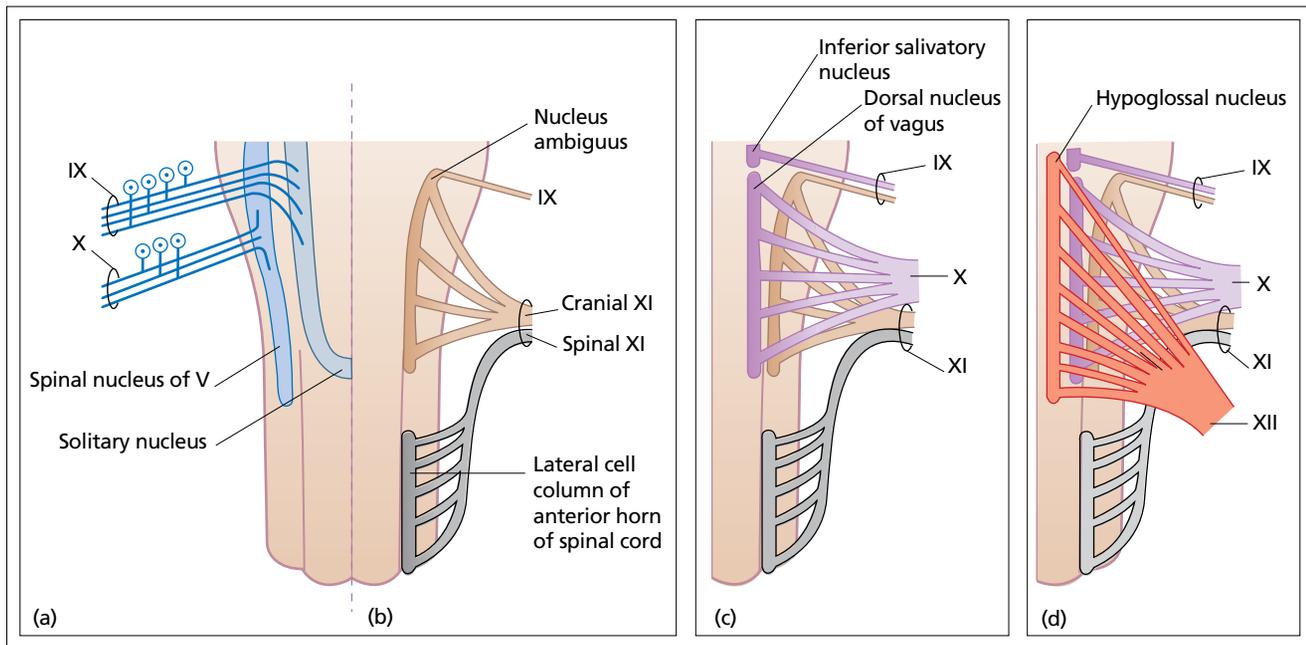

- Startle and waking responses, via the reticular formation.
- Dampening of sounds (e.g. the sound of one’s own voice) via tensor tympani (V) and the stapedius reflex (see Audiological investigation, Chapter 15). The stapedius reflex consists of a contraction of stapedius muscle in response to loud noise. Hyperacusis occurs when the muscle is paralysed (e.g. in Bell’s palsy; Chapter 13).
- Head turning and eye turning in response to sounds.
- Pleasurable experience (e.g. of music and rhythm).
- Automatic responses to the call or command of a dominant mate or pack leader.

### IX, X, XI and XII: glossopharyngeal, vagus, accessory and hypoglossal nerves

These four cranial nerves are grouped together. These notes indicate their intricacy, multiple nuclei and complex pathways both afferent and efferent. Their distribution is shown in Figure 2.62 and the complex nuclear arrangement in Figures 2.63 and 2.64.

#### XI: spinal accessory nerve

The spinal accessory (XI) is the motor nerve to extrafusal and intrafusal fibres of trapezius and sternomastoid. The nuclear column ( $\alpha$  and  $\gamma$  motor neurones) is in the anterior grey horn (lateral column) of the upper five segments of the cord, from which rootlets emerge (Figure 2.63b). The curious route of this nerve is upwards through the foramen magnum, then back, down and out through

**Figure 2.63** Nuclei of IX, X, XI and XII. (a) to (d) Brainstem – anterior views. (a) Sensory nuclei for IX and X. (b) Motor nuclei of IX, cranial XI and spinal XI (special visceral efferent column, contributing to IX and cranial XI). Source: FitzGerald 2010. © 2016 Elsevier. Reproduced with permission of Elsevier.

the jugular foramen. Some afferent twigs (cervical and thoracic nerves) combine with spinal XI as it pierces the trapezius, giving rise to a situation believed to be unique for the nerve supply of a muscle: muscle efferents (spinal XI) and muscle afferents (cervical and thoracic twigs) travel by separate pathways.

This anomaly may explain the pain that follows section of motor roots of XI, or spinal XI in the posterior triangle of the neck, where the nerve is superficial and readily damaged during lymph node biopsy (see Accessory nerve, Chapter 13).

### Cranial accessory XI, glossopharyngeal IX and vagus X – and their nuclei

Groups of medullary neurones known as the nucleus ambiguus and the solitary nucleus contain some of the cell bodies of nerves IX, X and cranial XI.

The nucleus ambiguus (Figures 2.63 and 2.64) provides special visceral efferent fibres of IX and cranial XI supplying:

- Pharynx (constrictor muscles)
- Stylopharyngeus and levator palati
- Larynx (intrinsic muscles), and
- Oesophagus (striated muscles of the upper third, via the recurrent laryngeal nerve).

The solitary nucleus (Figures 2.63a and 2.64b) merges with its opposite number to form the commissural nucleus. The four functional regions of the solitary nucleus are:

- 1 Gustatory – afferents from tongue, epiglottis and palate
- 2 Dorsal respiratory
- 3 Baroreceptor – afferents from carotid sinus and aortic arch, and
- 4 Visceral afferent – afferents from gut and respiratory tract.

The cranial (accessory) nerve XI arises from the nucleus ambiguus in the medulla and leaves the skull through the jugular foramen. Cranial XI shares a dural sheath with spinal XI, without exchanging fibres and becomes incorporated into the vagus.

### Glossopharyngeal nerve IX

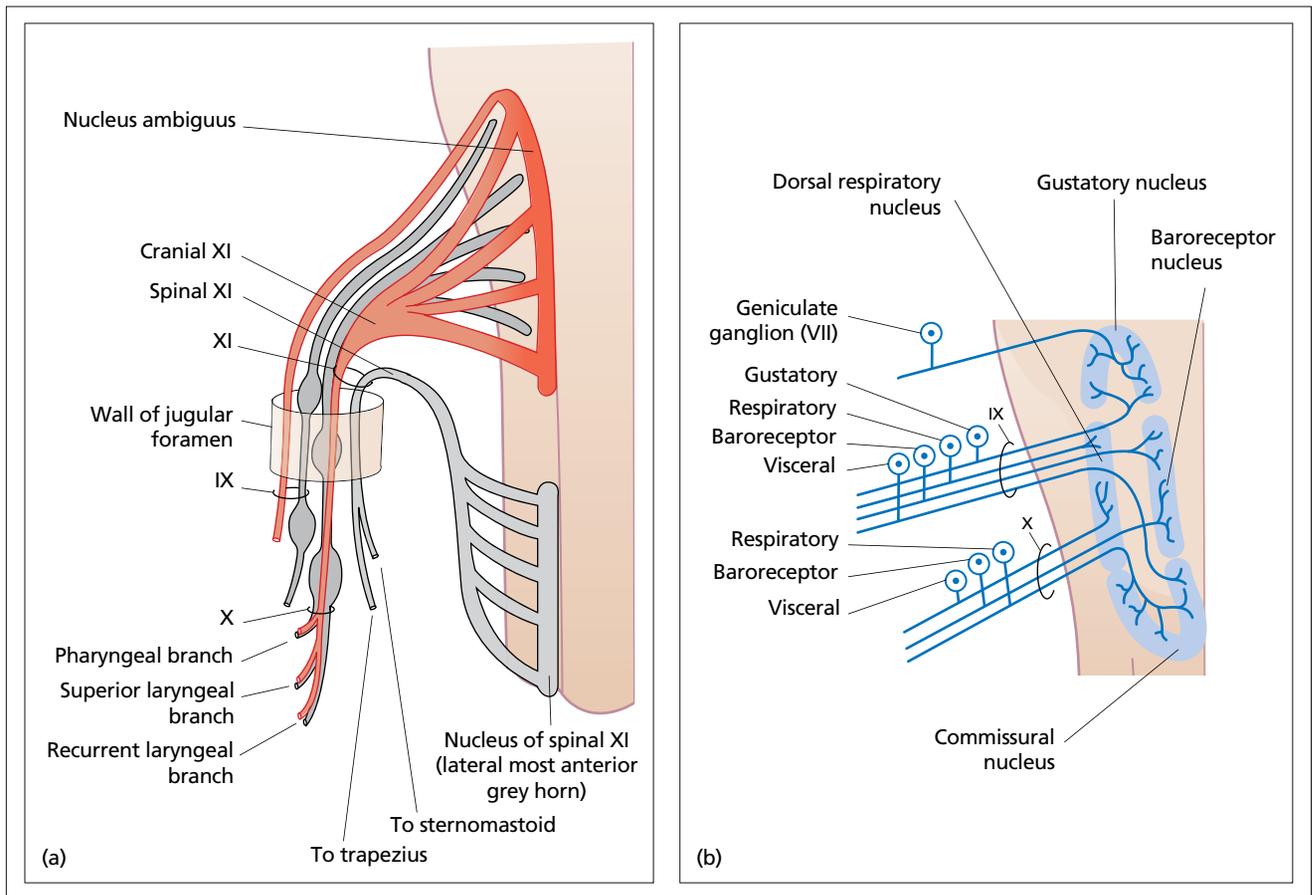

The IXth nerve, almost entirely sensory, leaves the skull via the jugular foramen to reach the mucous membrane of the pharynx and the ear. The tympanic branch of IX that leaves above the jugular foramen, supplies the tympanic membrane. Some central processes synapse with the spinal Vth nucleus. Some of the tympanic branch fibres are parasympathetic – they supply the parotid gland via the lesser petrosal nerve and otic ganglion. The oropharynx and posterior third of the tongue (touch) are supplied by fibres passing to the commissural nucleus. These provide the afferent limb of the gag reflex. Taste fibres (gustatory neurones in the circumvallate papillae of the tongue) terminate centrally in the gustatory nucleus. The carotid branch of IX contains two sets of fibres. One arises in baroreceptor neurones of the carotid sinus and passes to the solitary nucleus. The second arises in glomus cells (chemoreceptors) within the carotid body that terminate centrally in the dorsal respiratory nucleus. Stylopharyngeus muscle is supplied by branchial efferents of IX from the nucleus ambiguus.

### Vagus nerve X

The vagus (Latin: wandering) is the largest visceral afferent and a major parasympathetic nerve. Some fibres arise from the dorsal nucleus of the vagus (Figure 2.63c) and others from the nucleus ambiguus. Other cell bodies (for afferent fibres) lie within the solitary nucleus. XII rootlets in the medulla are in series with cranial XI and IX. The nerve emerges from the skull through the jugular foramen with cranial XI and IX. In the jugular foramen are the two small sensory ganglia of the vagus: the jugular and nodose ganglia.

A summary of branches of the vagus follows:

- *Parasympathetic (efferent) neurones* to the heart, lungs and gut originate from the dorsal nucleus of the vagus and nucleus ambiguus.
- *General visceral afferent fibres* from the heart, lungs and gut have cell bodies within the nodose ganglion. Central synapses are in the commissural nucleus. These pathways serve:

**Figure 2.64** (a) Nucleus ambiguus (special visceral afferent column): fibres within IX, X, cranial XI. (b) Solitary nucleus: four functional areas.

- The cough reflex
- The Hering–Breuer reflex (inhibition of the dorsal respiratory centre by pulmonary stretch receptors, preventing lung overinflation)
- The Bainbridge reflex (increase in heart rate following right atrial distension), and
- Gut afferents signalling satiety (to the hypothalamus).
- *Special viscerent efferent neurones* in the nucleus ambiguus supply pharyngeal and laryngeal muscles, levator palati and muscles (striated) of the upper third of the oesophagus.
- *The auricular branch* supplies skin of the external auditory canal. A meningeal branch supplies meninges of the posterior fossa. Both have cell bodies in the jugular ganglion. Central processes also pass to the spinal nucleus of V (Figure 2.63a).
- *Chemoreceptors* of the aortic bodies, baroreceptors of the aortic arch and taste buds of the epiglottis, are also supplied. The latter synapse in the gustatory nucleus.

### XII: hypoglossal nerve

The motor nerve to the tongue originates from the XIIth nucleus, in the same cell column as III, IV and VI, in the 4th ventricular floor (Figure 2.63d). Nerve rootlets leave the medulla between the pyramid and olive, form two fascicles and exit the skull via the anterior condylar foramen (hypoglossal canal), just below the jugular foramen. The nerve passes between the jugular vein and internal carotid artery at the skull base to reach the muscles of the tongue.

The hypoglossal nerve, like its fellow lower cranial nerves, has connections with others. It receives twigs from the vagus, from upper cervical roots, cervical sympathetic (see superior cervical ganglion) and has connections with the lingual nerve, a branch of  $V_3$ . Styloglossus, hyoglossus, genioglossus and geniohyoid are the muscles supplied.

A unilateral XIIth nerve lesion is followed by deviation of the tongue to that side and several weeks later by wasting and fasciculation. The surface of the normal tongue when protruded often flickers slightly. Lateral tongue deviation is the obvious physical sign. The larynx is also drawn to the side opposite a hypoglossal palsy on swallowing (Chapters 4 and 13).

### Autonomic nervous system

The autonomic, self-regulating sympathetic and parasympathetic system is a diffuse neural network.

- *Controlling centres* (hypothalamus and reticular formation) connect to
- *Preganglionic neurones* (grey matter of brainstem and cord) that project via
- *Preganglionic fibres* that leave the CNS, to synapse at
- *Peripheral autonomic ganglia* (multi-polar neurones), the origins of
- *Post-ganglionic fibres* (unmyelinated) that form terminal networks to reach
- *Target tissues*.

Chapter 24 outlines issues of particular clinical relevance and includes schematic diagrams of the system.

### Sympathetic system

The sympathetic outflow is thoracolumbar. Preganglionic neurones are located in the lateral grey horn at lower thoracic, L1, L2 and usually L3 levels. From these spinal neurones, preganglionic fibres leave the cord via corresponding anterior spinal nerve roots to form each paravertebral sympathetic chain.

Thereafter, preganglionic fibres reach sympathetic ganglia by four routes:

- 1 Some ascend, to synapse in cervical (superior, middle) and stellate ganglia.
- 2 Others descend to synapse in lumbar and sacral sympathetic ganglia.
- 3 Some synapse locally at a nearby ganglion. Postganglionic fibres within T1–L2 spinal nerves supply T1–L2 vessels, skin and sweat glands.
- 4 Some traverse the sympathetic chain, to leave as lumbar/thoracic splanchnic nerves (preganglionic) and reach mesenteric, coeliac, renal and pelvic ganglia.

Sympathetic activity dilates the pupils, increases sweating, increases blood pressure and heart rate, diverts blood from skin and gut to skeletal muscle and closes sphincters.

### Parasympathetic system

Parasympathetic preganglionic outflow is cranial and sacral. Fibres emerge via:

- IIIrd, VIIth, IXth and Xth cranial nerves
- Sacral nerve roots.

### Cranial parasympathetic III, VII, IX and X fibres and subsequent ganglia

Preganglionic fibres synapse at four cranial ganglia, and mural and intramural ganglia:

- Ciliary ganglion, via III to the pupil (see Near reflex in Optic nerve and visual system)
- Pterygopalatine ganglion, via VII to the lacrimal and nasal glands (secretion)
- Submandibular ganglion, also via VII to submandibular and sublingual glands
- Otic ganglion, via IX to the parotid gland, and
- Mural and intramural ganglia, via X to heart, lungs, oesophagus, pancreas, gallbladder, stomach, bowel.

### Sacral parasympathetic fibres and ganglia

From the cord lateral grey matter of S2, S3 and S4 (at L1 vertebral level within the conus), preganglionic fibres lie in the cauda equina within S2–4 ventral nerve roots. They leave the region via sacral vertebral foramina to emerge as pelvic splanchnic nerves. These synapse at:

- Pelvic ganglia (paired) that supply the detrusor muscle and tunica media of the internal pudendal vessels and cavernous tissue of the clitoris/penis, and
- Mural ganglion cells in the distal colon and rectum.

### Neurotransmission within the autonomic system

Data about neurotransmitters for one target organ may not hold for another: there is variation at local level.

### Neurotransmission at sympathetic and parasympathetic ganglia

This is cholinergic throughout. Preganglionic neurones liberate ACh at axodendritic synapses. Ganglion cell receptors are nicotinic.

### Neuro-effector junction transmission at target tissues

Neurotransmitters are secreted along terminal dendrites at target tissues (e.g. pupils, blood vessels, secretory glands). The chief neurotransmitter at sympathetic neuro-effector junctions is noradrenaline (i.e. postganglionic transmission is noradrenergic). An exception is the sympathetic supply to eccrine sweat glands, which is cholinergic. The chief neurotransmitter at parasympathetic neuro-effector junctions is ACh (i.e. postganglionic transmission is cholinergic).

### Junctional receptors at target tissues

Two factors influence the effect of physiological stimulation of target organs:

- 1 The nature of postjunctional receptors, and
- 2 The nature of prejunctional receptors.

*Sympathetic system receptors* For noradrenaline, two varieties of  $\alpha$ -adrenoceptor and two varieties of  $\beta$ -adrenoceptor are known to exist:

- *Postjunctional  $\alpha_1$ -adrenoceptors*: these initiate contraction of dilator pupillae, arteries and arterioles, sphincters and vas deferens.
- *Prejunctional  $\alpha_2$ -adrenoceptors*: these inhibit transmitter release at both sympathetic and parasympathetic terminals.
- *Postjunctional  $\beta_1$ -adrenoceptors*: in the heart these increase the force of ventricular contraction. In the kidney they increase renin secretion in response to a fall in blood pressure.
- $\beta_2$ -Receptors respond to circulating and locally available noradrenaline. Postjunctional  $\beta_2$ -receptors relax smooth muscle, such as in bronchi and the pupil. Prejunctional  $\beta_2$ -receptors on adrenergic terminals promote noradrenaline release.

*Parasympathetic junctional receptors* These are muscarinic in action. Stimulation:

- Slows the heart rate (vagal tone increases)
- Causes bladder emptying, pupillary accommodation for near vision, intestinal peristalsis, and
- Initiates glandular secretion (e.g. lacrimation).

### Other autonomic neurotransmitter systems

The complexity of the autonomic system is compounded by at least three further neurotransmitter lineages, known as non-adrenergic non-cholinergic (NANC) neurones:

- Dopamine is liberated from small interneurones in sympathetic ganglia, exerting a mild inhibitory effect on adrenergic neurones.
- Nitric oxide is important in the parasympathetic system as a powerful arterial dilator.
- Vasoactive intestinal polypeptide (VIP) is known to be active as a neurotransmitter in salivary and sweat glands. VIP acts as a co-transmitter to ACh and is a vasodilator, increasing blood supply to target organs already stimulated by muscarinic parasympathetic activity.

## Acknowledgements

The late Professor MJ Turlough FitzGerald, Emeritus Professor, Department of Anatomy, National University of Ireland, Galway, kindly agreed that figures and information from the award-winning textbook *Clinical Neuroanatomy and Related Neuroscience* (FitzGerald MJT, Folan-Curran J, 4th edition, 2002; WB Saunders, Edinburgh) were made available for use in our first edition. This cooperation proved invaluable. Details from figures in the subsequent *Clinical Neuroanatomy and Neuroscience* (FitzGerald MJT, Gruener G, Mtui E, 6th edition, 2012; Elsevier Saunders) have been used here, again with permission of Professor FitzGerald's family. The *Queen Square Textbook* authors and editors are most grateful for this continuing cooperation.

## CHAPTER 3

# Mechanisms of Neurological Disease: Genetics, Autoimmunity and Ion Channels

Dimitri Kullmann<sup>1</sup>, Henry Houlden<sup>1</sup> and Michael Lunn<sup>2</sup>

<sup>1</sup>UCL Institute of Neurology

<sup>2</sup>National Hospital for Neurology & Neurosurgery

Many neurological diseases share pathological processes that require an understanding of genetics or immunity. This chapter considers these from the perspective of the molecular lesion rather than the clinical manifestation. The following sections deal with genetic disorders and neuro-immunology, before examining abnormalities of ion channels, which can be affected by either inherited mutations or autoantibodies.

## Genetics

Advances in genetics have had an enormous impact on the field of the inherited neurological disorders, possibly more so than in other areas of medicine. This reflects the wide phenotypic spectrum of neurological conditions and the increasing number of Mendelian genes that have been identified in these disorders. Genetic diseases can be divided into five main categories:

- 1 Abnormalities in the structure or complement of chromosomes (chromosomal disorders)
- 2 Mutations or other defects affecting a gene
- 3 Nucleotide repeat expansions
- 4 Mendelian disorders that are likely to be caused by digenic or epistatic inheritance, and
- 5 Conditions in which genetic and environmental factors interact (multifactorial disorders).

## Modes of inheritance

Many neurological disorders follow single Mendelian gene inheritance, in both childhood and adult life. It is therefore essential to take a detailed family history and investigate appropriately.

A disease that is determined by a gene on one of the 22 autosomal chromosomes is said to be inherited as an autosomal trait. In the uncomplicated situation such traits affect both males and females alike and, according to the nature of the gene or mutation, may be either dominant or recessive. Similarly, traits determined by genes on one of the sex chromosomes may be either dominant or recessive, but here the effects on individuals of different sexes can vary greatly depending on which sex chromosome carries the gene and whether it acts in a dominant or recessive manner. Such traits are said to be sex-linked or often X-linked, because the vast majority involve genes on the X rather than the Y chromosome. A further form of inheritance is maternal, inherited from the mitochondrial

genome; this is transmitted only from the mitochondria and often leads to extreme variability in disease phenotype.

## Autosomal dominant inheritance

A dominantly inherited version of a gene, or allele, manifests in the heterozygous state. That is, a person who exhibits the effects of such a gene variant needs to possess it in only a single dose, as one member of the gene pair. When dealing with dominant alleles, an affected individual usually possesses both the mutant gene and its normal counterpart. Occasionally, a person may be found to be homozygous for a dominant allele, but this is extremely rare. An autosomal dominant trait affects both males and females alike and may be transmitted equally by either sex to their offspring of both sexes. When dealing with a condition in which the reproductive capacity is not limited, most affected individuals will have an affected parent, and the trait can often be traced from one generation to another within the family. Similar pedigrees can often be seen in large families with many of the more common autosomal dominant conditions that do not affect reproduction or survival until at least middle age, such as in Huntington's disease and myotonic dystrophy.

A person heterozygous for a dominant gene possesses both a normal and a mutant gene and will therefore produce gametes of two types in equal numbers, which bear one or the other allele. The partner will typically produce gametes only containing the normal allele. On average, half of their children will be affected, although of course with the small size of modern families the true proportion of affected offspring may deviate from this rule.

Autosomal dominant conditions can be very variable in their expression. In other words, the same allele can result in clinical manifestations that exhibit very varied degrees of severity in different individuals. For example, neurofibromatosis type 1 may cause a variety of very severe manifestation such as pseudoarthrosis of the tibia, mental handicap, intracranial tumours, scoliosis or even sarcomatous changes within neurofibromas. Yet, within the same family the gene can also be expressed mildly, resulting in no more than a few café-au-lait spots. When the degree of expression of the gene is very mild then such an individual may pass as normal and remain undetected – the gene is then said to be non-penetrant. It is lack of penetrance of the gene that gives rise on occasions to so-called skipped generations within affected families, when penetrance is defined only in terms of clinical manifestations. However minimal the clinical manifestation,

any individual carrying the gene in question has a 50% risk of transmitting the gene to any offspring and there is unfortunately no way of predicting how severely any offspring might be affected.

Another feature of dominant traits, which frequently complicates genetic advice, is the occurrence of new or *de novo* mutations. When dealing with a condition that is typically associated with a significant reduction in fitness, the affected individual is often a sporadic case within the family. Such cases are frequently the result of new mutations, which occurred in either the maternal or paternal gametes, both parents being normal, so that the risk to siblings is very small. An example of such a condition is tuberous sclerosis, a disorder classically associated with a triad of clinical manifestations: mental handicap, epilepsy and adenoma sebaceum. As over 80% of patients exhibit mental handicap, few affected individuals lead normal lives. Emerging evidence suggests that the rate of new dominant mutations correlates with paternal age, and a significant paternal age effect has been demonstrated in a variety of conditions including Apert's syndrome, myositis ossificans and Marfan's syndrome.

Sometimes, an autosomal allele manifests more frequently in one sex than the other, a phenomenon referred to as sex influence. When in the extreme situation only one sex is affected then the phenomenon is known as sex limitation. This effect is probably mediated by hormonal influences. Sex-limited traits are not common, but this mode of inheritance has been suggested for male pattern baldness, thought to be autosomal dominant in males but autosomal recessive (see next section) in females. Females therefore transmit the trait when heterozygous but are bald only when homozygous.

### Autosomal recessive inheritance

Disorders inherited in this way affect both sexes equally. Unlike autosomal dominant disorders, however, autosomal recessive conditions manifest only when the responsible gene variant is present in double dose (i.e. in the homozygous state). Thus, affected individuals usually have parents who are both heterozygous for the allele in question, but are clinically unaffected. Similarly, all the offspring of an affected person are usually healthy (although they are all heterozygous), so long as their other parent is not heterozygous for the same gene. As most of the recognised recessive traits are rare, however, this is not very likely in the absence of consanguinity. In the rare event that both parents are homozygous for the same recessive gene, then all of their children would be homozygotes and therefore affected. The pedigree pattern of an autosomal recessive trait is thus quite different from that of a classic autosomal dominant one. Characteristically, the disorder cannot be easily traced from generation to generation within the family; instead, affected individuals are often in the same generation, typically brothers and sisters. If a person is heterozygous for a particular abnormal gene then their gametes will be of two types and will contain either the mutant gene in question or its normal allele. On average therefore, one-quarter of the offspring of two heterozygotes will inherit a double dose of the recessive gene in question and be affected. Half of the offspring will be heterozygotes like the parents, and one-quarter will be normal homozygotes.

The gene variants responsible for most autosomal recessive conditions are rare in the general population. Two people related by blood are naturally more likely to carry a recessive allele in common than two strangers who are unrelated, because the former may have both inherited the allele from some common ancestor. It follows therefore that the two heterozygous parents of a person with an autosomal recessive trait are often found to be blood relatives (consanguineous marriage). The

chance that two first cousins will inherit the same gene variant from their common ancestors is 1 in 8. The chance that two unrelated individuals carry the same allele is much smaller, but depends on the frequency of the allele in the population as a whole. Thus, the rarer the allele the more likely it is that the parents of an affected child will be found to be cousins. Sometimes, however, an affected child has inherited two different recessive mutations of the same gene from unrelated parents. This is known as compound heterozygosity.

Often, a condition that appears to be homozygous can in fact result from homozygosity of any one of many different recessive genes. For example, in profound early-onset deafness one of no fewer than 32 different loci may be involved. Thus, two deaf parents who both seem to have an autosomal recessive form of deafness may have children with normal hearing if the parents' problems are caused by involvement of different loci. In some 88% of the marriages of deaf individuals the other partner is also deaf. This is because people with a problem such as deafness are more likely to mix with other individuals having the same handicap, both in institutions catering for their special needs and socially.

Individuals heterozygous for a recessive gene are usually phenotypically normal. However, a situation where heterozygote identification is of value is when a relatively small and well-defined population has a high incidence of a recessive disorder (the gene frequency being high) and hence heterozygote tests will identify high risk marriages and thus enable accurate genetic advice to be given, coupled where possible with effective prenatal diagnosis. The best example of such a situation is Tay–Sachs disease (a severe recessive disorder producing blindness, progressive mental deterioration and death in early childhood) amongst the Ashkenazi Jewish community.

### Sex-linked inheritance

Sex-linked inheritance is the mode of inheritance exhibited by genes carried on one or other of the sex chromosomes and can therefore be referred to as X-linkage or Y-linkage. Y-linked inheritance is extremely rare and mainly affects fertility. X-linked recessive traits are those determined by genes on the X chromosome that only manifest in the homozygous or hemizygous state. Females have two X chromosomes and therefore if they bear a mutant recessive defect on one of them it will be counteracted by the normal allele on their other X chromosome. Thus, females manifest such gene variants only in the homozygous state, which is extremely rare. Most females bearing such genes are therefore healthy female carriers of the trait who are themselves unaffected but who are at risk of having affected sons. As males have only one X chromosome they will always manifest an X-linked allele, even if it is recessive, as they have no normal allele to counteract it so all males who inherit such genes are affected. These diseases are transmitted within families either by healthy female carriers, if the disease is serious and leads to early death of affected males (such as Duchenne muscular dystrophy, Lesch–Nyhan syndrome and Lowe's syndrome), or by both female carriers and affected males, if the disease does not appreciably affect fertility and allows survival into the reproductive period (such as Fabry disease and Becker-type muscular dystrophy).

Occasionally, a woman may show manifestations of a disorder known to be an X-linked recessive trait, for example, some known carriers of Duchenne muscular dystrophy show manifestations of the disease, ranging from mild calf pseudohypertrophy to moderately severe proximal muscle weakness. In fact, such manifestations can result in diagnostic confusion and suggest a limb girdle form of muscular dystrophy, in the absence of a family history. The distinction between the two situations has important implications.

An X-linked dominant trait manifests both in the hemizygous male and in the heterozygous female. The mutant gene is transmitted by affected females to half of their daughters and by affected males to all of their daughters. The trait is also transmitted by affected females to half their sons, but all the sons of affected males are normal. There is thus an excess of affected females in such families. Examples of conditions showing this less common mode of inheritance are vitamin D-resistant rickets and the oral-facial-digital syndrome. Some rare X-linked dominant traits, such as incontinentia pigmenti, are believed to be lethal in the hemizygous affected male. In such a situation all affected individuals are female and occur in a direct line of descent. Affected females have a deficiency of live-born sons and an excess of abortions (which may be shown to be male fetuses).

### Mitochondrial disorders

This group of conditions is caused by dysfunctional mitochondria. More than 70 different polypeptides interact on the inner mitochondrial membrane to form the mitochondrial respiratory chain. The vast majority of subunits are synthesised within the cytosol from nuclear gene transcripts, but 13 essential subunits are encoded by the 16.5 kilobase (kb) mitochondrial genomic DNA (mtDNA).

Mitochondrial diseases are, in about 15% of cases, caused by mutations in the mtDNA that affects mitochondrial function. Other causes of mitochondrial disease are mutations in nuclear mitochondrial genes, whose gene products are imported into the mitochondria, and a variety of acquired disorders. mtDNA defects are transmitted by maternal inheritance. Deletions generally occur *de novo* and thus cause disease in one family member only, with no significant risk to other family members. mtDNA point mutations and duplications, however, may be transmitted to several individuals down the maternal line. The father of a proband is not at risk of having the disease-causing mtDNA mutation, but the mother usually carries the mitochondrial mutation and may or may not have symptoms. An affected male does not transmit the mtDNA mutation to his offspring.

Included in this group are progressive disorders of childhood and adult life, which may affect the central nervous system (CNS), muscle, or both, as well as other systems. Commoner neurological diseases caused by mitochondrial point mutations include myoclonic epilepsy with ragged red fibres (MERRF), mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS), and Leber's hereditary optic neuropathy. Chronic progressive external ophthalmoplegia (CPEO) is usually the result of a large deletion. Mitochondrial disorders can present with quite variable features. For instance, the m.3243A>G point mutation may cause MELAS, CPEO, diabetes mellitus or deafness.

An important determinant of disease severity is the variable proportion of mutant mtDNA occurring in cells, known as heteroplasmy. A female harbouring a heteroplasmic mtDNA point mutation may transmit a variable amount of mutant mtDNA to her offspring, resulting in considerable clinical variability among siblings within the same family. mtDNA heteroplasmy complicates prenatal genetic testing and the interpretation of test results for mtDNA disorders. Unfortunately, molecular testing is often unable to predict the severity of the condition, as the degree of heteroplasmy varies from tissue to tissue, and can only be an approximate guide to the likelihood of clinical problems occurring.

### Expanded repeat disorders

Repeats of simple nucleotide sequences occur frequently throughout the genome, and the vast majority are not associated with any disease. In 1991, an expansion in a trinucleotide (CAG) repeat in the androgen receptor gene was identified as the cause of Kennedy's disease or spinal and bulbar muscular atrophy 1 (SBMA). The repeat, which normally consists of 13–30 CAGs, lengthens to 40 or more CAGs in patients with this disease. Over the last 25 years, over 20 further disorders have been found to be caused by expanded trinucleotide repeats, including Huntington's disease and a number of spinocerebellar ataxias (Table 3.1). More recently, an expanded hexanucleotide repeat (GGGGCC in the *C9orf72* gene) has been

**Table 3.1** Disorders caused by expanded trinucleotide repeats. (a) Polyglutamine disorders caused by a gain-of-function mechanism. The repeat unit is (CAG)*n* in all these disorders.

Disease	OMIM number	Gene product	Normal repeat length	Expanded repeat length	Main clinical features
HD	143100	Huntingtin	6–34	36–121	Chorea, dystonia, cognitive decline
SCA1	164400	Ataxin1	6–44	39–82	Ataxia, cognitive impairment
SCA2	183090	Ataxin2	15–24	32–200	Ataxia, axonal neuropathy
SCA3	109150	Ataxin3	13–36	61–84	Ataxia, parkinsonism
SCA6	183086	CACNA1A	4–19	20–33	Ataxia
SCA7	164500	Ataxin7	4–35	37–306	Ataxia, maculopathy
SCA17	607136	TBP	25–42	47–63	Ataxia, cognitive decline, chorea
SBMA	313200	Androgen receptor	9–36	38–62	Motor weakness, swallowing, gynaecomastia
DRPLA	125370	Atrophin	7–34	49–88	Ataxia, seizures, dementia

DRPLA, dentatorubral pallidolusian atrophy; HD, Huntington's disease; SBMA, spinobulbar muscular atrophy; SCA, spinocerebellar atrophy.

**Table 3.1** (b) Other unstable repeat disorders.

Disease	OMIM number	Repeat unit	Gene product	Normal repeat length	Expanded repeat length	Main clinical features
<b>Loss-of-function mechanism</b>						
FRAXA	309550	(CGC) <sub>n</sub>	FMRP	6–60	>200	Mental retardation
FRAXE	309548	(CCG) <sub>n</sub>	FMR2	4–39	200–900	Mental retardation
FRDA	229300	(GAA) <sub>n</sub>	Frataxin	6–32	200–1700	Sensory ataxia, cardiomyopathy
<b>RNA mediated toxicity</b>						
DM1	160900	(CTG) <sub>n</sub>	DMPK	5–37	56–10 000	Myotonia, weakness, cardiac involvement, diabetes, cataracts
DM2	602668	(CCTG) <sub>n</sub>	ZNF9	10–26	75–11 000	Similar to DM1, more proximal weakness
FXTAS	309550	(CGC) <sub>n</sub>	FMR1	6–60	60–200	Ataxia, tremor, parkinsonism
C9ORF72	105550	(GGGGCC) <sub>n</sub>	C9ORF72	1–29	Usually >1000	ALS, FTD can present as CBD
<b>Unknown pathogenic mechanism</b>						
SCA8	608768	(CTG) <sub>n</sub>	SCA8 RNA	16–34	>74	Ataxia, cognitive decline
SCA10	603516	(ATTCT) <sub>n</sub>		10–20	500–4500	Ataxia, tremor, dementia
SCA12	604326	(CAG) <sub>n</sub>	PPP2R2B	7–45	55–78	Ataxia and seizures
HDL2	606438	(CTG) <sub>n</sub>	Junctophilin	7–28	66–78	Similar to HD
SCA31	117210	(TGGAA) <sub>n</sub>	BEAN	1	2.5–3.8 kb	Ataxia and neuropathy
SCA36	614153	(GGCCTG) <sub>n</sub>	NOP56	1	650–2500	Ataxia, tongue fasciculations, deafness

ALS, amyotrophic lateral sclerosis; CBD, corticobasal degeneration; DM1/2, myotonic dystrophy types 1 and 2; DRPLA, dentatorubral pallidoluysian atrophy; FRAXA/E, fragile X mental retardation; FTD, frontotemporal dementia; FXTAS, fragile X tremor/ataxia syndrome; HD, Huntington's disease; SBMA, spinobulbar muscular atrophy; SCA, spinocerebellar atrophy.

shown to be the most common cause of familial amyotrophic lateral sclerosis and frontotemporal dementia in many populations.

The CAG codon is normally translated as a glutamine residue, and abnormal CAG repeats therefore result in expanded polyglutamine tracts in the respective proteins. These disorders often exhibit anticipation, where disease severity worsens in successive generations, and this correlates with an increase in the number of repeats. The expansion is also greater when inherited from the paternal line and interruptions in the expansion can modify the age at onset. Although the expanded polyglutamine tract itself can be toxic, it is in the context of the full-length protein that the distinctive selective neuronal loss occurs. Some nucleotide triplet expansion diseases cause polyalanine tracts. Triplet, penta- and hexanucleotide repeat expansions have also been identified in non-coding regions, typically causing a loss of gene function or toxic effects at the mRNA level.

### How heritable are neurological conditions?

#### Lessons from twins

Monozygotic ('identical') twins share the same genetic inheritance but their environments differ increasingly as they age. This unique aspect of twins makes them an excellent model for understanding how heritable a disorder may be and how genes and the environment contribute to certain traits, especially complex behaviours and

diseases. Identical or monozygotic twins share nearly 100% of their genes, which means that most differences between twins (such as height, susceptibility to boredom, intelligence, depression, etc.) are brought about by environmental factors. Fraternal or dizygotic twins share only about 50% of their genes and therefore act as a powerful control sample.

To illustrate this, if one of a pair of twins is affected by schizophrenia, the risk to a monozygotic twin is approximately 50%, while that to a dizygotic twin is only about 10–15%. This difference is evidence for a strong genetic component in susceptibility to schizophrenia. However, the fact that the monozygotic twin of an affected individual does not develop the disease 100% of the time indicates that other factors are involved. In migraine with aura the correlation of liability has been estimated at 68% in monozygotic twin pairs, with no significant difference between males and females. Similar twin studies have provided evidence that genetic factors have a role in many other neurological disorders (Table 3.2).

#### Mutation versus polymorphism

Every individual has over 20 000 genetic variants in the protein-encoding exons and flanking intronic regions. The vast majority of these variants are thought to have no deleterious consequences

(benign polymorphisms), but some of these genetic changes can be associated with human disease. Disease-causing genetic mutations are rare and proving the pathogenicity of a genetic variant is often difficult. The criteria to identify a sequence variant as a pathogenic mutation include the following:

- The variant causes a change to the encoded protein, through an amino acid substitution, insertion or deletion, or through a nonsense change (frameshift and premature stop codon).
- The affected amino acid is conserved across species.
- The variant occurs in more than one family and segregates with the disease.
- The genetic variation is absent in normal controls.

Not all of these criteria are always satisfied. Other factors can help clarify the status of candidate variants, such as the putative gene function and pathway being defective in other neurological disorders with similar features, and evidence from gene expression in affected tissues.

**Table 3.2** Examples of monozygotic twin concordance rates for different neurological disorders.

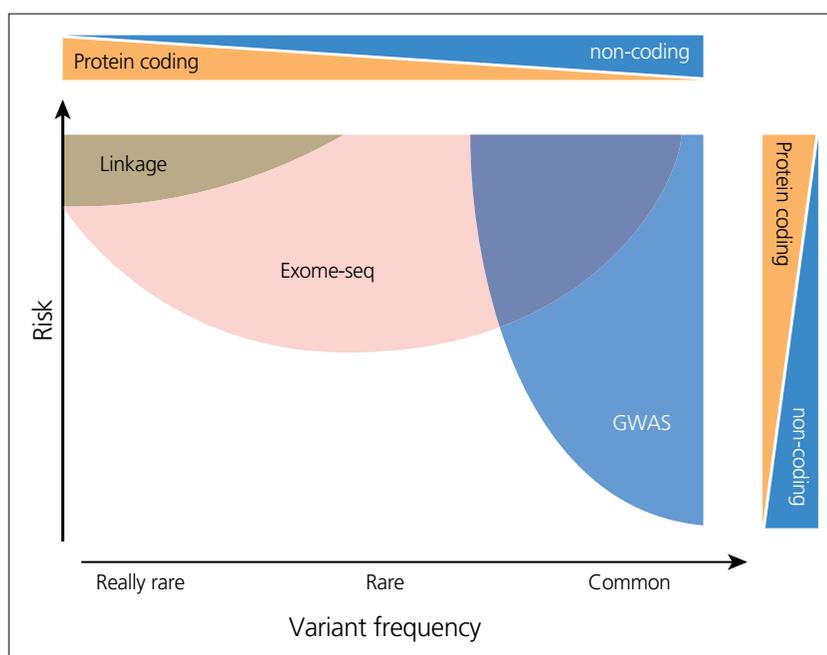

Alzheimer dementia	60–80%	Twin studies
Autism	70–90%	Twin studies
Epilepsy	80%	Twin study
Frontotemporal dementia	42%	Family history data
Multiple sclerosis	25–76%	Twin studies
Migraine with aura	68%	Twin study
Restless legs syndrome	40–90%	Twin studies

Ethnic diversity can confound the search for disease-causing mutations, because the frequencies of individual polymorphisms vary across populations, some of which are under-represented in available databases. In addition, truly normal control series are difficult to identify for some age-dependent disorders.

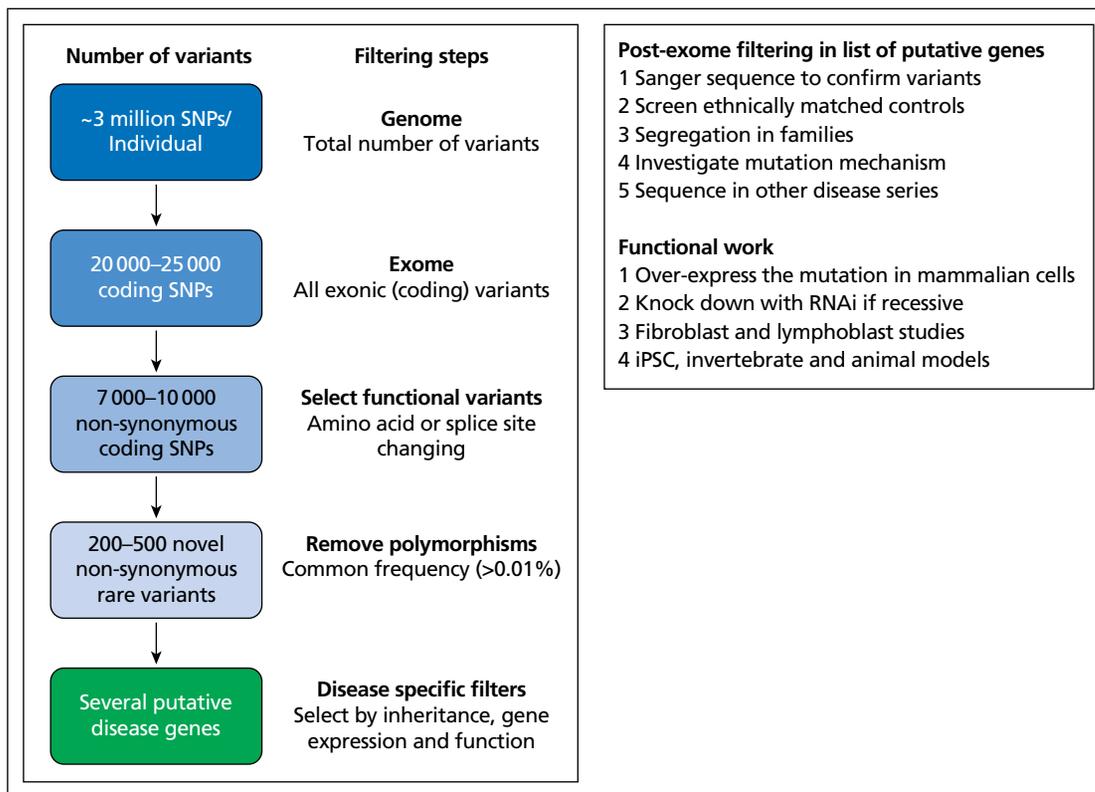

### The discovery process

In the early days of gene discovery the disease gene was identified by the nature of the disorder. For example, a known enzyme deficiency was shown to be caused by a genetic defect in the gene coding for that enzyme. Subsequently, many new disease genes were identified from analysis of rare large families, groups of smaller but clinically identical families or sibling pairs, and candidate or genome-wide association studies. Initially, linkage analysis or homozygosity mapping was carried out to identify the genetic region, followed by sequencing of candidate genes within this region using the Sanger method. This approach was, and still is in some areas, very effective, but it is very expensive and time consuming.

Recently, the technical barriers to identifying disease-causing mutations and rare variants have been overcome with next generation sequencing (NGS), where one of the most promising avenues is whole exome sequencing of all protein-encoding regions (exomes) and intron boundaries. Even more complete is whole genome sequencing (introns and exons). Next generation sequencing platforms produced by various companies use different technologies, but in general are high-throughput, producing thousands or millions of sequences at the same time. In finding mutations and risk variants this method offers four critical advantages over the traditional linkage and positional cloning approaches: cost, speed, the use of relatively little DNA and the capacity to use genetically less informative samples. A large number of samples that were previously unsuitable for gene identification can now be used to find novel mutations. Although exome sequencing is a relatively new method, it has already been used to identify mutations that cause Mendelian forms of disease (Figure 3.1). Although this technique generates enormous

**Figure 3.1** Exome sequencing will identify the Mendelian variants previously found using linkage as well as a proportion of variants identified using genome-wide association studies (GWAS).

**Figure 3.2** Filtering and functional analysis strategy for next generation sequencing data. SNP, single nucleotide polymorphism.

amounts of data, it does not overcome the challenge of differentiating between normal genetic variability and pathogenic mutations, and so it is important to analyse a large number of affected individuals, compare them with unaffected individuals, and interpret the data in the context of gene expression and gene network data (Figure 3.2).

Next generation sequencing typically involves exome sequencing of several affected and unaffected family members, where possible including affected cousins or other distant relatives. In the first instance DNA is extracted and a genome library made from each individual; after this libraries are enriched for exome regions, pooled and sequenced. The most difficult part of NGS is the data analysis which involves the need for a powerful computer cluster to align sequences, remove duplicates and annotate the data sequence and variants. When investigating disease-causing mutations, common polymorphisms and non-coding amino acid changes are then removed to leave a list of unique or very rare (<0.01% of the population) variants that are either heterozygous or homozygous. Another important issue is the degree of exome coverage, because sequencing has an inherent error rate. A high quality exome sequencing data set can achieve average exome-wide coverage of 30-fold, meaning that a typical sequence will have been read 30 times. Difficult regions to sequence are the GC rich exon 1 and repeat-rich regions.

### Practical considerations

When considering genetic testing of an individual it is important to understand the practical and financial considerations. Moreover, although genetic factors have a role in an increasing number of diseases, the yield and implications are very different in, say, Parkinson's disease, than in classically inherited disorders

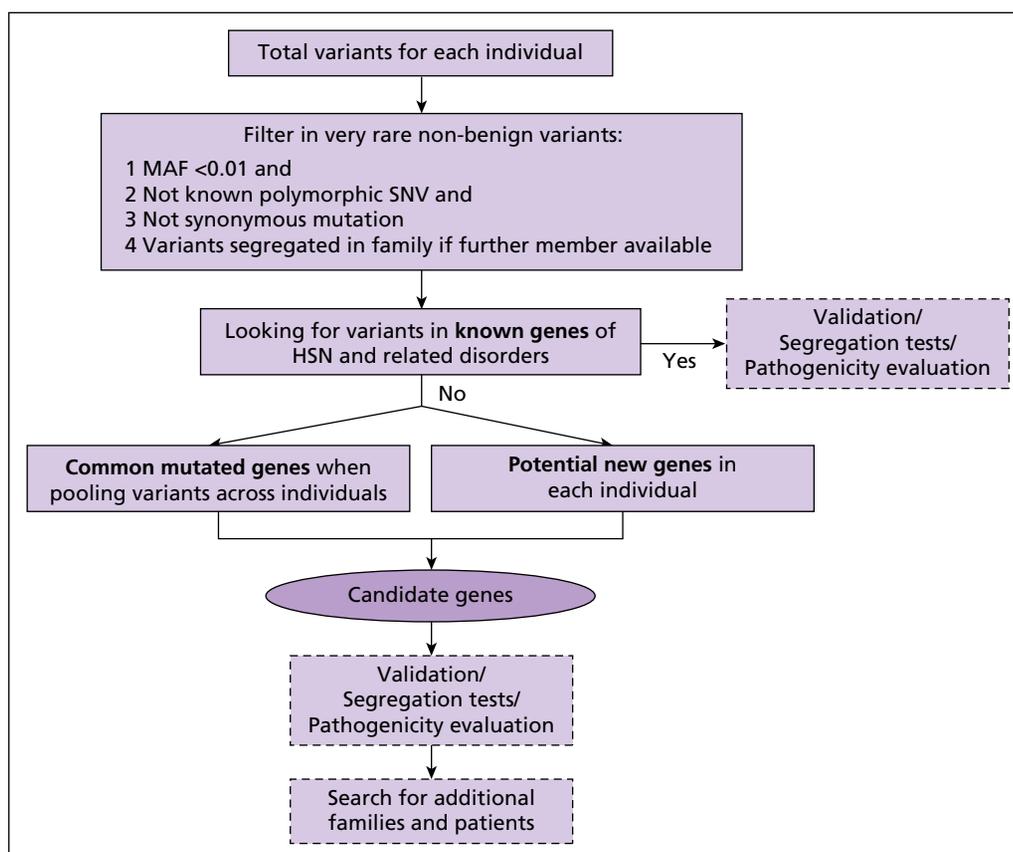

such as Charcot–Marie Tooth (CMT) disease. In the Neurogenetics Laboratory at The National Hospital for Neurology and Neurosurgery we have a three-tier approach to genetic screening (Figure 3.3):

- 1 Initial screening of the common genetic defects or disease genes, which can often also be screened at low cost (Figure 3.4)
- 2 Secondary screening of the rarer disease-associated genes using a gene panel approach, and
- 3 Diagnostic exome sequencing (Figure 3.5).

As a way to increase the chance of obtaining a genetic cause, many patients and families are enrolled in research programmes to sequence multiple individuals in the family. This can increase the diagnostic yield, but all research results must be first confirmed in a diagnostic laboratory before they are released to patients.

### Ethical considerations: predictive versus diagnostic

Predictive (presymptomatic) genetic testing is often offered to individuals at risk, typically in the late-onset autosomal dominant inherited conditions. Our experience of predictive testing mainly comes from Huntington's disease and other life-limiting conditions. More recently, patients with other conditions such as CMT or DYT1 dystonia are increasingly being referred for testing. The genetic counselling required for predictive testing is considerably different from that required for diagnostic testing, and requires a specialist team consisting of a neurogeneticist (or neurologist and clinical geneticist), clinical nurse specialist, local and actively involved diagnostic laboratory, and access to other specialists in fields such as psychiatry. For some conditions, at least two outpatient visits are required before a result is given on the third clinic

**Figure 3.3** Analysis strategy as applied to diseases such as hereditary sensory neuropathy (HSN). MAF, minor allele frequency; SNV, single nucleotide variant.

visit to ensure that the individual fully understands the serious implications of having a positive test result. Important considerations before a result is given are as follow:

- 1 Does the individual really wish for testing and can the person give full consent?
- 2 Do the individual and family understand all the implications (and limitations)?
- 3 Issues involving family, work, insurance, wider life, and
- 4 Disclosure and confidentiality issues.

Prenatal diagnosis is often undertaken in patients who have had a positive predictive test result or are in the early stages of the disease. In the past, prenatal testing was usually undertaken in recessive childhood-onset disorders, but prenatal testing is now frequently carried out in adult-onset dominantly inherited disorders. Testing is usually carried out at 10 weeks' gestation with chorionic villus sampling. More recently, pre-implantation diagnostic testing has become more readily available. This relies on *in vitro* fertilisation and selective implantation of mutation-negative embryos into the uterus. At present, various logistical and cost limitations mean that only about 20% of procedures result in a pregnancy going to term.

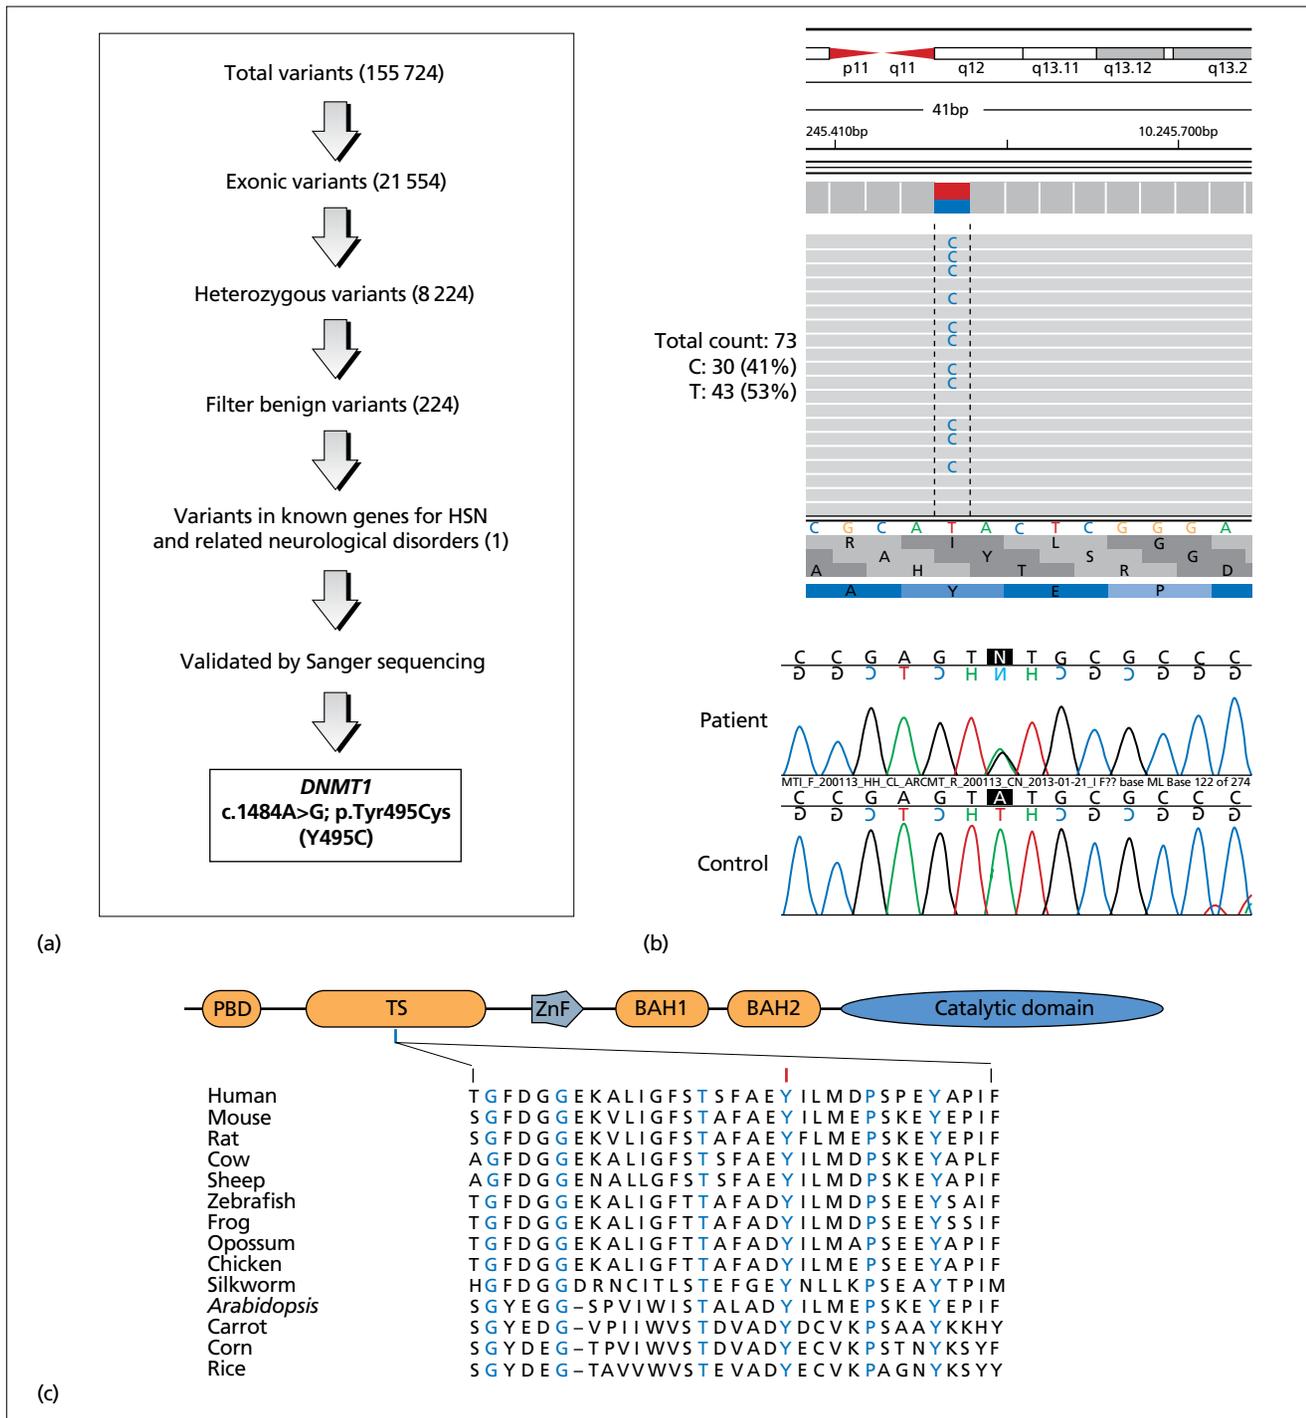

### Incidental findings in diagnostic exome and genome sequencing

Exome and genome sequencing reveal information on virtually every gene in the human genome, delivering disease predisposing variants on putatively every allele. Therefore, even if no primary

genetic result is obtained and the familial neurological disease gene is not identified, there are multiple and potentially hundreds of incidental results that can be offered to individuals and families. Whether all or some of these incidental results should be returned leads to complicated ethical and practical issues. Which incidental results should be returned? How can they best be used to improve health?

The lack of clear guidance for returning incidental results from exome and genome sequencing is compounded by challenges to how to communicate genetic results clearly. Recently, the American College of Medical Genetics and Genomics (ACMG) and the European Society of Human Genetics (ESHG) have issued recommendations on the return of incidental results from exome and genome sequencing. The ACMG recommended that from exome and genome sequencing, mutations in a list of 57 known disease-associated genes should be reported as the minimum. The ESHG made the subtly different recommendation that the results from only specific genes or sets of genes should be returned to patients, and genetic variants with limited or no clinical utility should be filtered out (if possible neither analysed nor reported). These recommendations have proven to be controversial and there are still divergent views on whether and, if so, what incidental results should be offered for return, issues of informed consent, and providing results for adult-onset conditions to the parents of children who undergo exome and genome sequencing.

The majority of individuals who have undergone exome or genome sequencing so far are of Northern European descent and

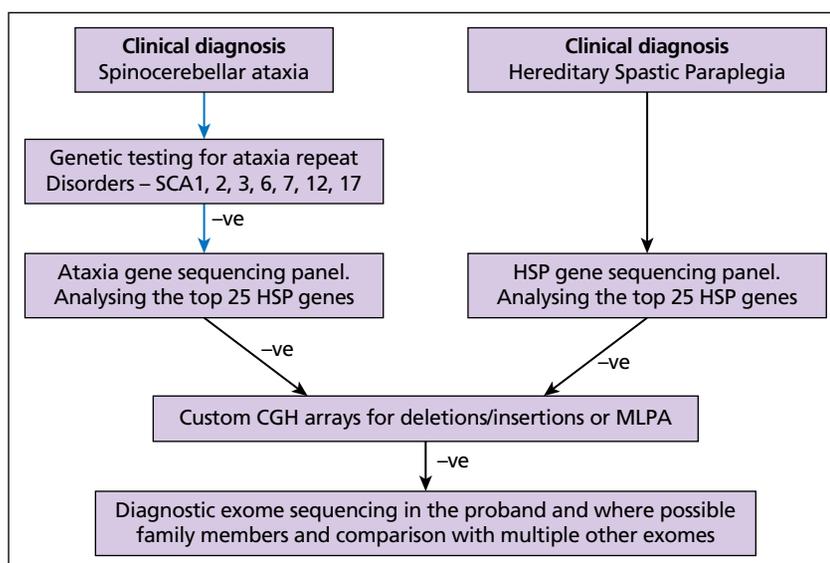

**Figure 3.4** Analysis strategy as applied to an autosomal dominant disease such as hereditary sensory neuropathy (HSN) identifying the *DNMT1* gene. (a) Filtering of exome data, total variants refers to exon and flanking intronic changes. (b) Exome viewer shows the proportion of A to G as in a dominant mutation. (c) Sanger sequencing to confirm the variant. (d) Species conservation of this mutation.

we therefore still have a great deal to understand about other population genetic variants and incidental findings. In large-scale exome sequencing in 500 European and 500 African descent adult participants, the number of incidental findings were lower than expected: 3.4% for European descent and 1.2% for African descent of the high-penetrance actionable pathogenic or likely pathogenic variants.

Although these data suggest there will be fewer significant variants to discuss and address with patients, the exome or genome will still contain variants of different risk potency for human disease, and other factors such as response to drug treatments.

The diagnostic efficiency of exome and genome sequencing far outweighs the drawbacks of using this technology. Careful

**Figure 3.5** The approach to diagnostic testing in disorders such as ataxia where the initial genetic analysis can identify around half of the cases and the extremely heterogeneous, hereditary spastic paraplegia (HSP) where a gene panel and exome approach are initially required. CGH, comparative genomic hybridisation; MLPA, multiplex ligation-dependent amplification.

consideration needs to be given when returning results to patients and families where the main focus must be on identifying the cause of their neurological disease as opposed to delivering uninterpretable incidental findings.

## Autoimmunity Fundamentals

The immune system is a dynamic tissue with a series of elements that perform a specific set of actions to maintain homeostasis of an organism. At its most fundamental, the immune system distinguishes the self from non-self organisms and acts to delete, disable or inactivate foreign invaders. In more complex functionality it also distinguishes damaged, irreparable or altered self from normal tissue to maintain a healthy homeostatic state, interacting closely with physiological and biochemical processes. Where surveillance or activity fail, infection or neoplasia can thrive; where active components become misdirected autoimmune disease (the horror autotoxicus of Ehrlich) may be the result.

The immune system has a number of tools at its disposal, varying in complexity, specificity and phylogenetic developmental diversity, which act in conjunction with one another in a complex interdependent immunological 'soup'. Interference in one aspect of the immune system inevitably causes imbalance in other aspects, although elements of redundancy and shared functionality provide a safety backup system. Therapeutic interventions can have unintended effects because of interference with a balanced system (sometimes already disturbed by disease processes), and these may be severe or life threatening. As therapeutics become increasingly potent and specific so we will see more specific 'lesional' pathologies as fallout from immunotherapeutics. When and if these events occur (not always predictably) they will inevitably teach us about how the immune system works, unfortunately at the expense of those exposed to them.

The CNS and peripheral nervous system (PNS) are afforded some special protection by and from the immune system resulting

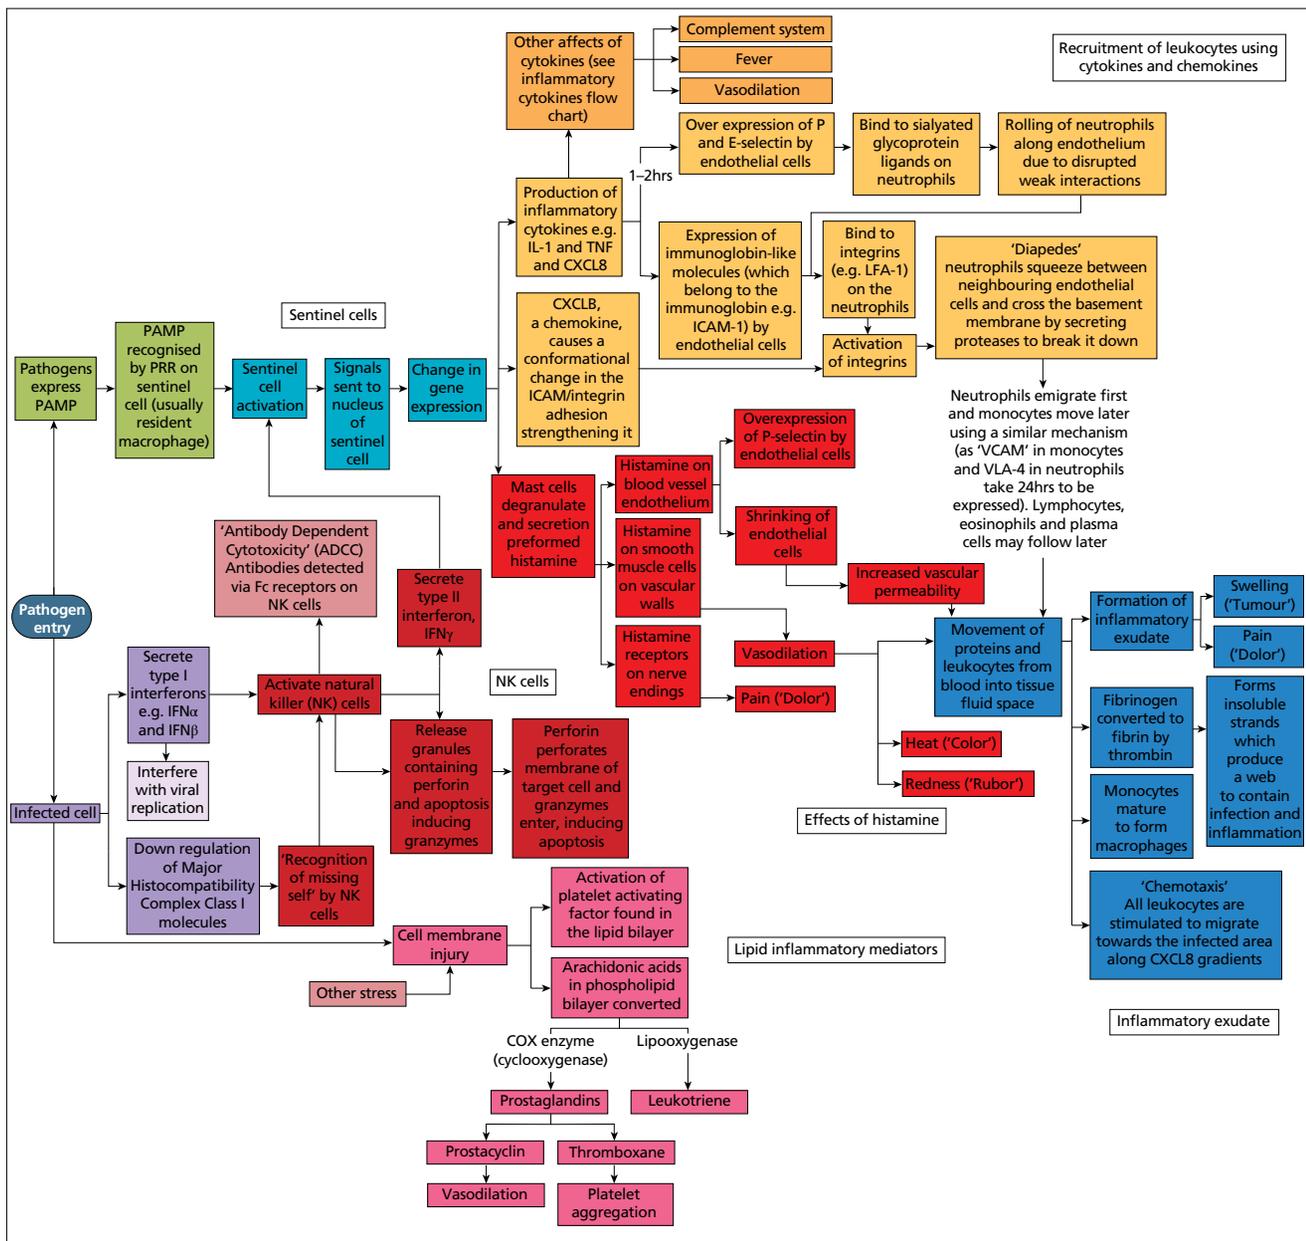

in a number of diseases caused by invading pathogens (e.g. meningitis), unsuppressed opportunists (toxoplasmosis or progressive multifocal leukoencephalopathy, PML) or autoimmune diseases (multiple sclerosis and Guillain-Barré syndrome). Each of these diseases are discussed in the relevant chapters but the purpose of this chapter is to introduce some broad concepts of disease to assist in understanding at a more general level. Readers who wish to study the specifics of immunology and its relation to disease are referred to excellent up-to-date textbooks of immunology and autoimmune disease.

## Components of the immune system

The immune system is a highly developed and as yet imperfectly understood homeostasis mechanism protecting us from pathogens, inflammation and tumours. A detailed description of all its elements is beyond the scope of this chapter. A basic understanding of the components of the immune system, how they interact and how they are modified to regulate immunity in the CNS and PNS is crucial to the understanding of immune diseases. Failure of one or more components or failure of the regulation of normal homeostasis results in disease through pathogen invasion, inflammation or autoimmunity. Modulation of components of the immune system is the basis of immunotherapeutics, a rapidly developing field. Some therapeutics are relatively non-discriminatory (e.g. steroids and cyclophosphamide), whereas newer biologic agents are highly specific and exceedingly potent (e.g. rituximab and alemtuzumab). The ability to lesion the immune system so specifically increases our understanding of individual component functions, but can result in unintended opportunist infection (e.g. PML) or other autoimmune dysregulation (e.g. glomerulonephritis following alemtuzumab use).

## Innate immune system

The innate immune system (IIS) refers to the germ line complex of recognition molecules and receptors, effector molecules and cells that provide the immediate recognition and response to invasion and which perform a crucial role in immunohomeostasis

**Figure 3.6** Innate immune system. Source: Architha Srinivasan (own work) used under the terms of the Creative Commons Licence CC-BY-SA-3.

(Figure 3.6). The IIS was considered to predate phylogenetically the acquired and adaptive immune system, but adaptive cell components utilise elements of the IIS, and each system interacts with the other such that they must have developed, for a large part, in parallel. The IIS, being the first line of defence, has elements that are concentrated at epithelial surfaces. The CNS and the PNS are sites of relative immune privilege and as such are relatively protected from invasion but also maintained in a state of immune hyporesponsiveness where innate reactions are not so florid. Nevertheless, the IIS has a crucial role in defence against neurological diseases. More importantly, its activity, inactivity or mal-direction has important roles in the genesis of some diseases. Modification of the the IIS can be important in the control and treatment of neurological disease.

The IIS is crucial in the early response to invasion by pathogens. When one considers the doubling time of most bacterial pathogens is 20–30 minutes and an adaptive immune response requires days to develop, control and restriction of invasion at an early stage is critical to survival of the organism. The IIS generates the cardinal features of inflammation (rubor, calor, dolor and tumor, or redness, heat, pain and swelling), which engage all the elements of the immune system in containment and control. It is also important in the later stages of disease where the clearance of non-specific debris from cell death an inflammation result in suppression and cessation of inflammation.

The components of the IIS include the following:

- 1 Physical barriers with tight junctions in epithelial and endothelial surfaces, for example the blood–brain and blood–nerve barriers.

- 2 Pathogen recognition molecules that are secreted, on the cell surface or cytosolic. These are non-adaptive peptides that recognise components of invading pathogens. They include Toll-like receptors, lectins (e.g. mannose binding proteins), defensins, cathelicidins, collectins and others. The diversity of these recognition molecules restricts the ability of pathogens to adapt and evade them. Furthermore, the pathogen-associated molecular patterns that pathogen recognition molecules target are usually so crucial to pathogen survival that mutation results in death of the pathogen.
- 3 Enzymes released extracellularly, or more usually into lysosomes, which result in death of endocytosed or nearby organisms (e.g. proteases, lysozyme and NADPH oxidase).
- 4 Signalling molecules such as cytokines, which attract cells of the innate and adaptive immune system to sites of inflammation or attack (e.g. interleukins 1 and 8, IL-1 and IL-8) as well as cytokines that turn down the response and turn off the response (IL-10).
- 5 The complement cascade, crucial to the opsonisation of pathogens and chemo-attraction. A further discussion of complement is beyond the scope of this chapter but its importance in disease is critical both in the immediate innate response to pathogen invasion and also through tissue damage caused in disease. The complement cascade is the focus of significant therapeutic interest as inhibition of the cascade almost entirely abrogates paroxysmal nocturnal haemoglobinuria and may also be effective in Guillain-Barré syndrome. A major consequence of inhibition of the system is the potential for severe and life-threatening infection with infectious organisms such as meningococci.
- 6 Cells recognising and presenting antigens to the adaptive immune system, such as macrophages, dendritic cells and epithelial cells.
- 7 Cells releasing killing substances (mast cells, neutrophils, natural killer cells).
- 8 Phagocytic cells (macrophages and monocytes) which endocytose pathogens and opsonised materials. These also phagocytose apoptotic effector cells, a process called efferocytosis, before they are able to spill their remaining toxic contents. This functions to turn off responses and maintain immunological homeostasis.

### Adaptive immune system

The adaptive or acquired immune system refers to cells of the lymphoid lineage and the genetically modifiable displayed and secreted molecules from those cells. The cellular components are B cells, which display and secrete immunoglobulin, and T cells, which display T-cell receptors and associated complexes. T cells include both effector cells, providing cell-mediated cytotoxic responses as well as antibody-dependent cellular cytotoxicity, and helper cells interacting with B cells and cells of the innate immune system. The secretion of affinity-matured antigen-specific immunoglobulins by B cells is their primary function and these mark out pathogens and debris for clearance. The adaptive immune system would function poorly without the innate immune system, and likewise the innate immune system requires the backup of the adaptive system to complete the clearance of suppressed foreign material.

Lymphoid cells are generated in the primary lymphoid tissues of the thymus gland (T cells) and the bone marrow (B cells). Lymphoid cells originate from the haematopoietic stem cells by a process of asymmetric division. During very early development the daughter cells migrate to the liver but during late embryonic and postnatal development further differentiation, selection, deletion and anergy takes place in the thymus and bone marrow.

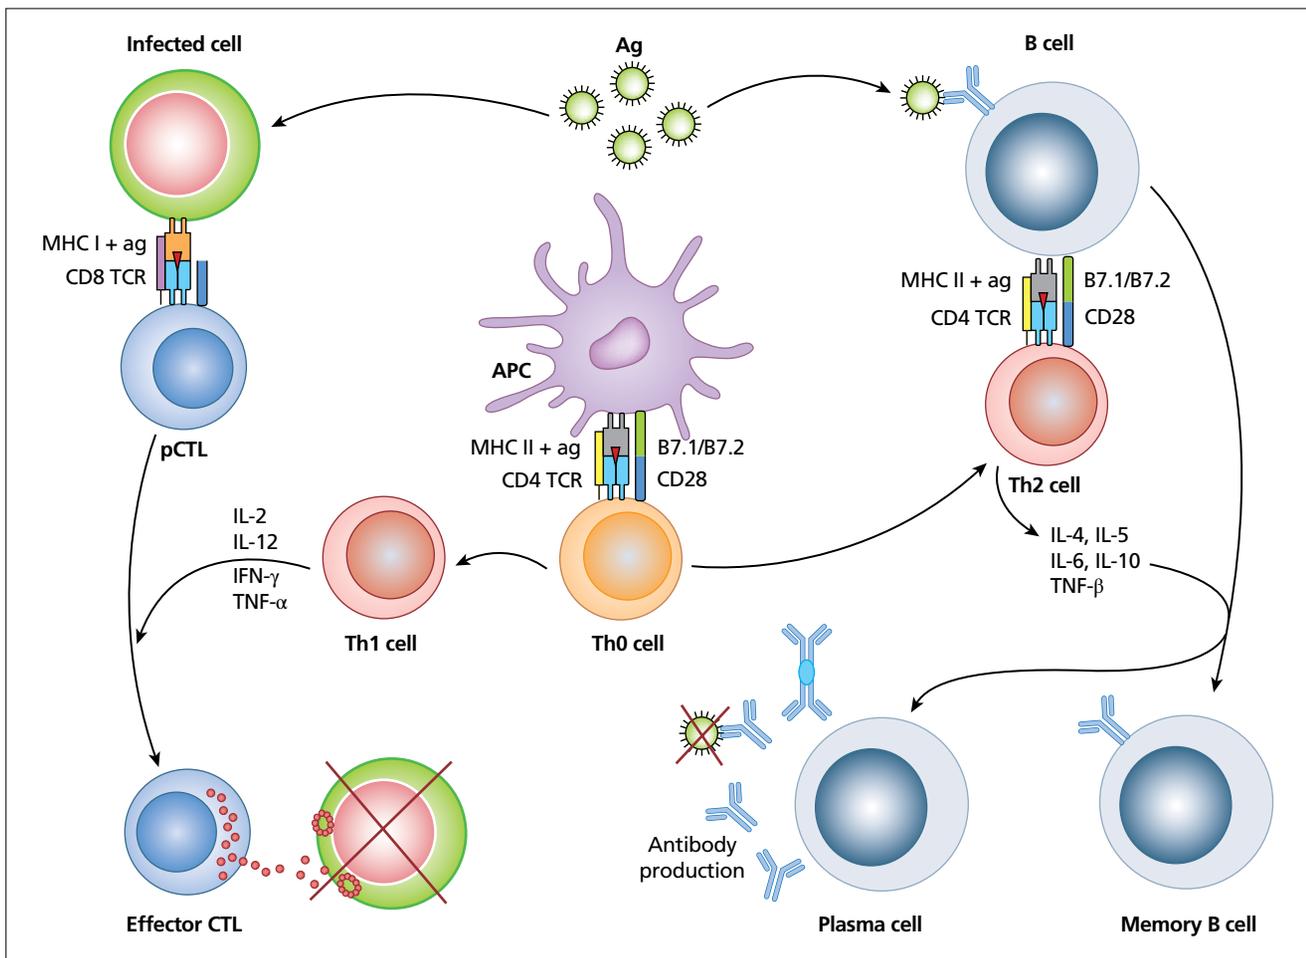

The secondary lymphoid tissues (lymph nodes and spleen) are the sites of antigen presentation to the lymphoid cells and B- and T-cell interaction resulting in activation, antigen affinity processing and expansion, following which escape to the peripheries releases cells to sites of activity.

**T cells** T cells orchestrate many of the functions of the adaptive immune response. T cells mediate their own activity, provide help to B cells and participate in cell-mediated immunity, destroying invading pathogens and neoplastic or potentially neoplastic cells. T cells derive their specificity from a cell-specific, genetically encoded, surface-bound, multi-subunit T-cell receptor (TCR) which recognises peptides presented in the context of major histocompatibility complex (MHC) class 1 or 2 on the surface of antigen presenting cells (APCs) following intracellular processing. About 95% of TCRs are of the  $\alpha/\beta$  lineage and the remainder are  $\gamma/\delta$  T cells.  $\gamma/\delta$  T cells are not well understood and may be more involved in processing non-peptide-like antigen, possibly encountered on epithelial surfaces. They develop and mature through slightly different processes to the  $\alpha/\beta$ , driving some autonomous development through various checkpoints in the thymus. They expand very little in lymphoid tissue but may undergo considerable expansion in the periphery (Figure 3.7). It is thought that  $\gamma/\delta$  T cells are more involved than  $\alpha/\beta$  T cells in the pathogenesis of inflammatory neuropathies such as chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) where the driving stimulus may be carbohydrate-rich invading pathogens.

During development, mononuclear cells of the lymphocyte lineage first become committed to being T cells and they then begin the process of TCR gene rearrangement. They are presented with antigen in the thymus as they transit through interactions in the thymic cortex and then medulla. T cells that have no recognition of self MHC are deleted (positive selection). Following commitment from double positive ( $CD4^+/CD8^+$ ) to single positive ( $CD4^+$  or  $CD8^+$ ) cells, they are presented with antigen. Those with strong affinity for self antigens are deleted, which protects against autoimmunity (negative selection). Those with rather weaker interactions may become anergic. Those that do not have a recognition event are rescued from pre-programmed apoptosis, matured and moved to the secondary tissues.

The TCRs on all T cells are non-covalently linked to the CD3 molecular complex. The five subunits of the CD3 complex transduce activating signals through the T-cell membrane following interaction with the peptide-MHC complex on APCs. Both CD4 and CD8 are associated with the intracellular src-family tyrosine kinase Lck, which is responsible for T-cell activation. CD4 and CD8 are also non-covalently associated with accessory molecules, which serve to determine the specific actions of the T cell as a helper or cytotoxic T cell. There are about 15 of these present on the surface of T cells which also serve as co-receptors and factors in T-cell adhesion and activation, such as CD2, CD27, CD28, CD134, and CD137.

Once matured, T cells are released to patrol the peripheries, and mostly are found in secondary lymphoid tissues. The classic mature T cells are either cytotoxic or modulatory/regulatory. Cytotoxic T cells are CD8-positive and see antigen presented in the context of MHC I. Conversely, CD4 cells recognise antigen presented in the context of MHC II and are conventionally referred to as T-helper cells. However, CD4 cells can be also cytotoxic in graft rejection. Further blurring the distinction into cytotoxic and modulatory cells, CD8 cells can participate in normal physiological

**Figure 3.7** Basic stimulation and maturation initiation of B and T cells. Antigen is displayed on the surface of antigen presenting cells (APC) and in the presence of co-stimulatory signals matures  $T_H$  cells which in turn assist in B-cell activation and T-cytotoxic responses. Maturation of both T-cell receptors and B-cell surface antibody through gene rearrangement matures specificity of responses. Immune responses are effected directly through B and T-cell mechanisms or the chemotactic recruitment of other cells and cytokines deliver appropriate immune responses. inflammation and have some helper roles. In addition, CD4 cells not only provide 'help' to modulate B-cell responses, but also act as regulatory T cells ( $T_{reg}$ ) and T-suppressor ( $T_{sup}$ ) cells. Th1, Th2, Th9 and Th17 responses are determined by different states of differentiation of CD4 cells from a Th0 state by the cytokine milieu. Th1 cells are traditionally 'inflammatory' driving T-help for delayed hypersensitivity reactions and some B-cell help. Th2 responses are more humorally directed, especially stimulating IgE and eosinophils. Th9 responses (driven by IL9) are thought to be tumour directed, but their actions and development remain under investigation. Th17 responses are thought to be those involved in many autoimmune diseases and previously classed as Th1. They are generated by IL-1 $\beta$  and IL-23 or IL-6 and express IL-17, IL-22, IL-26 and  $\gamma$ -interferon.

Memory T cells can be generated expressing CD27 and these may have extremely long survival.

**B cells** B cells are generated throughout postpartum life from haematopoietic stem cells (HSCs) in the bone marrow. HSCs are forced into B-cell commitment by the suppression of Notch signalling.

What induces this signal to force B-cell development is not known. Once a lymphocyte is committed to B-cell lineage it is moved to secondary lymphoid tissues where antigen exposure leads to the antigen-dependent development stage.

A number of stages of development are recognised, defined by the B-cell immunoglobulin gene rearrangements and the displayed cell surface markers. (Figure 3.8). These cell surface markers can be utilised as cell-specific biologic therapeutic targets, most notably CD20, which is displayed on the B-cell lineage from pre-B cells to mature B cells and is the target of rituximab. Plasma cells are CD20-negative hence the resistance of some humoral disease to rituximab treatment. Pro-B cells are also CD20-negative, hence the ability of the B-cell lineage to repopulate after rituximab treatment. CD19 is present on developing B cells from the pro-B cell stage. It is part of a multimolecular cell surface complex involved in the signalling of T-cell help during B-cell maturation. It is also a useful surrogate cell marker to assess the CD20 population (which appears at the following pre-B cell stage) after depletion of this population with anti-CD20 antibodies.

**Figure 3.8** Information about the human immune system and its inner working. Source: <http://immunologynow.com/post/67762750179/t-cell-maturation>.

The germ line rearrangements that determine immunoglobulin class and antigen specificity, as well as the cell surface display of the cell defining immunoglobulin, occur throughout B-cell development. Immunoglobulins are made up from the rearrangement of genes coding for a pair of heavy chains and a pair of light chains, which assemble to make a complete immunoglobulin molecule. Heavy chains (IgH) are made from a constant region ( $\mu$ ,  $\gamma$ ,  $\alpha$ ,  $\epsilon$  or  $\delta$ ) joined to one of a large number of variable (V-), fewer diverse (D-) or a few joining (J-) segments. Light chains are either  $\kappa$  or  $\lambda$  and have V- and J- but no D- segments. The heavy chains reorganise and assemble before the light chains, with kappa light chains the default position and lambda light chains used where kappa light chain rearrangement fails. When the complete immunoglobulin molecule is assembled it is displayed on the cell surface, which signals the final maturation stages of mature B cells.

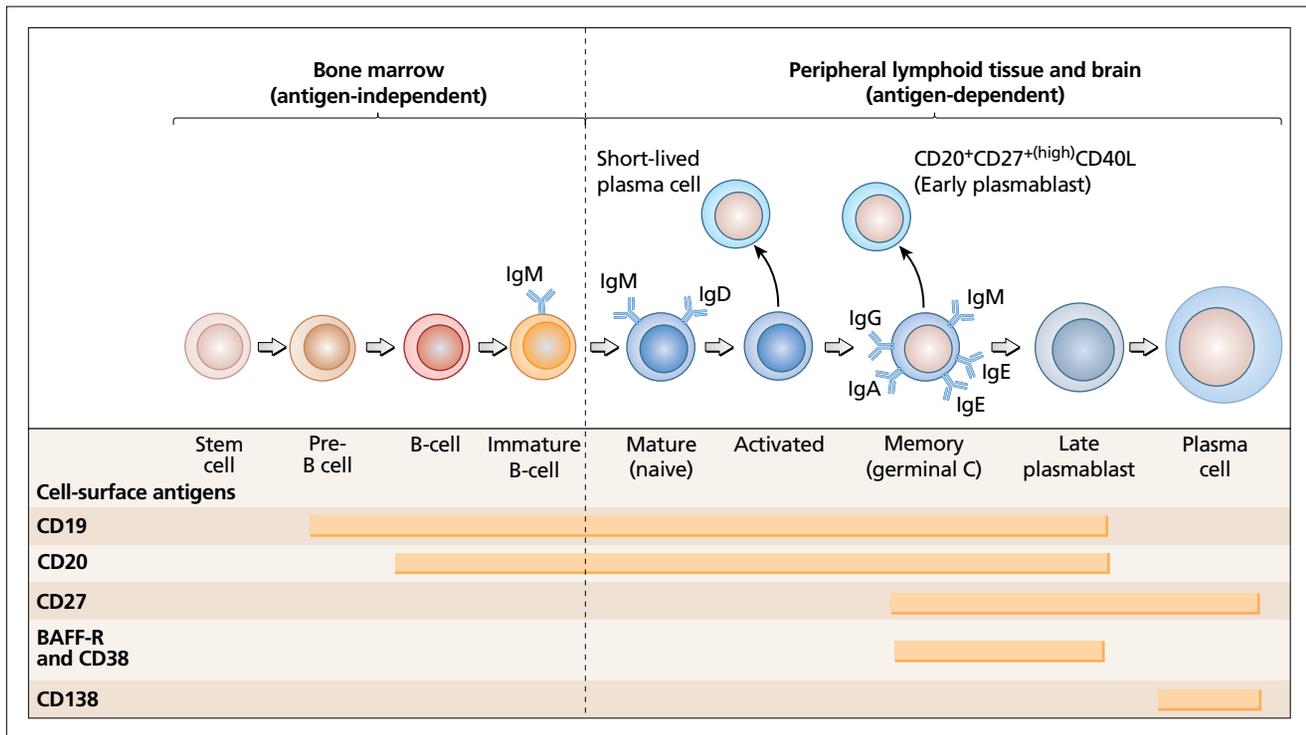

All mature B cells display CD19 and CD20 surface markers, but other markers differentiate specific functions. Most B cells are conventional CD5<sup>-</sup> (B2) cells. B cells displaying CD5 (CD5<sup>+</sup> – B1a and B1b cells) probably originate earlier in B-cell ontogeny and are not as tightly regulated as conventional CD5<sup>-</sup> B cells. CD5<sup>+</sup> B cells release low affinity IgM 'natural' antibody to a number of self antigens and these probably function in an immunoregulatory capacity, their IgG binding (rheumatoid factor) activity being an example. Common antigens recognised by CD5<sup>+</sup> elaborated IgM antibodies include insulin, single-stranded DNA, thyroglobulin and possibly myelin-associated glycoprotein. CD5<sup>+</sup> B cells probably react more quickly than conventional B cells, facilitating a quick but

low affinity humoral response. However, it is unclear whether the IgM elaborated can become pathogenic through affinity maturation as might be postulated in the IgM-associated anti-myelin associated glycoprotein (anti-MAG) paraproteinaemic demyelinating neuropathies.

Mature B cells migrate to secondary lymphoid tissues, with transmural migration through the high endothelial venules facilitated by CD44 and CD62-L (L-selectin). Once in secondary lymphoid tissues IgM and IgD are displayed on the B-cell surface marking these as mature naive B cells.

Mature B cells can be activated by a number of cytokines and cellular signals: CD25 (IL2R), present on other activated B cells, T cells and monocytes, CD23, a low affinity IgE receptor, and CD80 and CD86 which are the receptors for the TCR associated molecule CD28, which augments the B to T cell synaptic help interaction. Also involved in maturation are CD19, CD20 and CD21 helping to transmit extracellular to intracellular signals. CD40, the cognate partner for CD154 (CD40-L), which is displayed in T cells, is arguably one of the most important signals in B cell antigen-dependent development. The surface immunoglobulin displayed on each B cell provides the antigen specificity and links to intracellular signalling proteins in complex with CD79a and CD79b heterodimers.

Activated B cells move to the mantle zone of germinal centres and under the influence of cytokines undergo class switching to the appropriate Ig class. Many of the follicular B cells undergo apoptosis and it is only the ones with strong affinities that survive this process

**Figure 3.9** B-cell maturation from stem cells to plasma cells is accompanied by surface markers and surface antibody display that identifies the lineage maturity of the cells. These markers may be exploited in diagnosis of lymphomas as well as targeted by therapies such as rituximab, directed at the CD20 surface marker. Source: Dalakas 2008. Reproduced with permission of Nature Macmillan.

before leaving the germinal centre. The final pathway for differentiation is to plasma cells (Figure 3.9). Without T-cell help B cells become short-lived plasma cells secreting low-affinity antibodies. With T-cell help mature activated B cells are driven to memory B cells with a half-life of many years, or CD138<sup>+</sup> plasma cells, which secrete antibody in excess but have a shorter half-life of months. Both these cell types are CD20<sup>-</sup> and hence a humoral response once set and matured may persist even after rituximab is used therapeutically.

**Interactions of B and T cells** Within the adaptive immune system the interactions of B and T lymphocytes and APCs through immunological synapses are critical not only to maturation and activation, but also regulation and suppression. Failure of any of these processes can result in immunodeficiencies (e.g. systemic enterovirus infection, PML), autoimmunity through impaired tolerance (Guillain-Barré syndrome) or damage through overactivation of responses (pneumococcal meningitis). The critical co-dependency of the B-T cell interaction can be exploited in many autoimmune diseases, where reduction of one arm of the immune system often affects the other.

APCs set up the activation of the adaptive immune response with APCs presenting antigen to naïve T cells, which when activated provide T-cell help to B2 cells. Once activated, however, a number of processes central to turning off the T-cell response are put in motion. CD28 is down-regulated and CTLA4 expressed; CTLA-4 has a higher affinity for CD80 and CD86 than CD28 and reduces CD28 stimulation. In parallel PD-1 (programmed cell death 1) is expressed, which is the negative signalling homologue of CD28. Programmed cell death pathways

are set in motion as soon as T cells become activated and later expression of Fas and the tumour necrosis factor (TNF) receptor 2 result in apoptosis through suicide or homicide. The failure of cell death pathways (especially the Fas pathway) has been implicated in the maintenance of chronic relapsing autoimmune conditions such as CIDP.

**Cytokine network** Cytokines are hormone-like molecules elaborated by the cellular components of the immune system to coordinate cellular networks and direct cell types in activity and anatomical location. They function as pro-inflammatory up-regulators of the immune system (most cytokines), chemoattractants (chemokines) and negative regulators of the immune response (some cytokines and prostaglandins). They are important also as they can be targets for therapeutic intervention; a number of biological agents exist to interfere with cytokines (e.g. TNF inhibitors and anti-IL-6 agents).

The interleukin designation of many of the known cytokines has simplified the classification; however, some cytokines retain their descriptive terminology such as TNF or the interferons.

In T-cell maturation and response, cytokines are elaborated on the basis of the antigen-APC-T-cell interaction, the local cytokine milieu and the T cells that are anatomically localised to act. Cytokines are crucial in the initial antigen presentation event, and the subsequent inflammatory events that ensue rely on the elaborated cytokines. For example, Th1 cells produce interferons, TNF and IL-2 but not IL-4, and drive delayed type hypersensitivity responses. They are involved in localised inflammatory processes such as rheumatoid arthritis and granuloma formation. Th2 cells produce IL-4 and IL-10 and are responsible for more humoral-based

processes with more widespread activity. Asthma and host defence against attack are mediated by Th2. Pro-inflammatory attack and some host defence mechanisms may be mediated by Th17 responses. These are more recently described and previously thought to have been part of the Th1 response. They remain poorly understood. Th17 responses are driven by IL-21, IL-6, IL-1 $\beta$  and possibly IL-23. Th17 inhibition is the focus of active and ongoing research.

A 40-strong family of small protein cytokines known as chemokines are responsible for cellular adhesion and migration of cells to areas of immune need and are referred to as CXC chemokines, identified by a specific protein motif. IL-8 and the peptide C5a might also be considered in this group.

Negative regulation of the immune system is also promoted by cytokines. Transforming growth factor  $\beta$  (TGF- $\beta$ ), prostaglandins, IL-10 and IL-35 all down-regulate components of the immune system.

### Protection of neural tissues – the blood–brain and blood–nerve barriers

#### Intrathecal antibody synthesis and the blood–brain barrier

The blood–brain barrier (BBB) describes the complex concept of a physically impermeable structure that divides the systemic body compartment from that of the CNS across which fluids, solutes and cells can selectively pass resulting in a unique CNS milieu (Figure 3.10). There is a misconception that this provides immunological privilege to the CNS; in fact it enables a more controlled environment to exist within the environment of the body as a whole in which an additional degree of immunological control can be exerted. This results in the relative resistance of complex CNS machinery to immune attack but also generates the environment in

which a unique set of autoimmune diseases can occur and unique immune responses result in both damage and damage limitation.

The blood–nerve barrier (BNB) is less well described and understood, as the endoneurial space of the peripheral nerve is less amenable to study, especially in terms of its fluid and solute constituents. It is accepted that the BNB is more ‘leaky’ than the BBB, and that it undoubtedly modifies any immune responses that would be prone to occur if nerves were not ‘hidden’ behind it. However, it will not be discussed further here. Further descriptions are to be found in Chapter 10.

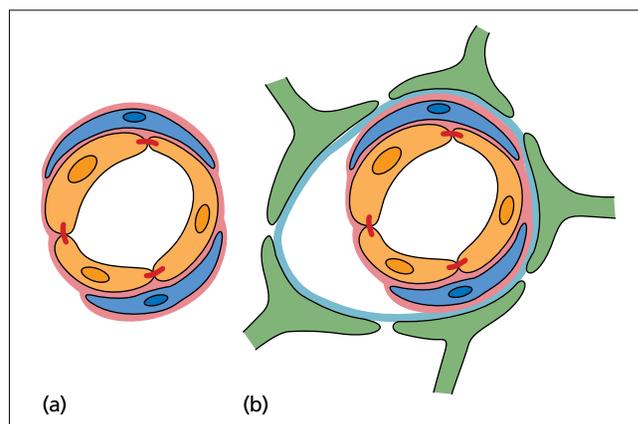

In clinical neurology the invasiveness of a cerebrospinal fluid (CSF) examination and the appearance of the CSF as an entirely colourless, translucent (‘gin clear’) fluid have often consigned it to the position of a ‘less useful’ body fluid in the diagnosis of disease. This was perhaps true when analytical techniques were only able to identify basic cell types and molecules in relatively large concentrations (‘CSF total protein’). Advances in qualitative and quantitative techniques of CSF analysis are beginning to reveal the CSF as an increasingly useful fluid from which to identify biomarkers with relevance to diagnosis, prognosis and response to treatment but discussion of most of this emerging field is beyond the remit of this chapter. However, there is a very solid basis for the use of the CSF as a biomarker in many diseases of the CNS and PNS that are discussed here.

#### Analysis of CSF solutes

In health, the CSF is maintained as a protein-poor solvent in which are dissolved proteins derived mainly from brain tissue. These are produced in the most part from physiological and pathophysiological processes of release and cellular decay and recycling. Perhaps of most interest in the clinical investigation of the CSF are normal levels of CSF antibodies, amyloid beta, tau and phosphotau proteins (as a baseline from which change indicates disease), and asialotransferrin (as an easy analyte as a marker of CSF as a fluid). Many other proteins contribute to ‘total’ CSF protein (e.g. transthyretin) but have less use, at present, in the assessment of health or disease.

In the most basic of clinical CSF analysis, CSF total protein is measured by one of a large number of methods. However, ‘CSF protein’ contains contributions from CNS and systemic compartments (if there is a dysfunctional BBB) and is a very non-specific measure. The measurement of specific protein is much more useful. No albumin is produced in the CNS and so any albumin detected in the CSF is there as the result of direct BBB transport and control or as a result of ‘leakage’ through a dysfunctional barrier. CSF albumin is easily measured and its ratio to the serum albumin is constant in health. This ratio (CSF<sub>alb</sub> : serum<sub>alb</sub>) is known as the albumin quotient ( $Q_{alb}$ ) and is a method-independent measure of BBB permeability. In health, all the IgG in the CSF is actively transported across the BBB (as are other immunoglobulins). A raised CSF IgG in comparison to the serum (raised CSF<sub>IgG</sub> : serum<sub>IgG</sub>) or the IgG quotient ( $Q_{IgG}$ ) can be used similarly. The IgG index ( $Q_{IgG} : Q_{alb}$ ), which is the ratio of these ratios, can define the permeability characteristics of the BBB, helping to define the pathogenesis of processes occurring inside or outside the CSF space with, or without, humoral drive.

Other CSF solutes can also be measured. Most are present in very small quantities and the current dynamic range of most assays as well as inter-individual differences in response is unable to distinguish solute profiles on an individual patient basis. However, some solutes released in large quantities (e.g.  $\alpha$ -beta amyloid proteins, tau, neurofilament proteins, S-100 $\beta$  and 14-3-3 protein) are easily

**Figure 3.10** The blood–nerve barrier (BNB) (a) and the blood–brain barrier (BBB) (b) have similar structures and function very similarly. Capillary endothelial cells (orange) are joined by tight junctions (red) and with pericytes (blue) and basement membrane form a passively impermeable barrier to the passage of cells and molecules. In the brain, beyond the pericapillary space is the glia limitans (light green) supported by astrocyte foot processes (dark green) which form a second layer of physical barrier. Permitted solutes and molecules cross the barriers by active receptor bound or vesicular transport. The function of the BBB and BNB is very similar in terms of molecular exclusion and transport permission. Source: Adapted from Kanda 2013 with permission of BMJ.

measured. The profiles of these solutes, assayed in the correct clinical context, can provide biomarker support for the diagnosis of Alzheimer's disease versus frontotemporal lobar dementias and degenerative brain diseases versus 'worried well' (Chapter 8). The collection of CSF samples and their immediate handling are crucial to these assays as considerable pre-process changes can occur as a result of interaction with plastic ware and at room temperature. Furthermore, assays should be carried out in recognised quality controlled laboratories where variances in assays are minimised.

Platforms for assays of low concentration solutes continue to develop. ELISA can be both sensitive and specific. However, multiplex assay systems with enhanced development techniques, mass spectrometry and 'single molecule detection' techniques will advance the field rapidly in the near future.

**CSF cells** The CSF is essentially an acellular fluid. The CNS is patrolled by a tightly regulated system of microglia generally maintained in a state of active patrol but hyporesponsiveness. Very few cells are found circulating in normal CSF. Most laboratories will quote <5 white cells per cubic millimetre as a normal range, but any cells in the CSF should provoke suspicion of an ongoing process, even if very non-specific. Cells are nearly always lymphocytes, and the identification of macrophages or neutrophils is almost certainly disease related and useful in diagnosis.

Cell counts are not reliable for the identification of other cell types and formal cytology or flow cytometry studies are necessary to provide positive identification. In malignant meningitis, cell type can both make the diagnosis and prompt a search for the primary process or other disseminated disease. In haematological malignancies, where the cell type may be lymphocytic, and where accurate diagnosis depends upon the lymphocytic type, clonal molecular flow cytometry can provide an accurate diagnosis as long as sufficient CSF is provided containing sufficient cells.

Red cells in the CSF are always abnormal, although the most common cause for these is a traumatic lumbar CSF tap.

**Other CSF constituents** Pathogens can be isolated from the CSF by a variety of methods. Direct visualisation of bacteria or fungi can be immediately useful. Polymerase chain reactions (PCR) for viruses are highly specific and variably sensitive. It must be remembered that PCR depends upon the primers chosen, the strain of the virus and the copy number within the fluid. A negative result should not always be taken as negative and alternative or repeated tests might be useful. Culture studies can grow both bacteria (especially TB) and fungi at a later date and the possibility of such pathogens should be considered at the time of sampling; the request for special cultures will be required as well as adequate volumes of fluid.

The use of immunoglobulin in the CSF covers total IgG, the comparison of serum and CSF oligoclonal banding patterns and specific immunoglobulins in disease. The total IgG level was discussed earlier and is quickly measured. The oligoclonal banding pattern of the CSF in relation to the serum is a more lengthy process but can identify the relative production of monoclonal or oligoclonal humoral responses from within the CSF. This is useful in diagnosis of inflammatory CNS diseases. However, it remains a mystery as to the antigenic targets of oligoclonal bands in any disease and particularly in multiple sclerosis; the identification of a target antigen in this and other diseases would be a huge contribution towards explaining pathogenesis. Attempts have been made to identify virus-specific oligoclonal bands in the CSF with limited success.

These techniques have been superseded by PCR and whole genome, next generation sequencing techniques with greater and highly specific coverage for expected or unexpected pathogens.

### Immune diseases of the nervous system

The immune system probably has roles in the causation, pathogenesis, resistance to and recovery from a vast number of diseases in the nervous system. Furthermore, clinical diagnosis is greatly assisted by the analysis of 'immune' biomarkers (antibodies, cells, cell-related factors and aberrantly released molecules), which are measured in immunology laboratories. The immune system is critically involved in the resolution (and occasionally the worsening) of infectious diseases but this is not described further here.

Immunology is a part of every chapter of this textbook and diseases may be described as B- or T-cell mediated, complement-dependent or cytokine-driven. It is not possible to make clean divisions of diseases in relation to their involvement of the immune system as each involves the interaction of many players in the 'immunological soup'. As duplication and redundancy of function both exist, the analysis of a single component of the immune system is unlikely to provide the explanation for any one disease. In treatment options, the balance of immune components in disease can be likened to the interaction of strings in a child's cat's cradle; removing any one significant string often leads to the collapse of the structure although sometimes, under particular tension, the disturbance of the wrong string may lead to exacerbation of the immune response in the opposite arm (e.g. the provocation or worsening of demyelinating diseases with inhibitors of TNF- $\alpha$ ).

There follows some brief examples of diseases that are discussed later in the book where the immune pathogenesis is felt to be polarised in one direction or another.

### Antibody-mediated neurological diseases

Antibody-mediated neurological diseases can be divided into those where the antibody defines the disease and probably is primarily responsible for the pathogenesis of that condition, and diseases where antibodies are markers for the disease without necessarily being causative. There are a number of diseases where there is good theoretical argument for the antibody identified to be pathological (e.g. in the stiff person syndrome associated with anti-GAD antibodies) but where good evidence supporting the theoretical mechanism does not yet – and may not – exist.

**Neurological disease with pathogenic autoantibodies** Diseases of the PNS and CNS exist with good evidence for predominant antibody-mediated pathogenesis. The fulfilment of the Witebsky postulates is only partial in most of these diseases, largely because the generation of antibodies in animal models in response to immunisation is limited because of self-tolerance. However, myasthenia gravis, Guillain-Barré syndrome, Lambert-Eaton myasthenic syndrome, the surface receptor based autoimmune encephalitides and perhaps stiff person syndromes are examples of a B-cell mediated disease with more or less evidence for a predominant humoral pathogenesis.

The neurological disease with the best evidence for an antibody pathogenesis is autoimmune myasthenia gravis. Antibodies to the post-synaptic acetylcholine receptor result in a complement-dependent disruption of the post-synaptic neuromuscular junction complex which results in fatigable weakness. However, the initiation of the humoral autoimmune antiacetylcholine receptor antibody response remains obscure.

In the acute motor axonal form (AMAN variant) of the Guillain–Barré syndrome the initiation of the antibody response resulting in the disease is understood. Some strains of *Campylobacter jejuni* elaborate human ganglioside-like epitopes on their lipooligosaccharide coat. Infection in individuals who probably both have impaired self tolerance mechanisms and in whom sufficient adjuvant stimulation exists are able to make antibodies to their peripheral nerve gangliosides. Subsequently, these antibodies have both complement dependent and independent effects to alter electrophysiological membrane characteristics at the node of Ranvier and neuromuscular junction, to damage cell structure of axons and myelin and to impair the normal repair mechanisms that result in recovery. Similar mechanisms may exist in the more common demyelinating Guillain–Barré syndrome, acute inflammatory demyelinating polyradiculoneuropathy.

Increasing evidence is emerging that some CNS diseases are directly antibody mediated. Antibodies to neuronal cell surface receptors have recently been described and their number is increasing. Antibodies to the voltage-gated potassium channel complex are mostly explained by antibodies to two of the complex components: LGI1 and Caspr2. Antibodies to LGI1 are responsible for the syndrome of limbic encephalitis with facio-brachial seizures, and those to Caspr2 with Morvan's syndrome (peripheral nerve hyperexcitability with psychiatric and sleep disturbance). Both of these conditions usually respond to broad-spectrum humoral immunosuppression. Antibodies to *N*-methyl-D-aspartate (NMDA) receptors, and more recently AMPA and GABA receptors, have increasingly well-defined phenotypes along with good theoretical, *in vitro* and *ex vivo* models of disease.

Antibodies to the water channel protein, aquaporin-4, and possibly to myelin oligodendrocyte glycoprotein (MOG), are associated with Devic's disease (neuromyelitis optica). The support for an antibody pathogenesis for these diseases largely rests upon there being a putative antigen at a feasible site, antibody binding experiments and response to immunotherapy.

**Neurological disease associated with systemic disorders and systemic autoantibodies** Several diseases are associated with antibodies that may have systemic effects, including effects on the nervous system, or have antibodies that are central to the diagnosis but which have questionable relevance in the pathogenesis.

The connective tissue diseases have a number of neurological manifestations which may or may not be related to the presence of the antibodies described as a part of the syndromes and sometimes more or less essential in the diagnostic criteria. The anti-neutrophil cytoplasmic antibodies (ANCA) are associated with some vasculitides. Although they may activate neutrophils and are necessary for the diagnosis in some diseases, for example in Wegener's granulomatosis (granulomatosis with polyangiitis), they are not essential to the pathogenesis or the pathology. Antibodies to the extractable nuclear antigens (ENA) are associated with a number of other connective tissue diseases such as primary and secondary Sjögren's syndrome which have associations with some neurological syndromes (e.g. sensory neuronopathy).

Antibodies to phospholipid and cardiolipin are associated with the antiphospholipid syndrome which may cause a catastrophic disorder of coagulation that may involve the CNS. In some cases this resembles multiple sclerosis and making the distinction between causation and association may be very difficult and lead to inappropriate therapies.

Paraneoplastic diseases overlap between humoral and T-cell mediated disease with the presence of antibodies defining the syndromes, and suggesting associated tumour types, but frequently T cells mediating irreversible damage to neural structures. These are discussed further here.

A paraneoplastic syndrome is a disease or symptom that is the consequence of the presence of cancer in the body, but not directly caused by the presence of cancer cells. The diseases are caused by immune factors presumably released by, or in response to, a tumour that cause damage to the end tissue and subsequently result in the phenotypic symptoms and signs. The agents causing the damage are presumed to be antibodies, T cells or other soluble molecules but these are often difficult to demonstrate. A number of well-known paraneoplastic antibodies are described (e.g. anti-Hu, anti-Yo and anti-Ri) which are associated with a group of phenotypically recognisable disorders such as sensory ganglionopathies, limbic encephalitis and the opsoclonus myoclonus syndrome. They are also associated with a number of underlying tumour types such as small cell cancers, breast and ovarian tumours but neither the antibody nor the tumour types co-segregate with one another (Table 3.3).

Many of the antibodies first described are to intracellular antigens and mechanisms of pathogenesis remain unexplained; in these the antibody may be an epiphenomenon and the disease mechanism T-cell mediated. These syndromes tend to be difficult to treat, and although identification and successful resection of the tumour may result in limitation of further progression, reversal or recovery is seldom seen. Increasing numbers of paraneoplastic syndromes are now being described where antibodies to surface antigens and receptors are present and where the antibody appears to have a direct effect. The first of these syndromes was the Lambert–Eaton myasthenic syndrome where voltage-gated calcium channel antibodies are almost certainly pathogenic. More recently, antibodies to surface channels in the encephalitides associated with antibodies to voltage-gated potassium channels, NMDA receptors and glycine receptors have been identified with a number of distinct phenotypical diseases associated with them.

### T-cell mediated neurological disease

T-cell mediated neurological disease is more difficult to define as the specific targets of T-cell receptors are more difficult to isolate. In clinical practice, T-cell mediated diseases are generally less reversible than B-cell mediated disease and perhaps because of this less responsive to current immunotherapy. However, increasing numbers of therapies are emerging that target key components of the T-cell immune response, especially cytokines.

Paraneoplastic diseases are described above and a number of these have T-cytotoxic mechanisms of cell injury (e.g. the anti-Hu, -Yo and -Ri associated syndromes).

The final common path to tissue damage in cerebral and peripheral nerve vasculitis involves T-cell infiltration of tissue and destruction of tissues associated with the T-cell infiltrate and the inflammatory milieu elaborated by those cells. The targeting of particular blood vessels has yet to be explained.

Multiple sclerosis is probably the most common and best described of the CNS neurological disorders, once again with perivascular T-cell infiltrates and myelin and subsequently axonal destruction in plaques of inflammation. Whether this process or a neurodegenerative underlying process is the primary mechanism of disease and whether underlying viral pathogens drive the initiation of inflammatory responses remains an ongoing debate.

**Table 3.3** Antibody-related paraneoplastic syndrome.

Name	Antigenic target	Function	Syndrome	Associated neoplastic tissues	Associated with tumour (%)
<b>Intracellular paraneoplastic antigens</b>					
Hu (ANNA1)	RNA-binding proteins	Neuronal development	Encephalomyelitis, LE, BE, PCD, sensory neuronopathy, gastrointestinal pseudo-obstruction	SCLC	98
Yo (PCA1)	Purkinje cell cytoplasmic target	Unknown	PCD, rare peripheral neuropathy	Ovary, breast	99
Ri (ANNA2)	Intracellular target unknown	Unknown	BE, opsoclonus myoclonus	Breast	96
CV2 (CRMP5)	Collapsin response mediator protein 5	Neuronal development and cellular plasticity in Purkinje cells	Hu-like. Also chorea, optic atrophy, myelopathy, neuropathies (various)	SCLC, thymoma	95
Ma2	40 kDa protein	Regulation of apoptosis	LE, BE	Testicular	96
Amphiphysin	Amphiphysin	Synaptic function	SPS, PERM, sensory neuronopathy	Breast, SCLC	95
Sox-1	Sry-related HMG box 1	Y-chromosome related DNA binding protein – neuronal differentiation	LEMS	SCLC	Unclear (no higher in paraneoplastic disease than tumour alone)
Recoverin	Retinal recoverin	Retinal calcium binding protein	Autoimmune retinopathy	SCLC, cervix, Müllerian tumour, endometrium, uterine	Uncommon – unclear percentage
GAD	Glutamic acid decarboxylase	Conversion of Glutamate to GABA	SPS	Infrequent or chance. Associated with type 1 diabetes	N/A
Zic4	Zinc finger binding protein 4	Neuronal development	PCD – often coexist with Hu	SCLC, gynaecological cancers	Unclear (no higher in paraneoplastic disease than tumour alone)

### Cell surface paraneoplastic antigens

Tr (DNER)	Delta notch-like epidermal growth factor-related receptor		PCD	Hodgkin's lymphoma	
VGKCh (LGI1)	Leucine rich, Glioma inactivated-1	Implicated in glioma metastasis. Transmembrane protein with unclear function	LE with faciobrachial seizures and serum hyponatraemia	Various tumours described – links not strong	<10
VGKCh (Caspr2)	Contactin associated protein-2	Paranodal structure	Morvan's syndrome and neuromyotonia	Thymoma	30–40
VGKCh (LGI1-Caspr-2 negative)	Unknown	Unknown	Epilepsies – phenotype and relevance unclear	Unknown	
VGCaCh	Voltage-gated calcium channel	Presynaptic transmitter release	Lambert–Eaton myasthenic syndrome	Small cell lung	>95
NMDAR	N-methyl-D-aspartate receptor	Glutamate receptor involved in plasticity responsible for learning and memory	Encephalitis with psychiatric features, dystonic movement disorder, stupor, dysautonomia and cognitive impairment	Ovarian teratoma Sometimes post inflammation/infection	~30–60
AMPA	$\alpha$ -Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor	Non-NMDA glutamate receptor involved in CNS plasticity, learning and memory	LE	Thymoma, lung, breast	50
GlyR	Glycine receptor	Inhibitory transmission in the spinal cord and brainstem linked to Cl <sup>-</sup> conductance	Atypical SPS and PERM	Thymoma, breast, lymphoma	10
GABA <sub>b</sub>	Gamma aminobutyric acid receptor	Inhibitory receptor linked to K <sup>+</sup> conductance	LE and seizures	Lung	~50–70
AQP4	Aquaporin-4	Water channel	Neuromyelitis optica	None	Rare
MOG	Myelin oligodendrocyte protein	CNS adhesion molecule responsible for myelin sheath completion and maintenance	NMO spectrum disorders	Unknown	Very rare

ANNA, antineuronal nuclear antibody; BE, brainstem encephalitis; LE, limbic encephalitis; NMDA, N-methyl-D-aspartate; PCD, paraneoplastic cerebellar degeneration; PERM, progressive encephalitis with rigidity and myoclonus; SCLC, small cell lung carcinoma; SPS, stiff person syndromes.

In the PNS there is evidence that CIDP is a T-cell mediated disease with evidence for deficiencies in the autoimmune regulator protein AIRE, reduced T-regulatory mechanisms, failure of Fas-Fas ligand lymphocyte down-regulation and mixed Th1 and Th2 cytokine profile up-regulation in the serum and the endoneurium. There is also evidence for B-cell mediated pathways.

### Cytokine-driven processes

Primary cytokine processes are less well described. A clear example of cytokine dysregulation occurs in the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M-protein and skin changes). Although there is a paraprotein in this disorder, it does not appear to play an obvious part in the pathogenesis. In addition, although plasma cells are frequently expanded, it appears that the central processes driving the disease are unregulated vascular endothelial growth factor (VEGF) and IL-6 production, possibly exacerbated by hypoxia-induced factor 1 $\alpha$  (HIF-1 $\alpha$ ). This unregulated cytokine drive results in proliferation, migration and maturation of B cells and increasing amounts of cytokine production resulting in multisystem symptomatology. Once again, interference with these processes within the pathway can result in stabilisation of the disease as long as there is not an essential requirement for the ablated aspect of the pathway (e.g. VEGF).

### Interfering with the immune system as a treatment for disease

The immune-mediated neurological diseases present opportunities for effective therapy. Immunotherapies work by a number of different mechanisms and sometimes more than one is required to effect a response. Sometimes, immunosuppression may be required in infection to modulate an overactive and damaging immune response. For example, in the treatment of HIV, TB meningitis or cysticercosis, antimicrobial treatment can result in a devastating immune response resulting in more damage than the primary infection.

Broadly, the mechanisms of action of drugs that modulate the immune system can be classified as follows:

- **Immunomodulatory:** intravenous immunoglobulin (IVIg) acts as an immunomodulatory agent by multiple mechanisms, plasma exchange by non-specific removal of soluble immune factors, and interferons by supplementation and modulation of the cytokine network. The mechanisms of IVIg action are poorly understood. Mechanisms interfering with B- and T-cell interactions, macrophage activity and complement are highly important but anti-idiotypic activity is unlikely to be a major mechanism. Plasma exchange non-specifically removes low molecular weight solutes including cytokines and antibodies (especially IgG) and can be quick and effective in its action in appropriate diseases (e.g. Guillain-Barré syndrome, systemic vasculitides and the antibody-mediated autoimmune encephalitides). Interferons modulate the immune response by unknown mechanisms.
- **Immunosuppressive:** steroids, oral immunosuppressants (azathioprine, methotrexate, mycophenolate, ciclosporin) or intravenous agents such as cyclophosphamide, depress immune responses more or less non-selectively. These agents are the backbone of the current immunotherapeutic pharmacopoeia. Steroids work quickly and effectively to suppress B- and T-cell mediated responses and sensitise cells to the effects of other immunosuppressants, particularly cyclophosphamide. However, their medium and long-term adverse event profiles limit their long-term use and in most circumstances the clinician is looking to

stop or substitute these agents as quickly as possible. Azathioprine, methotrexate and mycophenolate are easy to use with appropriate regular blood monitoring for adverse effects but they are rather slow to work. Cyclophosphamide is an excellent immunosuppressant and with cautious dose restriction, pulsed therapy and metabolite protection of the bladder epithelium by mesna toxicities are much less than with oral medication.

- **Replacement:** for example, IVIg in hypogammaglobulinaemic disorders. RNA enteroviruses are lytic and immunity relies on humoral rather than cytotoxic clearance. Patients with hypo- or agammaglobulinaemic disorders are susceptible to systemic RNA virus infection that may result in meningoencephalitis. Stabilisation relies upon supplementation of polyvalent immunoglobulins from donors with the normal commensal exposure to common viruses to maintain clearance.
- **Specifically targeted ablative therapies** (e.g. anti-CD20 and anti-CD52 monoclonal antibodies): these therapies are increasingly important in the treatment of immune-mediated disease, sometimes in combination with other immunosuppressants (e.g. rituximab and methotrexate in rheumatoid arthritis). The ability to directly interfere with, ablate or block a specific molecule in the immune system as a very powerful tool. Idiosyncratic and predictable but rare complications are the limiting factor in both the risks of initiating therapy and in long-term use. For example, PML is a known, usually fatal, complication of rituximab, natalizumab and others. Appropriate predictive testing and limitation of the length of exposure reduce the risks. However, for some diseases where death or severe disability is not an outcome then the use of these medications is probably not ethical, but in diseases with potentially worse prognosis they can be very powerful.
- **Specifically targeted molecules interfering with cytokine and chemokine networks** (e.g. anti-TNF, anti-VEGF and anti-IL-6 therapies): some of these therapies are targeted toxins (e.g. the '-cept' drugs, such as etanercept). Others are antibodies with anticytokine therapeutic activity such as bevacizumab which acts as an anti-VEGF agent, or tocilizumab which is anti-IL-6.<sup>1</sup>

### Inherited mutations of ion channels

Although rare, monogenic neurological channelopathies provide unparalleled insights into the mechanisms of neurological diseases. The clinical manifestations of some channelopathies are indistinguishable from common disorders whose aetiology is unknown, in particular primary generalised epilepsies and migraine. Thus, neurological channelopathies potentially identify signalling pathways and circuits involved in diseases that account for a large fraction of neurological practice. More broadly, they open a window onto the fundamental workings of the human brain, spinal cord, nerve and muscle.

A common feature of many channelopathies is that they cause discrete paroxysms, while the development of the nervous system is generally unperturbed, and affected individuals function normally

<sup>1</sup> The naming of the biological agents follows an organised schema. The last consonant describes the activity of the agent; for example, 'mab' is a monoclonal antibody and 'cept' a conjugated toxin. The penultimate syllable describes the structure and origin, such that 'xi' is a chimeric and 'zu' a humanised monoclonal. The second syllable describes the target activity, thus 'tu' is a tumour, li(m) the immune and 'ci' the circulatory system. Lastly, the first syllable is any euphonious collection of letters to make the drug name recognisable.

between attacks. In common with many other genetic diseases, ion channel mutations tend to present early in life. Some channelopathies are self-limiting, for instance causing neonatal seizures that remit spontaneously. Other disorders may not resolve and some present as attacks that give way to a fixed or progressive impairment, as seen in some muscle or cerebellar channelopathies. Among possible explanations for the developmental evolution of symptoms are changes in the expression of individual channels, maturation and compensatory alterations in CNS circuits, and excitotoxic damage to affected neurones and muscle cells.

Although most currently known channelopathies are dominantly inherited this pattern may, to some extent, reflect the difficulty of identifying families with recessive disorders, especially where penetrance is incomplete. Furthermore, some symptoms of channelopathies, such as migraine or seizures, are common and occur far more frequently as idiopathic disorders without clear Mendelian inheritance, so it is difficult to justify extensive sequencing of candidate genes in a patient without affected first degree relatives. A further difficulty is that some ion channel mutations have variable manifestations, even when the same mutation is inherited by different members of an affected family, consistent with an interaction with modifying genes or environmental factors.

### Channelopathies

Channelopathies can present in any area of clinical neurology (Figure 3.11).

#### Migraine

Two out of the three genes identified in dominant familial hemiplegic migraine (FHM) encode ion channels.

#### Epilepsy

Ion channel mutations can cause both focal and generalised seizure disorders, which range in severity from benign neonatal convulsions to early-onset epileptic encephalopathies. An important breakthrough was the realisation that an autosomal dominant pattern of inheritance occurs in some families where several individuals have febrile and other types of seizures. Febrile seizures are generally considered a benign and common self-limiting condition. In families with generalised epilepsy with febrile seizures plus (GEFS+), such seizures may persist beyond early childhood, or may be accompanied by non-febrile seizures. Mutations of at least four ion channel genes cause GEFS+ (Figure 3.12). Other epilepsy syndromes caused by ion channel mutations include malignant migrating partial seizures of infancy, Ohtahara syndrome, autosomal dominant nocturnal frontal epilepsy, rolandic epilepsy

(epilepsy with centrottemporal spikes), and Landau-Kleffner syndrome (a childhood epilepsy syndrome with language regression).

#### Movement disorders and ataxia

Channelopathies can cause paroxysmal dyskinesia, ataxia and hyperekplexia (exaggerated startle reaction).

#### Disorders of peripheral nerve and autonomic function

Mutations of one sodium channel gene can cause either paroxysmal pain or congenital insensitivity to pain. Some potassium channel mutations lead to neuromyotonia. Although not considered further in this review, CMTX (an X-linked hereditary neuropathy) is caused by mutations of connexin32. Connexins make up gap junction proteins, a type of intercellular channel.

#### Muscle disease

Channelopathies can result in congenital myasthenic syndromes, periodic paralysis or myotonia (Figure 3.13). Although myotonic dystrophy, the most common myotonic disorder, is not usually considered a channelopathy, it may have similar mechanisms because

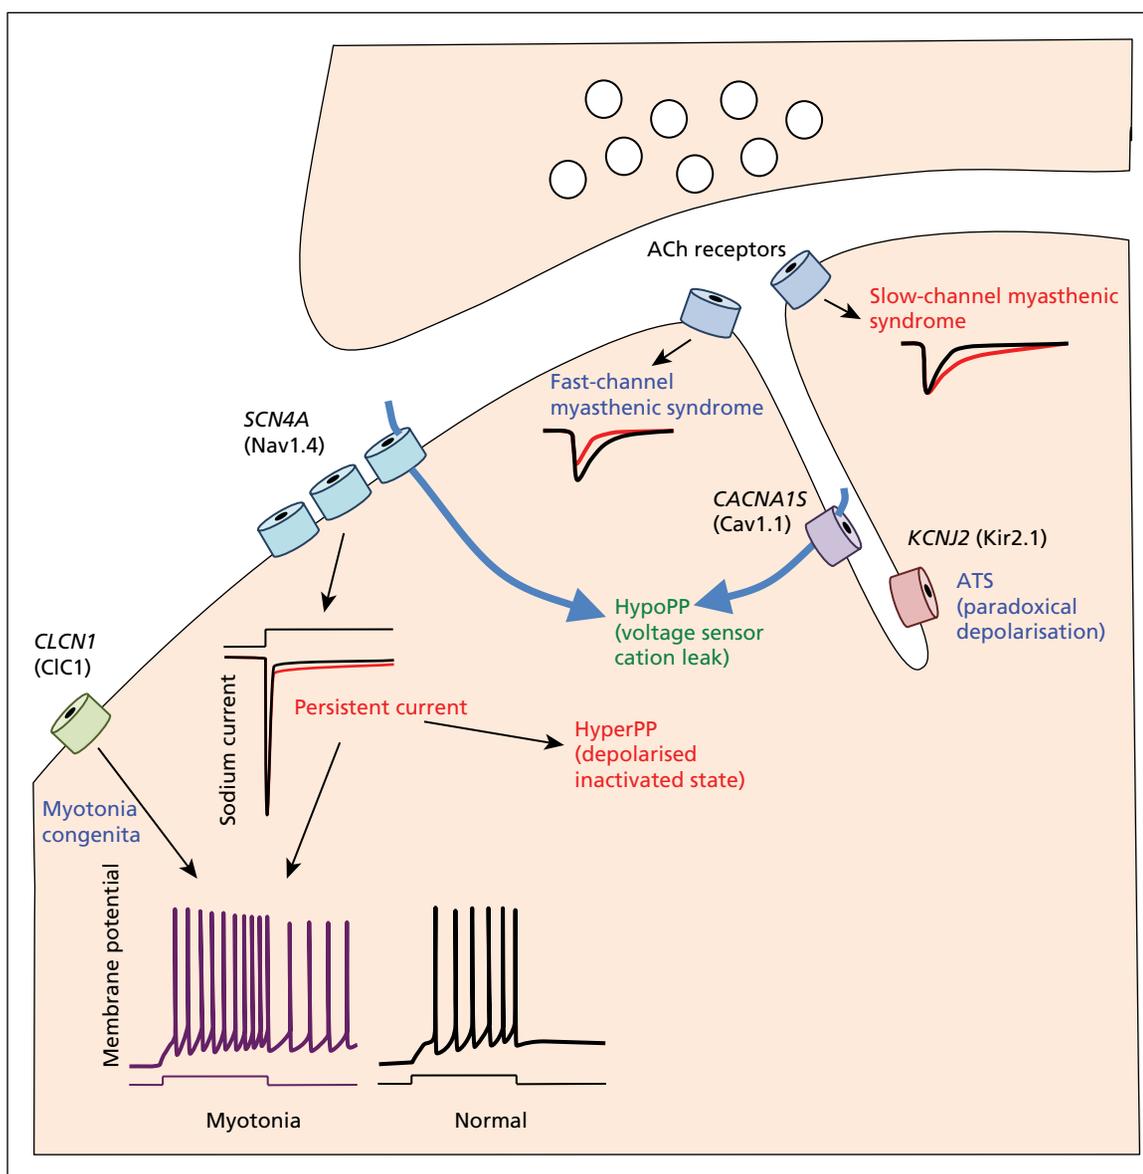

mutations of the *DMPK* gene in this disorder alter the processing of mRNA that encodes the muscle chloride channel.

#### Psychiatric and cognitive disorders

Mutations of glutamate receptors have recently been linked to autism and schizophrenia.

#### Disease causation in channelopathies

Understanding the features of a channelopathy requires knowledge of the cell type and regional expression of the mutated ion channel subunit, but also of the normal role of the ion channel in neuronal or muscle excitability, action potential propagation and synaptic transmission. Mutations can have multiple effects on ion channel biogenesis, trafficking and operation (Figure 3.14). Premature stop codons and splice site mutations may result in mRNA degradation, while other mutations can give rise to non-functional subunits that fail to assemble normally. Other, typically missense, mutations alter trafficking and voltage- or ligand-dependent gating. Larger scale deletions and duplications of entire exons or genes have recently been reported.

**Figure 3.13** Muscle channelopathies. Gain- and loss-of-function mechanisms that underlie muscle channelopathies are indicated in red and blue, respectively. The slowed end-plate current and persistent sodium current that occur in slow-channel myasthenic syndrome and hyperkalemic periodic paralysis (HyperPP), respectively, can lead to a vacuolar myopathy. The abnormal cation leak via the voltage-sensing pore of Cav1.1 or Nav1.4 that occurs in hypokalaemic periodic paralysis (HypoPP) represents a gain of abnormal function (green). ATS, Andersen–Tawil syndrome. Source: Adapted from Kullmann 2010, with permission of Annual Reviews.

Rather than listing all the known channelopathies we here group them according to the type of channel involved, and attempt to classify them as gain- or loss-of function.

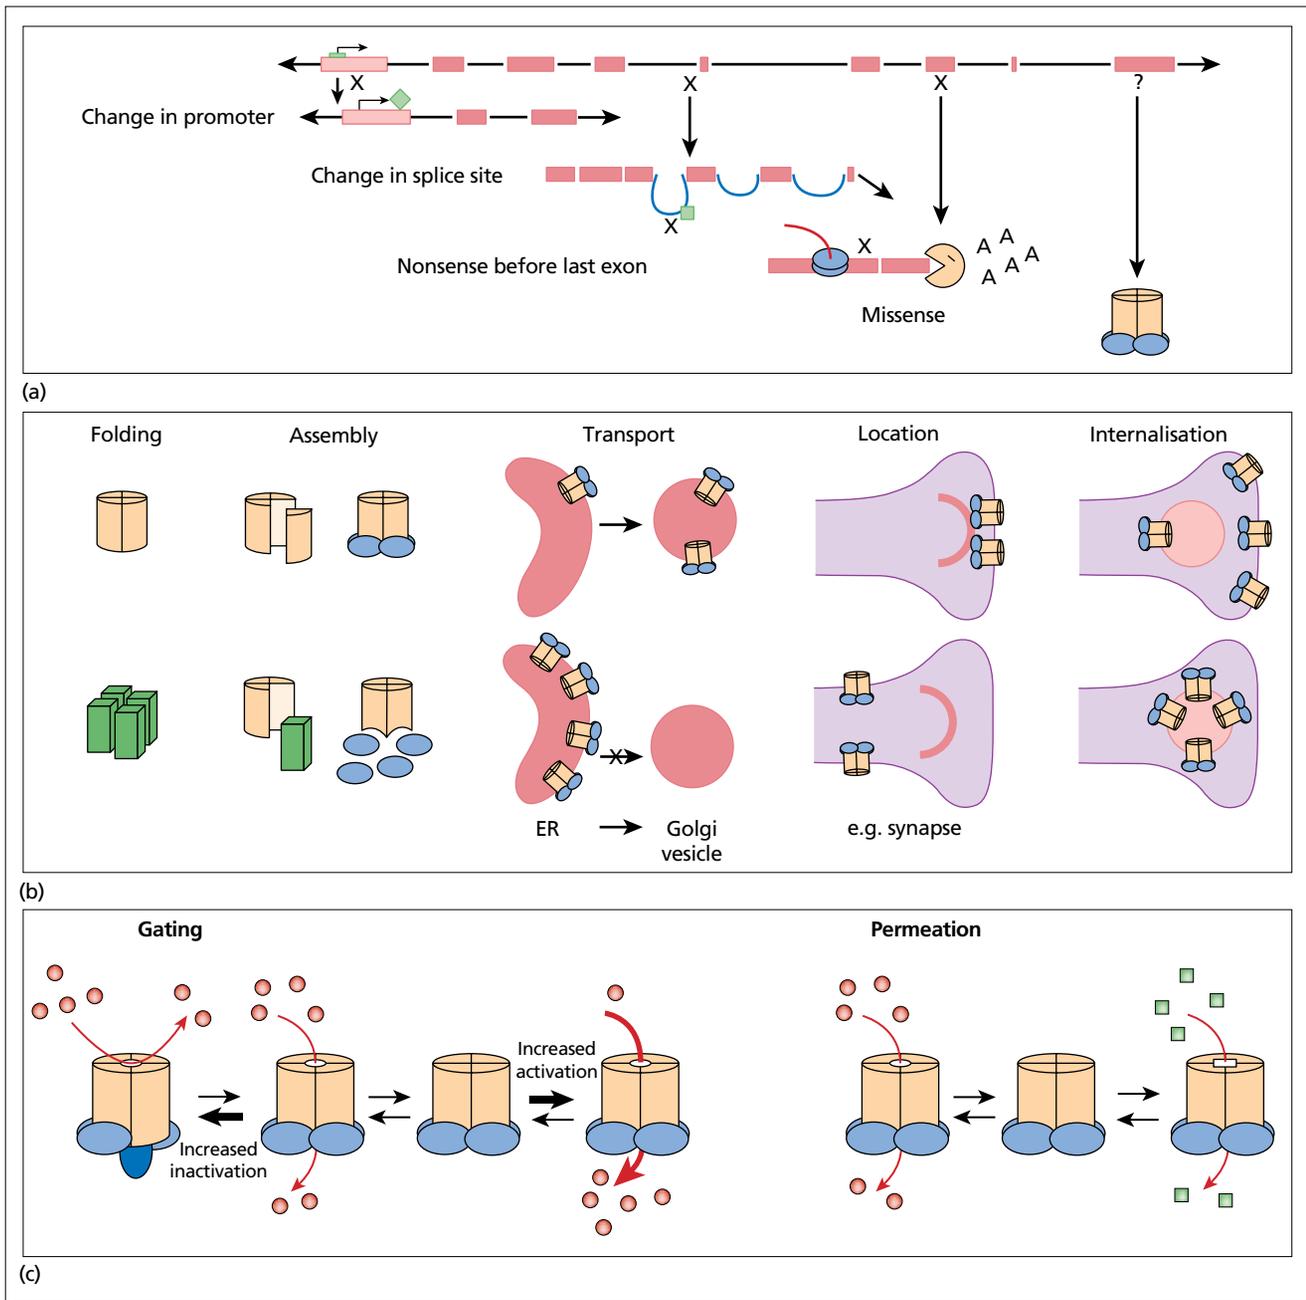

### Potassium channels

**Voltage-gated potassium channels** Voltage-gated potassium channels are the largest family of ion channels. They are composed of four homologous pore-forming subunits, as well as four intracellular beta subunits and normally contribute to regulating excitability or terminating action potentials. Each subunit of a voltage-gated potassium channel typically contains six trans-membrane  $\alpha$ -helices, of which the S4 segment acts as a voltage sensor (Figure 3.15). Such channels open upon membrane potential depolarisation. Their

activation kinetics vary extensively, and some are also modulated by intracellular messengers such as calcium or sodium.

The pore-forming subunits of inward-rectifying potassium channels, in contrast, lack the voltage-sensing module, and such channels conduct potassium ions preferentially at negative potentials. Thus, they have an important role in stabilising membrane potentials at rest, and only a minor role in repolarising action potentials.

To date, human mutations have been identified in only a few of the genes encoding potassium channels. Dominantly inherited loss-of-function mutations of *KCNA1*, which encodes the Kv1.1 potassium channel, cause episodic ataxia type 1, characterised by paroxysms of dyskinesia but also neuromyotonia. Other potassium channel mutations result in either progressive ataxia or paroxysmal

**Figure 3.14** Mutations can disrupt ion channel function through many different mechanisms: (a) alterations in transcription; (b) alterations in biogenesis; (c) alterations in function. Source: Kullmann and Schorge 2008. Reproduced with permission of Lippincott Williams & Wilkins.

dyskinesia and epilepsy. The finding that some gain-of-function mutations of a calcium gated potassium channel (*KCNMA1*) or a sodium-gated potassium channel (*KCNT1*) cause epilepsy is at first sight unexpected. A possible explanation is that enhanced repolarisation of the membrane potential reduces inactivation of sodium channels.

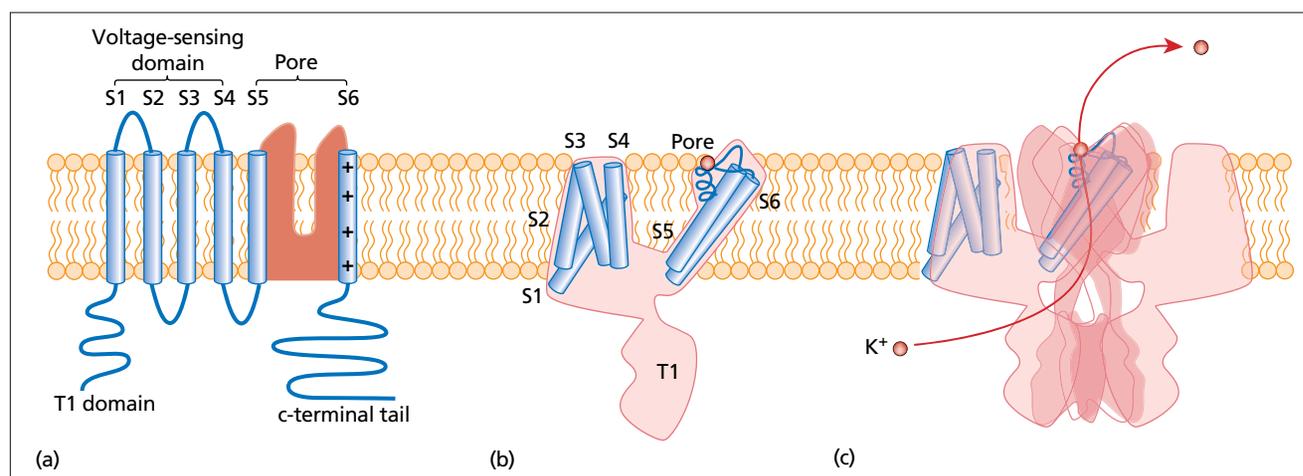

**Transient receptor potential channels**

Transient receptor potential (TRP) channels are closely related to voltage-gated potassium channels. They tend to be less selective for potassium ions (also allowing sodium and, in some cases, calcium ions to flow), and several members are sensitive to temperature and

various endogenous and exogenous chemical ligands. Several members of this group of channels have a major role in sensory transduction. Mutations of *TRPV4* can cause a broad range of abnormalities of peripheral nerve development and function, and mutations of *TRPA1* can manifest as a paroxysmal pain disorder.

**Sodium channels**

Sodium channels open rapidly in response to depolarisation and influx of sodium underlies the upstroke of the action potential. They are structurally homologous to voltage-gated potassium channels, although a single protein with four repeated domains plays the part of the four separate pore-lining proteins of potassium

**Figure 3.15** Structure of voltage-gated  $K^+$  channels. (a) Peptide chain showing the six transmembrane segments (S1–6) in the membrane, with the S4 voltage sensor indicated (+). The loop between S5 and S6 forms the pore and selectivity filter. The T1 domain and C-terminal are intracellular. (b) Conformation of a single subunit showing the approximate positions of S1–6 and the selectivity filter (Pore). The T1 domain is important for subunit assembly. (c) Four subunits assemble to make a channel in the membrane. The helices are only shown for one subunit for clarity. The path of a permeating  $K^+$  ion is indicated. Source: Kullmann and Schorge 2008. Reproduced with permission of Lippincott Williams & Wilkins.

channels. They have one or two associated  $\beta$  subunits with a single trans-membrane segment. An important feature of most sodium channels is that they close rapidly upon sustained depolarisation. Impairment of such fast inactivation occurs in gain-of-function mutations that affect the muscle sodium channel  $NaV1.4$  (encoded by *SCN4A*). Depending on the severity of the impairment in inactivation, muscle fibres are either prone to repetitive firing (myotonia) or can enter a persistent depolarised state, often accompanied by hyperkalaemia (hyperkalaemic periodic paralysis). Paradoxically, loss-of-function mutations of the *SCN1A* gene are an important cause of monogenic epilepsy. A likely explanation is that the encoded  $\alpha$  subunit of  $Nav1.1$  is preferentially expressed in cortical interneurons. Impaired excitability of these interneurons predisposes to seizures. A further unexplained finding is that other mutations of *SCN1A* are associated with FHM.

*SCN9A*, *SCN10A* and *SCN11A* encode different sodium channels expressed in peripheral nerve. Mutations that impair inactivation cause paroxysmal pain disorders, while recessive loss-of-function mutations manifest as congenital insensitivity to pain.

### Calcium channels

Calcium channels have a similar structure as sodium channels although their kinetics are generally much slower. They are divided into three groups according to their kinetics. One of the L-type channels,  $CaV1.1$ , has a central role in excitation–contraction coupling in skeletal muscle. P/Q type channels contribute to triggering neurotransmitter release at presynaptic terminals, but are also expressed abundantly in the cerebellar cortex. Low threshold, transiently activating T-type channels have an important role in burst-firing of thalamic neurones. The disease mechanisms of calcium channelopathies are incompletely understood. Hypokalaemic periodic paralysis is caused by mutations of *CACNA1S*, which encodes the muscle calcium channel. However, mutations of the sodium channel gene *SCN4A* can give the same phenotype. Remarkably, almost all mutations of either channel causing hypokalaemic

periodic paralysis affect arginine residues in the S4 voltage sensor. These residues are positively charged and sense the trans-membrane potential gradient. Although loss of an arginine residue might be expected to alter voltage activation, hypokalaemic periodic paralysis is actually thought to result from an abnormal cation pathway through a cavity lining the S4 segment, arising from substitution of an arginine residue by a smaller amino acid side-chain. The association of paralysis with hypokalaemia may reflect failure of inward-rectifying potassium channels to stabilise the membrane potential, because these channels fail to conduct when the extracellular potassium concentration is low.

Loss-of-function mutations of *CACNA1A*, which encodes the pore-forming subunit of the CNS calcium channel  $CaV2.1$ , cause episodic ataxia type 2, while gain-of-function mutations cause FHM. This channel contributes to triggering neurotransmitter release at synapses throughout the nervous system, and is also abundant in cerebellar Purkinje and granule cells.

### Chloride channels

These are unrelated to the voltage-gated channel super-family and are more closely related to some trans-membrane transporters. In skeletal muscle, dimeric  $ClC-2$  channels have a moderate open probability at rest, and have an important role in setting the resting membrane potential. They activate further upon depolarisation. Loss-of-function mutations destabilise the membrane potential and predispose to repetitive discharges. Both dominantly inherited and recessive mutations occur, described as Thomsen and Becker myotonia, respectively. Some cases are compound heterozygotes, where two different recessive mutations occur in an individual, making the task of genetic counselling more difficult.

### Ligand-gated ion channels

Fast neurotransmission is mediated by ionotropic receptors, or ligand-gated ion channels. Mutations have been identified in all the main groups.

**Acetylcholine receptors** Nicotinic receptors (so called because they are activated by nicotine) are either homopentameric or heteropentameric. At the neuromuscular junction ACh opens receptors made up of  $\alpha 1$ ,  $\beta 1$ ,  $\delta$  and  $\epsilon$  subunits, encoded by *CHRNA1*, *CHRN1*, *CHRN2* and *CHRN3*. Mutations of any of these subunits can cause a congenital myasthenic syndrome. These are caused by trafficking or assembly defects, or by a change in receptor kinetics (fast or slow channel syndrome), with different implications for drug treatment. Early in development a  $\gamma$  subunit, encoded by *CHRNA3*, takes the place of the  $\delta$  subunit. *CHRNA3* mutations cause multiple pterygium (Escobar's syndrome), thought to be mediated at least in part by impaired fetal motility.

Of the receptor subunits expressed in the CNS, mutations have been identified in *CHRNA4*, *CHRNA2* and *CHRN2* (encoding the  $\alpha 4$ ,  $\alpha 2$  and  $\beta 2$  subunits, respectively) in autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE). CNS nicotinic receptors mediate fast excitatory transmission to a subset of cortical interneurons, and indirectly modulate excitation of principal cells. Other presynaptic modulatory effects of ACh have also been reported. How the mutations give rise to epilepsy is incompletely understood.

**GABA<sub>A</sub> receptors** These receptors are structurally homologous to nicotinic receptors but are permeable to chloride ions instead of sodium and potassium. They mediate fast inhibitory transmission and are the sites of action of benzodiazepines and several other anticonvulsant, anaesthetic, hypnotic and anxiolytic drugs. Loss-of-function mutations in several subunits have been reported in epilepsy, including *GABRA1*, *GBRB3* and *GABRG2*, encoding the  $\alpha 1$ ,  $\beta 3$  and  $\gamma 2$  subunits, respectively.

**Glycine receptors** These are also structurally homologous to GABA<sub>A</sub> receptors, and mediate fast inhibition in the spinal cord and brainstem. Dominant or recessive loss-of-function mutations of *GLRA1* and *GLRB* cause familial hyperekplexia.

**Glutamate receptors** Glutamate receptor mutations were only recently reported. This was a puzzle because these receptors underlie the overwhelming majority of fast excitatory synaptic signals in the brain and spinal cord. They are heterotetrameric receptors, subdivided into three main classes. AMPA ( $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptors, which open and desensitise very rapidly; kainate receptors, with somewhat slower kinetics; and NMDA receptors. NMDA receptors are permeable to calcium but require not only glutamate but also another ligand (glycine or the D-isomer of serine), as well as membrane depolarisation, to open. This combination of properties explains their role as detectors of the coincidence of presynaptic and post-synaptic activity, which triggers calcium influx leading to synaptic plasticity.

The role of glutamate receptors in synaptic plasticity goes some way to explain why rare mutations of NMDA receptors occur in schizophrenia. One subtype, *GRIN2A* (encoding the NMDA receptor subunit GluN2A), is also associated with rolandic epilepsy and Landau-Kleffner syndrome (paediatric epilepsy with loss of language skills).

### Acquired versus inherited channelopathies

Several of the autoimmune disorders associated with (or caused by) antibodies recognising extracellular epitopes affect ion channels: AChRs, P/Q-type Ca<sup>2+</sup> channels, and glycine and NMDA receptors. Aquaporin 4 is also a transmembrane protein that permits the flow

of water between glial cells. As for Caspr2 and LGI-1, these interact with voltage-gated K<sup>+</sup> channels of the Kv1 family, although LGI-1 has also been implicated in modulation of AMPA receptor targeting and function. mGluR1 is a G-protein coupled receptor that is coupled to a cascade that leads to the opening of transient receptor potential channels. Intriguingly, several channels targeted directly or indirectly by autoantibodies are also implicated in inherited diseases. The hereditary channelopathies include mutations of AChRs, P/Q-type Ca<sup>2+</sup> channels, Kv1.1, and GlyR1 glycine receptors.

In some cases, the phenotype of the hereditary channelopathy overlaps extensively with the acquired autoimmune syndrome affecting the same channel. Thus, several congenital myasthenic syndromes caused by mutations of AChRs are characterised by muscle weakness and fatigability. However, cholinesterase inhibitors, which are effective in myasthenia gravis, are not always effective in the hereditary forms. This can be explained at a molecular level by taking into account the fact that some missense mutations lead to a prolongation of the opening duration of the receptor. For P/Q-type Ca<sup>2+</sup> channel mutations, in contrast, the hereditary channelopathies are dominated by symptoms attributable to neocortical or cerebellar circuits (hemiplegic migraine, episodic or progressive cerebellar ataxia). The channel is abundant both in the periphery and in the CNS, and a possible explanation for the neuromuscular presentation of Lambert-Eaton myasthenic syndrome is that the channels at the neuromuscular junction are more accessible to circulating antibodies. However, why do missense or truncating mutations of the *CACNA1A* gene that encodes the main pore-forming subunit of P/Q-type channels not detectably affect ACh release at the neuromuscular junction? A possible explanation is that the safety factor for transmission is sufficient to mask subtle derangements that are sufficient to unbalance signalling at probabilistic synapses in the CNS.

The phenotype of hereditary hyperekplexia affecting the GlyR1 subunit is very similar to acquired hyperekplexia. Acquired neuro-myotonia caused by anti-Caspr2 antibodies overlaps with the phenotype associated with missense or truncating mutations of the gene encoding Kv1.1. However, these mutations are also associated with disturbed cerebellar coordination, hence the term episodic ataxia type 1, used to describe this channelopathy. Mutations in the *LGI-1* gene, interestingly, lead to a form of non-lesional temporal lobe epilepsy, although the seizures in this condition frequently have auditory features (accompanied by auditory hallucinations or triggered by sounds), and therefore differ from the faciobrachial dystonic seizures associated with autoantibodies against the same protein.

## CHAPTER 4

# The Language of Neurology: Symptoms, Signs and Basic Investigations

Charles Clarke<sup>1</sup>, Matthew Adams<sup>1</sup>, Robin Howard<sup>1</sup>, Martin Rossor<sup>2</sup>, Simon Shorvon<sup>2</sup> and Jason Warren<sup>2</sup>

<sup>1</sup>National Hospital for Neurology & Neurosurgery

<sup>2</sup>UCL Institute of Neurology

Knowledge of neuroanatomy and basic neuroscience equips a clinician with the background essential for clinical work. However, there remains a gulf between these scientific aspects of neurology and its language, meaning the words we use to interpret and communicate clinical features in health and disease. The purpose of this chapter is to try to fill that gap and outline the practice of day-to-day neurology:

- To provide a framework for examination, clinical diagnosis and investigation
- To introduce terminology used to capture concepts and patterns – the vocabulary of neurology, and
- To discuss some illustrative patterns essential to recognise.

Facets of the history of neurology and some subtleties of clinical practice are mentioned to provide a brief working overview.

Practical neurology is sometimes straightforward but remarkably difficult at others. Our purpose as diagnosticians is to answer one question: whether or not there is a recognisable disease. In no other branch of medicine is recognition of clinical patterns more important, nor are they more reliable. Despite major advances in imaging, neurogenetics and neuropathology, clinical practice continues to follow a traditional systematic approach:

- Assemble the elements of clinical observation in a structured fashion commencing with the history and symptoms, physical signs found on examination and followed by results of appropriate investigations.
- Recognise by assessing and sifting the layers of information, the site of a lesion, its nature and/or the system affected.

Failure to follow this approach can lead to errors and especially misjudging the seriousness of a problem, either overestimating symptoms – thus leading to alarm and expense or, vice versa, missing a serious disease. Symptoms that do not relate to any serious structural disease are common in practice. These are discussed further in Chapter 22 (see Non-organic disorders in neurology).

## Elements of diagnosis

The components of clinical diagnosis in neurology – its essence and singularity – are the clinical history and examination and the interplay between the two. Many people find neurology hard, both because of this interplay and also because of its breadth: few specialities deal with such a wide range of conditions.

In some conditions, such as migraine or epilepsy, we rely on the descriptions of symptoms, that is a narrative from the patient or an eyewitness. There are no physical signs. In other situations, examination has a pivotal role, for example the signs indicating emergence of a spastic paraparesis or a neuromuscular disorder. When one pattern of symptoms might be explained by pathology in different parts of the nervous system or by different mechanisms, interpretation of physical signs is of particular importance. However, despite its sophistication the nervous system has a relatively limited repertoire of symptom complexes. For example, the pain of a headache is often much the same whether the problem is benign or sinister.

Diagnosis is a two-stage process:

- 1 Do the history and physical signs point to the site of the lesion, or lesions or to a system?
- 2 Do the time course and character of the findings point to a recognisable disease?

It is the recognition of these patterns that enables reliable diagnosis.

## History

The narrative, from the patient, relatives or other witnesses provides primary data. This is vital information. Details of symptoms or events at the onset of a condition are helpful as a first step towards a diagnosis. How to take a present, past and family history is assumed here but there are three areas where difficulties and pitfalls commonly occur.

First, vividness can only be provided by an account taken verbatim, of events. With electronic records and abbreviation overtaking written notes, simple narrative and a clear record of what happened remain important. For example, 'Fitted in bus on way to A&E – bitten tongue' is familiar medical shorthand seen in emergency notes. The inference is that a generalised tonic-clonic seizure took place. The phrase does not indicate what the patient actually said:

I was standing on the Number 73 bus near King's Cross first thing in the morning taking my mum to the hospital at University College. I felt all dizzy and sick, my eyes went all funny, then my legs went weak and out I went. I came to on the floor, between the seats, in a pool of blood. My mother says I fainted. But then the ambulance came and they said I was shaking. I had bitten my lip quite badly. I was right as rain within one minute but the lady in the ambulance said she thought I had had a fit.

From this description – the brief duration of loss of consciousness and transient shaking – syncope seems an obvious answer, and not the generalised tonic-clonic seizure implied by the original medical note. Shorthand and jargon leading to misdiagnosis can have far-reaching consequences.

Secondly, it is important to identify the temporal pattern of symptoms.

- Intermittent events or attacks with full recovery: common causes are epilepsy, migraine, syncope, transient ischaemic attacks. There are other much rarer causes such as paroxysmal dyskinesia.
- Intermittent, with relapses and remissions: multiple sclerosis (MS) is the typical example, but it should not be forgotten that many conditions fluctuate as a result of the patient's affective state and environmental factors.
- Progressive, chronic. Neurodegenerative and neoplastic disorders tend to follow this pattern.
- Acute or subacute and progressive. These are usually infective or inflammatory disorders.
- Acute onset, single insult, with some recovery. Stroke is the prime example. Guillain-Barré syndrome is another.

The long time scale of some neurological conditions can be important – a history of prolonged febrile convulsions in infancy or a head injury long forgotten may be of relevance to episodes of loss of consciousness in adult life.

Other aspects of the history can point to a diagnosis, such as the family history, the latter frequently overlooked.

Thirdly, there is the matter of a physician's attitude, that balance between critical appraisal and sympathy – and a reminder that our principal purpose is to help. Judgmental attitudes not only interfere with diagnosis; they are frequent causes of complaints and the need for second opinions.

Many patients find it difficult to answer unexpected or unfamiliar questions quickly and clearly. There is no such thing as a 'hopeless historian' and if a history is incomplete, it is often as much the fault of the interrogating physician as of the patient. Patients today are also better and more accurately informed than in the past. However, the unsympathetic neurologist is still described too frequently and vividly to be discounted. Whether or not symptoms reflect serious disease, patients do actually suffer from their complaints. That first visit frequently carries a burden – a serious diagnosis is often in mind. Patients and their relatives hang hopes and fears upon single words, phrases and comments made by medical or nursing staff. Furthermore, depression, and psychiatric co-morbidity are features of many neurological conditions and anxiety is common in any clinical situation, serious or apparently trivial.

### Nature of symptoms

Textbooks that provided the foundations of clinical practice emphasised the distinction between primary and secondary symptoms, and positive and negative phenomena. This approach needs to be understood, although the classification is not rigid. Most anatomical brain, cord, root and nerve lesions are destructive. They cause negative phenomena such as paralysis. Destructive lesions may also cause positive secondary phenomena, typically when neuronal inhibition is released (e.g. exaggerated tendon reflexes, clonus). Positive is also used to describe irritative phenomena, usually electrical such as seizures or myoclonus.

Abnormalities of function can thus be regarded in two ways:

- 1 Primary (direct) abnormalities, often negative: one part fails to work. Primary abnormalities can also be positive (irritative), for

example focal seizures resulting from a cortical glioma, pain in the distribution of a trapped median nerve or hemifacial spasm.

- 2 Secondary (indirect) abnormalities, usually positive, often indicate over-activity resulting from release of inhibition (e.g. clonus).

## Neurological examination

### Preliminary assessment

Many features become apparent during conversation, during the narrative history. The neurologist Gordon Holmes wrote in 1946: 'More can often be learned of a patient's disabilities by observing his ordinary actions, as dressing and undressing, walking when apparently unobserved than by specific tests.' We rely heavily on this apparently casual approach unconsciously on a daily basis. It is the way we form an impression when meeting someone new, and gauge our own friends and colleagues. There is much to be learnt from studying this approach before more formal examination. We all use such skills intuitively but can refine them. The following can be readily assessed prior to more formal examination on a couch:

- Greeting, manner, orientation, attention, mental state, mood, personal hygiene, dress
- Cognitive conversational clues – for example a mildly cognitively impaired patient turning towards a relative to answer a simple question
- Speech, language and facial appearance
- Gait and stance
- Clumsiness, weakness of one side
- Involuntary movements
- Patterns of sensory symptoms
- Risk factors, lifestyle, tobacco, alcohol, drug abuse
- Obsessions, religion, illness beliefs, fears
- Degree of disability, aids – both at home and outside, state benefits
- Aspects of daily living, travel, driving, employment, dangerous sports
- Endocrine or general medical clues, such as appearance suggestive of hypothyroidism or hypopituitarism.
- Relations with general practitioners, hospitals and paramedical staff, nursing staff and specialists
- Expectations and ideas about treatment.

### Brief neurological examination

It is assumed that the reader can carry out a general examination and understands the rudiments of neurology. Detailed neurological examination for every case is simply impracticable in busy clinical life. In many settings we need to rely on a robust, safe and practical examination tailored to the individual, and to be guided by the history. A man who faints on a bus does not need two-point discrimination to be assessed. A tendency to dwell on excessive detail of examination seemed to beleague generations of neurologists. Table 4.1 illustrates a brief neurological examination, completed easily within 5 minutes and readily adaptable to circumstance.

### Detailed neurological examination

More detailed examination is sometimes necessary and a full examination is often essential when evaluating a complex cases. The scheme developed at the National Hospital is widely used and

**Table 4.1** Brief 5-part neurological examination.

<b>1 Look at the patient</b>	<b>4 Lower limbs</b>
General demeanour	Tone
Speech, language, cognition	Power (hip flexion, ankle dorsiflexion)
Gait, heel-toe, possibly	Coordination
Romberg's test	Reflexes
Arm swinging	Plantar responses
<b>2 Head</b>	<b>5 Sensation</b>
Fundi	Simply ask, in most: is it normal?
Acuity (if appropriate)	
Pupils	
Eye movements	With an appropriate general
Facial movements	examination, including blood
Tongue	pressure this assessment is highly
	unlikely to miss serious disease
<b>3 Upper limbs</b>	
Posture of outstretched arms	
Wasting, fasciculation	
Tone, power	
Coordination	
Reflexes	

adapted into Table 4.2. This helps to avoid omitting important data and records information. The order presented here is the way in which most neurologists work; it is helpful to follow it.

### Cognition and mental state

Much will have taken place during the clinical history. A written record of the cognitive assessment is useful to document the situation. Many simple screening tests are used to assess basic data such as orientation, recall, naming and reading ability.

More detailed screening tests are also readily available. The Queen Square Cognitive Screening Tests are used widely; there are many others. These assess:

- Orientation and alertness
- Language
- Literacy
- Praxis
- Memory, and
- Right hemisphere function.

These screening tests provide an accurate assessment in a clinic or at the bedside and can be confirmed and explored by further detailed clinical psychometry (see later and Cognitive functions and their clinical syndromes; Neuropsychometry, Chapter 8).

Episodes of disturbed consciousness are discussed in Chapter 7 (see Differential diagnosis of epilepsy), and coma, stupor and similar states in Chapter 20 (see States of impaired consciousness).

### Skull, scalp and spine

Skull and scalp examination is often omitted; abnormalities of contour and circumference, old burr holes or gnarled pulseless scalp vessels and skull bruits may be found. One author uses the following technique for listening for bruits, to abolish extraneous noise from eyelid muscles and respiration:

- Ask the patient to close both eyes, gently
- Rest the bell of an old-fashioned stethoscope over one closed lid
- Ask the patient first to open the other eye, and
- To stop breathing, briefly.

Examine the spine and its contour. Assess for scars, stiffness, deformity, pain, spinal bruits and for tufts of hair, dimples, sinuses or suggestions of congenital abnormalities.

### Cranial nerves

#### I: olfaction

Two test substances from a selection of clove oil, peppermint, mint, eucalyptus oil – or simply soap, coffee or an orange – are adequate to determine whether someone can distinguish between odours. More complex olfactory test kits are becoming more widely used, for example in Parkinson's or Alzheimer's disease (see Olfactory nerve, Chapter 13). Ammonia is sometimes available, supposedly to assess trigeminal afferent responses. Such a highly irritant substance should be avoided.

#### II: vision, pupils and fundi

Visual acuity: a well-lit 3-metre handheld Snellen chart is usually adequate. Correction with the patient's distance lenses or a pin-hole (easily fashioned from paper) may be needed. A record of acuity is one hallmark of a careful examination (see also Chapter 14).

Visual field examination to finger confrontation is highly reliable for picking up hemianopic and visual attention defects. When appropriate, follow this by confrontation testing with a 5-mm white and 5-mm red pinhead, or other target. One technique is to ask the patient to cover their left eye and fix the gaze of their right with your own left eye – pupil to pupil. Remember that the visual field is not planar but part of a sphere: move a target along the circumference of a circle, about 50 cm away from the eye. Commence with the pinhead target behind the ear and thus outside the visual field and move it towards the point of fixation. In the normal person both a red and white pinhead will be perceived at around 90° from the visual axis.

There are various manoeuvres using white and red-headed pins. One suggestion is to ask for a single word response. With the white pinhead, tell the patient to say: 'NOW', when they see the pinhead. With the red pinhead, tell the patient to say 'RED' when they see it.

Central field defects: use an Amsler grid, or, ask the patient to look at newspaper text and indicate any holes in their vision.

Colour vision is speedily assessed with Ishihara plates (still in use after nearly a century), or with detailed 100 Hue Test cards.

Pupil reactions are seen best in low levels of illumination using a bright light shone through the lens, approaching from the temporal side to avoid producing convergence. Subtle abnormalities of the pupillary response to light (e.g. an early Horner's syndrome) can sometimes be picked up by darkening the room. Cross-illumination – a pen torch at right angles to the visual axis – will help light up an iris of a darker shade. Putting these two together (direct and cross-illumination), many a pupil apparently unreactive in daylight, such as in old age (senile miosis) can be seen to constrict. The swinging light test, especially in dim light, can identify a relative afferent pupillary defect. Other abnormalities of the pupils are discussed in Chapters 14 (see Examination) and 20 (see Pupillary responses).

Fundus examination takes experience to perfect. The crux is to develop a suitable personal technique. Suggestions are:

- Have the patient seated, gazing horizontally – not at the ceiling. Suggest that they gaze at some distant specific object. Mention there is no problem if they blink. These manoeuvres avoid one's own clothing or hair falling into the subject's face,

**Table 4.2** Detailed neurological examination.**Historical details**

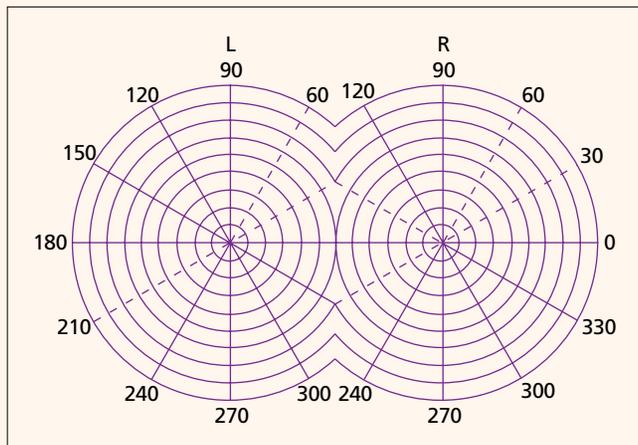

Main complaints  
 History of present illness  
 Past illnesses  
 Review of previous opinions, practice notes, etc.  
 Family history, with details of size of family  
 Social, personal, alcohol, drugs, tobacco, etc.  
 Travel, occupation, etc.  
 Review of systems:  
 cardiovascular  
 respiratory  
 gastro-intestinal  
 genito-urinary  
 endocrine  
 psychiatric history  
 allergies – drug and other

**Examination**

Physical appearance, initial appraisal  
 Mental state and cognition  
 Speech, language functions, evidence of higher function problems  
 Skull and spine  
 Gait, stance, balance  
 Hand preference – writing, etc.

**Cranial nerves**

I. Olfaction  
 II. Visual acuity  
 Visual fields – describe/chart

**Fundus**

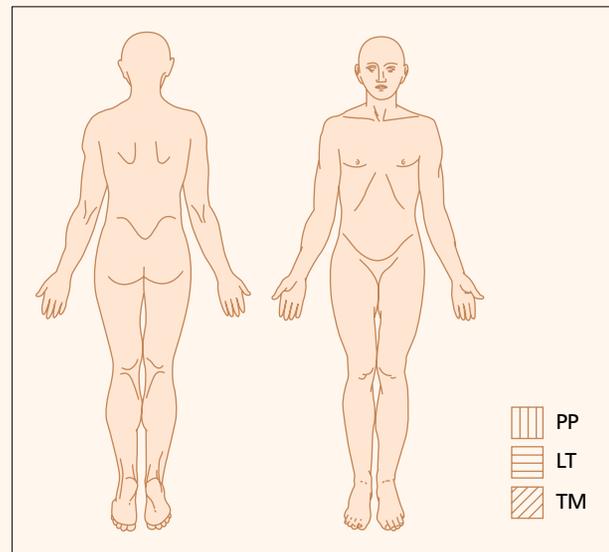

Pupils (mm, shape, reactions)  
 III, IV, VI. Range of ocular movements, nystagmus  
 Inspection of each eye, proptosis, cornea, primary position of gaze  
 V. Facial sensation, corneal reflexes. Power: masseter, temporalis.  
 Jaw jerk  
 VII. Facial symmetry, weakness, abnormal movements, taste  
 VIII. Hearing, Rinne, Weber, vertigo, nystagmus  
 IX, X. Swallowing, phonation, gag reflex, pharyngeal sensation  
 XI. Sternomastoids, trapezii  
 XII. Tongue appearance, speed, central protrusion, fibrillation

**Motor system**

Abnormal movements – describe  
 Posture of upper limbs – describe  
 Tone  
 Power  
 MRC Scale 1/5 and/or describe wasting; fasciculation, muscle consistency  
 Assess limbs, neck, diaphragm, abdomen  
 Coordination (finger–nose, heel–shin, alternating movements, foot tapping, etc.)  
 Reflexes:  
 jaw jerk  
 biceps jerks  
 supinator jerks  
 triceps jerks  
 finger jerks  
 abdominals (upper and lower)  
 knee jerks  
 ankle jerks  
 plantar responses  
 other reflexes (state)

**Sensation**

Assess posterior columns: vibration (128 Hz, VS), joint position (JPS), light touch (LT), 2-point  
 Assess spinothalamic pathway: pain (PP), hot/cold (TM)  
 Chart findings: PP, TM, LT, etc.

**General physical examination**

Cardiovascular, BP, respiratory, abdomen, endocrine, skin, nodes, joints

**Summary of findings****Formulation****Provisional diagnosis**

help fixation and discourage following the ophthalmoscope light source.

- For the left fundus, look through the ophthalmoscope with your own left eye. This encourages the patient to look past your head and to fixate. Do not close your own right eye; if this is hard to achieve, cover it with a free right hand. This helps your viewing left eye to focus on infinity through the ophthalmoscope, and allows your face to relax.

### III, IV and VI: eye movements

Recently acquired double vision is a frequent reason for urgent referral and for many doctors a cause of confusion and anxiety. This seems especially so if the 'four formal rules' for diplopia (Table 4.3) are followed rigidly for every case. An alternative, shorthand system relies much on recognition at a glance: every experienced neurologist uses this technique. This simple scheme diagnoses most cases immediately by seeing if the diplopia fits one of four patterns. A tendon hammer shaft is a convenient tool for the patient to follow.

**VI: abducens nerve palsy** This causes:

- The complaint of double vision with two images side by side (i.e. diplopia with horizontal separation)
- An evident convergent squint
- Double vision that disappears on looking away from the weak lateral rectus muscle and vice versa – worse towards the weak muscle in the obviously squinting eye, and
- No abnormality in reaction to light in the pupil, and no ptosis.

Remember that a lateral rectus palsy can be caused either by a VIth nerve lesion or by disease of the lateral rectus muscle or neuromuscular junction.

**III: oculomotor nerve palsy** A complete IIIrd nerve palsy causes:

- Ptosis – the upper lid drops, covering the eye completely
- A large pupil unreactive to direct light (the contralateral pupil constricts normally)
- An eye (on lifting the upper lid gently) facing down and out.

Compression of the IIIrd nerve by an enlarging posterior communicating artery aneurysm is a common cause.

The term partial IIIrd nerve palsy usually implies sparing of the pupillary and lid parasympathetic fibres; these lie on the undersurface of the IIIrd nerve and have a separate blood supply. The pupil remains normal. Ptosis is incomplete. The eye faces down and out. A complication of diabetes is a typical cause (see Diabetes mellitus, Chapter 26).

**Internuclear ophthalmoplegia** Damage to the medial longitudinal fasciculus in the brainstem causes an internuclear ophthalmoplegia (INO):

- Disconjugate horizontal eye movements (i.e. movements not yoked together – the eyes move horizontally at different velocities). One suggestion to help observe disconjugate movement is to look at the

centre of the patient's forehead, otherwise there is a tendency for the examiner to fixate on one eye and miss what is happening to movement in the other.

- Incomplete adduction of one eye – and when this is so:
- Coarse jerk nystagmus is seen on lateral gaze in the other eye (i.e. on abduction).

Internuclear ophthalmoplegia is described as left-sided when there is failure of left adduction (i.e. looking to the right). There are various varieties of INO (see Internuclear ophthalmoplegia, Chapter 14).

**IV: trochlear nerve palsy** A IVth nerve palsy, causes:

- A complaint of double vision on looking down (e.g. descending stairs)
- Twisted images (i.e. one at an angle to the other), known as torsional diplopia
- Head tilt away from side of superior oblique muscle weakness
- No obvious squint.

This is a distinct rarity compared with IIIrd and VIth nerve palsies and INO.

**Four rules for diplopia assessment** There are numerous other varieties of weakness of the extraocular muscles and the more detailed approach becomes necessary when cases do not fit into the patterns above. The four formal rules established in the early twentieth century are logical and invaluable in such complex cases (Table 4.3). Even using them, some cases of ocular muscle disease (e.g. myasthenia, ocular myopathy) can prove difficult. It is usual to track movements in the shape of an H. Lateral movements are assessed, followed by elevation and depression at about 30° of lateral gaze.

A minor degree of diplopia is an almost normal finding at the extremes of gaze; blurring and false-framing of objects is also easily accomplished, either in error or deliberately, by converging on an object closer than one's natural near point.

### V: trigeminal nerve – sensory and motor

Most people with sensory loss in the distribution of one or more trigeminal nerve branches complain of numbness and tingling in a clearly defined zone making detailed assessment of pain, temperature and light touch superfluous (see Figure 4.21 for V distribution). Most people have had temporary partial V<sub>3</sub> sensory loss following a lidocaine injection at the dentist, so this is familiar. Conversely, the loss of corneal sensation found with an early acoustic neuroma, or other lesion at the cerebello-pontine angle (CPA) is usually imperceptible until corneal sensation is actually tested.

**Corneal reflex and other aspects of Vth nerve examination** Approach the cornea from the lower temporal side to avoid a visual threat, with a pointed wisp of cotton wool. Gently draw down the lower lid. Rest the tip of the cotton wool gently upon the inferolateral cornea – between 6 and 9 o'clock for the right eye. Ask the patient what they feel and observe the surrounding conjunctiva for the normal reddening and tearing. Someone with an early depressed corneal reflex may say 'I can feel you touch me but it isn't painful as on the other side.' When the corneal reflex is depressed, conjunctival reddening and tearing are diminished.

The fine detail of the corneal reflex is that V<sub>2</sub> supplies the lower 60° corneal sector, between about 5 and 7 o'clock; V<sub>1</sub> supplies the upper 30°. This is occasionally of clinical value.

Neurologists vary in the emphasis they attach to evident blinking which is the VIIth nerve reflex response to corneal nociception

**Table 4.3** Four rules for recognition of a weak ocular muscle.

1	The false image is usually the less distinct and more peripheral
2	Diplopia occurs in positions that depend upon contraction of a weak muscle
3	The false image is projected in the direction of action of the weak muscle
4	Image separation increases in the direction of action of the weak muscle

during testing the corneal. Many test the corneal reflex to examine the Vth nerve alone. However, the blink ( $V \rightarrow VII$ ) response is sometimes valuable in ITU (see Other cranial nerves (blink reflex), Chapter 20).

There are several aspects of Vth nerve examination that relate to the distribution of its three divisions:

- The distribution of  $V_1$  extends to the scalp as far as the vertex via the supra-orbital nerve. Supra-orbital nerve lesions, often traumatic or surgical, can cause persistent headaches and scalp numbness.
- $V_3$  does not supply the skin of the neck. Patients with non-organic sensory disturbance of the face and neck are sometimes misinterpreted as suffering from a Vth nerve lesion.  $C2$  supplies the posterior scalp, including the area up just in front of the angle of the jaw.
- A slight difference in temperature perception between one side of the face and the other is common. This is rarely of any significance. Brainstem lesions cause onion skin sensory loss (Chapter 2, Figure 2.53 and Chapter 13, Figure 13.2). Complaints of sensory disturbance around the mouth should not be dismissed.

**V motor examination** Motor lesions of V are unusual, but easy to miss unless jaw deviation to the weaker side on opening the mouth is observed (though a rarely seen sign). Look at the incisor teeth: establish the centre line of the upper and lower incisors and see if the lower incisor centre line remains central or moves laterally as the jaw opens against slight resistance. The jaw jerk should also be assessed.

### VII: facial nerve

A complete lower motor neurone (LMN) facial palsy affects all facial muscles on one side, whereas upper motor neurone (UMN) weakness affects lower parts of the face; this spares blinking and wrinkling of the forehead. This difference between UMN and LMN lesions is explained by bilateral innervation of parts of the VIIth nuclei supplying upper facial muscles (see Facial nerve, Chapter 2). There are some subtleties of facial examination. In early UMN facial weakness, all that may be evident is a hint of slowing or delay of a blink, spontaneous grin or grimace. There may be dissociation between voluntary and involuntary movement: formal 'show your teeth' examination can remain normal, while a spontaneous smile is slow on one side.

For LMN examination, divide up the face and suggest definite actions:

- *Frontalis*: 'look upwards' normally produces frowning of the brow – the response required. A 'wrinkle your forehead' suggestion tends to produce a variable grimace
- *Orbicularis oculi*: try 'screw up your eyes tightly'
- *Alae nasae*: 'wrinkle your nose'
- *Orbicularis oris*: 'now try to whistle gently'
- *Risorius* (and others): 'and now please show me your teeth'
- *Platysma*: men who use a razor find this muscle easy to demonstrate – they tension the skin of the neck. With women, it is said that eversion of the lower lip is the way to demonstrate platysma; another suggestion is to: 'stick out your chin and grunt' – neither seems appropriate. Attempting to copy the examiner usually solves the problem.

Involuntary movement of the face (e.g. myokymia; see later and Other involuntary facial movements (myokymia), Chapter 13), fasciculation and minor degrees of hemifacial spasm can be hard to see. Illuminate the face well, and look closely.

Finally, as a practical point, the gradual emergence of patchy facial weakness is distinctly unusual in Bell's palsy – the most common cause of acute LMN weakness. If LMN facial weakness develops gradually over weeks, suspect a cause other than Bell's. In Bell's (see Bell's palsy, Chapter 13), weakness is usually at its worst within 12 hours; there is frequently pain around the mastoid, hyperacusis and loss of taste.

### VIII: auditory nerve

Formal testing is often unnecessary when there is no problem with hearing. If there is a degree of hearing loss, record the distance at which a whisper (or speech) is heard. The Rinne test (Heinrich Rinne, German otologist 1819–1868) is excellent for conductive deafness but of less value for the sensorineural deafness of particular interest to a neurologist.

Here is a simple pragmatic approach to the assessment of hearing:

- Record the distance a whisper is heard from the ear.
- Occlude gently both external auditory meati with the tips of each index finger. Rustle with each middle finger the skin/hair over the mastoid. This provides a rough-and-ready measure of bone conduction. If there is an evident difference between each ear, perceptive (sensorineural) loss is usually present. It is remarkable how accurate this is.

Rinne and Weber tests (Ernst Weber, Leipzig 1795–1878) are discussed in Chapter 15. In practice, suspicion of a cerebellopontine angle lesion (in full, surely?) will be followed by detailed MR imaging and specialised audiometry.

### VIII: vestibular nerve

Dizziness, vertigo and nystagmus are dealt with in more detail in Chapter 15 (see Dizziness and vertigo). The basic balance tests are observation of gait and station, and Romberg and Unterberger tests (R+U). Opinions vary about the value of these two named tests. One view is that they are obsolete, pointing out that injuries occur if tests are carried out carelessly. The Romberg test (Moritz Romberg, Berlin 1795–1873) was once used in the diagnosis of tabes dorsalis. In this variety of neurosyphilis, joint position sense became so severely impaired that the patient would lurch wildly on closing the eyes. The Unterberger test ('Stand to attention with arms extended forwards, march on the spot and close the eyes') is a non-specific test developed in 1938 for either vestibular or cerebellar problems. There is turning towards the side of the lesion. One, perhaps cynical, view is that tests show theatrical responses in those with no organic disease – but in these cases particular care must be taken to avoid injury. Most find R+U tests of some value – Romberg's is useful for detection of subtle proprioceptive loss.

With nystagmus a common error is to over-diagnose a few beats of nystagmus at the extremes of lateral gaze. This is normal, not pathological. Nystagmus must usually be sustained, and well within binocular gaze, to be pathological.

### IX and X: glossopharyngeal and vagus nerves

Take these nerves together. Observe uvula and fauces with the patient on saying 'Aaah' if there is need to test the gag reflex. Look also for pooling of saliva and residual food remnants. The gag reflex is no longer used alone as a measure of safety for swallowing. Some patients with an intact but hyperactive gag continue to swallow, but do so in a disorganised way and may aspirate; others with a depressed gag are shown on videofluoroscopy to swallow safely

without aspirating. If there is a question of bulbar weakness or difficulty swallowing:

- Listen to the voice – this sounds ‘wet’ in the early stages of bulbar muscle weakness (see Bulbar and pseudobulbar palsy, Chapter 13)
- Ask the patient to cough
- Look for deviation of the palate/uvula (away from the side of the lesion)
- Watch the patient begin to drink a glass of water, if this seems safe and look for spluttering, choking and pooling after a mouthful.

An isolated IXth nerve palsy – a rarity and hard to identify – causes impaired sensation on one side of the pharynx. Tickling the area with a cotton wool bud in the normal person causes discomfort and elicits gagging, via the vagus.

### XI: accessory nerve

Examine trapezii and sternomastoids; look for winging of the scapula, weak shoulder shrugging and head turning (see Accessory nerve, Chapter 13). The most common cause of an isolated spinal accessory nerve lesion is attempted biopsy of a node in the posterior triangle of the neck. The nerve is superficial here and easily damaged on its route to trapezius. Muscle weakness is immediate, but weeks or months later, pain around the shoulder and upper scapula may develop, typically intractable and neuralgic in quality.

### XII: hypoglossal nerve

Tongue wasting and deviation to the weak side when protruded is the sign of a unilateral XIIth nerve lesion. It is also useful to look at tongue movements. Speed and amplitude of tongue movement are diminished in bilateral pyramidal lesions and commonly early in Parkinson's disease. Tongue fibrillation, seen in motor neurone disease, should be diagnosed only when the tongue rests within the mouth; tongue twitching occurs in normal people when it is protruded.

### Gait and disorders of movement

The pattern of walking and abnormal movements will have been noted in the initial appraisal. Reflect on that first impression and analyse it.

Record whether gait is:

- Normal and symmetrical without limp, or abnormal, perhaps in some ill-defined way
- Spastic – narrow-based, stiff, or toe-scuffing
- Hemiparetic
- Extrapyramidal – shuffling, festinant (meaning hurrying), with poor arm swinging, or simply slow
- Apraxic – perhaps with gait ignition failure, or with walking difficulty but with preserved ability to move the legs rapidly while on a bed or seated, with normal imitated bicycling movements
- Ataxic – broad-based, unsteady
- High stepping, foot drop, myopathic, antalgic, neuropathic, or
- Unusual in any other way, for example, affected by dystonia, chorea or myoclonus, or apparently theatrical and non-organic.

It is feasible to categorise most gait problems by observation, but the issue is to avoid missing something subtle yet quite evident. For example, fidgetiness of early chorea can easily pass unnoticed. Early dystonia is easy to miss. Many gait disorders labelled initially as non-organic or even deliberate turn out to be caused by an organic movement disorder. A brief video, now readily available on a mobile phone, can be helpful.

### Motor system

Limb function and motor abnormality is a pivotal part of neurological examination. This is an area where eponyms became attached to hard physical signs – Babinski being the lasting example.

### Posture of outstretched upper limbs

The posture of the outstretched upper limbs is a useful way to begin. This manoeuvre establishes physical rapport with the patient; examination candidates demonstrate immediately familiarity with neurology. The hands and nails are also readily visible.

Ask the patient to extend the bare arms symmetrically, palms uppermost, and then close the eyes. Upper limb wasting and abnormal movements become evident. Drift with pronation and descent towards the midline is a cardinal sign of an early pyramidal lesion, as valuable diagnostically as an extensor plantar. Postural tremor appears; rest tremor diminishes. Chorea and the asterix of hepatic disease become apparent. Pseudochorea, the waving movements of denervation (peripheral nerve disease) or parietal lobe disease, may be seen.

Gentle downward pressure at the wrists is then applied, and released. Rebound on one side suggests a cerebellar lesion.

Fatiguability appears as inability to maintain the arm outstretched horizontally, the basis for the arm outstretched duration test in myasthenia.

Non-organic problems are often accompanied by aimless waving around.

### Tone

To distinguish between signs of spasticity with pyramidal increase in tone and the stiffness of an akinetic-rigid syndrome requires two distinct examination techniques.

In Parkinson's disease, the extrapyramidal lead pipe rigidity is detectable throughout all passive movements of a joint. Begin with the wrist; take the hand through slow, extension, flexion and rotation movements, so that the wrist joint is moved in all directions. This manoeuvre elicits early signs of stiffness in forearm muscles and cogwheeling. This stiffness becomes more marked when the opposite limb is moved actively (known as synkinesis), a sign that is found in Parkinson but is not specific for the condition. By contrast, in spasticity, the early pronator catch or the beats of emerging ankle clonus will become apparent, but only if sought by brisk rather than slow passive movements – supinating the forearm or dorsiflexing the ankle. Slow passive movements can miss early pyramidal signs because spasticity increases with the rate of passive movement. The catch of increased tone at the ankle becomes apparent before demonstrable sustained clonus is found (i.e. when there are >4 beats of ankle clonus).

### Power, muscle bulk and consistency

Various scales have been devised to record weakness, including a 10-point system. The six-point, MRC 0–5 Scale is usually used (Table 4.4) but has two limitations: the inability to record easily slight weakness, and dependence on effort/cooperation. A brief description (e.g. ‘I could just overcome hip flexion’) deals more effectively with slight weakness than 4+ and 4-. ‘Give-way’ weakness implies poor effort, or can be caused by pain. Skilled hand and foot movement assessment is important: ask the patient to play an imaginary piano and/or touch sequentially with the tip of the thumb the fingertip of the fifth, fourth, ring and index finger, back and forth – and ask them to wriggle the toes. These are good tests of pyramidal function.

Fatiguability should be assessed by repeating a movement if the story suggests this might be present. The slow relaxation of myotonia should also become apparent – provided one remembers to consider it.

Focal or general muscle wasting, fasciculation and muscle consistency should be assessed.

**Table 4.4** Six Medical Research Council grades of weakness.

5	Normal power
4	Active movement against gravity and resistance
3	Active movement against gravity
2	Active movement with gravity eliminated
1	Flicker of contraction
0	No visible muscle contraction

Note: these UK Medical Research Council grades (0/5 to 5/5) were designed to record changes in power during poliomyelitis. Although more applicable to lower motor neurone weakness they remain widely used throughout neurology.

### Coordination – cerebellar signs

Signs of early cerebellar disease (Chapter 17) may have been noted during initial assessment, such as dysarthria, tremor or an ataxic gait. Rebound on testing upper limb posture is seen. Proceed by looking for dysmetria (past pointing) and action tremor. It is important to appreciate that unsteadiness and shakiness do not equate to cerebellar disease or cerebellar damage – sometimes a pit-fall in legal cases following head injury.

Dysmetria: ask the patient to place their forefinger on the point of a tendon hammer shaft, held at the limit of their reach, and then to touch the tip of their nose. For the return cycle, move the tendon hammer to a different position. The finger–nose test is a not a measure of speed, though one still, frequently hears: ‘Do this as fast as you can.’ Rapid movements can obscure early cerebellar signs.

Follow with other cerebellar test sequences. In early disease, one test will frequently be more abnormal than others. For example:

- Circular polishing of the dorsum of the opposite hand with a single finger.
- Alternating forearm pronation and supination. Demonstrate this test: with forearm vertical, make rotational back-and-forth movements. Next, repeat with the forearm horizontal and palm uppermost. Next, show how pronation–supination is combined with tapping the fingertips of one hand on the dorsum of the other. The clumsy word dysdiadochokinesia is used to describe this abnormality, to distinguish it from dysmetria. Practical tests, such as screwing in a light bulb, are also sometimes helpful.

In the lower limb heel–shin test, ask the patient to:

- Raise one leg, touch the opposite ankle with the heel, and then
- Repeat this circular sequence of movement (i.e. raising the leg again). Simply gliding one heel up and down the opposite shin can miss early ataxia.

Foot tapping against the examiner’s palm is another test to elicit lower limb incoordination. In cerebellar disease, tendon reflex abnormalities are rarely of much diagnostic value. Knee jerks with a pendular pattern, meaning slow and swinging when the shins are dangled vertically over the couch, and absent reflexes are seen.

Cerebellar dysarthria is usually evident without resorting to asking for pronunciation of ‘West Register Street’ – which is in Edinburgh, or ‘baby hippopotamus’ but these appear to remain entrenched.

The nystagmus of cerebellar disease rarely occurs without other cerebellar features. Finally, remember that midline cerebellar (vermis) lesions may cause gait and trunk ataxia without signs in the limbs.

**Table 4.5** Tendon reflexes.

Symbol	Description	Inference
0	Absent with reinforcement	Usually pathological
+/-	Present with reinforcement	Sometimes normal, but may be pathological
+	Present	Normal
++	Brisk	Normal
+++	Very brisk	Pathological if tone is increased but can be a normal finding
CL	Clonus	>3 beats of ankle clonus = pathological; 2 beats may be normal

Do not miss the slow relaxing reflexes of hypothyroidism.

**Table 4.6** Spinal levels of tendon reflexes.

Spinal level	Reflex
C5–6	Supinator
C5–6	Biceps
C7	Triceps
C8	Finger jerks
L(3)–4	Knee
S1	Ankle

### Tendon reflexes

Strictly, these are the deep tendon reflexes (DTRs of US texts). The full-size tendon hammer, with a 33 cm (13 in) shaft, is the preferred tool; miniature versions are discouraged. A soft rubber O-ring is preferable to hard one. Make sure the patient is relaxed – with the head and trunk supported comfortably. The 0 to +++ and CL nomenclature is shown in Table 4.5. Minor degrees of reflex asymmetry are common in normal people, as are relatively reduced knee jerks compared with ankle jerks, and sometimes vice versa. Table 4.6 indicates spinal levels of the tendon reflexes. Reinforcement, the method of attempting to elicit tendon reflexes that are at first sight absent, is achieved by several actions. One is to ask the patient to clench their teeth and then relax; another is to clench the hands. The original Jendrassik manoeuvre is to hook the fingers each hand together and pull firmly (Ernö Jendrassik, 1858–1921, Budapest). Areflexia without other physical signs is not in itself an absolute abnormality, but is usually pathological.

**Extensor plantar (Babinski) and Hoffmann reflexes** Joseph Babinski (1857–1932, Paris) wrote the 26-line description entitled the *phénomène des orteils* (toe phenomenon) in 1896. The extensor plantar

response is an indication of an UMN lesion of the brain or spinal cord. Babinski is said to have used a bodkin, a sharp instrument, originally an arrowhead; an orange-stick is now usual. The crux of the matter is that if a reproducible upgoing toe can be produced by any reasonable stroking action on the sole, then this is abnormal. There are over a dozen additional ways to elicit a similar phenomenon, many eponymous, such as Chaddock, Gordon, Oppenheim and Gonda signs; none rivals the original Babinski.

Extensor plantars are exceptional in the normal adult, but are occasionally found. Johann Hoffmann (1857–1919, Heidelberg) described finger reflex hyper-reflexia on flicking the thumb or fore-finger. This is little used by most neurologists today; in practice, other UMN signs are usually evident.

**Superficial abdominal reflexes** Superficial abdominal reflexes are elicited by gentle stroking in each upper and lower quadrant with an orange-stick. This evokes a local subcutaneous muscle twitch in the normal subject. The stimulus should not be sharp. Superficial abdominal reflexes are lost with pyramidal lesions and hard to elicit or absent in the obese, or following abdominal surgical scars. The preservation of upper abdominal reflexes with absent lower abdominal reflexes helps confirm a thoracic level in cord compression; the umbilicus is at T10.

**Respiration, diaphragm and abdominal muscles** Respiration and the diaphragm can be assessed by observing inspiration and expiration and abdominal muscles. Selective weakness of the diaphragm causes paradoxical upward movement of the umbilicus on inspiration; this is well seen with the patient supine during sniffing. If there is any question of respiratory failure, assess and monitor vital capacity (erect and supine), blood gases and chest X-ray.

### Lower and upper motor neurone lesions

Features differentiating LMN and UMN lesions are outlined in Table 4.7. In UMN (pyramidal) lesions, the pattern of weakness is of value diagnostically. In the lower limbs, there is weakness of hip flexors, knee flexors and ankle dorsiflexors compared with their

antagonist muscles, while in the upper limbs there is relative weakness of all extensors and of finger abduction. Weakness is usually accompanied by reflex changes but in early UMN lesions, not all features of Table 4.7 need be present. In a very early lesion, loss of finely skilled finger and toe movements, or simply drift of an out-stretched arm can be the only sign of abnormality.

### Sensory system

Sensory abnormalities are rarely found when the patient is articulate and there are no sensory complaints or other signs.

Focus sensory examination anatomically:

- Assess first the posterior columns, meaning here vibration (VS) and joint position sense (JPS). Then move to the spinothalamic tracts. This is an anatomical approximation, but it is useful.
- Test VS at the ankles using a 128-Hz tuning fork. Familiarise the patient with the test by placing the heel of the vibrating fork on the sternum.
- Test toe and then finger JPS – holding the sides of the digit, take it through the smallest movements.
- Quantification of JPS is achieved by recording responses at the toes, ankles and knees and similarly in the upper limbs. VS can also be recorded similarly, to include its absence at the ankles, knees or even at the xiphisternum or clavicles. If the latter two high levels of apparent sensory loss are recorded, an organic problem is rare.
- Examine spinothalamic sensation first with cold metal and then with a disposable sharp object, not a needle or pin.
- Test light touch with a finger tip or cotton wool. Avoid stroking or tickling; these are spinothalamic modalities. Touch tests with fine hairs of various calibres are obsolete for clinical purposes.
- Chart areas of sensory loss or altered sensation. In loss of sensation move from the anaesthetic area to that of normal sensation. In hypersensitivity states move from normal skin towards hypersensitive skin.
- Two-point discrimination (0.5 cm on finger tips, 2 cm on feet) is useful for completeness if circumstances warrant it. A paperclip can be bent to make a two-point tool if discriminator forceps are not available.

**Table 4.7** Lower (LMN) and upper motor neurone (UMN) lesions.

Feature	Lower motor neurone	Upper motor neurone
Focal muscle wasting	Visible	Absent
Fasciculation	Visible	Absent
Fibrillation potentials	Recordable on EMG	Absent
Tone	Flaccid/normal	Increased/spastic type
Weakness pattern	Root, nerve or distal	Pyramidal + reduced dexterity
Tendon reflexes	Depressed/usually absent	Exaggerated*
Clonus	Absent	Present
Abdominal reflexes	Present	Absent
Plantar responses	Flexor (normal)	Extensor

\* Tendon reflexes can be temporarily depressed or absent following an acute UMN lesion.

Two areas of sensory examination require particular attention:

- 1 Determination of a thoracic sensory level in a possible compressive cord lesion, and
- 2 Charting dissociated sensory loss in a possible central cord lesion, such as syringomyelia.

In an early compressive cord lesion, a distal sensory disturbance may not be a complaint. If signs of a mild spastic paraparesis are found during motor and reflex testing, check sensation on the thorax and abdomen with care. Move up from the lower limbs, to the lower abdomen using a cold tuning fork blade. Ask if sensation changes. In the normal person, there is often an apparent slight increase in cold perception as one reaches the groin, again at the lower costal margin and around the clavicle. At other levels, diminished sensation distally may well be pathological. The level of a cord lesion can be determined in this way and tested subsequently with a sharp object and light touch. Be aware that on the thorax, a sensory level on the back is typically higher by a segment or so than on the front of the chest.

In syringomyelia, sensory loss may also pass unrecognised. Painless burns or painless minor injuries should be noted. The areas of dissociated spinothalamic loss on the trunk and upper limbs can be bizarre, conforming to no obvious pattern, because the syrinx involves crossing spinothalamic fibres in the cord central grey matter. Look also for loss of sensation to a sharp object on the posterior scalp (C2).

Generally, when complex sensory loss is found, note the initial findings and return after an interval to re-examine sensation.

### Formulation and diagnosis

Drawing together historical data and physical signs is an essential part of assessment but frequently skimmed. To conclude that a fall with loss of consciousness and residual weakness is 'collapse ?cause' or 'probably a fit', an evident hemiparesis is 'a CVA' or that a complex headache history is 'migraine' (all common comments in A&E notes) are not formulations any medically qualified person should reach. A structured approach is essential, teasing out features from the history and building on the signs found, to reach either a diagnosis or at least a direction for investigations. Such attention to detail can be hard in an emergency, but it is in acute neurology that many mistakes occur. For example, cases of sudden headache are discounted as benign when the reality is a subarachnoid haemorrhage. A careful history and thoughtful appraisal usually provides the correct answer and safe management. Another common error is the distinction between a seizure and syncope; seizures are over-diagnosed. Mistakes occur if one fails to adopt a structured approach.

As a generalisation, the history often points towards a pathological process, while examination either simply confirms suspicions or suggests anatomical localisation.

### Difficulties with the history and examination

When a diagnosis is unclear, try to sort out relevant and entirely secure details within the history and examination. Establish whether or not physical signs are hard (certain). For example, a definite historical fact is a clear witnessed account of a tonic-clonic seizure and unequivocal physical signs are sustained ankle clonus and extensor plantars. Separate these from the less clear such as vague weakness, or dizziness without vertigo. Also, be prepared to recognise, accept and record uncertainty: it may be unclear whether the blackout was a fit or faint. It is obvious that this is advice easier to write than to practice.

While it is sometimes taxing to formulate a possible diagnosis, and one risks making an error, it is essential to try.

## Diagnostic tests in clinical neurology

In clinical neurology, and in medicine generally, the substantial majority of investigations do not alter the course of a disease. However, we are surrounded by technology, by defensive practice and the need to provide reassurance that all has been done to exclude sinister conditions. It is essential to be aware of the cost-benefits and to target studies for some real purpose. However, there is often an uncritical approach which results in waste and sometimes confusion. The principal investigations of neurology are outlined here.

### Imaging

There has been a revolution in imaging. The first patient was imaged by computerised tomography (CT) in 1971 in London and before the 1980s, CT scanning was sparsely available. At that time, carotid and vertebral angiography, air encephalography and myelography were the standard investigations in specialist units. The human brain was first imaged by magnetic resonance (MR) in Nottingham, UK in 1978. Standard, high resolution MRI is now readily available and even functional MRI (fMRI) is now used in clinical practice. Some basic principles of imaging techniques are mentioned here.

Neuroimaging has a vital role in clinical neurosciences. It offers a range of powerful diagnostic tools, providing *in vivo* information about the structure, function and physiology of the nervous system and the pathologies that afflict it. In addition, there is an ever-expanding range of image-guided therapeutic procedures that enable neuroradiologists to be at the heart of patient treatment, not simply diagnosis. In order for clinicians to utilise radiology departments effectively and efficiently it is essential that they are familiar with the various imaging modalities, their potential risks and benefits and the therapeutic options now available.

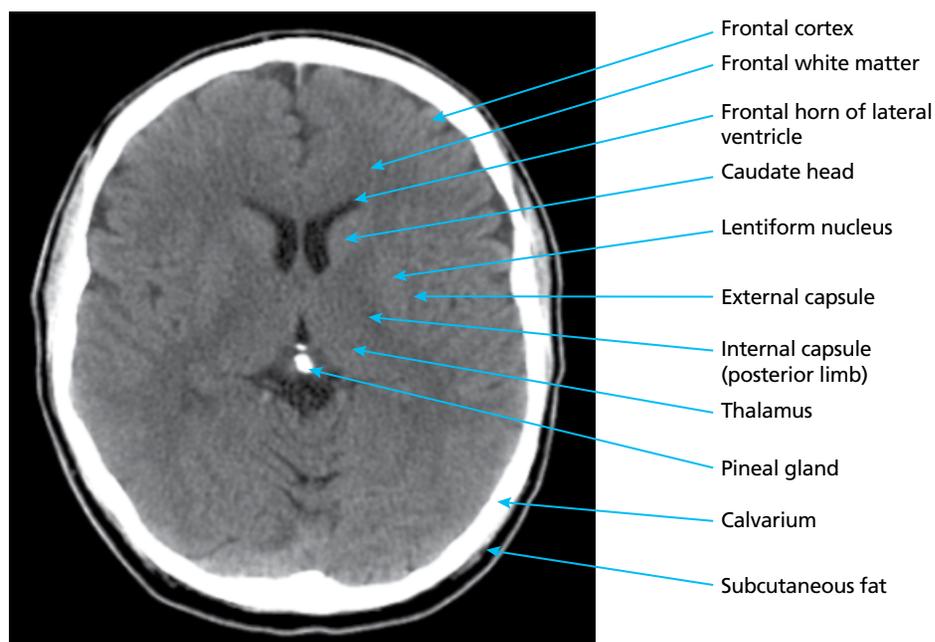

### Conventional radiography (plain X-rays)

Conventional radiography continues to have a limited role in imaging the skull, spine and skeleton and other radio-opaque structures such as metallic implants and ventricular shunts. However, overlapping structures are superimposed and soft tissue contrast is poor. This presents a problem for imaging the central nervous system (CNS) as it is encased in bones, masking the soft tissues of the brain and spinal cord.

### Computerised tomography

Computerised tomography (CT) uses ionising radiation to produce thin tomographic images (slices) that overcome many of the problems inherent in plain X-rays caused by superimposition of tissues. Conventional CT scanners employ a circular assembly consisting of a fan beam of X-rays placed opposite a curvilinear array of detectors. This assembly rotates rapidly around the subject and covers the region of interest either by stepwise acquisition of multiple slices (sequential scanning) or by moving in a continuous spiral (helical scanning). Modern scanners have multiple rows of detectors allowing several slices to be acquired simultaneously, reducing scan times to the order of seconds or minutes.

CT relies on different tissues stopping (attenuating) X-rays to different degrees to provide image contrast. The image is composed of a matrix of volume elements (voxels), akin to pixels in a

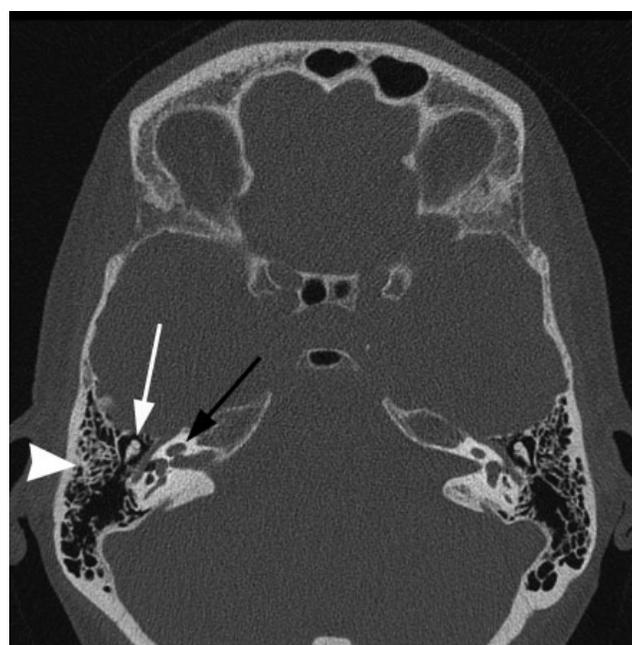

**Figure 4.1** Axial computed tomography (CT) image using brain windows. Note that grey matter appears slightly brighter than white matter due to its higher attenuation values. The highly attenuating bone and calcified pineal gland appear white, cerebrospinal fluid (CSF) in the frontal horn appears dark and the poorly attenuating subcutaneous fat and air around the head are black.

two-dimensional digital image, but with an additional depth dimension equal to the slice thickness. Each voxel is assigned a value, in Hounsfield units (HU), reflecting its ability to attenuate the incident X-rays. Grey-scale images are constructed from the voxel matrices, with high attenuation voxels depicted towards the brighter, white end of the spectrum, and low attenuation voxels towards the darker end. These grey-scale images can then be 'windowed' in order to optimise contrast within the tissues of interest (Figures 4.1 and 4.2). The words attenuation and density are often used interchangeably, with high attenuation value voxels described as being hyperdense and low attenuation voxels as hypodense.

Current detector arrays are also able to acquire cube-shaped isotropic voxels that can be manipulated to reconstruct images in any plane (multiplanar reformatting, MPR) and allow 3-D images such as maximum intensity projections (MIPs) and volume renderings (Figure 4.3). Iodine-based contrast media can be used to increase tissue contrast, highlight pathologies such as tumour and infection, obtain relatively selective images of the vessels in CT angiography produce measures of tissue perfusion and, when injected intrathecally, allow detailed depiction of the theca and its contents in CT myelography (Figure 4.4).

### Magnetic resonance imaging

Clinical MRI utilises strong magnetic fields and radiofrequency pulses to generate a signal from protons in water molecules. By convention, high signal voxels are depicted as bright (often described as hyperintense) and low signal voxels as dark (hypointense). A variety of pulse sequences can be used to interrogate different physical properties of the water protons and image contrast can therefore be generated in multiple ways. The two most commonly used MRI sequences produce images based mainly on the variations in T1 and T2 relaxation times of water protons in different tissues, generating T1-weighted (T1-w) and T2-weighted (T2-w) images, respectively (Figure 4.5a,b). Other commonly used sequences include Fluid

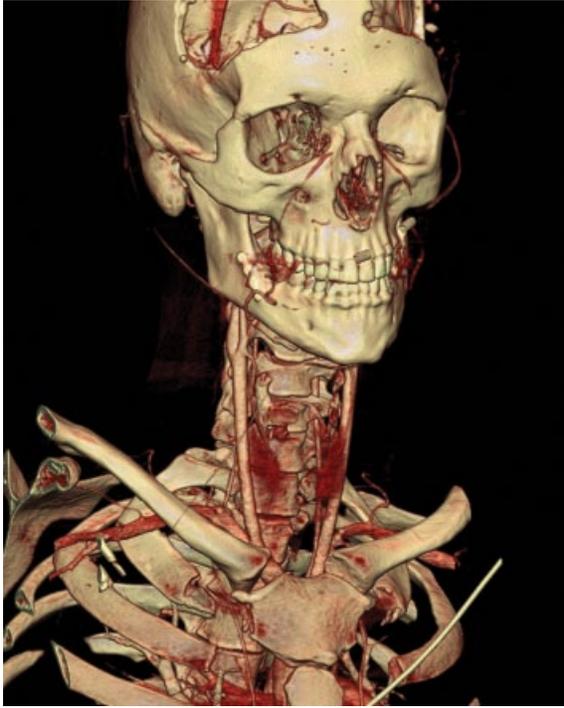

**Figure 4.2** Axial CT of the petrous temporal bones using bone windows and processing algorithms to optimise bony detail. Note that the bony architecture of the middle and inner ear, such as the ossicles (white arrow), cochlear (black arrow) and trabeculations of the mastoid (arrowhead) are all well seen but soft tissue contrast is lost and the brain parenchyma appears homogeneously grey.

Attenuated Inversion Recovery (FLAIR; Figure 4.5c), diffusion-weighted imaging (DWI; Figure 4.6) and sequences that are particularly sensitive for detecting blood degradation products such as T2 gradient-echo (T2\*) and susceptibility-weighted imaging (SWI;

Figure 4.7). Chelates of gadolinium can be used as contrast media with similar roles to those of iodine-based agents used in CT and several types of magnetic resonance angiography (MRA) are available for selective vascular imaging (Figure 4.8).

#### Advanced MRI

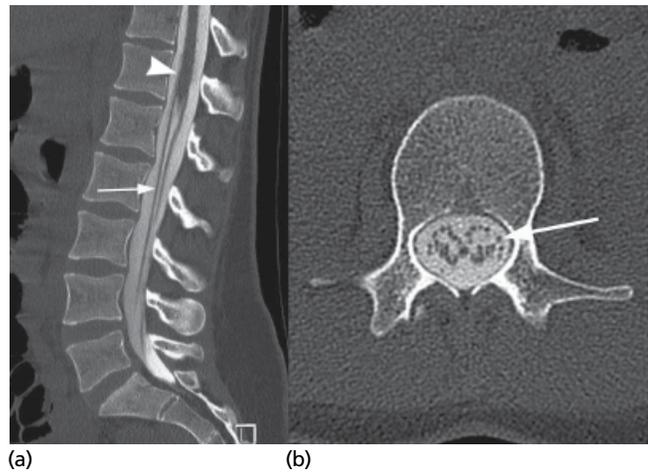

In addition to the routine sequences there are many other sequences grouped under the umbrella term 'advanced MRI' that have been developed to probe tissue structure, function, physiology and

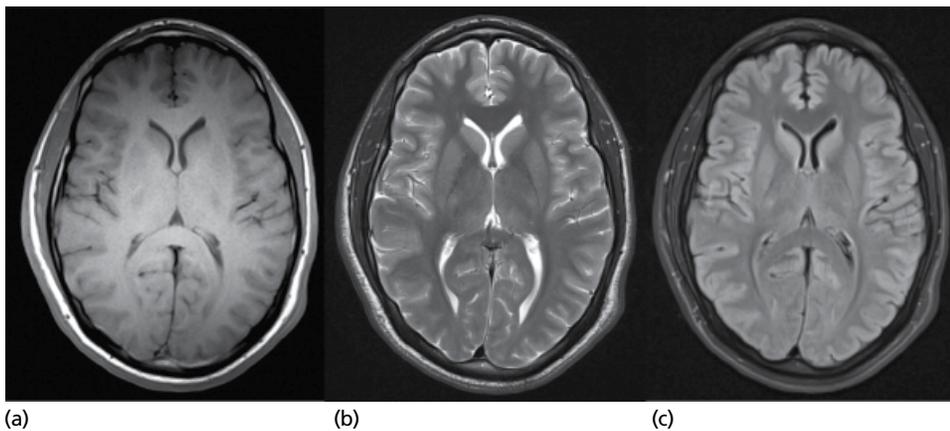

**Figure 4.3** Volume rendered image (VRT) produced from a CT angiogram showing the anatomical relationship of the neck vessels and adjacent bones.

biochemistry. The major techniques that have translated from the research to clinical arenas are outlined here.

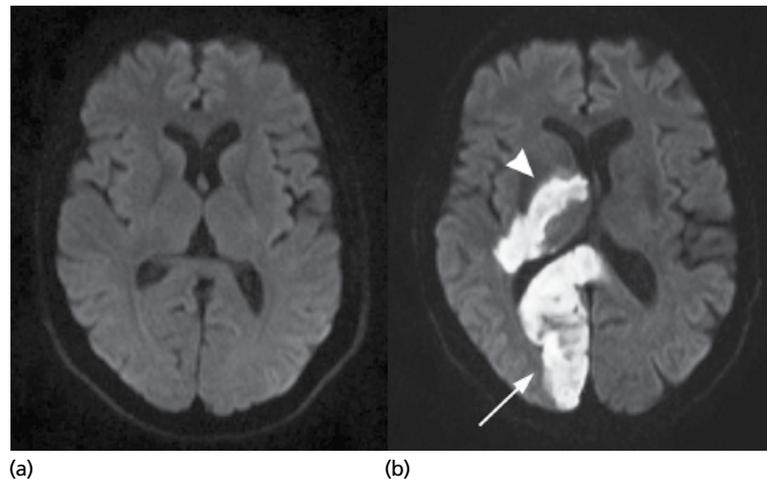

The advanced MRI technique most used in clinical practice is perfusion MR. Of the many techniques available, dynamic susceptibility contrast (DSC) and dynamic contrast-enhanced (DCE) perfusion have gained the most traction clinically. As their names suggest, both involve the dynamic acquisition of images during injection of a contrast bolus and provide a number of measures of tissue perfusion. Clinically, perfusion MR is mainly used for the assessment of cerebrovascular disease (Figure 4.9), for estimating histological tumour grades (principally gliomas) and differentiating tumour from therapy-induced radionecrosis. A third technique, arterial spin labelling (ASL) magnetically tags water in flowing blood rather than using an injection of potentially harmful contrast and is likely to find increasing clinical application in the future.

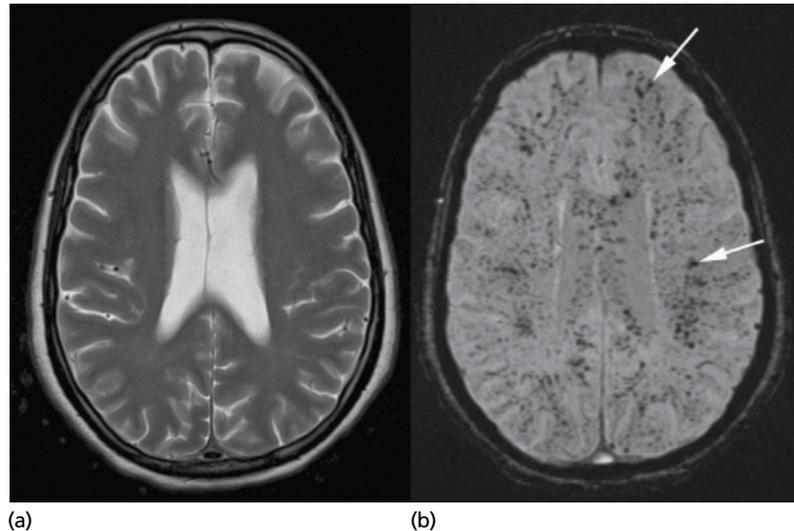

**Figure 4.4** CT myelogram, sagittal (a) and axial (b) images. Intrathecal contrast injection creates high attenuation CSF, outlining contours of the vertebral canal, spinal cord (arrowhead) and nerve roots (arrow).

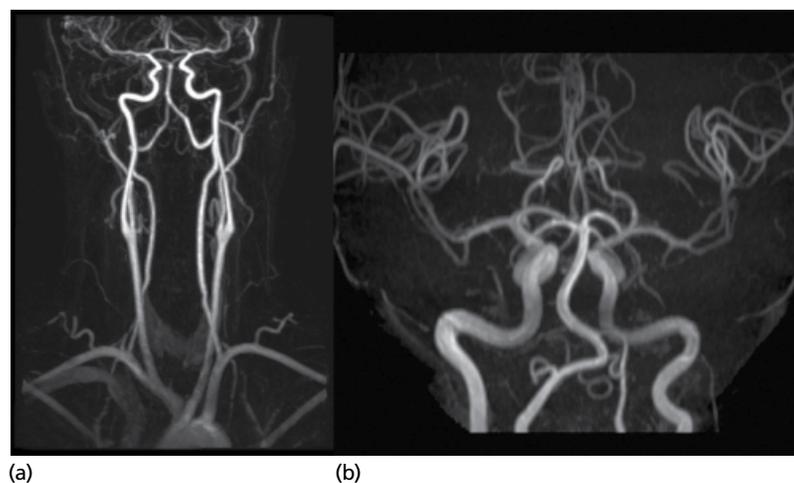

**Figure 4.5** Axial MR (a) T1-weighted (T1-w), (b) T2-weighted (T2-w), and (c) Fluid Attenuated Inversion Recovery (FLAIR) images of normal brain at the level of the basal ganglia. On the T1-w image white matter appears hyperintense compared to grey matter and CSF appears very hypointense. This image contrast is reversed on the T2-w image with grey matter appearing hyperintense to white matter and CSF appearing very bright. Note that FLAIR images are essentially T2-w, with grey matter appearing hyperintense to white matter. However, the signal from bulk water is nulled, making CSF appear dark and increasing the conspicuity of T2-hyperintense pathologies, such as multiple sclerosis (MS) plaques, particularly around ventricular margins and other CSF spaces.

**Figure 4.6** Axial MR diffusion weighted imaging (DWI). (a) Normal brain: the contrast in DWI is partly generated by the diffusivity of water molecules. Voxels in which water is free to diffuse, such as CSF, are depicted as dark and those in which there is restricted diffusion are depicted as bright. Structures such as cell membranes act as natural barriers to diffusion in normal brain parenchyma, which has an intermediate diffusivity and appears mid grey. (b) Acute ischaemic infarction: the archetypal pathology exhibiting restricted diffusion, caused by interstitial pathways for water diffusion being impeded by cell swelling (cytotoxic oedema). In this example, acute infarcts are seen in both posterior cerebral (arrow) and anterior choroidal artery (arrowhead) territories.

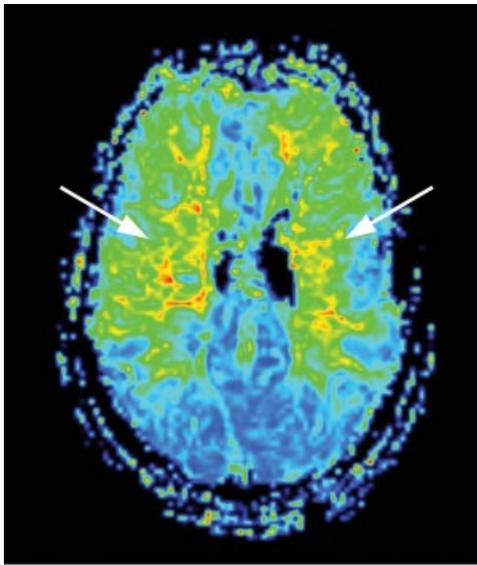

**Figure 4.7** Axial MR susceptibility weighted imaging (SWI): disseminated intravascular coagulation. SWI is particularly sensitive to paramagnetic substances that include many blood breakdown products and other sources of iron. (a) Routine T2-w images. (b) SWI image shows multiple punctate foci of hypointensity (two are arrowed) that are microhaemorrhages not visible on the T2-w image.

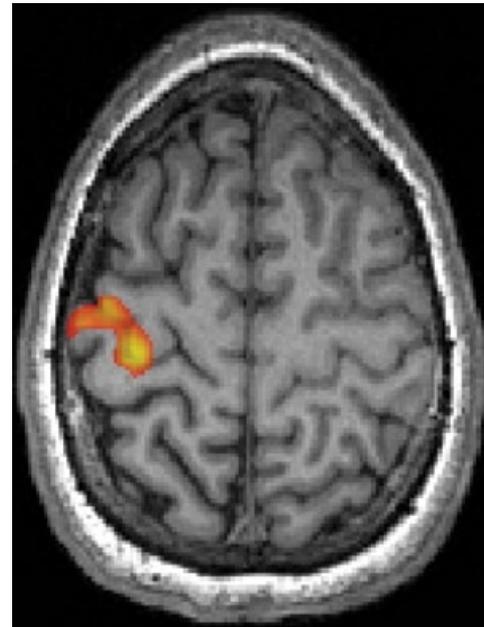

**Figure 4.8** Magnetic resonance angiography (MRA). (a) Contrast-enhanced MRA is the preferred MR method for imaging extracranial neck vessels. (b) Time-of-flight (TOF) is the sequence of choice for imaging intracranial arteries.

**Functional MRI and other MR modalities** Functional MRI (fMRI) measures changes in blood oxygen levels, known as the BOLD effect, as a surrogate marker of brain activity. A variety of paradigms such as finger tapping and silent word generation tasks can be used to localise eloquent cortex such as the primary motor and language areas (Figure 4.10). The main clinical use of fMRI is for pre-operative planning when functionally important cortex is expected to lie close to the surgical field.

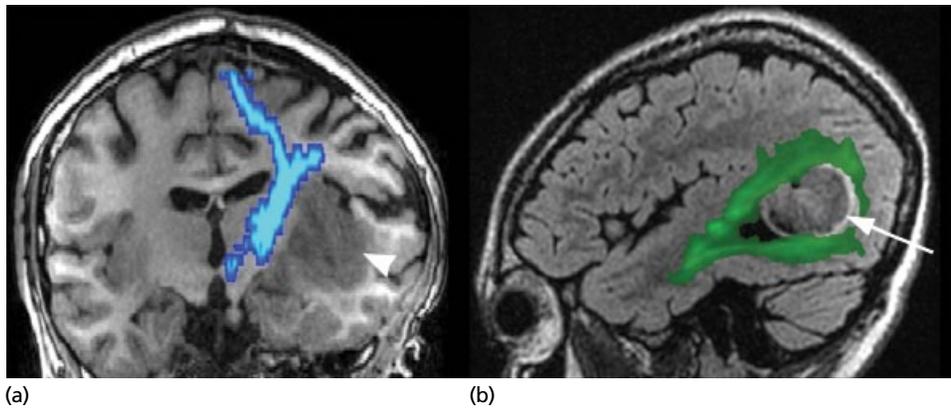

Diffusion tensor imaging (DTI) exploits the anisotropy of *in vivo* diffusion (i.e. the fact that water diffusion has a directional component dependent on the structure and organisation of the tissue it passes through), to provide information about tissue integrity at a cellular and microstructural level and to allow anatomical modelling of highly anisotropic structures such as white matter tracts (Figure 4.11). The images from white matter tractography can be combined with fMRI to produce more complete functional maps, incorporating both eloquent cortex and its associated white matter projections.

**Figure 4.9** Perfusion MR. A dynamic susceptibility (DSC) study of a patient with moyamoya disease showing abnormal perfusion in the middle cerebral artery and deep border-zone territories bilaterally (green and orange voxels highlighted with white arrows).

**Figure 4.10** Functional MR image: orange and red voxels represent activation of the hand motor area.

**Figure 4.11** White matter tractography derived from diffusion tensor imaging. (a) Corticospinal tract outlined in blue and deflected medially by an insular tumour mass (arrowhead). (b) Optic radiation (in another patient) outlined in green and splayed around a posterior temporal tumour (arrow).

Proton MR spectroscopy (MRS) is used to produce a biochemical profile of tissue with the relative proportions of target metabolites such as creatine, *N*-acetyl aspartate, choline, lactate and lipids being used as markers of neuronal viability, membrane turnover and metabolic status. The hope that MRS would allow pathologies to be identified by their specific biochemical profiles has not been realised but it may serve as a useful adjunct in imaging certain diseases such as metabolic disorders and tumours.

**Magnetic field strength, advantages and safety issues** The majority of current clinical scanners use either 1.5 Tesla (1.5 T) or 3 Tesla (3 T) magnets. Higher field strength 3 T magnets are able to generate better signal-to-noise ratios than their 1.5 T counterparts, which offer several advantages including the potential for higher resolution and/or faster imaging. However, higher field strengths are in general more prone to artefacts and more stringent MR safety rules need to be applied.

The advantages of MRI include the fact that it does not use ionising radiation, it is able to generate very good contrast between many tissues and a diverse range of sequences can be employed to provide information not only on structure, but also the chemical composition, physiology and function of tissues. In general, it is unimpeded by the presence of bone and is therefore better suited to imaging the spinal cord and posterior fossa than CT. These benefits are weighed against relatively long scan times, poorer patient tolerance, the requirement for greater specialist physics support to maintain and optimise the scanners and greater overall expense compared with CT. In addition, the movement of ferromagnetic materials within the very strong magnetic fields and heating caused by radiofrequency pulses have safety implications that preclude some patients with metallic implants or foreign bodies from undergoing MRI and require the use of specially designed MR-compatible equipment in and around scanning areas.

**Positron emission tomography** Positron emission tomography (PET) is a technique that images the spatial and temporal distribution of positron-emitting radioisotopes. Radionuclides such as  $^{18}\text{F}$ ,  $^{11}\text{C}$  and  $^{15}\text{N}$  can be tagged to injectable pharmaceutical agents to provide *in vivo* assessment of perfusion, glucose metabolism and DNA synthesis. Combination PET-CT and PET-MR scanners are now available and allow simultaneous acquisition and fusion of structural and functional imaging.

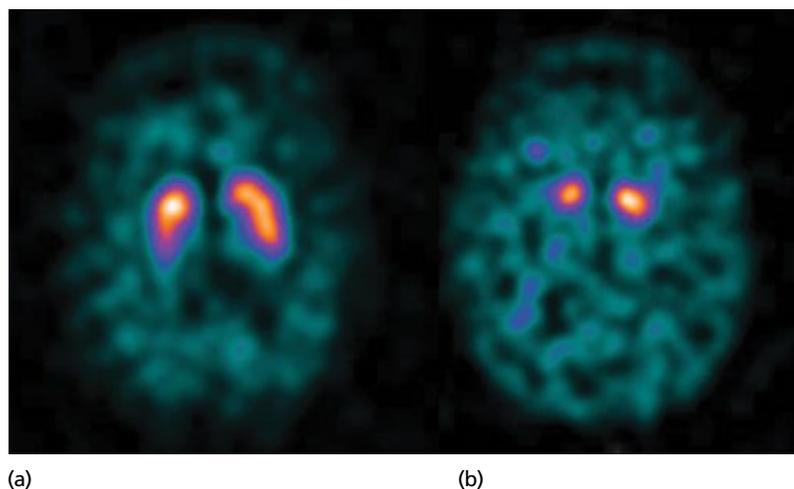

The most commonly used PET tracer is  $2[^{18}\text{F}]$  fluoro-2-deoxy-D-glucose (FDG) which accumulates in the brain via the same pathway used to take up glucose and can be used as a marker of regional cerebral metabolism. It has a range of potential clinical applications including tumour, dementia, cerebrovascular and epilepsy imaging. In the context of CNS tumours it has been used to discriminate between high and low grade neoplasms, between post-therapy radionecrosis and residual tumour and to localise occult malignancy elsewhere in the body when a paraneoplastic syndrome is suspected. It has been used to identify Alzheimer's very early in the disease course and certain patterns of hypometabolism may help discriminate between different dementia aetiologies. In cases of intractable epilepsy, interictal and ictal PET imaging may be used to localise epileptogenic foci preoperatively where structural MRI has failed.

**Single-photon emission computed tomography** Single-photon emission computed tomography (SPECT) generates images using gamma-emitting radioisotopes bound to specific ligands and injected as radiopharmaceuticals. A gamma camera rotating around the patient acquires images from multiple projections, allowing tomographic images to be reconstructed in any plane using similar principles to conventional CT.

The two most common neurological uses of SPECT are perfusion and striatal dopamine transporter imaging. Perfusion SPECT is most commonly performed using  $^{99\text{m}}\text{Tc}$  based tracers that pass freely across the blood-brain barrier and are distributed in the brain proportional to blood flow. In pathologies where vascular supply to the brain is compromised this allows regional perfusion to be mapped and, when used in conjunction with a vasodilator challenge using agents such as acetazolamide, may be used to assess cerebrovascular reserve. In the absence of cerebrovascular disease the coupling of blood flow to metabolism and neuronal activity also allows brain function to be studied. Different patterns of regional hypoperfusion have been associated with different dementia types and may have a role in discriminating between them when structural imaging is non-specific. Early post-ictal SPECT has been used to localise epileptogenic foci in a similar way to PET.

Imaging with  $(^{123}\text{I})$  ioflupane, tradename DaTSCAN, is another SPECT technique now commonly used in neuroimaging.  $(^{123}\text{I})$  ioflupane selectively binds to presynaptic dopamine transport receptors in the striatum and can be used to detect loss of functional dopaminergic neurones (Figure 4.12). Its main licensed role is in distinguishing between essential tremor, in which  $(^{123}\text{I})$  ioflupane uptake is preserved, and extrapyramidal syndromes in which tracer uptake is reduced such as idiopathic Parkinson's disease, multiple system atrophy and progressive supranuclear palsy. Its other licensed use is in differentiating Alzheimer's disease from dementia with Lewy bodies, striatal uptake being reduced in the latter. However, DaTSCAN is unable to discriminate between the various pathologies in which striatal dopaminergic neurones are reduced.

**Ultrasound** Ultrasound is safe, well tolerated by patients and has the additional advantage that most machines are portable, allowing scanning at the bedside where required. In neonates, ultrasound can

**Figure 4.12** Ioflupane ( $^{123}\text{I}$ ) SPECT scans (DaTSCAN). (a) Normal scan showing symmetrical comma-shaped uptake in the striatum. (b) Parkinson's disease: markedly reduced tracer uptake in the putamina, with preservation of uptake in the more anteriorly positioned caudate heads ('full stops').

be used to image the brain and spine but as bones develop and fontanelles close its role in neuroimaging becomes limited. Duplex ultrasound, known as carotid Doppler, is commonly used to assess the extracranial carotid arteries, principally for detecting atherosclerotic stenoses in patients presenting with transient ischaemic attack (TIA) and ischaemic stroke. Transcranial Doppler (TCD) can be used to obtain velocity and spectral information from intracranial vessels, most commonly via limited acoustic windows in the temporal region. It has a number of applications, the best established being vasospasm monitoring in patients following aneurysmal subarachnoid haemorrhage and assessment of vascular stenoses and occlusions in the context of ischaemic stroke. Elevated middle cerebral or internal carotid artery TCD velocities have also been shown to be an important predictor of stroke in children with sickle cell disease and can be used to guide the use of prophylactic blood transfusions.

**Digital subtraction catheter angiography** Digital subtraction catheter angiography (DSA) is considered the gold standard for imaging vascular anatomy. It is an invasive procedure in which iodinated contrast is injected directly into the vessels of interest, usually through a catheter introduced via femoral artery puncture. It allows specific vascular territories to be imaged selectively and can separate arterial, capillary and venous phases, yielding information about haemodynamics as well as vascular anatomy and structure (Figure 4.13). The unrivalled spatial and temporal resolution of DSA means it remains the most sensitive investigation for detecting subtle structural vascular abnormalities such as small aneurysms and for demonstrating arteriovenous shunts, particularly those associated with dural arteriovenous (AV) fistulae. However, in addition to the hazards associated with ionising radiation and iodinated contrast media, DSA also carries risks related to peripheral arterial puncture such as pseudoaneurysm formation and retroperitoneal bleeding and the risk of neurological deficit caused by embolus. Complication rates of diagnostic cerebral angiography are low, the risk of permanent neurological deficit is approximately 0.5%. Patients should be selected and consented carefully.

**Interventional neuroradiology** Interventional neuroradiology encompasses all image-guided therapeutic procedures, but in neuroradiology it commonly refers to endovascular techniques used to treat vascular pathologies. Since the landmark ISAT trial published in 2002, endovascular treatment of aneurysms has become established as a safe and effective alternative to surgical clipping and is now the preferred route of management for the majority of aneurysmal subarachnoid

haemorrhage cases. The technique uses platinum coils delivered via intra-arterial catheters to alter flow and promote thrombosis from within the aneurysm, obviating the need for craniotomy. It should be noted that not all aneurysms are suitable for coiling and selection of cases is best carried out by multidisciplinary teams involving both neuroradiologists and neurosurgeons. Many craniospinal AV malformations and dural fistulae are also amenable to endovascular treatment and certain tumours such as meningiomas and paragangliomas are sometimes embolised to reduce vascularity pre-operatively.

Spinal procedures constitute another subgroup of interventional neuroradiology, the most common interventions being image-guided injections and vertebroplasty–kyphoplasty. Perineural or peri-articular injections of local anaesthetic and steroid, usually under CT or fluoroscopic guidance, can provide diagnostic information to localise the source of a patient's symptoms and also provide effective relief of pain.

Vertebroplasty and kyphoplasty are designed to treat painful vertebral insufficiency fractures by introducing cement or a balloon respectively into the vertebral body percutaneously.

### Clinical neurophysiology

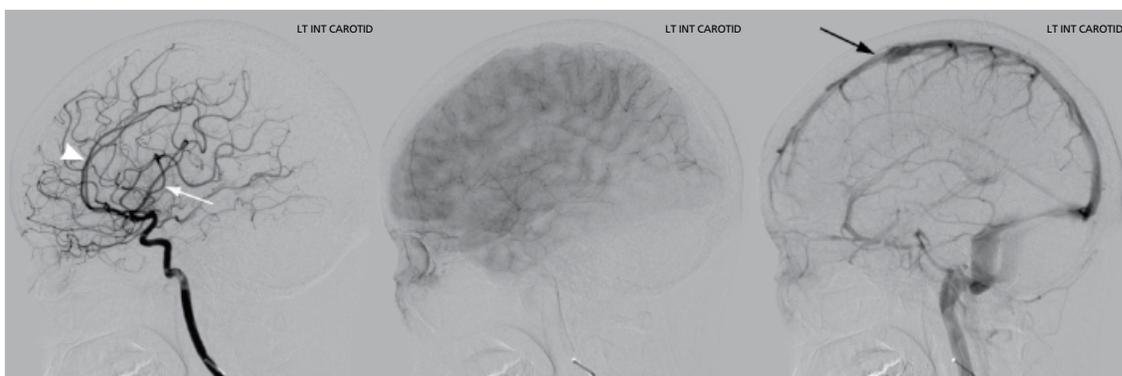

Measurement of central and peripheral electrical function has a useful role: the usual tests are outlined here.

### Electroencephalography

Electrical potentials generated by largely synchronous activity of millions of neurones are recorded simultaneously from scalp electrodes in various montages usually via 16 channels. The precise sources of the rhythms first described by Berger in 1929 remain contentious. The main role of electroencephalography (EEG) is in the investigation of epilepsy and diffuse brain diseases, in ITU in states of altered consciousness and in sleep disorders. It has been widely used in other situations, such as in headache, and in cognitive or psychiatric disorders, but it is rarely of particular value.

Videotelemetry, which combines prolonged EEG recording with simultaneous film of the patient, is very helpful in the assessment of attacks of uncertain nature and for localisation of seizures prior to epilepsy surgery (see Neurophysiology for assessing patients for epilepsy surgery, Chapter 7). Sometimes, the video is more useful than the EEG, and where there is diagnostic uncertainty, a home video (often from a mobile phone) of an attack can be extremely useful.

Specially placed EEG electrodes are also sometimes used, such as nasopharyngeal, sphenoidal and intracranial grid and strip

**Figure 4.13** Digital subtraction catheter angiogram. From left to right, the three images illustrate arterial, capillary and venous phases of a left internal carotid artery injection, in lateral projection. Note landmarks such as the anterior cerebral artery (arrowhead), branches of the middle cerebral artery (white arrow) and the superior sagittal sinus (black arrow).

electrodes and intracerebral depth electrodes to localise a seizure focus prior to potential surgery. EEG sleep studies and EEG monitoring in coma are discussed in Chapter 20 (see Coma; Sleep and its disorders; Psychogenic unresponsiveness). The principal features of the EEG are summarised here; more detailed discussion of the value of EEG in epilepsy is found in Chapter 7 (see Electroencephalography).

**Alpha, theta, delta and beta activity in normal subjects** Alpha activity seen prominently in normal subjects over the occipital lobes is an 8–14 Hz (usually 11 Hz) roughly sinusoidal waveform with amplitude some 150  $\mu$ V. Typically, alpha rhythm attenuates on eye opening. Amplitude of alpha rhythm is usually slightly higher over the non-dominant hemisphere.

Theta activity of 4–7 Hz is also seen, bilaterally and usually symmetrically. In normal subjects theta activity is more prominent below the age of 30 and during drowsiness. In many brain diseases excessive theta activity appears non-specifically.

Delta activity is a slower frequency, less than 4 Hz. Delta activity lower than 1 Hz is recorded from frontal electrodes during the first non-REM sleep period. Historically, the appearance of localised delta activity when awake was used in the diagnosis of hemisphere tumours.

Beta activity describes a rhythm faster than 14 Hz recorded normally from frontal electrodes. Excess beta activity is an effect of drugs such as barbiturates and benzodiazepines.

**EEG artefacts** Non-pathological waveforms are usually straightforward to recognise. The most common are due to eye opening – high amplitude frontal activity from scalp muscle contraction and eye movement or various sleep phenomenon. These need to be distinguished from frontal intermittent rhythmic delta activity (FIRDA), an EEG abnormality seen in raised intracranial pressure and deep midline lesions.

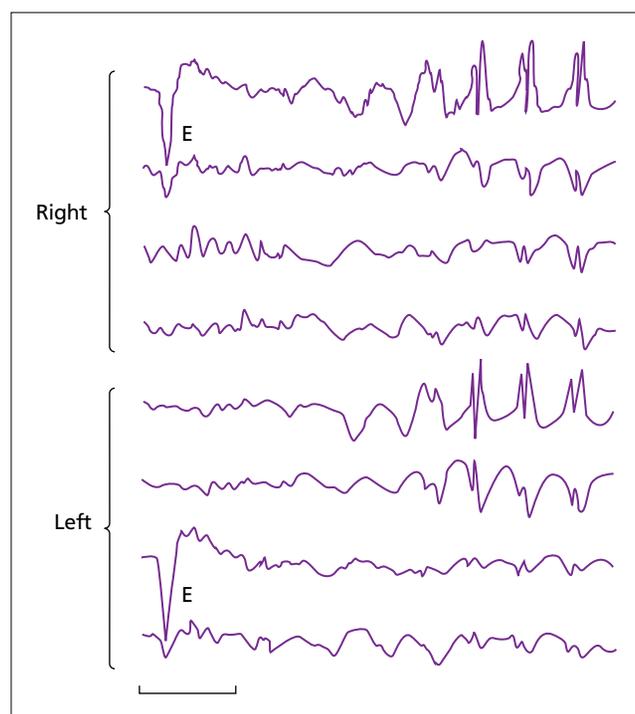

**Epilepsy** Spikes, or spike-and-wave abnormalities (Figure 4.14), are hallmarks of epilepsy but it is emphasised that over 50% of patients with epilepsy have a normal EEG between seizures. Epileptic activity is described as generalised when it is bilateral and focal (localised) when recorded over one or several neighbouring electrodes, such as over a temporal lobe. Hyperventilation, photic stimulation and sleep may enhance EEG epileptic activity and are commonly routinely employed.

‘Sharp waves’ describe waveforms that are not sinusoidal and may occur in patients who have seizures but in whom epileptic spikes are not seen. Sharp waves are sometimes seen in the normal population and are not diagnostic of epilepsy.

The value of EEG in the management of seizures, in the choice of anticonvulsant drugs and in status epilepticus is discussed in Chapters 7 (see Status epilepticus) and 20 (see Status epilepticus, EEG monitoring).

**Diffuse and focal brain disorders** Recognisable EEG abnormalities appear in several diffuse and focal brain disorders:

- Periodic lateralised epileptic discharges (PLEDS): herpes simplex encephalitis, cerebral abscess, severe anoxic brain damage or occasionally cerebral infarction.
- Repetitive generalised sharp waves at 0.5–1 second intervals: non-specific, but seen in some prion disease cases.
- High voltage stereotyped slow wave complexes, every 3–10 seconds: subacute sclerosing pan-encephalitis (SSPE).
- Triphasic slow wave complexes: metabolic disorders, typically in hepatic coma.

**Figure 4.14** Normal electroencephalogram (EEG) followed by frontal spike and wave activity. E, eye movement artefact.

**Brainstem death** The EEG is isoelectric (flat) in brainstem death and may also be so in deep coma (e.g. with barbiturates and hypothermia). An isoelectric EEG is not necessary to confirm brain death (see Brainstem death, Chapter 20).

**Clinical interpretation of EEG reports** Difficulties surround EEG reports. Reporting is not standardised, traces can be hard to interpret and many clinicians will be unfamiliar with how to report an EEG. Conclusions can only be reached within a clinical context. Some useful questions are:

- Is there generalised epileptic activity?
- Is there localised epileptic activity?
- Is there generalised abnormal slow wave activity? If so, how specific is it?
- Is there localised slow wave activity? If so, where is it?
- Could slow wave activity (theta, delta) reported be seen in the normal population?
- Is beta activity reported abnormal?
- Are ‘sharp waves’ reported truly pathological?
- In coma, is there EEG responsiveness to stimulation?

Responses to these questions, which will sometimes require discussion with a neurophysiologist, help a clinician reach a conclusion in a clinical context. In an effort to standardise EEG reporting, computerised and fractal analysis and pictorial EEG brain mapping have been tried, but none has proved generally useful. EEG records are usually now paperless but written reports by the clinical neurophysiologist and technician remain the usual way results are presented.

#### Magneto-encephalography and transcranial magnetic brain stimulation

These are largely research tools used in the study of seizures and degenerative brain diseases. Transcranial magnetic brain stimulation is used in central motor conduction velocity measurement.

A copper coil (the magic halo) is placed over the scalp. A current induces a magnetic stimulus sufficient to discharge cortical motor neurones. Muscle contraction is recorded from surface electrodes on an appropriate limb.

### Clinical neurophysiological studies of nerve and muscle

Techniques of measurement and data interpretation from studies of peripheral nerves and muscle continue to advance. This is a brief overview of a complex subject.

### Electromyography

A concentric needle electrode (CNE) is inserted into voluntary muscle. Amplified recordings from muscle (electromyogram, EMG) are viewed on an oscilloscope and heard through a speaker. Three main features are recorded:

- 1 Normal motor unit recruitment
- 2 Denervation and reinnervation changes, and
- 3 Myopathic, myotonic, myasthenic and changes such as myokymia, cramps, hemifacial spasm, or continuous motor unit activity.

Much depends upon the precise observations of the clinical neurophysiologist. Printouts of EMG traces are somewhat unhelpful compared with practical experience in an EMG laboratory. DVD clips of EMG recordings are useful.

**Normal motor unit recruitment** Normal muscle at rest is silent electrically although noise from motor end-plates may be heard if the CNE is placed nearby. End-plate noise is a steady 'shhhuush', not unlike noise within a seashell held to the ear. These are high-frequency 10–30  $\mu\text{V}$  brief (<1 ms) potentials. When a single anterior horn neurone fires, all muscle fibres connected to it contract. The contraction of each muscle fibre of the motor unit is not synchronous because of slight differences in conduction along pre-terminal branch axons, giving each motor unit action potential (MUAP or MAP) a compound broad-based waveform lasting up to 12 ms.

The interference pattern is the term used in EMG reports for the appearance and sound during muscular contraction of voluntarily activated individual motor units running together. During a gentle voluntary contraction, a single motor unit can be distinguished both audibly and on the oscilloscope. Initially, this single motor unit fires quite slowly at a rate of approximately 5 impulses per second, but at an increasing rate as voluntary contraction increases. It is then joined by a second motor unit, recognisable by its own waveform, then a third and so on. As voluntary contraction increases, more units are recruited and overlap so that individual units are no longer identifiable. This 'interference' between the units with increasing force of contraction produces the characteristic picture and sound known as a full interference pattern.

**Chronic partial denervation** If one anterior horn cell (A) fails, for example in motor neurone disease, adjacent anterior horn cells B and C produce sprouting axons that re-innervate muscle fibres originally supplied by A. In chronic partial denervation, the EMG reflects this:

- Decreased number of motor units on voluntary contraction
- Motor units are of larger amplitude than normal
- The mean duration of each muscle action potential increases; new axonal sprouts conduct impulses more slowly than normal
- Motor units may be of abnormal complexity (polyphasic); reversals of polarity are seen.

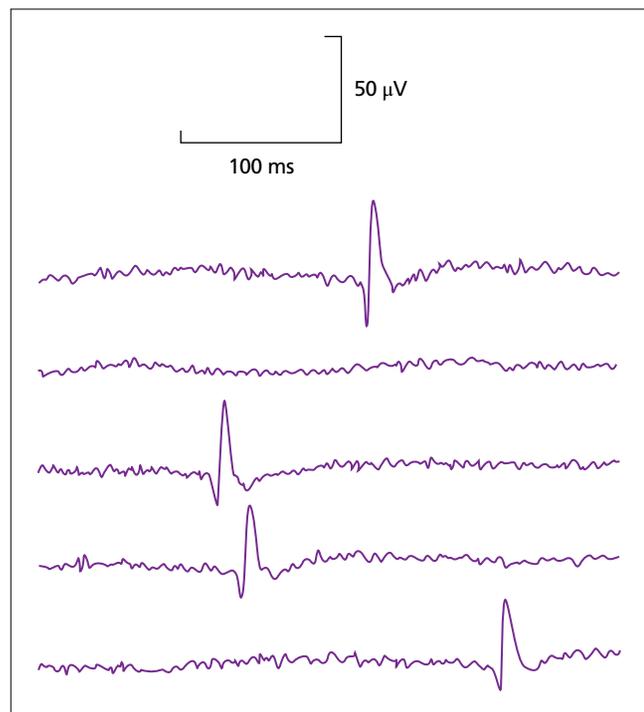

The EMG hallmarks on an oscilloscope of chronic partial denervation are thus reduced numbers of polyphasic, long duration, high voltage muscle action potentials.

**Fibrillation, positive sharp waves, fasciculation and insertion activity** When a muscle is denervated, spontaneous contraction of individual fibres begins to occur, typically after some 7–14 days in limb muscles. These contractions produce tiny spontaneous fibrillation potentials of amplitude <10–200  $\mu\text{V}$  (Figure 4.15). These have a triphasic or biphasic waveform with duration <5 ms and an initial positive deflection, displayed by convention in a downgoing direction. These movements of fibrillating subcutaneous fibres in a limb are invisible to the naked eye. However, in the tongue, involuntary movement of denervated fibres (tongue fibrillation) beneath the thin mucosa may be clearly visible. Positive sharp waves are biphasic potentials with a longer duration (<10 ms) than fibrillations and usually with amplitudes of 10–200  $\mu\text{V}$ , though occasionally, when there are also chronic neurogenic changes, up to 2 mV.

Fasciculation describes the visible twitching of a muscle seen in various situations. In normal people, benign fasciculation is common in calf muscles and in other muscles. This is sometimes cause for concern. In denervated muscle, fasciculation potentials with waveforms of dimensions similar to motor unit potentials are produced by spontaneous discharges of motor units. These cause visible twitching (fasciculation), often widespread in motor neurone disease. Typically, this visible involuntary movement flits from place to place, moving on as soon as a twitch catches the examiner's eye.

Insertion activity describes the brief, <2 second volley of muscle activity provoked by the CNE impaling a muscle fibre. This volley becomes prolonged in denervated muscle, which develops exquisite sensitivity to mechanical distortion: showers of fibrillation potentials and positive sharp waves continue for several seconds after CNE insertion. The term 'increased insertion activity' describes these features.

**Myopathic EMG changes** Myopathic muscle has, on average, fewer than normal fibre numbers in each motor unit. As each motor unit

**Figure 4.15** Fibrillation potentials from denervated voluntary muscle. Source: Hopkins 1993. Reproduced with permission of Oxford University Press.

shrinks, muscle action potentials become smaller in amplitude and of shorter duration. Surviving fibres may become sufficiently separated so that the spikes they generate do not summate to form the smooth contour of the normal motor unit. Damaged motor units are inefficient, generating less tension than their normal counterparts. Thus, for a given force, additional units must be summoned into activity. The myopathic EMG is characterised by:

- Individual units of low amplitude, of short duration and of polyphasic form
- Rapid motor unit recruitment to a full interference pattern at lower than normal voluntary effort, and
- A recognisable crackly pattern on the loudspeaker.

**Myotonic EMG changes** Myotonic muscle (see Dystrophia myotonica; Chapter 10) responds to mechanical or electrical stimulation with high frequency action potentials lasting 2–5 seconds. The discharge frequency, initially up to 150 Hz diminishes as the seconds pass producing a whine likened to a dive-bomber of propeller-driven vintage pulling out of its steep descent. Such obvious EMG findings are of less critical diagnostic value than one might expect: myotonia is usually picked up clinically when power is tested, but it can be missed. A softer sound can sometimes be heard through a stethoscope resting over a contracting myotonic muscle.

**Complex repetitive discharges** (also known as pseudomyotonic discharges) are abnormal discharges that commence and end abruptly. These are the complex polyphasic high frequency waveforms seen in both chronic neuropathic and myopathic disorders.

**Hemifacial spasm, cramps, myokymia, neuromyotonic discharges and stiff person syndrome** Hemifacial spasm (Chapter 13) is believed to be caused by ephaptic transmission (i.e. transmission between adjacent facial nerve fibres). EMG shows isolated bursts of high frequency motor unit discharges of normal waveform. There is no denervation.

Muscle cramps in normal people are also seen as repetitive high frequency motor unit potential discharges typically at frequencies of 35–70 impulses per second. In myophosphorylase deficiency (see McArdle's disease, Chapter 10), cramps occur but these discharges are not found.

Myokymia (see Other involuntary facial movements (myokymia), Chapter 13) refers to two facial phenomena:

- Quivering facial movements around the eye, common and invariably innocent, often caused by fatigue
- Worm-like wriggling movement, persistent and usually around the chin; this occurs in brainstem gliomas and MS.

Myokymic discharges are rhythmic grouped repetitive discharges of the same motor unit at burst frequencies of 5–60 impulses per second separated by a brief pause.

Neuromyotonic discharges are high frequency >150 impulses per second discharges of a single motor unit, indicating sustained electrical activity.

In stiff person syndrome (see Stiff person syndrome, Chapter 6), continuous normal motor unit activity or low-frequency activity is found simultaneously in opposing muscle groups, as one might expect from the stiffness. The stiffness and pattern of firing is reduced by agents acting either peripherally or centrally (curare, IV diazepam, general anaesthesia).

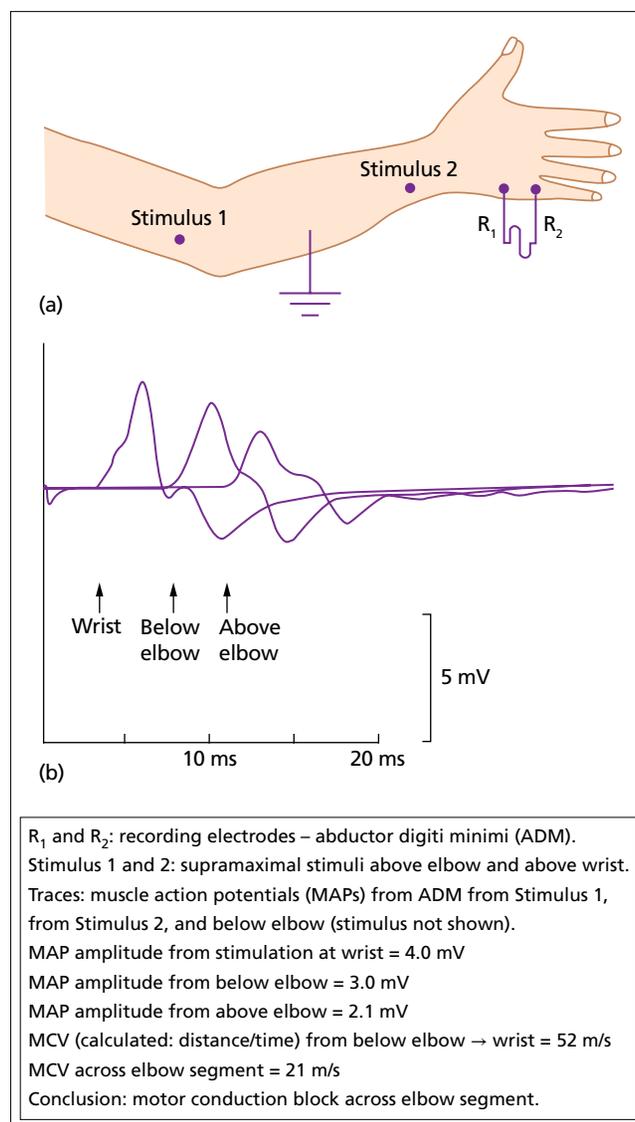

### Peripheral nerve conduction studies

Five electrophysiological measurements are of principal value in the study of neuropathies and peripheral nerve entrapment:

- 1 Motor conduction velocity (MCV)
- 2 Sensory conduction velocity
- 3 Distal motor latency (DML)
- 4 Sensory (nerve) action potentials (SAPs or SNAPs), and
- 5 Compound muscle action potentials (MAPs or CMAPs).

Accurate electrode placement and attention to detail is essential. Additional information is gained from repetitive muscle stimulation (e.g. in myasthenia). Central conduction is assessed by recording somatosensory evoked potentials (SEPs) and magnetic stimulation of the motor cortex (MEPs).

Unlike EMG in which the CNE records normal or pathological physiological responses from muscle fibres, peripheral nerve conduction studies (NCS) are carried out using supramaximal electrical stimulation. This measures conduction in the fastest myelinated nerve fibres. While NCS are useful, conduction measurement is a blunt instrument compared with the finesse of EMG methodology and interpretation. Motor conduction measurement is illustrated in Figure 4.16. Tables 4.8 and 4.9 illustrate normal values from nerves commonly tested.

**Figure 4.16** Ulnar nerve motor conduction studies: compression of nerve at the elbow. Source: Hopkins 1993. Reproduced with permission of Oxford University Press.

**Table 4.8** Motor nerve conduction studies: normal values.

Motor nerve	Recording electrode	Amplitude (mV)*	Conduction velocity (m/s)	Distal latency (ms)*
Median	Abductor pollicis brevis	≥4.0	≥49	≤4.4
Ulnar	Abductor digiti minimi	≥6.0	≥49	≤3.3
Radial	Extensor indicis	≥2.0	≥49	≤2.9
Peroneal	Extensor digitorum brevis	≥2.0	≥41	≤6.5
Peroneal	Tibialis anterior	≥5.0	≥44	≤6.7
Tibial	Abductor hallucis brevis	≥4.0	≥41	≤5.8

\*Distal latencies depend on distal distances used. Amplitudes are given as baseline to negative peak.

**Table 4.9** Sensory and mixed nerve conduction studies: normal values.

Nerve	Electrodes	Amplitude (mV)	Conduction velocity (m/s)
Median*	Digit II → wrist	≥10	≥50
Ulnar*	Digit V → wrist	≥4	≥50
Radial	Snuffbox → wrist	≥15	≥50
Sural	Dorsum → ankle	≥7	≥40
Superficial peroneal	Foot → ankle	≥4	≥40
Medial plantar*	Medial foot → ankle	≥2	≥40

\*Orthodromic technique used in United Kingdom. Amplitudes for all sensory or mixed nerve studies given as peak-to-peak values.

**Polyneuropathy** In axonal neuropathies, MCV is initially well preserved and there is primarily a reduction in CMAP amplitude. SAPs are lower than normal in amplitude. In demyelinating neuropathies, nerve MCV is markedly slowed. Slowing of motor nerve conduction below 38 m/s in the upper limbs and 30 m/s in the lower limbs cannot be explained by axonal dropout of fastest conducting fibres alone and is an unequivocal neurophysiological indicator for demyelination. SAPs are lost or diminished (see Chapter 10).

**Entrapment neuropathies** Increased distal motor latency in distal neuropathies such as in carpal tunnel syndrome, slowing of nerve conduction across the site of entrapment with diminution of relevant sensory action potential are hallmarks of nerve entrapment. Overall, MCV is preserved. Denervation occurs in affected muscles when entrapment is severe.

**F waves** These are small-amplitude muscle responses to a peripheral stimulus produced by antidromic discharges of anterior horn cells. Prolonged F wave latency or loss of F waves are seen in root lesions and in acute inflammatory polyneuropathies (Table 4.10).

**H reflexes** The H reflex, named after Paul Hoffmann (German neurophysiologist, 1884–1962, Freiburg), is generated by electrical stimulation of proprioceptive afferents. Usually the tibial nerve is

**Table 4.10** F and H waves: normal average values. Values depend on limb length and age.

Nerve	Minimum latency (ms)
Median	F ≤31
Ulnar	F ≤32
Tibial and peroneal	F ≤56
Tibial	H ≤34

stimulated at the knee, and muscle contraction of triceps surae (gastrocnemius and soleus) recorded. This is the neurophysiological correlate of a monosynaptic stretch reflex via anterior horn cells. H reflexes are delayed when peripheral conduction is slowed, such as in polyneuropathies or in (when testing the tibial nerve) an S1 root lesion.

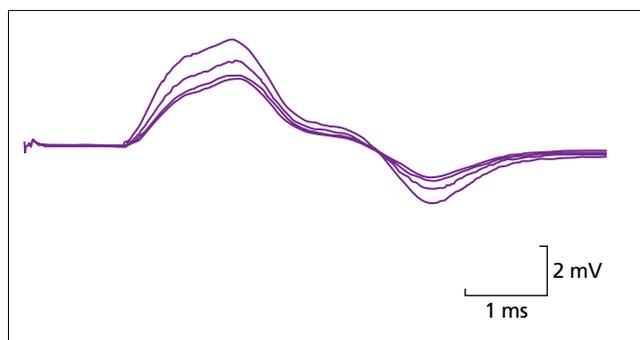

### Neuromuscular transmission studies

**Repetitive stimulation: myasthenia and myasthenic-myopathic syndromes** In myasthenia gravis, a surface electrode, for example on proximal muscles such as trapezius or a facial muscle, is positioned so that supra-maximal stimulation of the accessory or facial nerve evokes the largest demonstrable response. The nerve is then stimu-

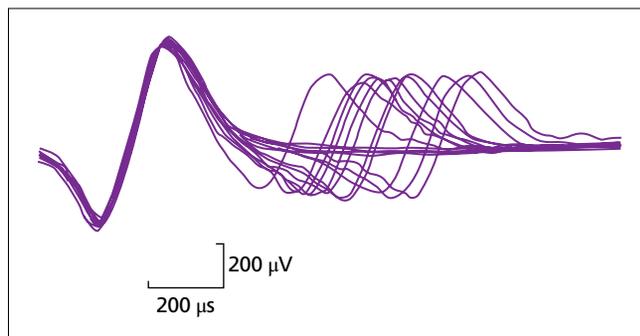

lated repetitively at 3 Hz for several seconds. In myasthenia, the responses decrease in amplitude over time (Figure 4.17). If repetitive nerve stimulation does not produce a decrement in a rested muscle, repetition after exercise for 30 or 60 seconds may do so.

In Lambert–Eaton myasthenic syndrome (LEMS), the converse is seen – facilitation (increase) of the motor response with high frequency stimulation as the train of stimulation proceeds. The amplitude of an initial response to low-frequency stimulation is lower than normal. However, repetitive stimulation or brief voluntary contraction for 10 seconds produces an increment in amplitude three to four times that of the initial response.

**Jitter phenomenon in myasthenia gravis** In myasthenia gravis, the phenomenon known as jitter can be recorded by single fibre studies. The single fibre electrode has a very small pick-up surface. Within a weakly contracting muscle, the voltage of one recorded muscle fibre potential is used to trigger the oscilloscope sweep. Action potentials from another fibre in the same motor unit are recorded but with some delay. In normal muscle, the time difference between discharges from the two fibres remains close to constant and is typically less than 50  $\mu$ s. In myasthenia, abnormal neuromuscular transmission causes variation in depolarisation time and thus in the inter-discharge interval; the second potential is seen to ‘jitter’ along the screen (Figure 4.18). Blocking, where one of the pair of muscle fibres intermittently fails to depolarise at all, is an expression of a more severe abnormality of neuromuscular transmission and is the

**Figure 4.17** Myasthenia gravis. MAP recorded from ADM. 3 Hz stimulation at wrist. First response is 4.1 mV in amplitude. Second response is 3.2 mV. Third and fourth responses (superimposed) are 2.4 mV in amplitude. Decrement = 59% – typical of myasthenia. Source: Hopkins 1993. Reproduced with permission of Oxford University Press.

**Figure 4.18** Jitter recorded in myasthenia gravis. Source: Hopkins 1993. Reproduced with permission of Oxford University Press.

basis of the myasthenic decrement on repetitive stimulation, and of clinical weakness and fatigability.

### Cerebral-evoked potentials

Evoked potentials record the time for a visual, auditory or other sensory stimulus to reach the cortex. Visual evoked potentials measure amplitude and latency of a repetitive pattern visual stimulus to the cortex. Their value in day-to-day practice is chiefly to confirm previous retrobulbar neuritis, which leaves a permanently prolonged latency despite clinical recovery. Brainstem auditory evoked potentials and somatosensory evoked responses are discussed in Chapters 11 (see Visual evoked responses) and 15 (see Baseline audiometric tests).

### Specialised blood and urine tests

Diagnostic data gained from routine blood tests are not dealt with here. Table 4.11 outlines some tests that may be unfamiliar to a newcomer to neurology and provides a reference base. Frequently, it is necessary to consult a clinical pathologist, microbiologist, neurogenetics laboratory or other specialist unit about specialised tests, their yield, relevance and cost (see appropriate chapters).

### Cerebrospinal fluid examination

CSF is the clear, colourless, almost acellular fluid around the brain, cord, nerve roots and within the ventricles. Examination provides information about these, the meninges, integrity of the blood–brain barrier and intracranial pressure. Before non-invasive imaging, lumbar puncture (LP) and CSF examination were performed frequently. Eponyms of that era such as the ‘paretic Lange’ used in the diagnosis of neurosyphilis and the ‘colloidal gold reaction’ are consigned to history. Today, indications for CSF examination are more specific. However, the reality in observed clinical practice overall is that LP remains overused and its risks underestimated. These notes outline the value, risks and procedure of LP and CSF examination. Cervical puncture is now rarely performed; it is not considered here. Ventricular CSF is sometimes examined in a neurosurgical setting, via a ventricular catheter.

### Indications for LP and CSF examination

Principal indications for LP are:

- Diagnosis in an emergency in most cases of suspected meningitis and encephalitis
- Studies of blood products within CSF following suspected subarachnoid haemorrhage (on occasion)
- Measurement of CSF pressure (e.g. idiopathic intracranial hypertension, low pressure headache, CSF leaks)
- Removal of CSF therapeutically (e.g. idiopathic intracranial hypertension, CSF leaks)
- As an aid to diagnosis by assay of CSF constituents in various neurological conditions (e.g. MS, neurosyphilis, sarcoidosis, Behçet’s disease, chronic infection, neuro-inflammatory and neuro-immunological disorders, neoplastic meningeal involvement, polyneuropathy and some cases of dementia)
- Intrathecal injection of contrast media and drugs.

In suspected CNS infection, meticulous attention should focus on examination for cells, cell types and microbiological tests. Close liaison between clinician and microbiology laboratory is essential. In addition to cell counts on fresh CSF, bacterial stains (Gram, Ziehl–Neelson), stains for fungi (India ink and others) and specific microbiological techniques (e.g. polymerase chain reactions for bacterial antigens, syphilis serology) are invaluable (Table 4.12).

**Table 4.11** Some specialised tests in neurological diseases.

Clinical problem	Laboratory tests	Comments
Wilson's disease and rare cases of cord disease	Serum copper and caeruloplasmin	Extrapyramidal disorders below 40, liver disease; unexplained cord disease with normal B <sub>12</sub>
Huntington's disease	CAG repeat assay	Chorea and extrapyramidal disease below 40 (see Chapter 6)
Hereditary neuropathies and ataxias	Various genetic tests, depending on features	See Chapters 10 and 17
Acquired neuropathies	Antiganglioside antibodies	See Chapter 10
Paraneoplastic syndromes	Antineuronal antibodies	See Chapters 8, 17, 21
Mitochondrial disease	Muscle biopsy, neurogenetic tests	See Chapter 10
Neurology with coeliac disease	Anti-endomysial and antigliadin antibodies	See Chapter 17
Leukodystrophy	Enzyme studies and genetic tests	See Chapter 19
Aminoacid metabolic disorder (e.g. homocystinaemia)	Urinary and blood amino acids	Homocystinaemia (cystathionine synthase deficiency); see Chapter 19
Adrenoleukodystrophy	Urinary very long chain fatty acids	See Chapter 19
Stiff person syndrome	Anti-GAD antibodies	See Chapter 6
Myasthenic syndromes	Anti-acetylcholine receptor, anti-MuSK antibodies, etc.	See Chapter 10
Myopathies, dystrophies	Creatine kinase, striated muscle antibodies, genetic tests	See Chapter 10
Devic's syndrome	Aquaporin 4 antibodies	See Chapter 11
Porphyrias	Urinary porphyrins	See Chapter 19
Autoimmune limbic encephalitis	Voltage-gated potassium channel antibodies, thyroid microsomal antibodies and other antibodies, depending on clinical context	See Chapter 8

Repeated CSF examination may be necessary in chronic infections such as TB. Paired CSF and blood sugar estimations are valuable in suspected infections.

Clinical and laboratory procedures for CSF spectrophotometry (e.g. rapid transport of specimens) should be clearly established if estimations of CSF methaemoglobin and bilirubin are to be made following suspected subarachnoid haemorrhage. For any specific CSF test, such as oligoclonal band (OCB) and immunoglobulin G (IgG) estimations, requests should be clearly stated with the initial CSF specimens. Parallel blood samples (e.g. sugar, OCB) should be taken when these are appropriate.

**Informed consent, risks of LP, CSF removal and intrathecal drugs** The LP procedure should be explained to the patient and its potentially painful nature. Written consent should be sought and if possible obtained.

The principal risks of LP relate first to the removal of CSF because this changes the pressure relationships within the system. Coning can occur. CSF often continues to leak into the tissues around the lumbar dura where it was punctured. This leads to low pressure (low volume) headaches (see Low pressure headaches, Chapter 12) and exceptionally to intracranial subdural haematoma.

Secondly, there are local complications at the site of LP:

- Local infection and meningitis
- Trauma – local pain, nerve root damage
- Bleeding
- Spinal epidural haematoma
- Arachnoiditis (see Arachnoiditis, Chapter 16).

Inappropriate intrathecal injection of drugs, such as antibiotics and cytotoxics, can have fatal consequences. Such tragedies are typically due to inexperience. LP should not be performed without clear risk appraisal, especially in the presence of raised intracranial pressure.

**Table 4.12** Normal CSF appearance and constituents.

Observation/measurement		Comment
Appearance	Crystal clear, colourless	Crystal (gin) clear when held to light
Pressure	60–150 mm CSF	Patient must be relaxed, recumbent with needle patent for CSF to oscillate in manometer
Cell count	<5/mm <sup>3</sup> . No polys: mononuclears only	One polymorph/mm <sup>3</sup> just acceptable
Protein	0.2–0.4 g/L	Slightly raised protein <0.7 g/L rarely pathological
Glucose	<sup>2</sup> / <sub>3</sub> to <sup>1</sup> / <sub>2</sub> of blood glucose	CSF glucose < <sup>1</sup> / <sub>2</sub> blood glucose suspicious
Culture	Sterile	Do not accept contaminants
IgG	<15% of total CSF protein	Usually only on request
Oligoclonal bands	Absent	Parallel blood sample

#### Contraindications to LP

- Suspicion of a mass lesion within the brain or spinal cord. Caudal herniation of the unci and cerebellar tonsils (coning) may occur if an intracranial mass is present and the pressure below is reduced by removal of CSF. Spinal cord compression may worsen, or even develop, if an unsuspected cord tumour is present. Such complications can develop within minutes of LP. Unconscious patients and those with papilloedema must have CT or brain MRI before LP.
- Any cause of suspected raised intracranial pressure, without careful consideration.
- Local infection near the LP site.
- Congenital abnormalities in the lumbosacral region (e.g. meningo-myelocoele).
- Platelet count below  $40 \times 10^9/L$  and other clotting abnormalities; anticoagulant drugs. Anticoagulation should be reversed before an LP is performed.

These contraindications are relative: there are circumstances when LP is carried out despite them, for example when there is papilloedema and benign intracranial hypertension is suspected. The rare issue of unsuspected and symptomless low cerebellar tonsils, which can descend further through the foramen magnum following lumbar CSF removal, will probably in future dictate that before LP, a brain MRI will be needed except in an emergency.

#### LP technique

The patient is placed on the edge of a bed or trolley in the left lateral position with knees and chin as close together as possible. The spine should be as horizontal as possible. An experienced assistant is invaluable. Several pillows are useful to help with the patient's alignment and comfort.

The third and fourth lumbar spines are felt and marked. The fourth lumbar spine usually lies on a line joining the iliac crests. Using sterile precautions, 2% lidocaine (lignocaine) is injected into the dermis, raising a bleb in the skin of either third or fourth lumbar interspace. Deeper injection of local anaesthetic should follow. The LP needle (22 gauge atraumatic disposable) is pushed through the skin in the midline. The needle is pressed steadily forwards, slowly and slightly towards the head, the operator feeling with the needle tip for the spinal interspace, pausing and/or re-aiming the needle if local resistance is encountered or substantial pain provoked. In difficult cases, radiological help may be necessary and LP carried out under screening control. When the LP needle tip is felt to penetrate the tense dura mater, the stylet is withdrawn and a few drops of CSF allowed to flow.

The CSF pressure is then measured by connecting a manometer to the shaft of the needle. Normal pressure is 60–150 mm of CSF. The CSF fluid level in the manometer oscillates slowly with respiration and transiently with the pulse and rises briefly on coughing or gentle pressure on the abdomen, assuming the bore of the needle is freely patent. CSF specimens are collected in three sterile containers. An additional fluoride sample for CSF sugar level, with a simultaneous blood sample, should be taken when relevant such as in meningitis. Some 5–15 mL CSF is usually removed for diagnostic tests (Table 4.12).

CSF pressure and naked-eye appearance should be recorded in the notes: clear, cloudy, colourless, yellow (xanthochromic), red – and if red, whether or not the colour begins to clear after the first or subsequent sample. Patients are asked to lie flat for 24 hours after LP to avoid subsequent headaches, and to drink plenty, manoeuvres of uncertain value and based on doubtful evidence. Analgesics may be needed for post-LP headaches and occasionally treatments for prolonged low pressure headaches (e.g. epidural autologous blood patches; see Low pressure headaches, Chapter 12). Post LP headaches often last several days but may continue for weeks or occasionally longer.

#### Biopsy of brain, nerve and muscle

CNS tissue is less accessible to biopsy than, for example, the liver, lung or intestinal mucosa and all biopsies in neurology require specialised techniques. Careful attention to detail, for collection of specimens, transport and processing is essential. Detailed assessment of biopsies of muscle, nerve, brain and meninges are not considered here, but some general observations may be helpful.

Biopsy of brain or of brain lesions, with or without meningeal biopsy, is carried regularly for diagnosis of brain tumours, for other mass lesions and other specific indications. Stereotactic procedures are employed increasingly (see Surgical management, Chapter 21). If there is any question of an infective process, specimens for microbiological study should be collected in appropriate media with close liaison between operating theatre and laboratory. Brain biopsy is also of some value in diagnosing the causes of dementia and for rarities such as Rasmussen's disease, Whipple disease or vasculitis. Biopsy should where possible be directed at structurally abnormal tissue, seen on imaging. Biopsy of MRI-normal brain has a low diagnostic yield. Blind biopsy of frontal regions is sometimes undertaken, where no imaging abnormalities are seen, but the chance of making a positive diagnosis in this situation is low. Meningeal biopsy is sometimes valuable in the diagnosis of chronic infection or inflammatory diseases, such as sarcoidosis. The principal risks are those of infection,

haemorrhage or damage to the surrounding brain. In competent hands, morbidity is below 2%.

Peripheral nerve biopsy (sural or radial) is commonly performed in the diagnosis of chronic neuropathies, and sometimes in vasculitis. The risks are few: infection is rare but painful paraesthesiae sometimes follow in the distribution of the nerve fascicles removed. A numb patch on the lateral aspect of the dorsum of the foot is to be expected following sural nerve biopsy and following radial nerve biopsy at the wrist, a small patch in the snuff box. Detailed microscopical studies are carried out, including electron microscopy. While many nerve biopsies do not alter management, any misgivings are brought roundly into focus by finding unexpected steroid-responsive chronic inflammatory demyelinating polyradiculoneuropathy (see Nerve biopsy; Chronic inflammatory demyelinating polyradiculoneuropathy, Chapter 10) or the occasional diagnosis of leprosy.

Muscle biopsy (deltoid or quadriceps) is a standard procedure for cases of inflammatory muscle disease, dystrophies, mitochondrial disease and metabolic myopathy with appropriate specialised stains and biochemical assays. All muscle biopsies need to be processed by specialised laboratories with ready access to electron microscopy. Open muscle biopsy rather than needle biopsy is now usual in most neurology units.

### Neuropsychological testing

The Mini Mental State Examination and Queen Square Cognitive Screening Tests have already been mentioned. More detailed testing of cognition is of value. However, there is variation in reporting, and in the scope of testing. In part, this is because of the disciplines with which neuropsychology has an interface such as neurology and psychiatry and its use in non-medical settings for assessing behaviour. The tests performed are specialised and their precise details outside the knowledge of a general neurologist. Reports tend to vary in emphasis, some dwelling on potential psychiatric diagnoses, others on treatment, while others, more within the ambit of neurology focus upon cognitive function. It is in the latter field that neurologists find most value.

### Intellectual function overall

The Wechsler Adult Intelligence Scale Revised (WAIS-R) is divided into subtests (David Wechsler, US psychologist, 1896–1981). The Verbal IQ with the National Adult Reading Test (NART) provides a measure of the premorbid optimal level of function, on the basis that reading vocabulary is relatively resistant to neurodegenerative and other processes that degrade other cognitive functions.

Performance IQ gives a measure of present overall cognitive, especially, non-verbal ability.

**Memory** Many tests to investigate different aspects of episodic memory are available:

- The Paired Associates Learning Test studies verbal memory and assesses learning of new associations between pairs of items, usually words.
- Story Recall addresses sequencing and importance of items within an incident.
- The Topographical Recognition Memory Test and Rey Figure Tests assess awareness and recall of spatial issues.
- The Recognition Memory Test is available in verbal (words) and visual (faces) versions, assessing identification of previously presented items among novel distractor items, in each domain.

Tests for verbal and non-verbal memory are useful in the localisation of damage to either the dominant or non-dominant temporal lobe, and especially medial temporal lobe structures such as the hippocampus, for instance in the work-up for possible epilepsy surgery.

**Language** Spontaneous speech is assessed for fluency, articulation, prosody and nominal impairment, content of speech and grammatical correctness.

The Graded-Difficulty Naming Test measures nominal ability (i.e. ability to name pictured items of varying familiarity).

**Literacy and calculation** Reading, spelling and calculation are assessed, for both speed and efficiency. The Graded-Difficulty Spelling and Graded-Difficulty Calculation Tests record the levels of attainment achieved.

**Perceptual function** Many tests focusing upon perceptual tasks are available: Silhouettes, Object Decision and Incomplete Letters – which are, for example capitals E, N and K in fragmented form. The Number Location Tests and the Visual Object and Space Perception (VOSP) battery study spatial perception.

**Frontal and executive function** Although included together, tests of frontal lobe and executive function are not synonymous.

Generally, these address ability to solve problems and test judgement. Unfortunately, many executive function tests are less reliable than one would wish for distinguishing whether or not a problem has an organic substrate. The Wisconsin Card Sorting Test is often used, testing ability to display flexibility and choice in the face of challenges. After seeing a number of stimulus cards, the participant is given additional cards and asked to match each to a stimulus card, and not informed whether one match is correct before progressing to the next.

The Hayling Sentence Completion Test consists of two sets of 15 sentences apiece, each with the last word missing. A sentence is read aloud; the participant has to complete it, using either a typical or a nonsensical concluding word, to provide a measure of response inhibition and lateral thinking

The Behavioural Assessment of Dysexecutive Syndrome (BADS) is a battery of six tests and also questionnaires that require planning, initiation, monitoring and behaviour adjustment to various demands:

- 1 Rule Shift Cards (testing perseveration)
- 2 Action Programme (practical problems, e.g. extracting a cork from a narrow tube)
- 3 Key Search (finding a lost key in a field)
- 4 Temporal Judgement (judgement/abstract thinking, e.g. a dog's life expectancy)
- 5 Zoo Map (formulation/implementation of plans), and
- 6 Modified Six Elements (ability to time-manage).

**Attention** Various tests of attention are used. Counting the number of letters A in a patchwork of letters is one of the simplest.

### Formulation and conclusions

The formulation carried out by the neuropsychologist draws together the results. Problems with concentration and attention must be given appropriate weighting, especially when pain, depression and anxiety are present. The neurologist needs to know whether non-organic factors might have influenced the test results

and thus close liaison with the individual psychologist is important. Interpretation of the tests needs to account for the clinical context.

## Terminology, or vocabulary of clinical neurology

Names for patterns of symptoms and signs can be called the vocabulary of clinical neurology – terms and phrases used to describe particular conditions. This is an overview of some important patterns seen in clinical practice.

### Focal cortical disorders

The cortical mantle is highly developed and differentiated in humans. Dementia (i.e. acquired progressive global cognitive impairment), with its various causes and particular modular features that frequently involve episodic memory and other specific aspects of cognition, is a common cortical problem (see Cognitive functions and their clinical syndromes, Chapter 8). This section outlines features of the principal focal lesions of the frontal, temporal, parietal and occipital cortex.

While cortical localisation by clinical assessment is greatly assisted by brain imaging, a general working knowledge of the cortex is essential. This section summarises some basic aspects within this field, but the reader should be aware of its complexity, the wide variation in approach between the disciplines of neurology, neuropsychiatry and psychology and that there is variation between individual brains. Many cortical functions are not strictly localised or depend upon interactions between the cortex and subcortical structures; beware theories that appear highly specific or didactic. In general, the more complex the behaviour or function, the less localised it is. The concept of a neural network, sometimes widely dispersed, is often a more accurate model.

### Language (and speech) disorders

Within a cultural group, language is that combination of sounds or writing with symbolic meaning necessary for interactive communication. A phoneme is the shortest unit of language, corresponding to individual consonant and vowel sounds.

A phoneme may have a different meaning in different languages. The phoneme ‘we’ the English pronoun sounds like ‘oui’ (yes) to a person speaking French.

- Dysphasia describes any disorder of language; aphasia is also often used, but see later.
- Dysgraphia describes disorders of written language, generally used to refer to a spelling deficit unless qualified as ‘motor dysgraphia’.
- Dyslexia is a disorder of reading ability; in day-to-day parlance, dyslexia is often used to refer to the common developmental problem rather than the less common acquired reading deficit caused by a focal brain lesion.
- Dysarthria is disordered motor production and/or coordination of speech sounds (articulation). Anarthria is complete inability to articulate.
- Dysphonia is a disorder of voice production, that is the speech abnormality caused by passage of expired air over poorly vibrating or paralysed vocal cords. Aphonia is complete inability, or apparent inability to produce sounds.

Aphasia should refer only to complete loss of language function, and dysphasia to some disorder of language function. The prefixes dys- (for disordered) and a- (for no or none), for aphasia/

dysphasia and related communication problems are often used interchangeably, if incorrectly, in practice and while there is some dispute about this point, we have adopted common usage – that they mean the same. We have also adopted the same practice for apraxia/dyspraxia, acalculia/dyscalculia and other focal cognitive deficits.

The study of cerebral localisation commenced with recognition in the nineteenth century that the left hemisphere was the seat of language in the majority of people. In 1861, Paul Broca (1824–1880 Paris), described non-fluent (expressive) aphasia in a patient with a tumour in the left third frontal convolution. In 1873, Carl Wernicke (1848–1905, Breslau) described fluent jargon aphasia (speaking unintelligible words) in a patient with a lesion more posteriorly placed, in the angular gyrus. Classic concepts that outlined the system as a whole such as those of Lichtheim (Ludwig Lichtheim, 1845–1928, Breslau) posited cortical modules for conceptual meanings, connected by pathways to a posterior (temporal) centre for processing phonemes, passing information via the arcuate fasciculus to an anterior (frontal) centre for programming and delivering speech output.

Difficulty naming objects – nominal aphasia – became established as a screening test, a common denominator for lesions over a wide area of the posterior frontal, temporal and lower parietal regions of the dominant hemisphere. Word retrieval in nominal aphasia correlates with frequency of a word in everyday life. Thus, slightly unusual objects, for example the winder button (stem button) rather than the wristwatch itself are preferable when asking the question: ‘What is this called?’

This section summarises features of four basic varieties of aphasia, derived originally from the concepts of Lichtheim and others. Mixed and incomplete varieties of aphasia are common, and terms such as fluency, while useful descriptively, have limited value for understanding the physiology of these disorders.

**Non-fluent aphasia (Broca’s aphasia, motor or anterior aphasia)** This is the most common variety of aphasia following stroke. The hallmark is the slow, incomplete and laboured production of language, with a major breakdown of grammatical output:

- The patient is fully aware of the problem and often distressed.
- Grammar and syntax are lost. Tenses of verbs are incorrect. Adjectives and conjunctions are lost more than the nouns for common objects.
- Perseveration is common.
- Prosody (normal rhythm) is lost.
- Ability to repeat phrases is lost.
- Comprehension is relatively preserved but complex multiple commands will usually reveal some lack of understanding.

The lesion is around the left, third (inferior) frontal convolution, lower (inferior) motor cortex and nearby temporal insula. The closeness of the motor strip to Broca’s area explains why contralateral UMN facial weakness and hemiparesis/hemiplegia are frequently seen. There may also be facial apraxia – dissociation between the idea and production of a non-verbal facial movement such as whistling. Cortical dysarthria, also known as speech apraxia describes the situation when this apraxia extends to speech itself, causing slurring and hesitancy.

**Fluent aphasia (posterior, sensory or Wernicke’s aphasia)** The essence of this variety of aphasia is production of fluent speech that lacks meaning. Patients typically appear to have little insight into an evident problem and are talkative. They look bewildered and tend to be

agitated. Phonemic and semantic confusions are common and sometimes prominent. Neologisms (new, meaningless words) are formed with outpourings of meaningless jargon. Prosody tends to remain normal. Ability to repeat phrases is lost; comprehension is lost.

Patients are sometimes mistaken for being psychiatrically ill. This is the aphasia subtype that is most likely to be mistaken for 'confusion' by the casual observer; occurrence of jargon and preserved alertness are clues to the correct diagnosis. If a patient with Wernicke's aphasia recovers, which is unusual, they say they were unaware they had been speaking nonsense. Also, they had been unable to grasp what others had been saying, as if they had been listening to an incomprehensible language.

**Conduction aphasia** Reduced ability to repeat spoken words or phrases but with reasonable comprehension are features of conduction aphasia, seen with a lesion of the arcuate bundle between posterior and anterior language areas, and posteriorly situated lesions in the cortical language area. The pattern consists of:

- Fluent speech, with nominal dysphasia, semantic confusions with phonemic errors but characteristic attempts at self-correction, often repeated
- Poor repetition - particularly marked for phrases
- Relatively preserved comprehension.

**Transcortical aphasias, motor and sensory** Preserved ability to repeat spoken words, phrases and sometimes longer passages is the striking feature of transcortical aphasias. The arcuate fasciculus remains intact. Transcortical motor aphasia (TMA) describes a non-fluent aphasia caused typically by a lesion in the left anterior superior frontal region. Patients with TMA have sparse spontaneous speech, with phrases that are short but grammatically correct. These patients have lost the ability to generate new verbal messages: a condition also called dynamic aphasia, because the language disorder is only evident under certain conditions, in particular where novel language output is required. However, they retain the ability to repeat words, phrases or sentences. Repetition is believed to be preserved because the arcuate fasciculus remains intact. Comprehension remains reasonably normal.

Transcortical sensory aphasia (TSA) is caused typically by lesions behind Wernicke's area in the temporal-occipital-parietal region, or more ventrally and anteriorly in the dominant temporal lobe. Patients with TSA have poor comprehension but fluent and reasonably grammatical speech, with preserved repetition. However, they tend to have marked anomia and produce semantic paraphasia (i.e. they do not use words that are correct, but substitute words of similar content, such as pear for apple, pen for writing paper, substituting approximate words or relying on circumlocutions such as 'thingy'). This condition closely resembles the aphasia of semantic dementia, in which a primary breakdown of verbal semantic memory leads to loss of vocabulary and single word comprehension caused by selective degeneration of the anterior temporal lobe.

Mixed transcortical aphasia (MTA) is characterised by both severely reduced language output and by impairment of comprehension, but with preservation of the ability to repeat words and phrases. Patients with this unusual form of transcortical aphasia have a major disability, with difficulty producing propositional language and understanding what is being said to them. However, they can repeat phrases and even complex sentences, and finish a familiar poem or song, once they hear the beginning of the

composition. Generally, in MTA, both Broca's and Wernicke's areas and the arcuate fasciculus between them remain intact. The surrounding regions are believed to be damaged, isolating these areas.

**Agraphia and acquired alexia** Written symbol comprehension depends on the integrity of the dominant angular gyrus. Lesions in this cortical region cause acquired alexia usually with agraphia. Isolated alexia without agraphia is seen with either anterior occipital lobe lesions and/or lesions of the splenium of the corpus callosum.

### Temporal lobe lesions

Many small (<2 cm) unilateral temporal lobe lesions are silent in terms of cognitive abnormalities. Epilepsy is common (see Partial seizures, Chapter 7). Upper quadrantic hemianopia is seen when the forward-looping fibres (Meyer's loop; see Optic radiation, Chapter 2) are damaged. A lesion in the more posterior dominant anterior temporal lobe often causes a posterior (Wernicke) aphasia, or less commonly (particularly if bilateral) 'word deafness', that is selective inability to understand spoken (but preserved understanding of written) speech, caused by damage or disconnection of auditory areas in or near Heschl's gyrus.

Non-dominant anterior temporal lobe lesions particularly when they involve more ventral cortex are sometimes associated with inability to recognise faces (prosopagnosia). Unilateral mesial temporal lobe lesions can also produce subtle changes in memory, more marked for verbal material in the dominant and faces and topographical features in the nondominant hemisphere, but often silent clinically until revealed by specific neuropsychological tests.

Bilateral temporal lobe lesions, such as those that follow herpes simplex encephalitis cause profound loss of memory for recent events. Bilateral temporal lobe injury in primates causes hypersexuality, hyperphagia, hyperactivity and aggressive behaviour (Klüver-Bucy syndrome: Heinrich Klüver, US neurologist, 1898–1979; Paul Clancy Bucy, US neuropathologist, 1904–1992). Sometimes, in humans, there are elements of this such as episodic temper dyscontrol but the usual outcome is aimlessness, diminished libido and impaired potency.

### Frontal lobe lesions

As in the temporal lobes, many frontal lesions remain silent, though this is likely in part to reflect our limited ability to measure complex behavioural changes reliably. Frontal cortical areas have multiple connections with subcortical structures including the basal ganglia and limbic systems and these distributed networks mediate a range of emotional, social and motivational behaviours. Lesions involving the dorsal frontal convexities are more likely to cause impassivity and apathy (more medial lesions may cause mutism) while lesions of the orbitofrontal cortex are more likely to produce disinhibition; however, anatomical localisation is imprecise.

Lesions involving the dominant inferior frontal gyrus cause anterior (Broca's) aphasia. Substantial damage such as traumatic frontal brain injury, direct or contra-coup) causes a highly disabling lack of social control. Examples of this are:

- Abandonment of the usual social inhibitions – from somewhat inopportune, often rude comments to profound disturbances such as urination, exposure or masturbation in public.
- Inappropriate jollity (*witzelsucht*) – jokes and tales often overlong and unwanted, and/or loss of empathy.

- Apathy (abulia), lack of initiative and poor planning (dysexecutive problems).
- Irritability, anger or the converse, inappropriate placidity in the face of irritation.
- Poor planning, distractibility or conversely obsessive behaviour.
- Continuing one action when another is appropriate, known as motor perseveration.
- Utilisation behaviour (environmental dependency). The subject sees a tool, such as a stethoscope during a consultation and begins to use it.

These frontal lobe features may be accompanied by release of primitive behavioural programmes dating from early infant development, such as grasp, rooting or sucking reflexes. Deep bilateral frontal lesions, such as small vessel disease in the elderly, can lead to gait apraxia and failure to initiate walking (gait ignition failure), often with sphincter disturbance.

Alleged brain damage associated with behavioural change has become a common plea in claims following minor head injury, when headaches and moodiness are common. The patient and relatives are asked leading questions about features such as impulsivity, temper, socialisation, fiscal ability, multi-tasking, planning, prioritisation, depression and anxiety – all of which are common problems in stressful situations. There is no evidence that these complaints are caused by brain injury following a minor blow to the head, when imaging is normal.

Frontal lobe seizures are described in Chapter 7 (see Frontal lobe epilepsy).

### Occipital lobe lesions

Field defects of occipital lobe lesions are mentioned in Chapter 14 (see Visual cortex). Neglect or even denial of virtually complete visual loss (cortical blindness or Anton's syndrome) are sometimes seen following bilateral occipital lobe infarction. An explanation for the phenomenon known as blind sight (perception of objects when the occipital cortex is destroyed) is the preservation of anterior visual pathways via the lateral geniculate bodies that are below the level of awareness. Epilepsy, with episodes of flashing lights or, rarely, more formed features, can occur with occipital lobe lesions.

### Parietal lobe lesions

These areas are concerned with the integration into perception of complex visual and somatosensory information, such as awareness of body parts in space and their relation to objects. A complex nomenclature has evolved to describe these perceptual defects. Attempts to associate precise parietal lobe areas to particular functions are bedevilled by variation between individuals, and because the brain is not divided into discrete compartments. The following are seen with lesions of either parietal lobe:

- Attention defects in the contralateral visual field and neglect of the opposite side of the body. Lower quadrantic homonymous field defects occur when the optic radiation is damaged.
- Astereognosis – inability to recognise common objects placed in the palm despite apparently normal peripheral sensation.
- Agraphesthesia – inability to recognise numbers drawn on the palm with the examiner's finger. However, the range of normal graphesthesia is so wide that this sign is only useful if there is clear asymmetry between the palms.
- Pseudo-athetosis (waving about) and/or drift of an outstretched contralateral hand.

- Contralateral cortical sensory loss manifesting as impaired two-point discrimination despite intact elementary peripheral sensation.

Sensory epilepsy is sometimes a feature of parietal lobe lesions.

**Dominant parietal lesions** Inability to execute a skilled movement despite no discernable weakness may be seen – apraxia. For example, the patient may not respond to verbal suggestions such as 'Imitate combing your hair' or 'Pretend to turn a key in a lock': this is 'ideational' apraxia, inability to execute learned motor programmes. Alternatively, the patient may have particular difficulty imitating a meaningless gesture made by the examiner: 'ideomotor' apraxia. Typically, they are bewildered, moving the hand in a non-purposive way or attempting to 'close in' on the examiner's hand.

Lesions of the dominant parietal lobe may produce impairment of literacy skills: alexia (impaired reading), agraphia (impaired writing/spelling) and acalculia (impaired arithmetic). The constellation of these with addition of finger agnosia (inability to name individual fingers) and right-left disorientation is often referred to as Gerstmann's syndrome (Josef Gerstmann, 1887–1969).

Auditory short-term verbal memory is conveniently measured at the bedside as a digit span; normally, a string of 7 ( $\pm 2$ ) digits can be repeated forwards while a string of 5 ( $\pm 2$ ) digits can be actively reversed. These measures assess working memory, meaning the short-term memory store used in everyday life when repeating a phone number. Working memory impairment frequently accompanies delirium but, if it occurs in a clear sensorium, has potential localising value as a dominant parietal sign. A discrepancy of  $>2$  digits between forward and reverse digit span is a useful marker of executive dysfunction.

Neglect of contralateral limbs is typically less prominent with dominant than non-dominant parietal lesions.

**Non-dominant parietal lesions** Patterns include:

- Neglect of the opposite limbs. Neglect can extend to denial that the limbs are the patient's own.
- Inability to construct or draw shapes such as a house or a clock face. The left side of a picture drawn (such as numbers 1–5 on a clock face) tend to be omitted by a right-handed patient with a right parietal lesion. This difficulty with reproducing visual designs is often termed 'constructional apraxia'.
- Visual apperceptive agnosia – inability to perceive objects under degraded viewing conditions or from an unusual angle.

### Motor abnormalities: brain and spinal cord

The patterns of abnormality within the motor system are both distinct and recognisable. Features of hemiparesis (and hemiplegia) and paraparesis, cerebellar syndromes and disorders of movement are summarised here.

#### Hemiparesis

Weakness of the limbs of one side resulting from a pyramidal tract lesion is known as hemiparesis, the term paresis indicating that weakness is not total (cf. hemiplegia, when there is total loss of power following a stroke). The signs of an early hemiparesis, sometimes before weakness becomes evident, are scuffing of the toe of one shoe, drift of one outstretched upper limb on examination or a

trace of impaired fine finger and/or toe movement. Thereafter emerge the five principal features of a pyramidal lesion:

- 1 Increase in tone
  - 2 Weakness in a typical pattern, with upper limb extensors weaker than flexors, and lower limb flexors weaker than extensors
  - 3 Progressive loss of fine movement
  - 4 Unilaterally exaggerated tendon reflexes, and
  - 5 Extensor plantar response (Babinski) and absent abdominal reflexes.
- These features gradually develop as a hemiparesis progresses or emerge following the sudden hemiplegia of a stroke. However, in either case, not all these features of a UMN lesion are required to make a firm diagnosis.

As a corollary, to find weakness alone as the sole feature of a hemiparesis is highly unusual and raises the question of whether or not the problem has an organic basis.

### Cerebellar syndromes

Features of cerebellar disease are well-defined and straightforward to recognise compared to our knowledge of the complexity of cerebellar function (Table 4.13). Perform examination correctly to elicit early cerebellar signs.

In established cerebellar disease there are several practical points. The first relates to clinical urgency. If an expanding mass lesion of the cerebellum is strongly suspected or found on imaging, there needs to be speedy liaison with a neurosurgeon. While all mass lesions of the brain are potentially serious, many brain tumours above the tentorium can be dealt with in an expectant manner. With cerebellar tumours the rapidity of progression and development of tonsillar herniation over several hours can catch out the unwary.

Secondly, when a severe cerebellar syndrome is part of a multi-system degenerative disease, pyramidal features can be masked. Extensor plantars may be the only pyramidal sign. Finally, ascribing ataxia of stance and gait of midline cerebellar lesions as non-organic has happened all too frequently. The causes of cerebellar syndromes are given in Chapter 17 (see The ataxic disorders).

### Disorders of movement

The broad distinction is between akinetic-rigid syndromes and dyskinesias; the principal disorders are listed in Table 4.14. No amount of written description surpasses looking at a disorder of movement, either in the flesh or on video. The types of movement disorders are considered in more detail in Chapter 6 (Movement).

Some presentations cause diagnostic difficulties regularly. First, when an akinetic-rigid condition becomes apparent, early idiopathic Parkinson's disease tends to be over diagnosed. The reality, evident

**Table 4.14** Principal disorders of movement.

#### Akinetic-rigid syndromes

Idiopathic Parkinson's disease  
 Parkinsonism-plus syndromes  
 Drug-induced parkinsonism (e.g. phenothiazines)  
 Post-encephalitic parkinsonism  
 MPTP-induced parkinsonism  
 Childhood akinetic-rigid syndromes

#### Dyskinesias

Tremors  
 Chorea  
 Hemiballismus  
 Myoclonus  
 Tics  
 Dystonias  
 Paroxysmal dyskinesias  
 Drug-induced dyskinesias

MPTP, 1-methyl 4-phenyl 1,2,3,6-tetrahydropyridine.

some years later, is that sometimes the cause is a less common akinetic-rigid syndrome. Parkinson's disease is almost always asymmetrical. Parkinson's disease should be diagnosed with caution if rest tremor is not apparent. Progressive supranuclear palsy or multiple systems atrophy tend to be symmetrical from the onset, although the poverty of movement is similar to that seen in Parkinson's disease. Early Wilson's disease should be considered in an akinetic-rigid syndrome beginning below the age of 40.

Benign essential tremor (BET) can cause difficulty. Usually in BET, tremor is seen when the limbs adopt a particular posture. However, there are forms of BET that mimic benign tremulous Parkinson's disease in the early stages. To complicate matters, occasionally action tremor is seen in BET, raising the possibility of cerebellar disease. The passage of time usually sorts out these difficulties.

Early chorea is also easy to miss, being mistaken for restlessness and normal fidgeting. A minor degree of dystonia can also escape recognition. Lower limb myoclonus can look remarkably like the ankle clonus of spasticity.

Finally, the diagnosis of a psychologically determined movement disorder is fraught with difficulty, and frequently wrong when made early. In movement disorder clinics, a substantial proportion of those labelled as functional, somatoform or conversion hysteria, whichever term is chosen, turn out to have organic disease.

### Paraparesis

Spastic paraparesis, meaning lower limb weakness of cord or, rarely, cortical origin, is one of the pivotal diagnoses of neurology. Prior to the era of MRI, clinical examination had a major role in differentiating between cord compression, a potential neurosurgical emergency, and other causes of paraparesis.

As with a hemiparesis, the clinical picture begins with subtle features:

- Scuffing the toes of shoes, often worse on one side
- Stiffening of gait (spastic gait) with retention of a narrow base

**Table 4.13** Principal features of cerebellar syndromes.

#### Lateral cerebellar lobe lesions

Rebound  
 Action tremor  
 Past-pointing  
 Dysdiadochokinesis  
 Dysarthria  
 Nystagmus (towards lesion if vestibular connections involved)

#### Vermis lesions

Ataxia of stance, trunk and gait, sometimes with negative Romberg test (a test primarily of proprioception)

- Noticeable beats of ankle clonus (e.g. on a step or kerbstone)
- Changes in lower limb sensation.

Spinal pain is a common feature of cord compression. For example with a thoracic meningioma, pain at the level of the tumour, develops with an emerging spastic paraparesis and a sensory level, rising from below to the site of compression. The patient complains of numbness or altered sensation commencing in the feet that marches upwards over weeks or months. Brown-Séquard features (pyramidal signs on one side, spinothalamic on the other) may become apparent.

These features apply equally to tetraparesis (*syn.* quadriplegia).

The five principal features of a pyramidal lesion may not all be present. Pain may not be present in cord compression. Marked asymmetry can sometimes cause difficulty. Seek out subtle signs.

Two questions arise when signs of spastic paraparesis are found:

- 1 Is the paraparesis caused by spinal cord compression?
- 2 Is the paraparesis the result of a condition in which it is part of the clinical picture?
  - Multiple sclerosis
  - Motor neurone disease
  - Subacute combined degeneration of the cord
  - Syringomyelia
  - Cortical lesions such as a parasagittal meningioma, hydrocephalus and other brain lesions can occasionally present as a paraparesis.

Paraparesis is also caused by many rarities, such as vascular anomalies of the cord, adrenoleukodystrophy and copper deficiency (Chapter 16).

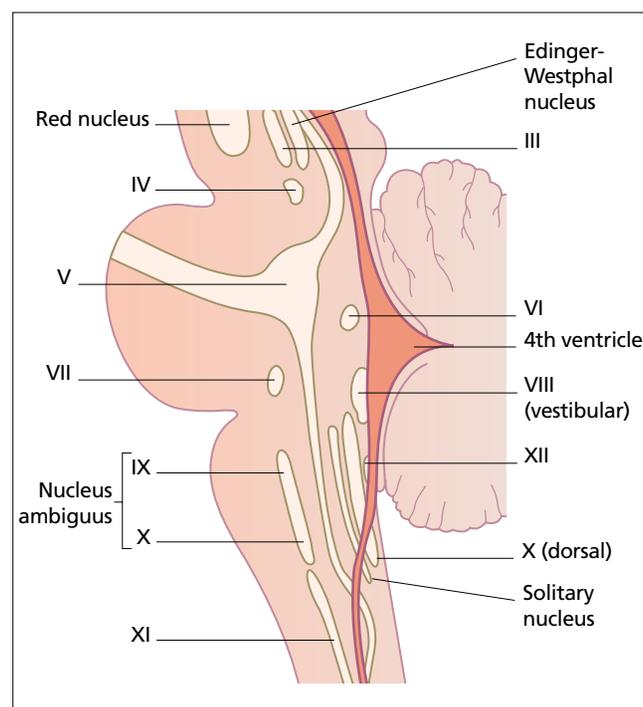

There can be many difficulties with the diagnosis of paraparesis, both in the referral process and within neurology. First, in the community and in primary care, the emergence of difficulty walking is sometimes not taken seriously, and early features of a paraparesis can pass unrecognised unless a neurological examination is carried out. The onset of any gait disturbance demands an explanation. A second issue, within neurology, is misinterpretation of lower limb signs, thinking that they are pyramidal in origin when they are not:

- Parkinson's disease affecting predominantly the lower limbs can be mistaken for spinal cord disease.
- Cortical myoclonus in the lower limbs can be mistaken for pyramidal ankle clonus.
- Stiffness of inflammatory muscle disease, such as polymyositis can be mistaken for spasticity.
- Brisk but normal lower limb reflexes are misinterpreted as pathological, thus prompting investigation for a paraparesis.

### Brainstem syndromes

Brainstem anatomy is outlined in Chapter 2 (see The brainstem). Figure 4.19 is a helpful diagram: think of the level within the brainstem and of the dorso-ventral plane. The usual hallmark of a brainstem lesion is the coexistence of features of damage both to motor and/or sensory fibres passing through it and to cranial nerve nuclei. Syndromes involving oculomotor nerves III, IV and VI indicate upper or mid brainstem disease affecting the area dorsally. Mid and lower brainstem disease affects cranial nerve nuclei VII–XII.

Bulbar and pseudobulbar palsy are terms used to describe common lower brainstem syndromes (see Bulbar and pseudobulbar palsy, Chapter 13). Both cause dysarthria, dysphagia, drooling and respiratory problems. Bulbar palsy describes disease of the lower cranial nerves (IX, X, XII), that is the nerves of the medullary bulb,

**Figure 4.19** Brainstem: lateral schematic view. Source: Hopkins 1993. Reproduced with permission of Oxford University Press.

their nuclei and muscles supplied. Pseudobulbar palsy is shorthand for UMN lesions of lower cranial nerve nuclei. MS, brainstem stroke and motor neurone disease cause pseudobulbar palsy, the latter usually both bulbar and pseudobulbar. Advanced Parkinson's disease and other extrapyramidal syndromes also cause poverty of movement of the bulbar muscles.

### Anterior horn cell disease

The anterior horn is the ventral grey matter in the spinal cord. It contains the motor neurones, that are flowing out of the spinal cord, through the spinal roots, to innervate muscles. Anatomically, the neurones are somatotropically organised (medial innervation of proximal muscles and lateral innervation of distal muscles), and the pattern of weakness depends on the level of the spinal root(s) affected. There are relatively few diseases that afflict the anterior horn; are all serious. The most common are: motor neurone disease (MND), the spinal muscular atrophies, Kennedy's disease, poliomyelitis and some viral diseases (notably West Nile virus, see Chapter 9). The conditions produce lower motor neurone signs of wasting and weakness in the affected muscles (see Anterior horn cell diseases, Chapter 10). Motor neurone disease is the most common anterior horn disorder in western neurological practice, often characterised by prominent fasciculation with additional upper motor neurone signs. Typically too in all anterior horn cell diseases, initially at least, the pattern of weakness is highly selective, reflecting the somatotropic and root pattern of innervation. For instance, patients with motor neurone disease can present with weakness of one or two finger flexors only before more widespread changes occur. Neurophysiological tests are characteristic with normal conduction velocities, small amplitude CMAPs, normal sensory conduction, larger than normal motor unit potentials, denervation and reinnervation patterns.

### Sensory abnormalities: patterns at different levels

Sensory symptoms and signs are difficult to evaluate. The pattern of symptoms may be unfamiliar, examination time-consuming and its results less certain than reflex and motor abnormalities. Eponyms abound, such as positive Tinel, tic douloureux, causalgia, anaesthesia dolorosa, lightning pains, Lhermitte, Brown-Séguard, dissociated sensory loss, suspended sensory loss, sacral sparing, thalamic pain and astereognosis. The principal patterns of sensory disturbance are outlined here.

An approach that some find valuable is to view sensory symptoms in one of two ways. First, if a sensory symptom is the principal complaint, such as the pain of trigeminal neuralgia (see Trigeminal neuralgia, Chapter 13) or nocturnal tingling of the hands in early median nerve entrapment at the wrist (see Carpal tunnel syndrome, Chapter 10), the quality of the symptom is frequently diagnostic. In other situations, the combination of the history, sensory signs and other neurological signs point to an anatomical diagnosis. An example is the sensory signs that point to the level spinal cord compression when the principal feature is spastic paraparesis. Figure 4.20 summarises various patterns of sensory loss.

### Peripheral nerve lesions

A lesion of an individual peripheral nerve produces symptoms and signs within its distribution. Nerve section is followed by complete sensory loss. Demarcation is clear-cut. The areas of sensory loss found in individual nerve lesions are discussed in Focal and compressive neuropathies, Chapter 10. In nerve entrapment or partial damage, the quality of sensory disturbance varies between numbness, tingling and painful pins and needles. Jules Tinel (1879–1952, Le Mans and Paris) wrote about gunshot wound nerve injuries in 1917. He described painful tingling in the distribution of a damaged nerve when it was percussed, now known as a positive Tinel's sign. In some cases of carpal tunnel syndrome when the median nerve at the wrist is tapped lightly at the wrist, there is sharp tingling in the thumb and the three and a half fingers innervated by the median nerve.

Neuralgia (see Neuropathic pain, Chapter 23) describes pain of great severity in the distribution of a nerve or nerve root. In trigeminal neuralgia (*tic douloureux*; see Trigeminal neuralgia, Chapter 13), the paroxysmal nature of the pain, its distribution and electric shock-like quality are diagnostic.

Causalgia (see Complex regional pain syndrome, Chapter 23) describes chronic pain after nerve section or crush injury and is sometimes seen after amputation. Anaesthesia dolorosa is spontaneous pain occurring in an anaesthetic area. It is used to describe discomfort or chronic debilitating pain, developing for example after destructive procedures to the trigeminal nerve.

### Sensory root and root entry zone lesions

The distribution of spinal dermatomes is shown in Figure 4.21. Unlike peripheral nerves there is some overlap between adjacent dermatomes making the area of sensory loss following a single nerve root lesion smaller than shown. Root pain is typically perceived both within the dermatome and within the myotome but tends to be less demarcated than pain in a peripheral nerve lesion. For example, with an S1 root lesion resulting from a lumbosacral disc, the sensory disturbance is down the back of the leg, typically without clear dermatome demarcation. Stretching of the nerve root by straight leg raising or increasing local spinal CSF pressure (coughing, straining) typically makes matters worse.

When a root is affected within the cord, such as in tabes dorsalis, sudden, irregular, very intense stabbing pains involve one or more spots, typically on the ankle, calf, thigh or abdomen. These are known as the lightning pains of tabes and are seldom seen today.

Neuralgia in a nerve root distribution can follow shingles (see Post-herpetic neuralgia, Chapter 23). This is a persistent distressing burning pain.

### Spinal cord lesions

**Posterior columns** Symptoms, although they may be worse on one side, are often not clearly demarcated. Patients describe various patterns of symptoms:

- Band-like sensations around trunk or limbs
- Limb clumsiness and deadness
- Numbness and burning
- Electric shock-like sensations.

Joint position sense, vibration, light touch and two-point discrimination become diminished below a cord lesion. Stamping gait and pseudochorea of the outstretched hands are the product of failing position sense.

Lhermitte's sign is a sudden electrical sensation down the back and into the limbs produced by bending the head forward, stretching the cervical cord. Lhermitte's is diagnostic of lesions of the posterior columns or occasionally caudal medulla. It is seen in:

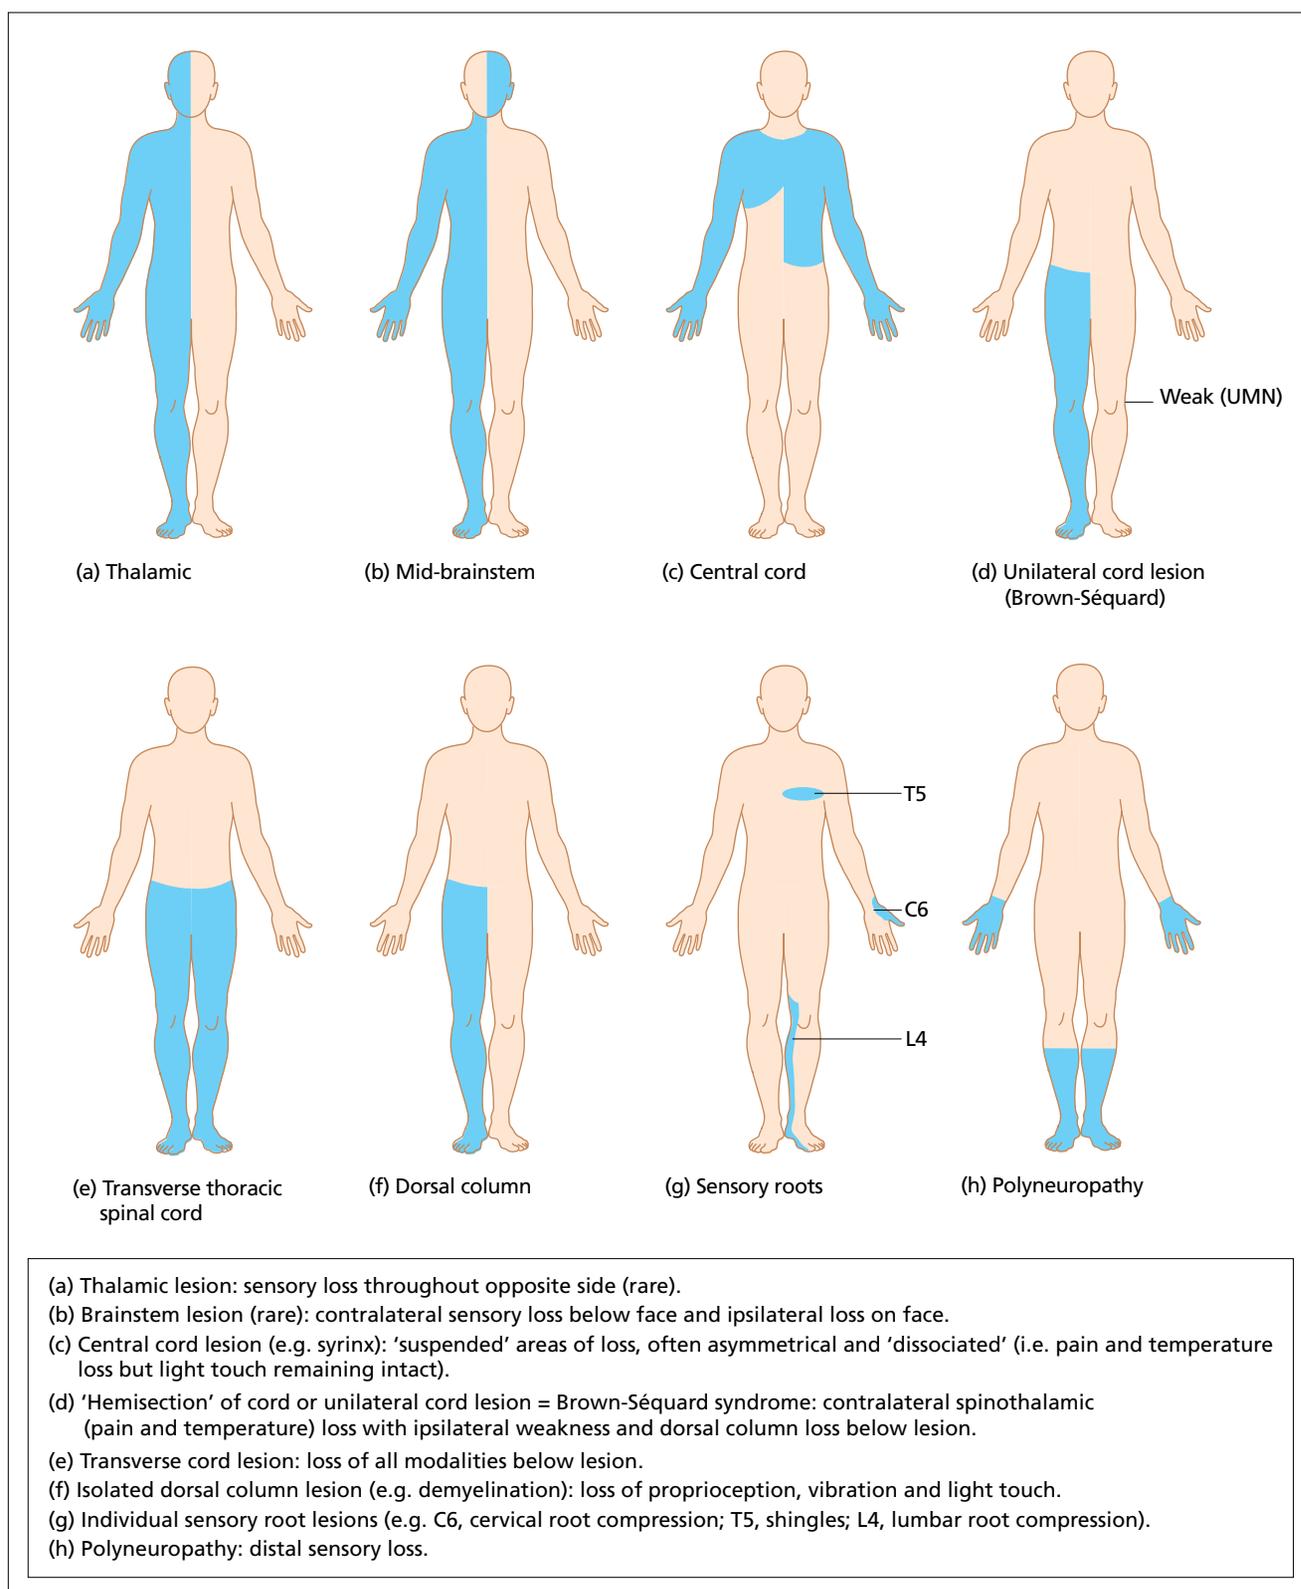

- MS, typically in exacerbations
- Cervical myelopathy
- Radiation myelopathy
- Subacute combined degeneration of the cord, and occasionally in
- Cord compression, Behçet's, Arnold-Chiari syndrome and following trauma.

The phenomenon was probably first described by Pierre Marie and Charles Chatelin (Paris, 1917); Jean Lhermitte re-described it in 1920, writing the seminal article some 4 years later.

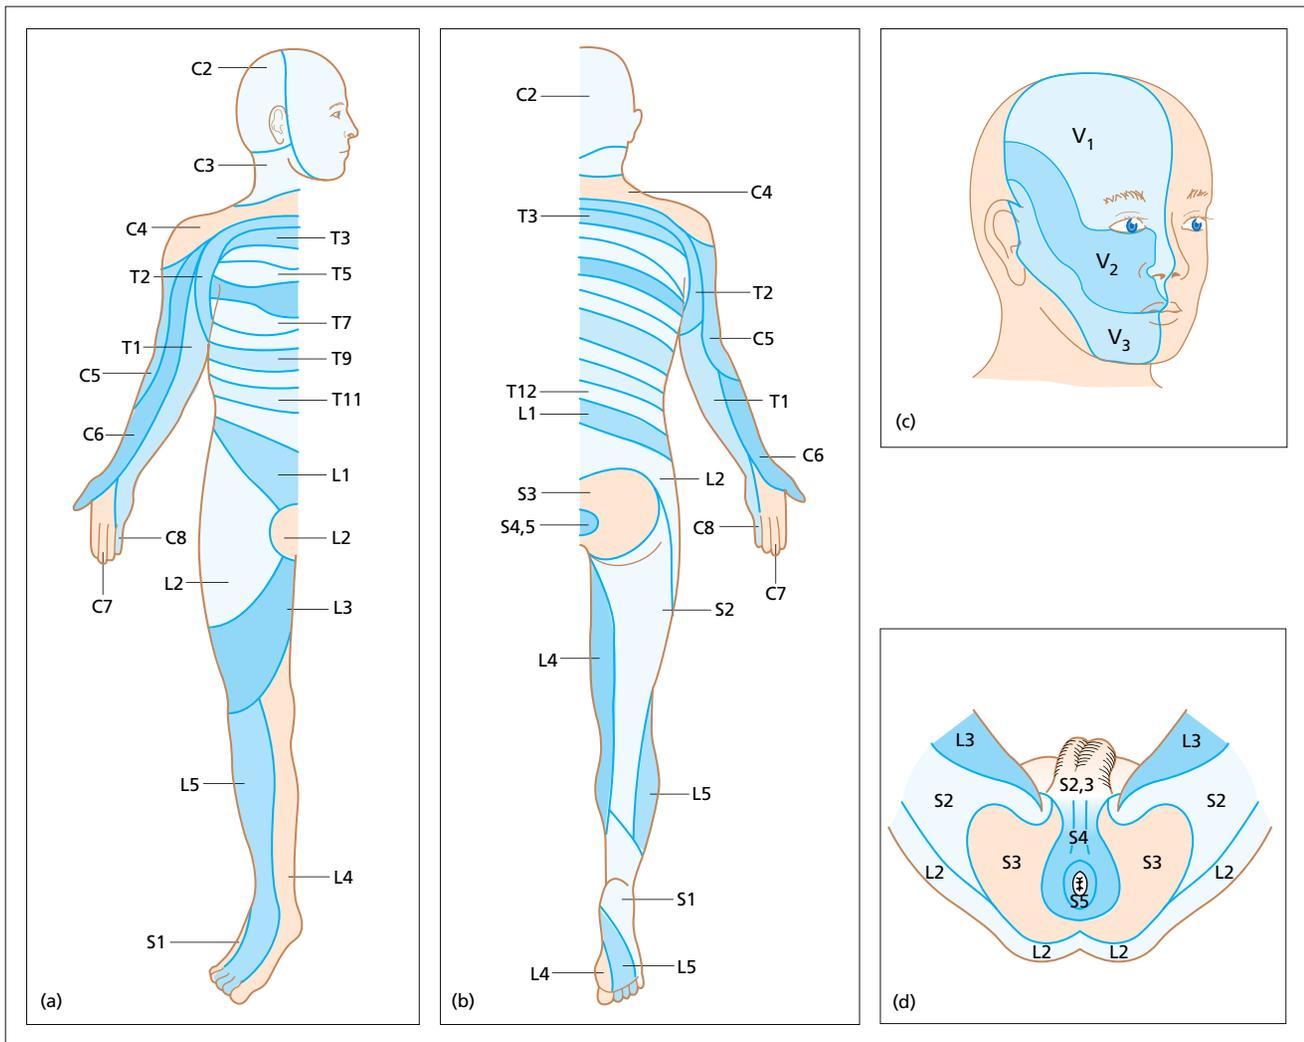

**Spinothalamic tracts** A lesion within the spinothalamic tracts of the cord that blocks conduction produces changes in pain and temperature sensation below its level. With progressive compression from outside the cord, such as by an enlarging thoracic meningioma (extramedullary cord compression), the sensory level will tend to commence in the feet and rise until the level of the tumour is reached. This is because of the lamination of spinothalamic fibres in the cord. The patient may notice loss of spinothalamic sensation, for example being unable to gauge water temperature with their foot. Extramedullary cord compression tends to affect both principal cord sensory pathways (i.e. both posterior column and spinothalamic).

When a lesion is within the cord (intramedullary) such as a syrinx (a central cavity) sensory loss can initially be confined to the spinothalamic pathways. Spinothalamic sensory loss occurs in isolation: the phrase dissociated sensory loss implies that a syrinx or other central cord lesion is suspected. Suspended sensory loss is a term describing another aspect also seen typically with a syrinx. The patch of dissociated sensory loss does not extend to the lower limbs and is thus hanging, on the thorax or abdomen.

Sacral sparing is another phrase used to capture the phenomenon of preserved sacral and perineal sensation when a central cord lesion expands centrifugally, damaging first centrally placed fibres and reaching last the spinothalamic sacral fibres on the periphery of the cord.

Source: Patten 1996. Reproduced with permission of Springer Science + Business Media. Precise distribution varies amongst published sources, especially for sacral dermatomes, perineum and Vth nerve.

As a cavity develops within one side of the cord, dissociated sensory loss on one side occurs with pyramidal signs such as a spastic lower limb on the other. This carries the eponym Brown-Séquard. Charles-Edouard Brown-Séquard (1817–1894) published a treatise in 1849 on traumatic hemisection of cord. Originally from Mauritius, Brown-Séquard became a physician at the National Hospital. Brown-Séquard findings mean spinothalamic signs on one side with pyramidal and dorsal column signs on the other. They point to a cord lesion, on the same side as the pyramidal and dorsal column loss. The patient may report: 'I cannot feel the bathwater with my left foot, but it's my right that drags.'

#### Sensory changes in brainstem lesions

Complex patterns of sensory loss occur with lesions in the brainstem, their character depending on the level of the lesion. Trigeminal sensory loss (see V: trigeminal nerve, sensory and motor nuclei, Chapters 2; V: Trigeminal nerve, Chapter 13) and dissociated (spinothalamic) sensory loss in the limbs, are seen, such as in the

lateral medullary syndrome (see Vertebral artery, Chapter 5). The site of a brainstem lesion is usually determined more from signs from cranial nerve nuclei and brainstem connections than by the pattern of sensory loss.

#### Sensory changes following thalamic lesions

Destructive lesions of the complex thalamic nuclei and thalamocortical projections are relatively unusual causes of sensory symptoms. Two principal patterns are found. When the ventral posterior lateral (VPL) and ventral posterior medial (VPM) thalamic nuclei (Chapter 2) are damaged, such as following a thrombo-embolic stroke, contralateral hemi-anaesthesia follows immediately. All sensory modalities are usually affected. Sometimes, however, during the weeks or months following the stroke, highly unpleasant disabling persistent pain (see Thalamic pain, Post-stroke central pain, Chapter 23) develops in the partially anaesthetic limbs. This pain is usually permanent. Spontaneous pain does not develop following cortical lesions, nor following damage within the internal

capsule or basal ganglia nuclei outside the thalamus, but does so occasionally when the spinothalamic tract is damaged in the cord or brainstem.

### Sensory changes in parietal lobe lesions

Features of parietal lobe lesions such as astereognosis (i.e. the inability to perceive the shape of an object in the hand) are mentioned earlier in this chapter. Attacks of tingling or odd altered sensation caused by sensory epilepsy can occur with parietal tumours. Negative sensory symptoms, meaning complaints of sensory loss, are unusual. It is more typical that a patient says that a hand or limb 'doesn't work properly' or 'doesn't feel quite right'.

### Mononeuropathy, polyneuropathy, root lesions

These notes summarise features of peripheral nervous system conditions, dealt with in detail in Chapters 10, 13 and 16.

#### Mononeuropathy

Common isolated single nerve lesions (mononeuropathies) are distinct and easy to recognise once seen. Ulnar, median, radial, common peroneal (lateral popliteal), lateral cutaneous nerve of the thigh and sural nerve lesions are the most common. Most are caused by entrapment but there are other causes such as nerve tumours and vasculitis. Cranial nerve lesions are discussed in Chapter 13.

#### Multiple mononeuropathy

This means the occurrence of two or more peripheral nerve lesions. Principal causes worldwide are leprosy, diabetes, hereditary neuropathy with liability to pressure palsies (HNPP), and vasculitis such as polyarteritis.

#### Polyneuropathy

Polyneuropathy (formerly known as peripheral neuropathy and polyneuritis) describes conditions in which nerves die back, usually symmetrically to cause peripheral sensory loss, muscle weakness and wasting with loss of tendon reflexes. It is sometimes hard to characterise a neuropathy from its phenotype and thus to distinguish between genetic and acquired neuropathies.

Abnormal myelin is more prone to inflammatory change than normal myelin: both genetic and inflammatory neuropathies can coexist.

#### Neurogenic muscle wasting

The crux of the matter is to distinguish between:

- Generalised muscle thinning, a normal finding in old age, and loss of muscle bulk seen in cachexia
- Widespread wasting seen motor neurone disease, polyneuropathy and some myopathies
- Focal wasting that follows denervation.

Neurological examination seeks out sites of predilection:

- Small hand muscles, supplied by ulnar and/or median nerves (T1)
- Guttering of the forearm flexors
- Wasted anterior tibial compartment – sunken appearance lateral to the leading edge of the tibia
- Wasted extensor digitorum brevis muscles – concave dished appearance of the small oyster-like muscles below each lateral malleolus.

Generalised thinning of muscles with advancing age is common and contributes to a gaunt appearance and spidery hands. However,

the muscles are strong on bedside testing. In pathological states, muscles are weak. Muscles that are clinically normal (bulk, consistency and power) are usually electrophysiologically and histologically.

### Root lesions

Characteristics of a lesion affecting a nerve root are:

- Radicular pain
- Wasting and weakness of affected muscles
- Sensory loss or referred sensory symptoms, and
- Loss of or depression of one or more deep tendon reflexes.

Two descriptive terms are used. Radiculopathy is often applied to root lesions that are part of an inflammatory, vascular or neoplastic process (i.e. part of a disease), with derivative complex terms such as polyradiculomyelopathy. The phrase 'cervical or lumbar root problem' usually implies a compressive lesion, caused typically by degenerative disc and/or spinal disease. There is no real difference between the two; the shorter English word, root, is preferred to the longer, radiculopathy (from Latin *radix*, a root) but the longer terms remain in widespread use.

Root pain or discomfort is caused by distortion or stretching of the meninges surrounding a nerve root and is perceived both in the myotome and the dermatome (Table 4.15). This clinical point is relevant in C7 root compression: pain is felt deep to the scapula (C7 muscles) and the sensory disturbance runs in the C7 dermatome to the middle finger. The triceps jerk is lost. For further discussion see Chapters 10 and 16.

### Cauda equina syndrome

The cauda equina (horse's tail) is the leash of roots emanating from the lower end of the cord below vertebral body level L1/L2. Pressure (e.g. central L4/L5 disc) on the cauda equina affects all lumbo-sacral roots streaming caudally. There is loss of bladder and bowel control, numbness of buttocks and thighs with paralysis of ankle dorsiflexion (L4), toes (L4, L5), eversion and plantar flexion (S1). The S1 reflexes are lost (ankle jerks). A cauda equina syndrome from a central disc can progress rapidly over several hours or less, sometimes with little back pain and is a neurosurgical emergency.

Difficulties occur in distinguishing between a cauda equina lesion and a lesion of the conus medullaris, the lowermost part of the cord, such as an MS plaque in the conus. In both, weakness, sensory loss and loss of sphincter control occur. In an acute conus lesion lower limb tendon reflexes can be lost, as in a cauda equina lesion. Extensor plantar responses and patterns of sensory loss typical of a cord lesion, such as a sensory level in the abdomen or Brown-Séquard signs usually enable distinction clinically. Theoretically the two conditions may coexist; urgent MR imaging is likely to settle the matter and indicate any surgical emergency.

### Myopathy

Muscle disease tends to produce symmetrical abnormalities. Details and difficulties in the diagnosis of muscle diseases are discussed in Chapter 10 (see Muscle diseases).

Inflammatory muscle disease, such as polymyositis, causes induration, pain and weakness. Dystrophies and most metabolic muscle diseases present typically with weakness alone; pseudohypertrophy (excessively bulky muscles) may be seen. Slow relaxation is a feature of myotonic conditions. Fatigability is characteristic of myasthenia gravis, and the reverse, an increase in power on exercise is sometimes seen in LEMS.

**Table 4.15** Principal limb movements, nerve root values, muscles and peripheral nerves.

Movement	Root	Muscle	Peripheral nerve
Shoulder abduction	C5, (C6)	Deltoid	Axillary
Elbow flexion (supinated)	(C5), C6	Biceps	Musculocutaneous
Elbow flexion (mid-prone)	C5, (C6)	Brachioradialis	Radial
Wrist extension	(C6), C7, (C8)	Triceps	Radial
Tip of thumb flexion (and index finger flexion)	C7, C8	Flexor pollicis and digitorum profundus I, II	Median
Tip of ring and Vth finger flexion	C8	Flexor digitorum profundus IV, V	Ulnar
Thumb abduction	T1	Abductor pollicis brevis	Median
Finger abduction	T1	Dorsal interossei	Ulnar
Finger flexion	(C7), C8, (T1)	Long and short flexors	Median and ulnar
Hip flexion	L1, L2, (L3)	Iliopsoas	Nerve to iliopsoas
Hip adduction	L2, L3, L4	Adductor magnus	Obturator
Knee extension	L3, L4	Quadriceps femoris	Femoral
Ankle dorsiflexion	L4, L5	Tibialis anterior	Deep peroneal
Big toe extension	L5, (S1)	Extensor hallucis longus	Deep peroneal
Ankle eversion	L5, S1	Peroneal muscles	Superficial peroneal
Ankle inversion	L4, L5	Tibialis posterior	Tibial
Ankle plantar flexion	S1, S2	Gastrocnemius, soleus	Posterior tibial
Knee flexion	S1, (S2)	Hamstrings	Sciatic
Hip extension	S1, (S2)	Gluteus maximus	Inferior gluteal

### Subacute paralytic conditions

This loose term is used to describe increasing weakness over the course of days, up to an arbitrary period of 3 weeks. Spinal cord compression, poliomyelitis, Guillain-Barré syndrome, vasculitic neuropathies, myasthenia gravis, LEMS, botulism, periodic paralyses and MS are potential causes (Chapters 9, 10 and 11). These cases are often challenging diagnostically.

Respiratory impairment is of critical importance and easy to miss with severe limb weakness. Remarkably, even with widespread knowledge, initial paralytic symptoms are regarded as non-organic in about one-quarter of patients when they first seek help from a doctor.

### Unexplained symptoms, abnormal illness behaviour and somatoform disorder

Symptoms that are unexplained or only partially explained by organic disease are features in 20–30% of new cases seen in any general neurology clinic. Many neurologists have been tempted to

think that deliberate symptom exaggeration and even fabrication are more frequent than they are believed to be today. The fact is that many patients have real symptoms that are worrying, painful, unpleasant or uncomfortable but which do not reflect any serious underlying disease. For example, unexplained fatigue, give-way weakness or paralysis with non-organic sensory loss are symptoms for which no organic disease is likely to be found. In a more psychiatric context, abnormal illness behaviour is a diagnosis in common use; the phrase suggests that the patient complains about symptoms in a way believed to be disproportionate, but also reflects the attitude and reactions of medical staff, implying unnecessary admissions to hospital, investigations or treatment. For example, about one-third of cases of apparent status epilepticus seen in A&E and some 15% of cases of recurrent seizures referred to epilepsy specialist clinics are believed to be non-organic, but these conditions are treated initially, very largely as if they were seizures, often on the grounds of safety. These matters are discussed in Chapter 22 (see Non-organic disorders in neurology).

One suggestion as an approach to this issue is to accept that the majority of patients do have the symptoms of which they complain. This comment excludes those involved in legal claims, where non-organic features are especially prominent and of more doubtful nature. The second suggestion is to exclude organic disease with all reasonable certainty. Specialised tests may be necessary. The third requirement is to understand the psychiatric diagnoses that might lead to or explain such symptoms. These include:

- Anxiety and depression.
- Somatic symptom disorder, usually implying symptoms in more than one system, often lifelong, such as irritable bowel, chronic fatigue or unexplained pain, with the implication that psychological problems have been somatised.
- Hypochondriasis, meaning a state of fear, distress and anxiety about possible disease.
- Conversion and dissociative disorder: motor or sensory symptoms thought to relate to psychological factors.
- Somatic manifestations of depressive illness or anxiety.

Factitious disorder (symptoms to gain medical attention) and malingering (symptoms for material gain) are also possible, if rare explanations. However, in many cases of apparent illness behaviour, no formal psychiatric diagnosis is apparent.

The approach to anxiety and/or aggressive behaviour needs qualification. Anxiety is ubiquitous; we all experience it. Most symptoms do not reflect serious disease but fear of illness is common. This may all seem obvious, but there remains a tendency to equate anxiety with non-serious problems. The reality is that substantial anxiety occurs as frequently in sinister as in less serious medical conditions. A sympathetic understanding of symptoms of a non-organic nature is essential.

## Epidemiology

Stroke is a major public health problem, being the third most common cause of death after myocardial infarction and cancer, and the leading cause of adult disability. Stroke accounts for 9% of deaths in England and Wales. The incidence of stroke has fallen over the last 10 years and prevalence increased, as a result of more effective primary prevention and treatment. Nevertheless, every year in the United Kingdom about 100 000 people will have their first stroke and about 40 000 patients will have a recurrent stroke. About 12% of patients die within 56 days of their stroke. Stroke is more common than most people realise. Approximately one-quarter of 45-year-old men will have a stroke before they reach the age of 85 (Table 5.1). Stroke is a very labour-intensive and expensive condition to manage, mainly because of the long length of stay in hospital. The mean length of stay in an acute hospital bed after stroke is about 16 days. Around half of all stroke survivors are left dependent on others for everyday activities: if a patient can return home, the burden on carers is significant. It is clear that new models of care are significantly reducing various aspects of this burden as time goes on and more stroke patients are treated expediently in hyperacute and multidisciplinary units.

About 5% of the UK National Health Service budget is spent on looking after stroke patients in England and Wales. The cost of looking after an individual patient with stroke is around £14 000 just for the acute phase. When longer term and informal care costs are included, this increases considerably. Stroke will become increasingly expensive in the future because the prevalence will increase as the population of elderly people in many parts of the world continues to rise.

Stroke is also an important condition in young people and can occur at any age, including *in utero* and in the neonatal period – it is a major cause of cerebral palsy, in childhood and young adult life. One-quarter of all strokes occur in people below the age of 65.

The incidence and types of stroke vary in different racial groups. Asian people appear to have a higher incidence of intracranial atherosclerosis than Caucasians and the incidence rates of first ever stroke are higher in black people of African or Caribbean descent than Caucasian populations living in the same cities. However, whether these differences reflect genetic or social and environmental factors is uncertain.

## Clinical approach to stroke

Stroke can be briefly defined as an acute focal neurological deficit resulting from vascular disease. The World Health Organization provides a longer definition: ‘rapidly developing clinical signs of focal (or global) disturbance of cerebral function, with symptoms lasting 24 hours or longer, or leading to death, with no apparent cause other than of vascular origin.’ This definition has become outmoded as treatment and understanding have evolved. In 2013, the Stroke Council of the American Heart Association/American Stroke Association recommended an updated definition that would better reflect current practice, and seeks to provide a single terminology for brain, retinal and spinal cord events. This updated definition of stroke includes ischaemic stroke as well as stroke secondary to intracerebral haemorrhage, cerebral venous sinus thrombosis and subarachnoid haemorrhage. The new definitions incorporate clinical and tissue criteria and try to address difficulties with current terminology. The guiding philosophy behind these changes is that the duration of the clinical event should be of secondary importance to the evidence from imaging (or pathology). In the new terminology central nervous system (CNS) infarction is defined as cerebral, spinal cord or retinal focal ischaemic injury. This is based on either pathological, imaging, or other objective evidence of focal ischaemic injury in a defined vascular distribution *or* on clinical evidence of ischaemic injury lasting greater than 24 hours or until death, with other aetiologies excluded. Whereas an ischaemic stroke is to be defined as “an episode of neurological dysfunction caused by focal brain, spinal or retinal infarction” (as above). Silent CNS infarction has imaging or neuropathological evidence of infarction without a history of acute neurological dysfunction attributable to the lesion. The term transient ischaemic attack (TIA) will remain and will apply to clinical events lasting less than 24 hours and without evidence of CNS infarction. Hence, the diagnosis of TIA will depend substantially on the imaging modality used to evaluate the clinical event, as around one-third of clinical TIAs show acute infarction on diffusion weighted imaging (DWI) despite the fact they last less than 1 hour and the proportion increases to over 50% in those whose TIA lasts more than 3 hours. These infarcts are often small and not seen on computed tomography (CT) scan, but are nevertheless associated with an increased risk of subsequent stroke. Thus, MRI with DWI sequences is the

**Table 5.1** Cumulative probability (%) of a 45-year-old person having a stroke before the age listed in the left-hand column.

Age	Men	Women
65	3	3
75	10	6
85	24	18
90	33	28

imaging of choice for suspected TIA or minor stroke. In keeping with the above, intracerebral haemorrhage is defined as a focal collection of blood within the brain parenchyma or ventricular system that is not caused by trauma, and stroke caused by intracerebral haemorrhage as “rapidly developing clinical signs of neurological dysfunction attributable to a focal collection of blood within the brain parenchyma or ventricular system that is not caused by trauma”. Silent intracerebral haemorrhage is defined as “a focal collection of blood products without history of acute neurological dysfunction”.

The use of the term “stroke” should be restricted to a description of the clinical event experienced by the patient. Appearances on brain imaging should not be described as showing a stroke – but concordant with the above – the scan may show infarction or haemorrhage, which may either have been responsible for a stroke or may have been asymptomatic. Also, to say someone has had a stroke is not sufficient as a medical diagnosis. Accurate diagnosis requires the cerebral circulatory disturbance to be defined in terms of pathology (ischaemia, infarction or haemorrhage), its anatomical location within the brain (e.g. left middle cerebral artery territory), and the underlying mechanism (e.g. cardio-embolism). One task of the stroke physician is to make an accurate pathophysiological diagnosis in these terms to guide appropriate management. This requires a basic knowledge of the clinical and radiological patterns that different stroke syndromes produce and the underlying pathophysiology of stroke.

Those patients with acute neurological disturbances that may be the result of stroke require immediate assessment in hospital for consideration of reperfusion therapy (e.g. thrombolysis). Equally, patients with a recent history of TIA require urgent investigation and treatment to prevent a recurrence. The fact that a patient with a TIA appears to recover fully gives a false sense of security that there is no urgency for assessment. However, in a UK population-based study in Oxfordshire, the average risks of recurrent stroke at 7 days, 1 month and 3 months after TIA were 8%, 12% and 17%, respectively. In patients with specific risk factors for recurrence, the 7-day risk may be as high as 31%. The need to emphasise these aspects of acute stroke and TIA has led to the use of the term ‘brain attack’ to emphasise to the public the urgency of the situation. It also has the value of emphasising that acute focal neurological events have a differential diagnosis, in that stroke mimics will need to be distinguishable from stroke and TIA. The older term, cerebrovascular accident (CVA) should be avoided completely. Stroke is not accidental; the term CVA implies a negative approach to the patient and their illness.

The underlying pathology responsible for the persistent symptoms of stroke is either infarction or haemorrhage. Haemorrhage is subdivided according to location into intracerebral haemorrhage

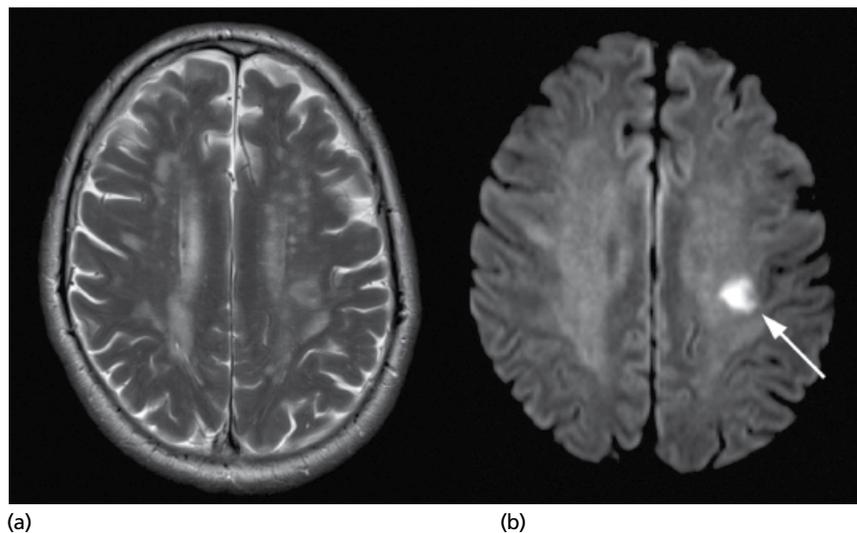

**Table 5.2** Underlying pathology of stroke.

Pathology	Anatomical subdivision
Infarction	Small vessel (lacunar) infarction
	Total or partial territorial infarction
	Border-zone infarction
Intracranial haemorrhage	Lobar
	Deep/basal ganglia
	Posterior fossa
Subarachnoid haemorrhage	Aneurysm, AVM
Cerebral venous thrombosis	Vein, venous sinus

AVM, arteriovenous malformation.

and subarachnoid haemorrhage (Table 5.2). In about 85% of cases, stroke is secondary to infarction. When infarction involves only a small volume of the tissue in the subcortical white matter (<1.5 cm in diameter on brain imaging) secondary to occlusion of a penetrating artery, the resulting death of tissue is known as a lacune or a lacunar infarct. The underlying pathology responsible for lacunar infarction is often referred to as small vessel disease. This may also lead to asymptomatic changes on imaging of the deep white matter known as leukoaraiosis, discussed in more detail later. Lacunes are generally found in subcortical white matter or the basal ganglia (Figure 5.1). Larger infarcts usually involve a wedge of both cortical and subcortical white matter and result from occlusion of the trunk or branches of the major cerebral arteries, most commonly the middle cerebral artery (MCA). The size of infarction resulting from arterial occlusion will depend on the adequacy of the collateral supply via the circle of Willis and pial collateral vessels. Infarction may therefore affect all or only part of the territory of the occluded artery. Occasionally, infarction occupies the border-zones between arterial supplies, particularly if the infarction follows an episode of generalised reduction in cerebral blood flow (e.g. after cardiac arrest) or results from occlusion or near-occlusion of the ipsilateral internal carotid artery. It is then known as border-zone or watershed infarction.

About 10% of acute strokes are caused by intracerebral haemorrhage (i.e. within the substance of the brain). When the bleeding occurs from deep penetrating arteries, often secondary to small vessel disease, the centre of the haemorrhage is usually located within the basal ganglia, particularly the lentiform nucleus or the deep white matter tracts. More superficial haemorrhages are known as lobar haemorrhages and are more commonly caused by vascular malformations or cerebral amyloid angiopathy. In about 5% of cases, intracranial bleeding occurs primarily within the subarachnoid space. Subarachnoid haemorrhage is distinctive in that there may be no focal damage to the brain if the patient only has meningeal irritation (e.g. headache and/or neck stiffness). Subarachnoid haemorrhage is therefore not always classified as a form of stroke. However, the arguments are stronger in favour of including subarachnoid haemorrhage within the definition of stroke, because subarachnoid haemorrhage may be accompanied by intracerebral

**Figure 5.1** Subcortical infarct. Extensive background small vessel disease is seen on T2-weighted imaging (a) but diffusion weighted imaging (DWI) (b) reveals the acute subcortical infarct (arrow).

haemorrhage with focal deficits. Also, subarachnoid bleeding frequently causes constriction of the intracranial arteries, known as vasospasm, which can result in cerebral infarction with focal symptoms identical to those seen in other causes of ischaemic stroke.

The well-known vascular risk factors (e.g. hypertension, diabetes and smoking) are not in themselves causes of stroke, but instead promote the development of the underlying pathological processes (e.g. atherosclerosis) responsible for stroke. Their importance is therefore to provide targets for interventions to prevent stroke, rather than in diagnosis.

The majority of strokes result from arterial pathology but a small proportion, less than 1%, result from cerebral venous thrombosis. Although rare, this is an important cause to recognise because of the need for specific investigations and treatment. Cerebral venous thrombosis may cause isolated cerebral infarction, haemorrhagic infarction, intracerebral haemorrhage or subarachnoid haemorrhage. Patients with venous thrombosis can also present with raised intracranial pressure and epileptic seizures without focal cerebral features.

It is usually impossible to distinguish reliably between infarction and intracranial haemorrhage from the history and examination. Headache can occur in both, although the features of very sudden onset of severe headache and neck stiffness in subarachnoid haemorrhage are usually distinct. Cranial imaging is the only reliable method to distinguish between infarction and haemorrhage. Imaging also plays a major part in confirming the anatomical location of the pathology. The location may also provide clues to likely mechanisms. Other investigations are required to establish the underlying mechanism of the infarction or haemorrhage in order to plan appropriate treatment and prevention.

Medical assessment of the stroke patient on admission should concentrate on establishing the diagnosis in terms of pathology, anatomy and mechanism. It is important that initial assessment and the response to treatment and therapy should include an assessment of the patient's functional abilities, as well as their neurological examination. Validated scoring systems have been developed specifically for use in stroke patients. The most widely used scores for neurological impairment, based on the standardised neurological

examination, are the Scandinavian Stroke Scale and the National Institutes of Health Stroke Scale (NIHSS). The most widely used functional outcome scores are the Barthel Index and the Modified Rankin Scale. A number of schemes have also been developed to assist in classifying subtypes of stroke. These include the Oxfordshire Community Stroke Project Classification, which divides stroke on clinical features alone into total anterior cerebral infarction (TACI, usually total MCA territory infarction), partial anterior territory infarcts (PACI), lacunar infarcts (LACI) and posterior cerebral infarction (POCI). However, this classification is not particularly accurate in the first few hours after onset and only predicts the size of infarction on imaging in about three-quarters of patients. A more specific approach, originally developed for use in a clinical trial, is known as the TOAST Classification. This divides ischaemic stroke on the basis of detailed investigations, into athero-thrombotic, cardio-embolic, small vessel occlusion, other determined cause and undetermined cause. Other more detailed classification systems have been proposed, but are not widely used.

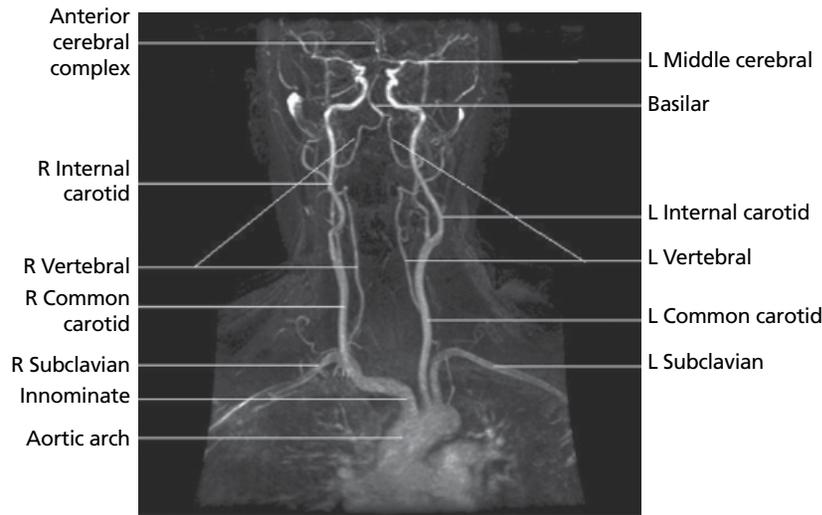

## Ischaemic stroke

### Important vascular anatomy

#### Heart and great vessels

The left ventricle gives rise to the ascending aorta and then to its arch. Arising from the arch from right to left are the innominate, the left common carotid and the left subclavian arteries. The innominate bifurcates into the right subclavian, which gives off the vertebral and the right common carotid artery. The left subclavian gives rise to the left vertebral (Figure 5.2). Multiple anatomical variations of this common arrangement have been described. The most common anomalies are a common origin of the left common carotid and the brachiocephalic trunk or origin of the left common carotid from the left brachiocephalic trunk. Very rare anatomical arrangements can allow the left and right common carotid arteries to arise from a common trunk and this may very occasionally explain an unusual pattern of brain infarction.

It therefore makes sense that embolic material arising from the heart or ascending aorta can enter any vessel or combination of

**Figure 5.2** Contrast enhanced magnetic resonance angiogram (MRA) of the heart, great vessels, cervical and intracerebral circulation. L, left; R, right.

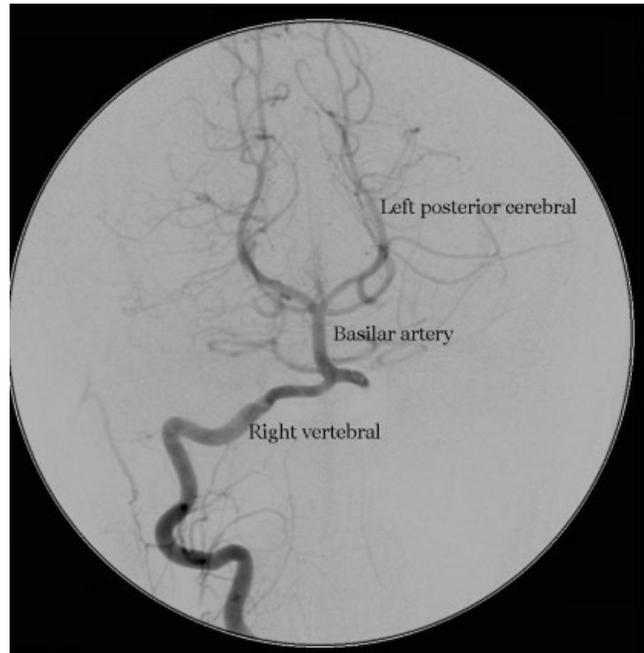

vessels. An innominate plaque of atherosclerosis may cause embolism within the right carotid and right vertebral territory or even very occasionally within the left carotid territory.

#### Extracranial and intracranial arteries

The internal carotid arteries (ICAs) begin in the neck at the carotid bifurcation, usually near the angle of the jaw, and ascend cranially. Note that it is the common carotid pulse that is palpated in the neck. The ICAs travel behind the pharynx but give off no branches in the neck. This makes them readily identifiable on angiography and distinct from the external carotid arteries which do branch. The ICAs enter the skull through the carotid canal in the petrous bone and then pass through the cavernous sinus. The cavernous carotid pierces the dura and then gives off the ophthalmic artery. The supraclinoid portion of the carotid gives off the anterior choroidal and posterior communicating artery before bifurcation into anterior and middle cerebral arteries. The external carotids give branches to the neck, face and scalp. Some of these are easily palpated (e.g. the superficial temporal artery). The external carotids can act as a collateral blood supply to the hemisphere via meningeal branches, especially in the event of ICA occlusion. Often, the only clinical symptom of this is a throbbing unilateral temporal headache caused by diversion through superficial channels. Biopsy this at your peril.

The anterior choroidal arteries are small and course posteriorly along the optic tract. They give off branches to a zone between the other internal carotid branches (anterior and middle cerebral artery) and the posterior circulation. They supply perforating branches to the globus pallidus, posterior limb of the internal capsule, temporal lobe, thalamus and lateral geniculate body.

The anterior cerebral arteries (ACAs) course medially then run posterior over the corpus callosum. They supply the anterior and medial portions of the hemispheres, basal frontal lobes and caudate. Within the cortical territory of the ACA is the leg area of the motor homunculus. The two ACAs are usually joined together by an anterior communicating artery (ACOM) and there are various anatomic variations that dictate the pattern of ischaemic damage. In carotid occlusion the ACA territory is often spared because of collateral supply from the ACOM. If there is no ACOM then this mechanism fails. Sometimes, both anterior cerebral arteries are supplied by a single carotid, so carotid occlusion may infarct both ACA territories or neither.

**Figure 5.3** Vertebrobasilar circulation (catheter angiogram).

The MCAs course laterally after their origin; the proximal MCA trunk gives off numerous penetrating lenticulo-striate arteries to the basal ganglia and internal capsule. Near the Sylvian fissure the MCA usually trifurcates into small anterior temporal branches and large superior and inferior trunks. The superior trunk supplies the lateral portion of the hemisphere above and the inferior trunk the portion below the Sylvian fissure. Amongst its cortical supply the MCA supplies the arm area of the homunculus.

The vertebral arteries arise from each subclavian and are unusual in that they anastomose to form a larger artery, the basilar artery (Figure 5.3). The vertebral arteries course upwards and backwards entering the transverse foramina at C5 or C6. They run up through the intravertebral foramina exiting to pierce the dura and enter the foramen magnum. Their intracranial portions anastomose at the

ponto-medullary junction to form the basilar artery. In the neck the vertebral arteries give off many spinal and muscular branches. The intracranial vertebral gives rise to the posterior and anterior spinal arteries, penetrating branches to the medulla and the posterior inferior cerebellar arteries. The basilar artery then runs up in the midline giving off the bilateral anterior and inferior, superior cerebellar arteries and also penetrating branches to the brainstem. At the ponto-mesencephalic junction the basilar terminates into posterior cerebral arteries (PCAs). The PCAs give off perforating branches to the midbrain and thalamus, course around the cerebral peduncles and then supply occipital and inferior temporal lobes. The anatomy of the vertebral circulation is more varied than that of the carotid. Commonly, one vertebral is hypoplastic or may terminate in the posterior inferior cerebellar artery (PICA).

The ACAs, MCAs and PCAs are connected via communicating vessels and all these vessels together form the circle (or pentangle) of Willis. In most cases, the posterior and anterior communicating vessels on both sides form a complete circle but, in some individuals, the circle is interrupted by absence of one or more of the communicating arteries. The most common abnormality in 5–10% of people is the fetal PCA pattern in which the P1 segment linking the basilar with the PCA is missing on one side. In these cases, the ipsilateral PCA territory is entirely supplied by the internal carotid artery. This fact is important to remember when investigating patients with PCA infarcts.

### Venous anatomy

The cerebral veins may be divided into the venous dural sinuses and the superficial and deep venous systems. The dural sinus walls are formed by the layers of the dura itself and are situated at the junction of the falx and tentorium. The intracranial veins drain into the sinuses which then drain into the jugular veins. The ophthalmic and facial veins drain into the cavernous sinuses which lie symmetrically in the parasellar region. The important venous sinuses are the midline sagittal and straight sinus and the transverse sinuses (Figure 5.4).

### Pathophysiology of ischaemic stroke

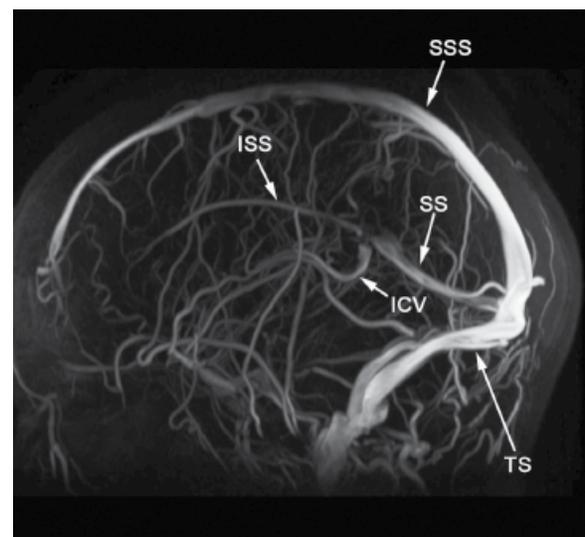

#### Thrombosis, embolism and hypoperfusion

There are three potential mechanisms of ischaemic stroke:

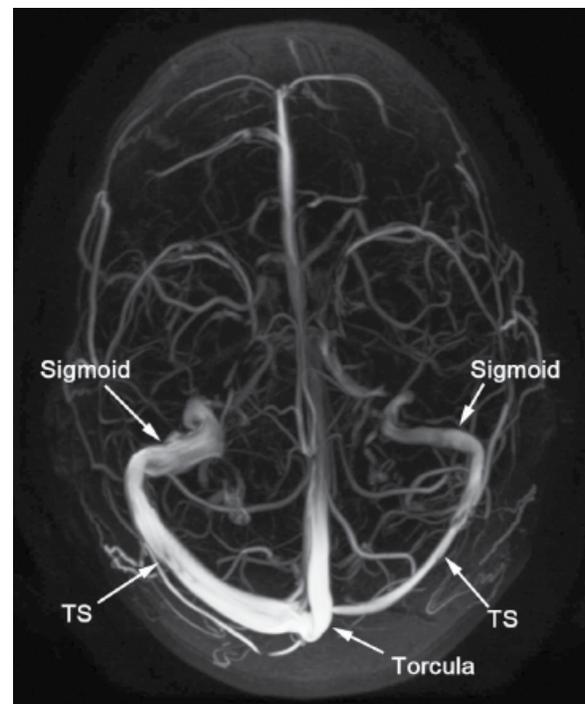

- 1 Thrombosis
- 2 Embolism, and
- 3 Hypoperfusion (haemodynamic failure).

While these are inter-related, each mechanism can produce distinct clinical syndromes. It is important to think about these mechanisms when assessing patients as ultimately this guides treatment.

The effect of a localised blood vessel occlusion on blood flow in the area supplied by the vessel will depend on the following factors: the extent of the occlusion, the time that the occlusion lasts, and the adequacy of collateral circulation. The resulting focal symptoms will depend on the area of the brain in which blood flow is reduced below the level sufficient to impair neuronal activity. Consider how these factors interact: one patient has a 95% internal carotid stenosis on which a thrombus forms and occludes the vessel. There may be no symptoms if this thrombosis remains localised (i.e. does not embolise to the brain) and the collateral circulation to the hemisphere above the occluded carotid is adequate. Conversely, even if the thrombosis remains localised, the absence of an effective collateral circulation may result in infarction of the whole of the carotid territory. If the collateral circulation is poor, then the most vulnerable areas will infarct; these are the areas with the poorest perfusion pressure and furthest away from the occluded artery. An example is shown in Figure 5.5 as a linear areas of infarction in the

(a)

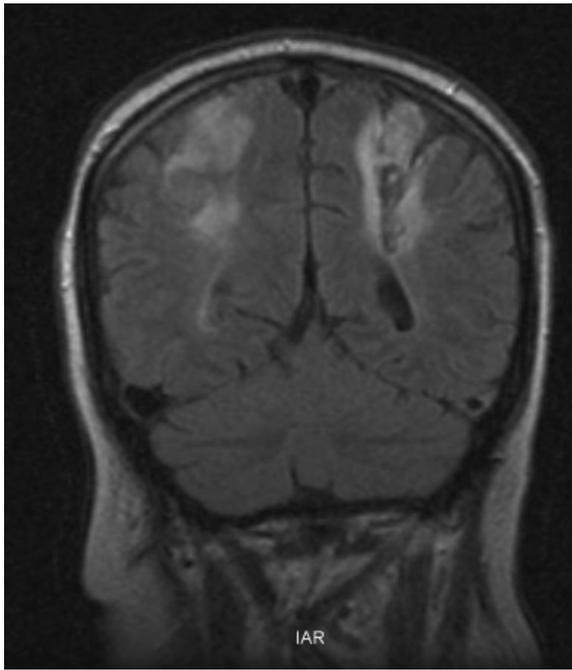

(b)

ISS	inferior sagittal sinus	Torcula	torcula herophili
Sigmoid	sigmoid sinus	TS	transverse sinus.
SS	straight sinus		

**Figure 5.4** Sagittal (a) and axial (b) images from a MR venogram illustrating intracranial venous anatomy.

border-zone between the anterior and middle cerebral artery territory. The occluded carotid artery is very unlikely to recanalise as the obstruction is principally hardened atheroma.

Another scenario is this: on the roughened surface of the 95% stenosis, platelets activate to form a white thrombus which embolises to the brain. The thrombus may lodge in the origin of the anterior cerebral artery and have no effect because the territory has an adequate collateral circulation via the anterior communicator.

**Figure 5.5** Coronal MR FLAIR image of bilateral border-zone infarction following carotid occlusion.

Maybe it lodges at the origin of the MCA for an hour before it lyses. The meningeal collaterals over the surface of the hemisphere maintain some cortical areas for the time but the lenticulostriate perforators arising from the MCA origin are all blocked and the deep territory fails rapidly as there is no collateral blood supply. The deep territory has irreversibly infarcted but the superficial collateralised territory is hanging on. Unfortunately, the patient develops a pneumonia and becomes hypotensive: the tenuous collaterals can no longer perfuse the hemisphere. The entire hemisphere infarcts.

Stenosis and occlusion are distinct. Occlusion of a vessel may occur without pre-existent stenosis or other localised disease. This is usually a result of embolism from the heart or a more proximal arterial stenosis. For example, atrial fibrillation and atherosclerotic stenosis of the internal carotid artery are both risk factors for intracranial occlusion upstream (e.g. MCA occlusion).

Thrombosis is difficult to distinguish from embolism, but hypoperfusion may be more easily recognisable. However, it is important to think about the macroscopic mechanisms of ischaemia. It is unlikely that an occluded atheromatous carotid will recanalise with thrombolysis, but if the patient has border-zone ischaemia, then keeping up their blood pressure may help. Conversely, thrombolysis of fresh red cardio-embolic thrombus obstructing the proximal MCA is a practical proposition.

Patterns of stroke are discussed in detail later. The adequacy of collateral circulation depends not only on systemic perfusion pressures, but many factors including the anatomy of the circle of Willis and other collateral pathways and the degree of acquired small and large blood vessel disease, particularly the effects of atherosclerosis, diabetes and hypertension.

### Microscopic and metabolic changes

The brain is metabolically a highly active organ. Although it accounts for only 2% of body weight, it uses 20% of cardiac output when the body is at rest. Brain energy use is also dependent on the degree of neuronal activation. The brain uses glucose exclusively as

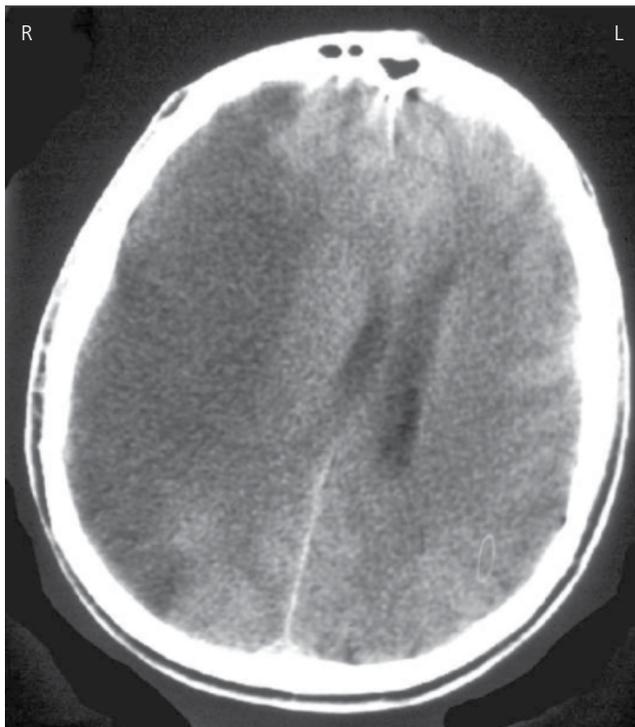

a substrate for energy metabolism by oxidising this to carbon dioxide and water. This metabolism allows conversion of adenosine diphosphate to adenosine triphosphate (ATP). A constant supply of ATP is essential for neuronal integrity and this process is much more efficient in the presence of oxygen. Although ATP can be formed by anaerobic glycolysis, the energy yielded by this pathway is small and it also leads to the accumulation of lactic acid. The brain needs and uses approximately 500 mL oxygen and 100 mg glucose each minute, hence the need for a rich supply of oxygenated blood containing glucose. Cerebral blood flow (CBF) is normally approximately 50 mL/minute for each 100 g of brain. By increasing oxygen extraction from the blood adequate compensation can be made even if blood flow is reduced to approximately 20–25 mL per 100 g/minute. Sophisticated systems exist that allow the cerebral circulation to maintain constant levels of CBF in the face of changing systemic blood pressure, usually called autoregulation. In the healthy state, CBF remains relatively constant when mean arterial blood pressure is 50–150 mmHg.

As cerebral blood flow falls, metabolic paralysis ensues and this may be reversible. However, if prolonged, infarction is inevitable. When CBF falls below 20 mL/100 g/minute, oxygen extraction starts to fall and changes may be detected on electroencephalography (EEG). At levels below 10 mL/100 g/minute, cell membrane functions are severely disrupted. Below 5 mL/100 g/minute, cell death is inevitable within a short time.

When neurones become ischaemic, a cascade of biochemical changes potentiate cell death. These pathophysiological changes have been of considerable interest to those developing treatments to lessen the damage caused by ischaemic stroke. In the ischaemic brain, ion channels fail, potassium ions move out of the cell into the extracellular space and  $\text{Ca}^{2+}$  moves in, where it further compromises the ability of the cell to maintain ionic homeostasis and leads to mitochondrial failure. Hypoxia leads to the generation of free radicals which peroxidise fatty acids in cell membranes causing further cell dysfunction. Anaerobic glycolysis results in lactic acidosis further impairing cellular metabolic functions. Excitatory neurotransmitter activity (e.g. glutamate) is greatly increased in areas of brain ischaemia because of increased release and failure of uptake mechanisms. These neurotransmitters are themselves toxic at these increased levels by causing further calcium and sodium ions influx into cells through their actions on NMDA receptors. Hence, ischaemia triggers a vicious cascade of events leading to cell electrical failure and then death. At some point the process becomes irreversible even after reperfusion of tissues. Even if the severity of ischaemia is inadequate to cause necrosis, it may trigger apoptosis.

### Ischaemic penumbra

The degree of ischaemia caused by blockage of an artery varies, partly depending on collateral supply. At the centre of an infarct the damage is most severe but at the periphery collateral flow may allow continued delivery of blood, although at a lower rate. This zone may become dysfunctional secondary to electrical failure although not dead and is referred to as the ischaemic penumbra. In any solar or lunar eclipse there is an umbra (the dense shadow) and the penumbra surrounding it. It is this outer zone that is further at risk following the onset of stroke. Sophisticated imaging can now define areas of irreversible brain damage and areas in which perfusion is suboptimal but where irreversible infarction has not taken place. The penumbra is the area of brain with the potential to survive. It is entirely likely that high-quality simple supportive management in the acute stage aimed at maintaining normal physiological parameters decreases the degree of this further secondary brain damage.

**Figure 5.6** Unenhanced computed tomography (CT): Cytotoxic oedema in middle cerebral artery (MCA) distribution leading to brain swelling.

### Pressure changes

Energy failure results in cytotoxic oedema where water accumulates inside cells. This is the radiological hallmark of early cerebral infarction and its distribution obeys vascular territories, unlike vasogenic oedema (extracellular accumulation) which spreads along white matter tracts. Significant brain swelling follows cytotoxic oedema increasing intracranial pressure and further decreasing CBF compromising the penumbra and surrounding brain (Figure 5.6). Large MCA infarction associated with significant mass effect is known as malignant MCA infarction because ultimately coning may occur with brainstem compression or there may be important local pressure effects (e.g. posterior cerebral artery occlusion from stretching of the artery across the tentorium). Similarly, oedema of cerebellar infarction may lead to brainstem compression.

### Risk factors and causes of ischaemic stroke

Ischaemic stroke is the result of vessel occlusion from *in situ* thrombosis, embolism or haemodynamic failure. Embolism may be from artery to artery (30–40%) or from the heart (30–40%). In 25% of cases, disease of the walls of small penetrating intracranial blood vessels is responsible for lacunar infarction.

It should be recognised that risk factors are not direct causes of stroke, but instead are for the most part demographic factors, pre-existing diseases or lifestyles of individuals that promote diseases of the heart or blood vessels. Hence, the main risk factors for stroke are the risk factors for atherosclerosis and heart disease (Table 5.3). Non-atherosclerotic vasculopathies and primary haematological disease are much less common.

Both the clinical syndromes and risk factors of lacunar stroke and large vessel occlusion overlap. The effect of more than one

**Table 5.3** Major risk factors for stroke.

Age
Hypertension
Smoking
Diabetes mellitus
Atrial fibrillation
Heart disease
Dyslipidaemia
Alcohol
Obesity
Symptomatic and asymptomatic carotid stenosis
Drug misuse

risk factor on an individual's risk of stroke is multiplicative, not additive. Stroke is therefore often associated with a combination of risk factors coming together rather than a single entity. It should be borne in mind that the presence of a risk factor does not imply causation. For example, stroke can only be attributed to the effects of smoking in about half the smokers with stroke, while a hypertensive patient presenting with symptoms suggestive of stroke may in fact have another neurological condition mimicking stroke.

### Age, hypertension, smoking, lipids and drug misuse

The incidence of stroke rises dramatically with age, doubling each decade past 55 years. Half of all stroke occurs in the over-70 age group. At least 25% of the adult population have hypertension >140/90 mmHg. After age, this is the most important and modifiable risk factor. The Framingham data show a linear relationship between risk of stroke and arterial hypertension and this effect is seen across all levels of blood pressure.

Smoking remains a leading preventable cause of death and an independent risk factor for stroke, especially in young adults where smoking increases the risk of stroke by four times the risk in non-smokers. In older patients, it particularly predisposes to carotid stenosis. Diabetes mellitus increases the risk of stroke by about two- to fourfold when compared with those without diabetes. The excess diabetic risk is independent of age and blood pressure status. High total cholesterol and low-density lipoprotein (LDL) correlate with atherosclerosis. Although low levels of high-density lipoprotein (HDL) correlate well with coronary artery disease, the relationship is less clear for cerebrovascular disease where elevated LDL concentrations have been shown to be more strongly linked with disease progression. Alcohol consumption demonstrates a J-shaped relationship; heavy drinking being associated with a higher risk of all stroke, both ischaemic and haemorrhagic. The presence of asymptomatic carotid disease carries a greater cardiovascular than cerebrovascular risk. Asymptomatic stenosis of greater than 75% carries an annual stroke risk of only 2% or less. In contrast, if the stenosis is recently symptomatic, the annual risk increases to 15% and is even higher if the stenosis is greater or the symptoms very recent. This is discussed in greater detail in the section on secondary prevention. Plaque structure rather than the degree of narrowing is important, with ulcerated heterogeneous plaques being more likely to rupture or allow thrombosis on their surface. Drug-related stroke is an increasing problem and may be multi-factorial. The mechanisms of stroke after drug misuse are very broad (Table 5.4).

**Table 5.4** Mechanisms of stroke associated with drug misuse.

Complications of parenteral administration (e.g. heroin, cocaine)
Infective or non-bacterial (marantic) endocarditis – infarction or haemorrhage from associated mycotic aneurysm
Direct embolisation of particulate matter – infarction via right to left shunt (e.g. patent foramen ovale or pulmonary shunt) or from direct carotid administration
Acute severe hypertension (TIA, infarction or haemorrhage)
Arterial vasospasm (infarction or TIA), e.g. crack cocaine, cocaine, amphetamine, possibly cannabis
Arterial dissection
Hypersensitivity vasculitis: associated with amphetamine, heroin, cocaine and crack cocaine (headache encephalopathy, stroke-like episodes, seizures) – all rarely proven

TIA, transient ischaemic attack.

**Table 5.5** Cardiac causes of stroke.

High risk	Atrial fibrillation (especially combined with other risk factors)
	Valvular heart disease
	Prosthetic heart valves
	Bacterial endocarditis
	Non-infective (marantic) endocarditis (Chapter 21)
	Cardiac surgery
Low risk	Myocardial infarction
	Ventricular/atrial aneurysm
	Cardiomyopathy (e.g. amyloid, alcohol, cocaine)
	Septal abnormalities (e.g. ASD, patent foramen ovale, atrial septal aneurysm)
Rare	Intracardiac lesions (myxoma, fibroelastoma)

ASD, atrial septal defect.

Another effect of drugs of abuse is rupture of a coincidental underlying aneurysm or arteriovenous malformation. This is a common cause of intracranial cerebral haemorrhage (ICH; either subarachnoid or parenchymal) in users of stimulant drugs (e.g. amphetamine, crack and cocaine). All patients with drug-related subarachnoid haemorrhage (SAH) or ICH need careful evaluation to exclude such causes based on the pattern of haemorrhage. In some patients, induction of antiphospholipid antibodies has been associated with cocaine and heroin. Whether they confer a specific risk is not clear and it must be noted that antiphospholipid antibodies are also associated with infection and vasculopathies of many causes.

### Cardiac disease

Heart disease may be divided into high or low risk (Table 5.5). Atrial fibrillation remains the most important cause of cardio-embolism. Atrial fibrillation is a common cardiac disorder, with up to 5% of over-60-year-olds affected. Atrial fibrillation is an important risk factor for stroke, with a general risk of about 4% per year in patients who have not had prior embolic symptoms and about 12%

per year in patients with prior TIA or stroke. Other coexistent risk factors (e.g. age, hypertension or left ventricular dysfunction) also increase the risk. Sick sinus syndrome through atrial dysfunction may also result in embolism. As many as 10–20% of patients with valvular heart disease have a stroke as the abnormal valve surface promotes thrombosis and embolisation. The most important used to be rheumatic mitral stenosis but this is now overtaken by endocarditis on native or prosthetic valves. The manifestations of endocarditis are protean and include ischaemia, ICH and SAH, encephalopathy and meningitis. Endocarditis is much more common on prosthetic valves and often resistant to treatment. Non-infective endocarditis was first described by Libman and Sacks; the condition spans simple valve thickening to frank vegetations containing platelets and fibrin. Systemic lupus erythematosus (SLE), antiphospholipid syndrome and malignancy are potential causes.

After myocardial infarction (MI), there is a systemic embolism rate of about 3%. Most emboli will affect the brain. Most thrombi arise in the ventricle after anterior MI. Left ventricular thrombi can be detected in approximately 30% of patients after anterior MI. The thrombi develop within 3 days and embolism occurs on average 2 weeks after MI. Stroke is therefore rarely the presenting feature of MI, but this can occur in patients who have had an asymptomatic (silent) MI. The risk of stroke associated with impaired cardiac function and heart failure is substantial.

Paradoxical embolus resulting from venous thrombosis entering the arterial circulation is an increasingly recognised and potentially important cause of stroke. However, in patients with a potential route for paradoxical embolism and stroke (e.g. patent foramen ovale), it is often not clear if emboli have been formed *de novo* in the heart or arose in the venous circulation (e.g. from deep vein thrombosis) to cause paradoxical embolism, whether the stroke is related to arrhythmia, or whether the stroke is unrelated to the cardiac abnormality. However, a classic triad is recognised that suggests true paradoxical embolism:

- 1 Deep vein thrombosis has been demonstrated prior to the stroke or there is a good reason for a venous thrombus (e.g. thrombophilia)
- 2 The stroke happens at a time when shunting and paradoxical embolus are possible (e.g. during a Valsalva), and
- 3 The stroke syndrome is typically cardio-embolic (e.g. posterior cerebral artery occlusion or small cortical infarct).

The most common potential intracardiac shunt is patent foramen ovale (PFO). However, this is present in about 25% of the population, making its presence difficult to put into context. In young apparently idiopathic stroke, the incidence of PFO approaches 50%. Recent studies suggest PFO alone after stroke carries a small 2% risk per year of further stroke. However, this seems to be increased to 15% by the concomitance of an atrial septal aneurysm (ASA), suggesting that this is an important co-factor. Isolated ASA without PFO is a very rare occurrence and hence no reliable prognostic information pertains to this group.

### Stroke and the blood

Many haematological conditions can lead to stroke (Table 5.6), especially when other risk factors are present.

Sickle cell disease may produce stroke in childhood by intracranial stenosis and occlusion of the terminal carotid and proximal MCA. A channel of friable collaterals may form at the skull base (secondary Moyamoya syndrome, see later). In adults with sickle cell disease, ischaemic stroke is more frequently caused by small vessel disease or occlusion and often several other risk factors are

**Table 5.6** Haematological causes of stroke.

Important	Sickle cell disease
	Polycythaemia of any cause
	Thrombocythaemia
	Antiphospholipid antibody syndrome
Rare	Thrombotic thrombocytopenic purpura
	Paroxysmal nocturnal haemoglobinuria
	Leukaemia and myeloma
Uncertain (except by cerebral venous thrombosis or paradoxical embolus)	Activated protein C resistance $\pm$ factor V Leiden mutation
	Protein C
	Protein S
	Antithrombin III deficiencies
	Prothrombin G20210 mutation
	Other thrombophilias
Other causes of hypercoagulability	Malignancy (especially stomach cancer)
	Vasculitis
	Homocystinuria
	Drugs (e.g. contraceptive pill, intravenous immunoglobulin)
	Nephrotic syndrome
	Disseminated intravascular coagulation

present. There are many neurological phenomena associated with sickling and stroke is only one of them. Migrainous symptoms are common in patients with sickle cell disease.

Of the hypercoagulable states, thrombophilia is commonly tested for in younger patients but rarely proven as a cause of arterial stroke. Cerebral venous thrombosis is a far more likely mechanism of stroke associated with thrombophilia, but the latter may be relevant if there has been paradoxical arterial embolism. The most common detectable abnormality in the population is activated protein C (APC) resistance; the others are very rare. Resistance to APC is one of the most commonly identified venous thrombo-embolic risk factors but there is no clear relationship to arterial stroke. APC resistance is inherited in a dominant fashion and in most patients associated with a single point mutation in the factor V gene (factor V Leiden). Patients may be homozygous or heterozygous. It is much more important to request a full blood count looking for polycythaemia and thrombocythaemia than a thrombophilia screen. Beware marginally high RBC and platelet counts which may be easy to dismiss but are common in JAK 2 positive myeloproliferation.

### Antiphospholipid antibodies and syndrome

One distinct haematological condition is the antiphospholipid antibody syndrome (APAS) in which arterial stroke is well documented. This is not the same as having antiphospholipid antibodies which may occur in association with other vasculopathies

**Table 5.7** Non-atherosclerotic vasculopathies which can cause stroke.

Idiopathic/traumatic arterial dissection
Drug misuse
CADASIL

CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy.

including atherosclerosis. In most cases, the finding of antiphospholipid antibodies in a patient with stroke is unrelated to the stroke, and follow-up studies show antiphospholipid antibodies are not associated with an increased risk of recurrent stroke. However, in a small proportion of patients antiphospholipid antibodies appear to have a pathogenic role in arterial and venous thrombosis. Ischaemic stroke is the most common arterial thrombotic event with APAS. Other neurological manifestations include neuropsychiatric features, movement disorders and migrainous headaches often with aura. There may be recurrent fetal loss and livedo reticularis. Antiphospholipid antibodies may be inferred by the presence of a circulating lupus anticoagulant (a functional test of coagulation) or IgM/IgG cardiolipin or beta 2 glycoprotein 1 antibodies (immunologic assays). These antibodies may be present in patients with systemic lupus erythematosus, chronic infection and neoplasia but a rarer subgroup has primary APAS with no other associated disease. Where relevant all antibody tests and the lupus anticoagulant need to be checked as relevant positivity may occur only in one test. Levels of antibodies can fluctuate considerably and the diagnosis cannot be made unless the antibodies remain present for more than 3 months.

Non-atherosclerotic vasculopathies and other rare cases of stroke are discussed elsewhere in this chapter (Table 5.7) and in Chapter 26.

### Clinical syndromes of cerebral ischaemia

#### Transient ischaemic attacks

We have tended to distinguish TIAs from completed stroke on an arbitrary basis but the pathophysiology behind the cause may be identical (e.g. severe carotid stenosis) and both require urgent specialist assessment and investigation. The term brain attack, used by some to describe the acute presentation of TIA and stroke, emphasises urgency. Careful history, examination and sophisticated neuroimaging often reveal that what has been labelled as a TIA is in fact

associated with infarction. It is nevertheless useful to distinguish transient as opposed to persistent symptoms and signs, as the differential diagnosis of transient events is different.

The symptoms of transient ischaemia are usually negative, maximal at onset and last typically for a few to 30 minutes. The definition of TIA allows the symptoms to persist for up to 24 hours. We often think of transient ischaemia as indicating atherosclerosis within a specific arterial territory but TIAs may occur in the setting of multiple risk factors without imaging evidence of vasculopathy; or they may occur secondary to a haematological cause (e.g. polycythaemia). High-frequency attacks (several a week) are likely to be brought about by embolism from severe stenosis of a large artery; very high-frequency attacks (several a day) tend to follow from intermittent haemodynamic failure above a critically stenosed artery with poor flow. Such haemodynamic attacks may be distinguished by their diurnal variation (more common in the morning) and at times when blood flow is diverted elsewhere in the body (e.g. after eating or on exercise). Sometimes they present with limb jerking, similar to a focal motor seizure, which may then give way to weakness.

As a general rule, if a patient has more than three TIAs there should be an identifiable reason for them. If there is not a good reason evident after thorough investigation, then the diagnosis should be questioned. Common sites often ignored are found by examining the heart in detail (by trans-oesophageal echocardiography, TOE), the aortic arch (also best seen on TOE), the great vessels, the vertebral arteries and their origins and the intracranial circulation. None of these sites is covered by carotid duplex and adequate investigation requires both echocardiography and CT or MR angiography.

TIAs are associated with a high rate of subsequent stroke: one-third of all untreated patients subsequently have a stroke. The immediate risk is high: 20% of strokes occur within a month and 50% within a year.

Within the carotid circulation (Table 5.8) the retinal circulation may be affected leading to transient monocular blindness (amaurosis fugax). This is usually described as a curtain or shutter coming down over one eye. Blindness usually lasts several minutes only; very occasionally, cholesterol emboli (a Hollenhorst plaque) may be seen after or during an attack. Hemisphere ischaemia is suggested by sudden onset contralateral weakness or dysphasia, when the dominant hemisphere is affected. The symptoms of hemisphere ischaemia usually last up to 20 minutes. Sensory loss in isolation is less common.

Within the vertebrobasilar circulation, attacks may cause diplopia, facial or tongue numbness, dysarthria, vertigo and bilateral visual loss. In some cases it is not possible to decide whether anterior or posterior circulation has been affected: an innominate stenosis with embolism (rare) may produce attacks with mixed features.

It is very unusual for isolated vertigo (Chapter 15) to be caused by vertebrobasilar ischaemia but not impossible – after all, infarction may be asymptomatic. Isolated vertigo is usually the result of an isolated vestibulopathy.

TIAs are usually considered unlikely to be caused by haemorrhage. However, better availability of MRI and blood sensitive acquisition sequences (such as T2\* weighted imaging or susceptibility weighted imaging, SWI) reveals that microhaemorrhage or small cortical or sulcal bleeds can be associated with transient neurological symptoms and are often linked with uncontrolled hypertension (Figure 5.7) or cerebral artery amyloidopathy.

**Table 5.8** Symptoms of transient ischaemia and other symptoms not of transient ischaemia.

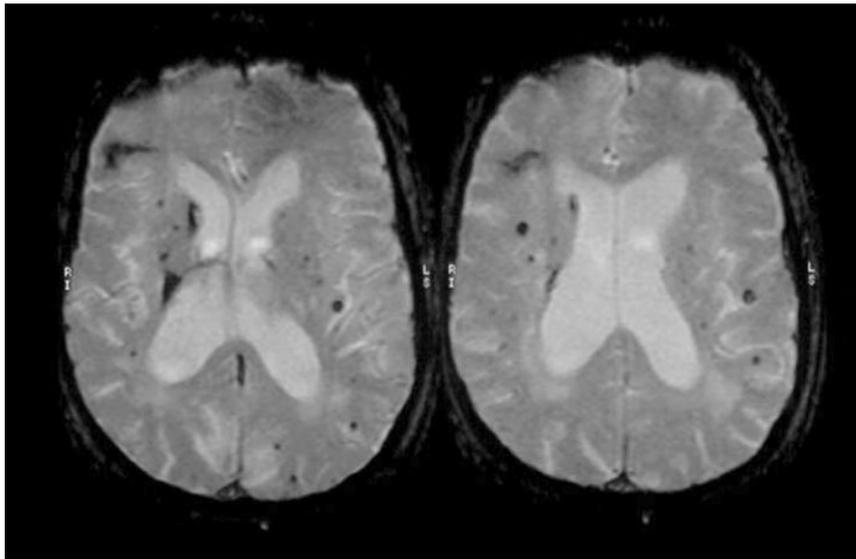

Symptoms of transient ischaemia	
Carotid territory	Monocular visual loss
	Unilateral weakness
	Dysphasia
Vertebrobasilar	Diplopia
	Vertigo/dysequilibrium
	Bilateral visual loss
Either	Bilateral weakness
	Headache
	Dysarthria
	Hemianopia
	Unsteadiness
	Sensory loss
Symptoms not usually suggestive of transient ischaemia	
Syncope	
Isolated amnesia	
Drop attacks	
Generalised weakness	
Confusional states	
Isolated vertigo	

### Alternative diagnoses

About one-quarter of people attending specialist cerebrovascular clinics with possible TIAs have alternative diagnoses (Table 5.9). The most common is migraine with focal symptoms. These are either part of an aura preceding headache (not usually confused with TIAs), or without headache (commonly confused) or following a migrainous headache – the extremely rare hemiplegic migraine. Stroke itself and TIAs are not infrequently accompanied by headache. Some serious conditions may cause both migrainous symptoms and infarction (e.g. cervical artery dissection, APS and giant cell arteritis).

The two main pointers toward migraine are positive phenomena and spread. Visual aura may consist of zigzag lines and scintillating scotomas. Sensory aura is tingling rather than numbness and in a mouth–hand distribution. Patients may complain of weakness but this is usually vague. Symptoms evolve slowly – taking several minutes for the visual disturbance to maximise, or for the tingling to spread from the hand to the face (the typical distribution). True hemiplegic migraine (Chapter 12) is a rare familial channelopathy and quite distinct from other forms of migraine.

Other commonly confused conditions are transient global amnesia and epilepsy. Transient global amnesia (TGA) is sometimes precipitated by Valsalva activated straining (e.g. immersion in cold water, travel or emotional stress). Hanging up curtains is a common precursor. Generally, in TGA, acute anterograde amnesia develops and patients usually appear bewildered and ask repetitive questions such as ‘Where am I?’ and ‘What’s going on?’ There is no loss of personal identity as in a fugue state. The attacks last several hours and after recovery the patient has little recollection of the event.

**Figure 5.7** Multiple microhaemorrhages on MR T2\*.

**Table 5.9** Differential diagnosis of transient ischaemia.

Migraine
Transient global amnesia
Epilepsy
Multiple sclerosis
Mass lesions, subdurals
Hypoglycaemia
Syncope

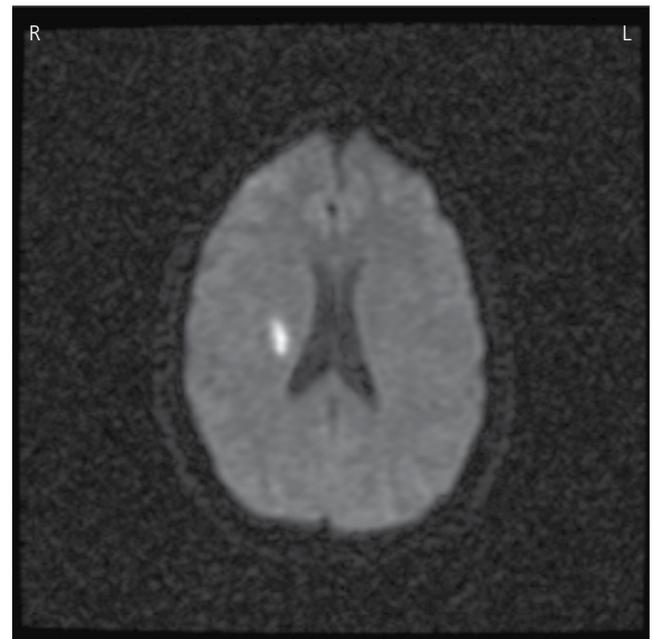

TGA is a heterogeneous disorder but in general is benign and not associated with a subsequent stroke risk. There does seem to be a subgroup of patients who have lost cognitive reserve (e.g. from chronic small vessel disease or otherwise silent Alzheimer pathology) who may present with TGA, and even rarer transient epileptic amnesia. Patients should be investigated with imaging and for vascular risk factors.

In addition, other serious intracranial pathology may cause transient symptoms such as tumours, subdural haematomas and multiple sclerosis. Hypoglycaemia may masquerade as all sorts of transient neurological disturbances, including hemiparesis but this is rare in practice. Syncope can sometimes produce confusing clinical pictures including focal deficits.

Investigation when true transient ischaemia is thought possible is the same as for completed stroke and is discussed later.

#### Lacunar stroke

Lacunae are small, subcortical or brainstem infarcts ranging from 1 to 15 mm in size. They need to be distinguished from the dilated peri-vascular spaces commonly visible on MRI. This is easy with MR FLAIR imaging: although both may be white on T2, lacunae are cavities and therefore black with a hyperintense rim. Lacunar infarction is caused by occlusion of small penetrating vessels most commonly arising from the MCA and basilar artery (Figure 5.8). Lacunae may be silent. They may be preceded by TIAs in some 20%;

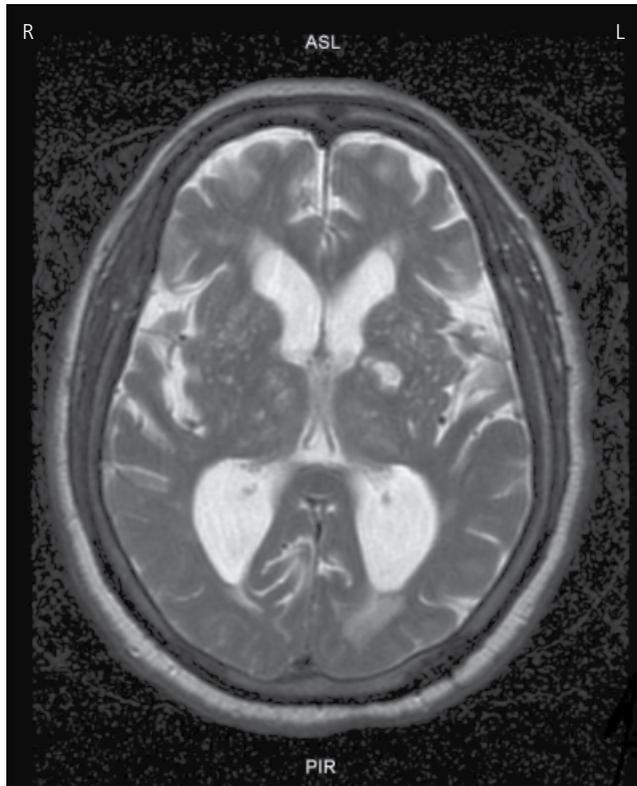

**Figure 5.8** Diffusion weighted MRI following lacunar infarction.

sometimes these are high-frequency attacks refractory to all treatments (capsular warning syndrome). Lacunar TIAs tend to be briefer and more stereotyped than large vessel TIAs. The two pathologies underlying vessel occlusion are usually lipohyaline change and/or microatheroma. Although lacunar infarction is also associated with carotid stenosis, it does not commonly happen as an embolic syndrome. The major risk factors for lacunar stroke are hypertension, diabetes and hypercholesterolaemia. Occlusion of small penetrating vessels is commonly asymptomatic but if eloquent structures are involved then the syndromes are fairly stereotypic. The most common sites for lacunar infarction are the putamen, pallidum, pons, thalamus, caudate, internal capsule and corona radiata.

**Table 5.10** Common lacunar syndromes.

Pure motor
Sensorimotor
Pure sensory
Ataxic hemiparesis
Dysarthria/clumsy hand

**Figure 5.9** Axial T2 MRI showing multiple lacunes in the deep grey and capsular white matter with periventricular abnormal signal reflecting diffuse small vessel disease.

The principal clinical feature of lacunar infarction is that patients lack cortical signs. Cortical signs include dysphasia, neglect syndrome, apraxia, hemianopia and conjugate eye deviation. It is difficult to tell clinically whether infarction has taken place affecting deep hemisphere structures or brainstem structures as the syndromes overlap. One is tempted to think that a profoundly dysarthric patient must have had brainstem infarction but this is unreliable. There are many lacunar syndromes but those commonly seen in practice are pure motor hemiparesis, pure sensory hemiparesis, sensorimotor hemiparesis, ataxic hemiparesis and clumsy hand-dysarthria syndrome (Table 5.10).

CT may not detect some smaller lacunar infarcts especially in the brainstem; MRI is much more sensitive. Often patients with lacunar infarction may have widespread changes (Figure 5.9) and it can be difficult clinically to identify the symptomatic lesion without DWI. Appropriate patients should also have evaluation of the extracranial carotids, looking for significant stenosis. The large carotid endarterectomy trials have shown that carotid stenosis is a risk factor for

lacunar stroke. Those with severe carotid stenosis benefit from endarterectomy, in terms of secondary prevention but the mainstay of secondary prevention is control of hypertension, diabetes, antiplatelet agents and statins where appropriate.

If sufficient damage from repeated penetrating vessel occlusion takes place, global problems appear. These patients often have diffuse peri-ventricular change on CT and MR imaging, known as leukoariosis and atrophy. They may develop gait apraxia (gait ignition failure, *marche à petit pas*) and postural instability with a predisposition to falling backwards, and dementia of a subcortical type with prominent lack of initiation and poor attention. Patients with small vessel disease may also be at greater risk of Alzheimer's disease (Chapter 8) and the two often coexist. These syndromes are distinct from multiple cortical stroke. Leukoariosis can also be found coincidentally without overt symptoms or signs in those over 50 years especially with appropriate risk factors. There is an increased incidence of depression and subclinical cognitive impairment in these patients.

#### Rarer causes of lacunar syndromes

APAS can present with lacunar infarction; often these patients also have a history of migrainous phenomena and headaches. Anticoagulation is often prescribed although there is not much evidence to support this practice. CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) presents in a similar fashion (see later, and Chapter 26).

#### Large vessel occlusion

The pattern of infarction after large vessel occlusion will depend on many factors. The common risk factors listed above are important, but compared to lacunar infarction the emphasis skews towards large vessel stenosis and heart disease as sources of embolism.

The main clinical distinction between large vessel occlusion and lacunar infarction in the carotid circulation is the presence of cortical signs (eye deviation, dysphasia, neglect syndromes, hemianopia). The hemiparesis produced by MCA occlusion affects the arm more than the leg because of cortical involvement (the leg cortex is in anterior cerebral artery territory).

#### Internal carotid artery disease

The major cause of this is atherosclerosis, with stenosis in the distal common carotid artery extending to the proximal ICA and external carotid artery. Occlusive disease of other arteries commonly accompanies ICA stenosis; coexisting myocardial ischaemia and limb ischaemia are common. Atherosclerosis in the ICA produces its symptoms either by embolism, thrombus formed on ulcerated plaque, haemodynamic failure from severe stenosis (>95%) or carotid artery occlusion.

An important clue to a potential ICA stenosis is transient monocular blindness, amaurosis fugax (the ophthalmic artery is the first branch above the ICA origin). Occasionally, the patient may develop a low flow retinopathy or global ischaemic ocular syndrome from a combination of small vessel and critical ICA stenosis. This may cause haemodynamic retinal symptoms including bleaching out of colours in sunlight and persistent after images from bright lights. Although a bruit may mark the presence of ICA stenosis and is an independent risk factor for stroke, the ICA flow can be so severely diminished that a bruit is absent. Embolism is most likely to produce a partial or complete MCA syndrome and is discussed later. Haemodynamic failure above a critical stenosis can lead to border-zone infarction. Horner's syndrome may be present

when the artery is acutely thrombosed. Carotid occlusion occasionally presents with a stuttering deficit, sometimes over many weeks.

Narrowing and thrombotic occlusion of the carotid siphon in the distal ICA is less frequent than at the origin but is usually caused by atherosclerosis. This may be more common in the Asian population. In younger patients, distal stenosis and occlusion may be caused by vasculitis, dissection or Moyamoya disease.

### Middle cerebral artery occlusion

**Total MCA occlusion** The MCA may be affected by embolism or thrombosis *in situ*. Patients with severe intracranial atherosclerosis have a high incidence of stroke because of thrombosis *en plaque*. People of Asian and African descent seem particularly affected by

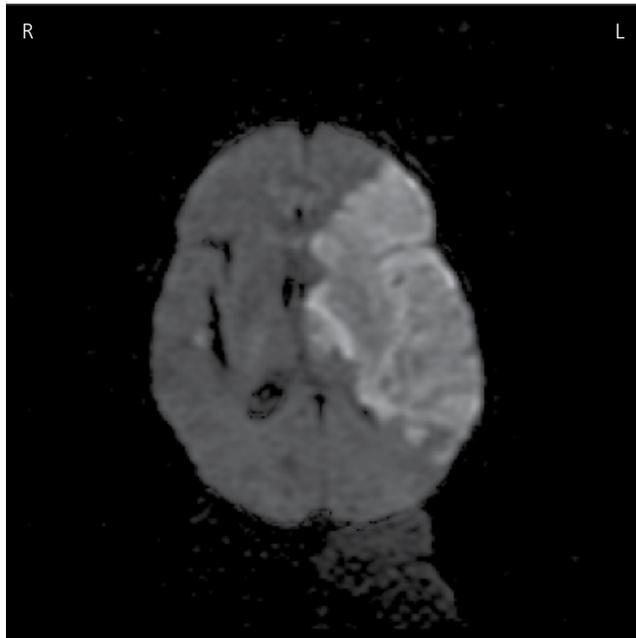

intracranial stenosis. In Caucasians, while MCA occlusion is common, MCA stenosis is rare.

If the main trunk occludes and there are inadequate collaterals then the whole territory infarcts (Figure 5.10). The clinical picture produced is sometimes known as ‘front-to-back’ infarction with conjugate eye deviation (frontal lobe damage), aphasia (dominant hemisphere), hemiplegia, hemisensory loss and hemianopia (parietal and temporal lobe damage). Neglect syndromes where the patient is unaware of the hemiplegic side occur acutely with both non-dominant and dominant hemisphere damage but generally only persist with non-dominant damage. Patients with complete MCA syndromes can develop fatal brain swelling (malignant MCA oedema) which peaks at 4–5 days and can lead to herniation and coning. In appropriate cases surgical decompression is required (Figure 5.11).

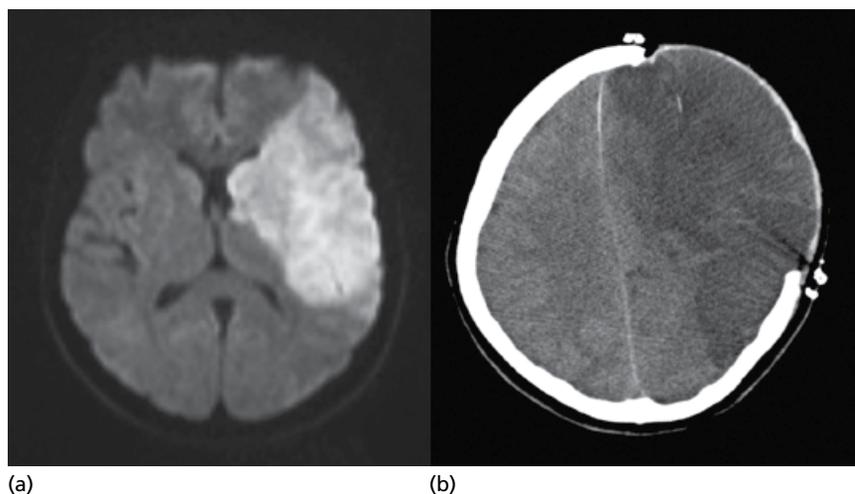

**MCA branch occlusions** These produce fragments of the syndromes described earlier. Upper branch occlusion affecting frontal structures produces hemiparesis, hemisensory loss, ocular deviation and non-fluent motor dysphasia (expressive) where the patient understands (intact temporal lobe) but cannot produce speech. Lower branch occlusions can affect the temporal lobe resulting in fluent dysphasia (receptive) where production of speech is good but incoherent and the patient does not understand (Chapters 4 and 8).

**MCA distal embolism** Small cortical branches occluded (e.g. by emboli) may present only with weakness or isolated cortical signs, difficult to distinguish from the effects of a lacunar infarct.

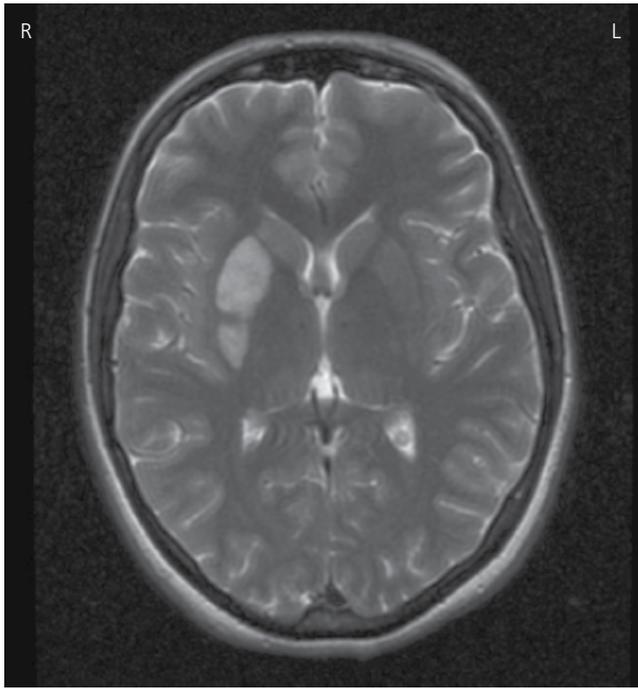

**MCA deep infarction (striato-capsular infarction)** This tends to occur when collateral circulation protects the cortex but deeper structures (the striatum and capsule) become infarcted (Figure 5.12). This pattern of infarction is also seen with MCA stenosis and when emboli obstruct the lenticulo-striate perforators and then break up. Patients have unilateral motor and sensory loss but also exhibit cortical signs (unlike pure lacunar infarction). These cortical signs resolve more quickly than when the cortex itself is damaged. Striato-capsular infarction should prompt a search for cardiac and ipsilateral carotid sources of embolism.

**Figure 5.10** Diffusion weighted MRI showing complete MCA territory infarction.

**Figure 5.11** Malignant middle cerebral artery (MCA). (a) A large acute left MCA infarct is seen on DWI. (b) CT at 5 days post infarct shows severe swelling and decompressive craniectomy.

**Figure 5.12** Axial T2 MRI of striato-capsular infarction.

#### Anterior cerebral artery occlusion

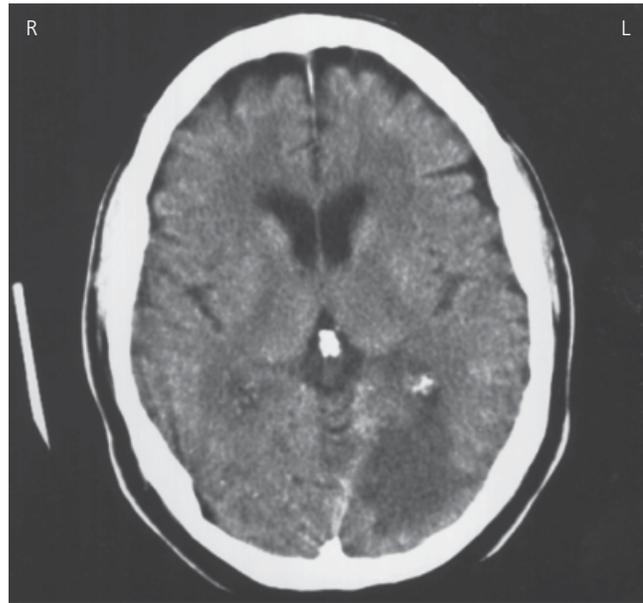

This territory is far less often affected than that of the MCA. Although the same risk factors apply, ACA territory infarction should raise the level of awareness for unusual aetiologies at play. This also occurs in the setting of SAH, secondary to vasospasm. The clinical features of ACA occlusion are contralateral hemiplegia. The leg is most affected as the cortical representation of the leg lies within the territory. Some patients may have motor neglect and apraxia.

#### Anterior choroidal artery occlusion

Syndromes include hemiparesis (face, arm and leg), prominent hemisensory loss and hemianopia, often temporary. However, unlike hemianopia associated with complete MCA infarction, other cortical signs may be subtle and transient.

#### Posterior cerebral artery

Occlusion of these arteries is commonly embolic. More patients with PCA syndromes are in atrial fibrillation than with other large vessel occlusions (Figure 5.13). The PCA supplies principally the occipital cortex: an isolated hemianopia is common. When infarction is more anterior, affecting parieto-occipital areas, neglect syndromes may accompany the hemianopia. The PCAs also supply the thalami and posterior-medial temporal lobes. If these structures are involved the patient may present with confusion, dysphasia (thalamic) or memory impairment (thalamic or temporal). If both PCA territories are infarcted, as may happen when an embolus lodges at the top of the basilar, cortical blindness and confusion ensues. Sometimes, these patients may be left with tunnel vision and may recognise small but not large objects. Memory impairment, especially for new information, may be severe.

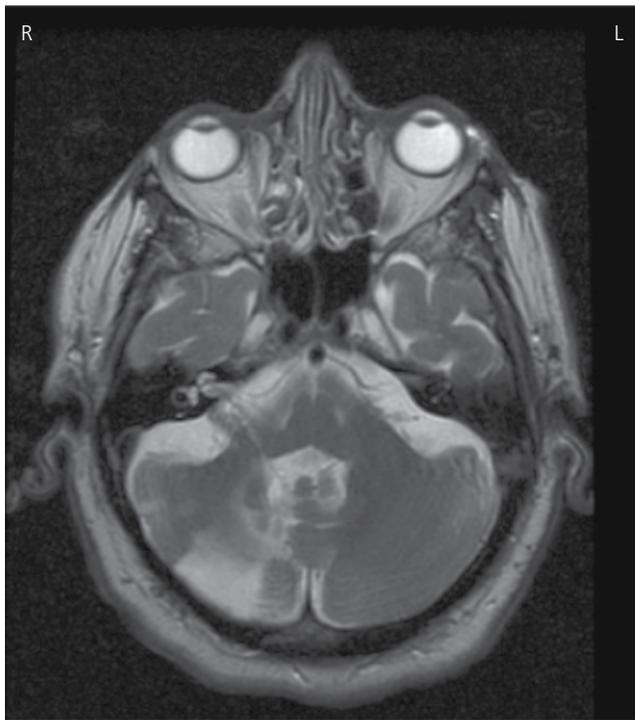

**Figure 5.13** Unenhanced CT showing area of infarction following posterior cerebral artery (PCA) occlusion.

#### Vertebral artery

The most common pattern produced by occlusion of or embolism from the vertebral arteries is infarction of the dorsolateral medulla within the territory of the posterior inferior cerebellar artery causing a lateral medullary syndrome (Wallenberg's syndrome). This results in a Horner's syndrome, dissociated (temperature and pain) sensory loss on the ipsilateral side of the face and the opposite side of the body, nystagmus, ataxia of the ipsilateral limbs, and ipsilateral palatal and vocal cord paralysis. Vertebral embolism or occlusion may also result in more extensive infarction of the brainstem and cerebellum; these syndromes are discussed next. The most common site for atheroma to affect the vertebral artery is at its origin from the subclavian.

#### Basilar artery

Whereas the middle and posterior cerebral arteries are more often affected by embolism than *in situ* thrombosis, the opposite is true of the basilar artery. This is because the basilar is wider than its two feeding vertebral arteries and it can be affected by severe atherosclerosis on which *in situ* thrombus can form (Figure 5.14). Basilar thrombosis may also result from propagation of thrombus from one of the vertebral arteries (e.g. after vertebral artery dissection) and can also occur without obvious precipitants, especially in younger adults. The basilar thrombus may obstruct blood flow into perforating vessels supplying the central brainstem structures or the two upper cerebellar arteries. A number of clinical pictures may be encountered. In the medulla, lower cranial nuclei may be affected giving rise to a lower motor neurone type bulbar palsy. Upper motor neurone impairment of the same structure may cause a pseudobulbar palsy, with brisk facial reflexes, brisk jaw jerk and a spastic tongue. This is often accompanied by spontaneous laughter or crying (emotional lability). Above the medulla, pontine infarction can cause a VIth nerve palsy, gaze paresis, internuclear ophthalmoplegia and pinpoint pupils. Emboli may also lodge at the top of the basilar causing midbrain infarction with loss of vertical eye movement, pupillary abnormalities, coma or locked-in syndrome.

**Figure 5.14** Axial T2 MRI: cerebellar infarction following basilar thrombosis (basilar artery: now patent).

Involvement of the origin of one or both of the posterior cerebral arteries may lead to a hemianopia or cortical blindness. All these syndromes will be accompanied by quadriplegia to some degree, which may be very asymmetric.

#### Border-zone syndromes and ischaemic encephalopathy

The brain is particularly vulnerable to a global decrease in perfusion. Most frequently, this is caused by cardiac disease (arrhythmia or pump failure) and hypoxaemia, although hypovolaemia alone may result in these syndromes. Hypoxia without ischaemia (i.e. without reduction in blood flow) does not lead to cerebral infarction. The usual circumstance in which these patients are encountered is following cardiac arrest, severe blood loss and cardiopulmonary bypass in which embolism may also occur. Acutely in the non-anaesthetised non-comatose patient, global perfusion failure results in non-focal brain dysfunction (confusion, attentional deficits, light-headedness). Following a profound insult a number of watershed syndromes brought about by damage to the border-zone regions are recognised.

The area particularly vulnerable to reduction in perfusion pressure is the parieto-occipital cortex that lies at the superficial border-zone between MCA and PCA territories. This is the area furthest from the heart. Infarction of this region results in abnormalities of behaviour, memory and vision. The visual abnormalities are complex and include inability to see all the objects in a field of vision, incoordination of hand and eye movement such that the patient cannot locate objects in the visual field, and apraxia of gaze in which the patient cannot gaze where desired. Other areas of vulnerability are the deep border-zones within the subcortical white matter of the centrum semi-ovale, and border-zones between the ACA and MCA, and the hippocampi, where infarction may result in a Korsakoff-type syndrome. In severe cases, necrosis can follow

within the basal ganglia, cerebellum and brainstem. The term watershed is often used to mean border-zone, though strictly speaking a watershed is a line dividing two drainage basins, which is a poor analogy with perfusion anatomy. Unilateral patchy deep border-zone ischaemia in the centrum semi-ovale is characteristic of ipsilateral internal carotid artery occlusion or severe stenosis and may be seen in patients presenting only with TIA or minor stroke.

#### Vascular dementia

Dementia (i.e. cognitive deficits in multiple domains) can follow multiple cortical or subcortical lacunar infarcts (multi-infarct dementia). Typically, patients have a stepwise deterioration associated with other features of stroke. In diffuse small vessel disease, the onset may be more subtle with the more gradual onset of cognitive impairment (Chapter 8) often accompanied by gait apraxia where patients exhibit failure to initiate gait, postural instability (often falling over backwards) and a shuffling small-stepped gait. Patients with diffuse small vessel disease may have prominent attentional difficulties in excess of discrete cortical patterns of dysfunction and often present with periods of encephalopathy associated with new infarction. Multiple cortical infarcts, from large vessel occlusions, are much rarer as a cause of dementia. In addition, it is important to note that patients with vascular disease (clinically and radiologically) are at an increased risk of Alzheimer's disease and it is the combination of the two pathologies that causes dementia in many patients with vascular disease (mixed dementia). This can be distinguished to some extent on clinical and neuropsychological ground, but it is often difficult to separate the effects of the two diseases.

#### Intracranial haemorrhage

Intracranial haemorrhage may be intracerebral, subarachnoid, subdural or extradural. This section deals principally with intracerebral haemorrhage (ICH), both supratentorial and infratentorial haemorrhage.

Approximately 10% of stroke is caused by brain haemorrhage with an annual incidence of 10–15/100 000 population. The incidence increases significantly after the age of 55 years and doubles with each decade to the age of 80. However, there has been a small but progressive decline in the incidence of both stroke and brain haemorrhage in the last three decades, because of an improvement in the management of risk factors and secondary prevention; the control of hypertension in primary care has been of particular importance.

Despite being less common than ischaemic stroke, haemorrhage has a significant impact because the subsequent mortality is so high. In one study of over 1000 stroke cases, 30-day mortality for supratentorial and infratentorial ischaemic stroke was 15% and 18%, respectively. Mortality following supratentorial and infratentorial haemorrhage was 58% and 31%.

Spontaneous ICH results from intracerebral arterial rupture, particularly perforating vessels, or less frequently from the venous system. The haematoma expands following the path of least resistance, usually along white matter tracts, and occasionally into the ventricular system. Neurological deficit results both from direct tissue destruction and indirectly from local compression and mass effect, usually in proportion to both the volume of haematoma and its rate of expansion. Intraparenchymal haemorrhage can occur at any site, although some areas are more susceptible than others. Eighty per cent of such intraparenchymal haemorrhages occur within the cerebral hemispheres and some 20% are infratentorial.

Traditionally, brain haemorrhage has been thought to have a sudden devastating presentation. While it is true that patients who present in coma or who have vomiting, headache and neck stiffness are more likely to have had a haemorrhage than ischaemic event, it is wrong to believe that patients with less severe stroke syndromes can be diagnosed on clinical grounds to have had ischaemic strokes. This is particularly illustrated by the recognition of microhaemorrhage with T2\* and SWI imaging which occasionally reveals minute bleeds as the underlying cause of clinical syndromes previously thought to have been caused by ischaemia.

### Risk factors

The most important risk factor associated with brain haemorrhage is hypertension, found in 40–60% of patients. Hypertension leads to disease of the small perforating arteries (hypertensive arteriopathy), which is an important cause of leukoaraiosis on imaging as well as promoting rupture of these vessels. Compared with brain haemorrhages from other causes, this type of bleed is more frequently fatal, a reflection of both its high incidence and its tendency to occur in critical locations. Hypertensive bleeds occur in deep white matter (36%), pons (11%) and cerebellum (8%), regions that are supplied by the lenticulo-striate branches of the MCA or the paramedian perforating branches of the basilar artery. The underlying weakness of these vessels is usually caused by hyaline degeneration of arterioles promoted by long-standing hypertension, but can also result from fibrinoid necrosis in patients with malignant hypertension or eclampsia. Identical pathology can be seen in elderly patients without known hypertension.

Other conditions important in the aetiology of brain haemorrhage are aneurysms (20%), vascular malformations (5–7%), coagulopathies (5–7%), tumours (1–11%), sporadic cerebral amyloid angiopathy and secondary haemorrhage into a recent infarct (haemorrhagic infarction) (Table 5.11). It is important to recognise that hypertension is a risk factor for haemorrhage from all these pathologies and thus a history of hypertension is not sufficient to diagnose a hypertensive bleed. Non-medicinal use of cocaine and amphetamines may cause haemorrhage, although there is often an underlying vascular malformation in these cases.

Aneurysms are saccular or fusiform arterial deformities, the result of protrusion of the intima through a structural defect in

the arterial muscular layer. Typical circle of Willis aneurysms, also known as berry aneurysms, most commonly cause SAH, although this is associated with intraparenchymal bleeding in 30% of patients. Mycotic aneurysms usually form in smaller cortical arteries when septic emboli lodge in the vessel. This is usually seen in the context of infective endocarditis, where up to 17% of patients develop cerebral emboli. Usually, these mycotic aneurysms thrombose, if the infection is treated adequately, and no further intervention is required. Rarely, the mycotic aneurysm continues to enlarge or ruptures; surgical intervention is necessary to clip and/or resect it. Arterial invasion by tumour or severe atherosclerosis occasionally leads to aneurysm formation, although rupture is rare. Other vascular malformations that cause brain haemorrhage include arteriovenous malformations (AVMs), cavernous malformations and capillary telangiectasia. Developmental purely venous anomalies were also thought to cause haemorrhage: however, the current understanding is that it is the cavernous malformation commonly associated with the venous anomaly that is the source of bleeding.

One of the most important and potentially treatable causes is anticoagulation, especially when poorly controlled and combined with other risk factors. Any patients on anticoagulants with new focal neurology must be assumed to have bled until proven otherwise with urgent cranial imaging. In those that have bled, anticoagulation should be immediately reversed. The mechanism by which anticoagulation promotes cerebral haemorrhage is uncertain. It is possible that what would be an asymptomatic microbleed in the non-anticoagulated patient becomes macroscopic and symptomatic in an anticoagulated patient. Certainly, cerebral haematomas associated with anticoagulation are larger and continue to enlarge for longer in patients on anticoagulants. Other causes of coagulopathy, including thrombocytopaenia, leukaemia and liver and renal failure, may also cause similar problems. Patients with coagulopathy are also much more likely to bleed into cerebral infarcts.

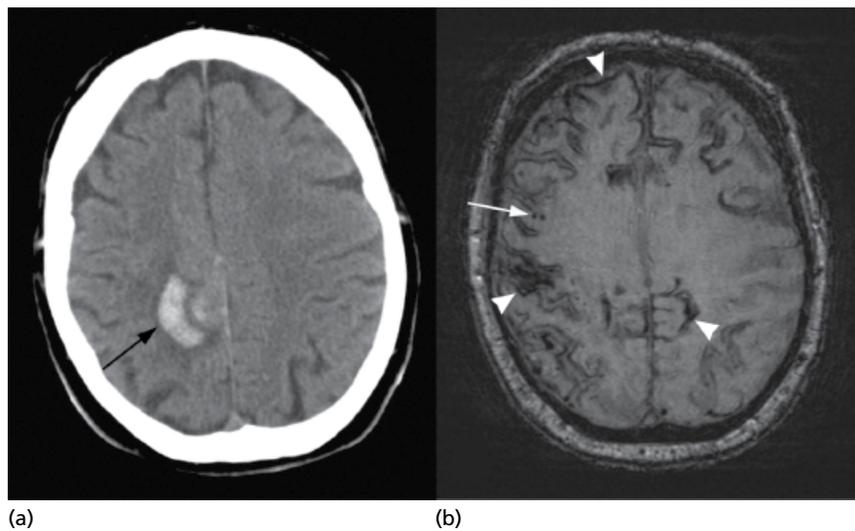

An increasingly important and recognised condition causing ICH is sporadic cerebral amyloid angiopathy (CAA). This is a common age-related cerebral small vessel disease, characterised by progressive deposition of amyloid- $\beta$  in the wall of small cortical and leptomeningeal arteries. Population-based autopsy studies show that the prevalence of CAA is 20–40% in non-demented, and 50–60% in demented elderly population. Deposition of amyloid- $\beta$  causes injury to the vessel wall, which in moderate to severe disease may rupture, causing cerebral microbleeds, cortical superficial siderosis or larger symptomatic ICH. Although CAA is most often recognised by the occurrence of spontaneous lobar ICH in the elderly, it can also cause transient focal neurological deficits, disturbances of consciousness and progressive cognitive decline.

CAA is also associated with transient focal neurological episodes (sometime called ‘amyloid spells’), which can resemble TIAs, migraine auras or focal seizures. Patients often complain of recurrent, brief (minutes), stereotyped attacks of paresthesias or numbness (spreading smoothly over contiguous body parts), visual symptoms (sometimes migraine aura-like), face or limb weakness or dysphasia. Although these symptoms may clinically suggest TIAs, increasing data suggest that ‘amyloid spells’ in CAA are more often associated with intracranial bleeding.

The radiological demonstration of haemorrhagic manifestations of the disease in the brain (especially using T2\*-GRE or SWI MRI) allow the *in vivo* clinical radiological diagnosis of CAA (Figure 5.15). The diagnosis of CAA currently relies on the demonstration of multiple haemorrhagic lesions in strictly lobar brain

**Table 5.11** Causes of brain haemorrhage.

areas – the Boston criteria, including both cerebral micro-bleeds, as well as ICH, although pathological validation for microbleed-only patients is limited.

#### Clinical syndromes of intracranial haemorrhage

The rupture of a vessel or microaneurysm results in the sudden development of haematoma, of variable size. These haematomas characteristically then slowly enlarge over the next few hours, and sometimes continue to enlarge over a matter of days especially in patients on anticoagulants, leading to progressive focal neurological deficit and then deterioration of conscious level secondary to mass effect. Haemorrhage may be divided into a number of categories depending on location. These are deep (centered on basal ganglia structures), lobar, pontine and cerebellar. In all sites, hypertension remains the most important risk factor and while amyloid angiopathy classically gives rise to lobar and not deep haemorrhage, hypertension is still the most important risk factor in lobar haemorrhage.

#### Deep haemorrhage

Haematomas may be centred on the putamen, caudate or thalamus. In putaminal haemorrhage, the picture is of contralateral hemiparesis and conjugate deviation of the eyes towards the side of the haematoma (Figure 5.16). Cortical function may be impaired. If the mass effect becomes critical then signs of herniation ensue. These haematomas may rupture into the ventricles leading to intraventricular haemorrhage. In the case of putaminal haemorrhage the presence of ventricular blood implies a very large haematoma with a poor prognosis. Caudate haemorrhage is much rarer and small haematomas may readily rupture into the ventricles. When the lesion is large the picture is similar to putaminal haemorrhage but if small, haematomas may mimic subarachnoid haemorrhage with acute headache and meningism with little in the way of focal signs. Thalamic haemorrhage predominantly produces sensory change in the contralateral limbs. If local midbrain compression occurs the eyes may be forced into downward gaze with small poorly reactive pupils. Thalamic haemorrhage in the dominant hemisphere may produce dysphasia with notable naming difficulties.

**Figure 5.16** Unenhanced CT showing large putaminal haematoma.

#### Lobar haemorrhage

These cortical lesions produce signs appropriate to their location. In the frontal lobe, ipsilateral eye deviation and contralateral hemiparesis is common. In the posterior frontal and fronto-parietal region, hemisensory loss is found, associated with dysphasia when the lesion is within the dominant hemisphere. Parietal lobe haemorrhage causes hemisensory loss and neglect/inattention syndromes. Bleeding into the dominant temporal lobe results in a fluent dysphasia with poor comprehension secondary to damage to Wernicke's area.

Lobar haemorrhages are more likely to be associated with structural abnormalities (e.g. a vascular malformation) than deep haemorrhages. Alternatively, amyloid, trauma, haemorrhagic transformation of infarction and a haemorrhagic tumour should be considered within the differential diagnosis.

### Infratentorial haemorrhage

The classic picture in pontine haemorrhage is coma associated with pinpoint pupils, loss of horizontal eye movements and quadriparesis. Hyperpyrexia and irregular respiratory patterns ensue. Although a large haematoma here is often fatal, the outcome may be surprisingly good in some patients.

Cerebellar haemorrhage accounts for some 10% of all brain haemorrhages. It is important to recognise that cerebellar haematomas may result in secondary fatal brainstem compression and hydrocephalus. Posterior fossa craniectomy to decompress the brainstem can be life-saving and patients may make an excellent functional recovery, even from deep coma. The usual picture is of acute headache and vomiting with unilateral ataxia. Unilateral gaze paresis in association with ataxia or in isolation may occur and also skew deviation. When brainstem compression is present from the onset or develops later, the picture suggests a pontine haemorrhage, with the patient either presenting or deteriorating into coma. Emergency CT scanning is essential.

### Intraventricular haemorrhage

This mimics SAH (see later) with headache, vomiting, neck stiffness and depression of consciousness. There may be associated pyramidal signs, particularly if associated with a parenchymal haematoma. This may be caused by extension of blood following deep haemorrhage, aneurysmal rupture or a subependymal angioma. This is particularly the case with caudate haemorrhage as this nucleus lies adjacent to the ventricular margin.

### Specific issues in intracerebral haemorrhage

Brain imaging is mandatory, without delay. Although MRI is greatly superior to CT at refining the pathophysiological diagnosis, it is not currently available for most patients in the emergency situation. The appearances of haemorrhage on CT are also easier to interpret than on MRI, especially in non-expert hands and CT is therefore often the preferred imaging technique at presentation. Acutely, a CT is essential to distinguish infarction from haemorrhage or reveal mimics of the stroke syndrome such as tumour or subdural haematoma. Haemorrhages seen on MRI undergo complex changes depending on the image sequence, the proportion of oxyhaemoglobin, deoxyhaemoglobin and methaemoglobin, and its distribution; this may make interpretation difficult. However, signal loss on susceptibility weighted MRI is more specific and sensitive to new and old haemorrhages than the older MRI sequences.

In appropriate patients it is necessary to exclude an aneurysm or underlying vascular malformations with angiography. In some cases, CT or MR angiography might be sufficient, but these may miss small lesions and catheter angiography is still required in a small proportion of cases. The decision to perform catheter-based angiography should be made after discussion with an interventional neuroradiologist and/or vascular neurosurgeon. If performed in the acute situation, consideration should be given to repeating angiography once the mass effect of the haematoma has resolved. In 10% of cases where initial angiography is normal, a small arteriovenous malformation is demonstrated on delayed imaging. This is caused by occlusion of the arteriovenous malformation by the mass

effect of the acute haematoma. In this situation either the angiogram should be delayed or repeated following resolution of the haematoma. MRI is often a useful complementary investigation in order to exclude underlying parenchymal lesions. Again this is best performed after some days once there has been resolution of some of the blood products.

Following a brain haemorrhage, the general supportive management issues are just as important as in ischaemic stroke. Medical treatment is aimed at correcting any underlying systemic disorder such as severe hypertension or coagulopathy, as well as preventing or limiting secondary complications such as pulmonary emboli, MI and pneumonia. Aspirin (often taken as an over-the-counter preparation) or any other medication with antiplatelet (clopidogrel, non-steroidal anti-inflammatory agents) or antithrombotic actions (dipyridamole) should be stopped. Early intensive lowering of blood pressure was shown to be safe in the second INTERACT trial, while secondary analyses suggested that this might improve outcome. Until recently, there were no specific haemostatic drugs that had been shown to alter outcome. Initial trials of recombinant activated factor VII showed that this pro-coagulant appeared to reduce haematoma size and improves outcome when given within 4 hours of onset; however, phase IIb/IIIa studies have been negative. Further trials are needed to explore similar products. Frequent neurological assessments, as well as serial CT scans, are necessary particularly early in the clinical course when management can be modified accordingly.

Anticoagulant-related haematomas often present as slowly evolving lesions. It is essential, even if they are small at initial imaging, to reverse warfarin immediately as delay may have devastating consequences. This maxim includes patients with prosthetic valves as the risk-benefit ratio is much in favour of anticoagulation reversal for a period of 2 weeks, after which the rebleeding rate is considerably lower. The rate of systemic embolism from thrombus on the prosthetic valve during this period is small.

Neurosurgical practice in relation to evacuating intracerebral haematomas varies. The middle of the road approach that the authors follow is to evacuate life-threatening cerebellar haematomas large enough to cause brainstem compression and hydrocephalus and superficial lobar haematomas that are causing marked mass effect. Few neurosurgeons will tackle deep-seated basal ganglia haematomas unless under exceptional circumstances, in the main because the associated morbidity is significant. The optimal management of this form of stroke beyond organised care is unclear from the evidence and the results of the two Surgical Trial in Intracerebral Haemorrhage (STICH) trials suggested no significant benefit to surgical evacuation. In these two prospective randomised studies of over 1000 patients, there was no overall benefit from early surgery when compared with initial conservative management.

### Prognosis of intracranial haemorrhage

The prognosis of brain haemorrhage depends primarily on the location and size of the haematoma. These factors are closely followed by the patient's age, the cause of the haemorrhage and the development and severity of post-haemorrhagic complications such as cerebral oedema, hydrocephalus and raised intracranial pressure, as well as systemic complications such as pulmonary embolus, MI and pneumonia. In gauging prognosis and discussing possible outcome with a patient or their relatives, it is worth pointing out that improvement following haemorrhage tends to be more delayed than following infarction, and that there are some cases where eventual recovery is good following resolution of the haematoma.

## Subarachnoid haemorrhage

The main cause of non-traumatic SAH is rupture of an intracranial aneurysm. This accounts for 85% of cases. SAH is a devastating condition with an overall case fatality of 50% (including pre-hospital deaths), with 30% of survivors being left dependent, with major neurological deficits. In spite of many advances in diagnosis and treatment over the last decades, the case fatality rate has changed little, if at all.

Non-aneurysmal peri-mesencephalic haemorrhage is seen in 10% of cases and carries a good prognosis with less frequent neurological complications. The remaining 5% of cases are caused by rare conditions, including AVMs (including spinal AVMs), cerebral vasculitides, tumours, dural arteriovenous fistulae, dural sinus thrombosis, carotid or vertebral artery dissections, coagulopathy and drugs.

The annual incidence of SAH in the United Kingdom is approximately 10/100 000, increasing consistently with age until the sixth decade, with a peak incidence at 55–60 years. There are marked variations in the incidence of SAH worldwide. The incidence is lowest in the Middle East and highest in Japan, Australia and Scandinavia, especially in Finland where SAH incidence is around three times that of the rest of the world. The age-specific rates for SAH tend to be higher in those of Afro-Caribbean origin than Caucasian. There is female preponderance, with male : female ratio of around 1 : 1.8.

### Risk factors

The risk of aneurysmal rupture depends on the size and location of the aneurysm. The International Study of Unruptured Intracranial Aneurysms (ISUIA) documented a 5-year cumulative rupture rate for all aneurysms of the anterior circulation (except posterior communicating [PCOM] artery aneurysms) of 0%, 2.6%, 14.5% and 40% if sized less than 7, 7–12, 13–24 and more than 25 mm, respectively. The same risks for posterior circulation and PCOM artery aneurysms were 2.5%, 14.5%, 18.4% and 50%, respectively.

Most cases of aneurysmal SAH are sporadic; however, there is considerable evidence to support the role of genetic factors in the development of intracranial aneurysms. There is a strong association between intracranial aneurysms and heritable connective tissue diseases, although these form a small proportion of any case load, in the order of 5%. These conditions include autosomal dominant polycystic kidney disease, Marfan's syndrome, pseudoxanthoma elasticum, Ehlers–Danlos syndrome and  $\alpha_1$ -antitrypsin deficiency. Familial intracranial aneurysms account for 7–20% of patients with aneurysmal SAH. Approximately one-third of asymptomatic members of affected families will have evidence of intracranial aneurysms on angiography. In a study of 8680 individuals, the prevalence of asymptomatic aneurysms in the subgroups with and without a family history was 10.5% and 6.8%, respectively. The relative risk of siblings of SAH patients having a haemorrhage is six times that of the general population, with a threefold increased risk in parents – an overall fourfold increased risk in first degree relatives. Familial aneurysms tend to rupture at a smaller size than sporadic cases and often display genetic anticipation, with haemorrhages occurring at progressively younger ages in successive generations. The occurrence of aneurysms at identical and/or mirror sites is more frequent in familial cases and appears to be a function of the degree of kinship between affected individuals.

Environmental factors have been extensively studied and cigarette smoking is the only factor consistently identified, raising the risk 3–10 times that of non-smokers. This also appears to be a

dose-dependent effect. The SAH risk decreases with the number of years since giving up smoking, with excess risk largely disappearing 2–4 years after cessation of smoking. Hypertension is almost certainly important but to a lesser degree, although there is conflicting evidence over its role as it is a common co-morbid condition. It seems that hypertension and smoking act as synergistic risk factors. The risk of SAH in hypertensive smokers is nearly 15 times that in the non-smoking non-hypertensive population. There is a strong temporal association between snorting cocaine (and other methods of ingestion) and both haemorrhagic and ischaemic cerebrovascular events. The use of sympathomimetic drugs, such as cocaine and methamphetamine, tend to increase the incidence and decrease the age at which aneurysmal rupture occurs; aneurysmal size at rupture also tends to be smaller.

### Clinical features

The cardinal clinical feature is the sudden onset of a thunderclap headache. Headache is present in the majority of patients. This is usually of unique severity and sudden onset and is often accompanied by nausea and vomiting (77%). Thunderclap headache, although a cardinal feature, is non-specific and only 1 in 10 of those presenting with a sudden explosive headache will turn out to have had an SAH. There are no highly reliable features from the history that distinguish benign thunderclap headache from SAH. Exceptionally, bacterial meningitis can present with SAH.

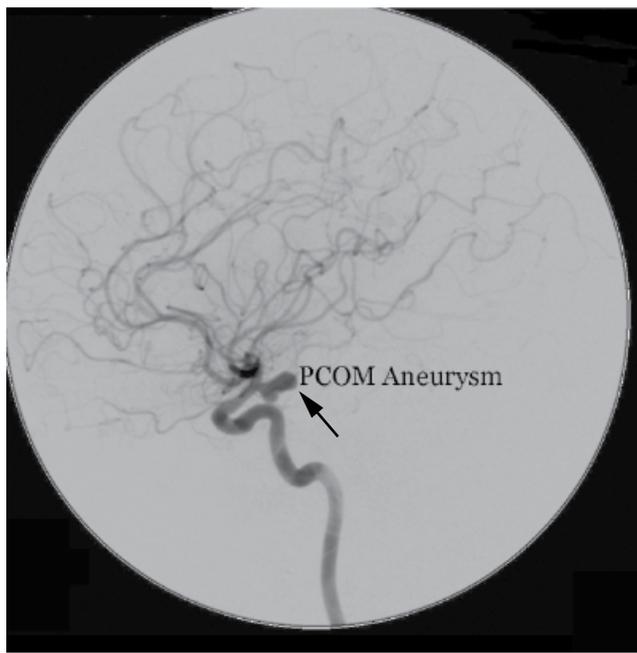

Signs of global or focal dysfunction may be found depending on the severity and location of SAH. Consciousness is frequently altered, with confusion and lethargy in 30%, transient loss of consciousness in one-third and coma in 17%. In these patients, a history of headache may be lacking. Signs of meningeal irritation are found in most but not all patients and it is a common error for these either not to be elicited or misinterpreted in patients with acute headache. Neurological abnormalities are seen in 64% of cases with focal signs such as hemiparesis, IIIrd or VIth nerve palsies in 21%. Focal deficits may be caused by intraparenchymal extension of blood or later by vasospasm with resultant ischaemia and infarction.

Symptoms do sometimes help to localise the aneurysm. Anterior communicating artery (ACOM) aneurysms may present with frontal symptoms (bilateral lower-limb weakness, bilateral extensor plantars, incontinence and abulia) and electrolyte disturbance is not uncommon. Both anterior choroidal (although uncommon) and MCA aneurysms may present with hemiparesis, aphasia or visuo-spatial neglect, while peri-callosal artery and distal ACA aneurysms present with a contralateral lower-limb monoparesis. A IIIrd nerve palsy suggests an aneurysm of the PCOM artery (Figure 5.17), or less commonly of the superior cerebellar artery. A painful pupil-involving IIIrd nerve palsy is usually a warning of potential imminent rupture of a PCOM artery aneurysm and should be investigated without delay.

Retinal and preretinal (subhyaloid) haemorrhages are seen in 25% of SAH patients. There are three types of haemorrhage that can occur alone or in combination with SAH:

- 1 Retinal haemorrhages may surround the fovea.
- 2 Subhyaloid preretinal haemorrhages are seen in 11–33% of cases as bright-red blood near the optic disc.
- 3 Terson's syndrome, consisting of haemorrhage within the vitreous humour, occurs in approximately 4% of SAH cases and usually bilaterally (Figure 5.18).

Subhyaloid and vitreous haemorrhages are associated with a high mortality rate. Patients with Terson's syndrome who survive should

**Figure 5.17** Large bi-lobed posterior communicating (PCOM) artery aneurysm (catheter angiogram).

**Figure 5.18** Terson's syndrome: CT of a patient with a subhyaloid haematoma (arrowhead) following extensive subarachnoid haemorrhage (Terson's syndrome). Blood is also seen tracking along the optic nerve sheath (white arrow).

be followed for the long-term complications of raised intra-ocular pressure and for retinal detachment.

Many retrospective studies comment on unusual or acute headaches predating the definite SAH by several days to weeks. These

headaches have been thought to represent warning leaks, intramural haemorrhage or aneurysmal enlargement and are sometimes called sentinel headaches. This may occasionally be the case. An alternative explanation is recall bias. A prospective study examining 148 patients with sudden onset headaches of thunderclap type showed that only 25% went on to SAH. Of these SAH patients, only two could recall a similar headache previously.

SAH tends to be misdiagnosed – as migraine or benign acute headache syndrome – typically when the headache is not catastrophic in severity, but simply sudden. Some of these SAH cases remain ambulant – and in these low back pain and sciatica resulting from local irritation by blood products can develop within 4–10 days of the haemorrhage. At the other end of the spectrum a small proportion of SAH cases are found dead, or are seen to die rapidly, within minutes or hours from massive haemorrhage.

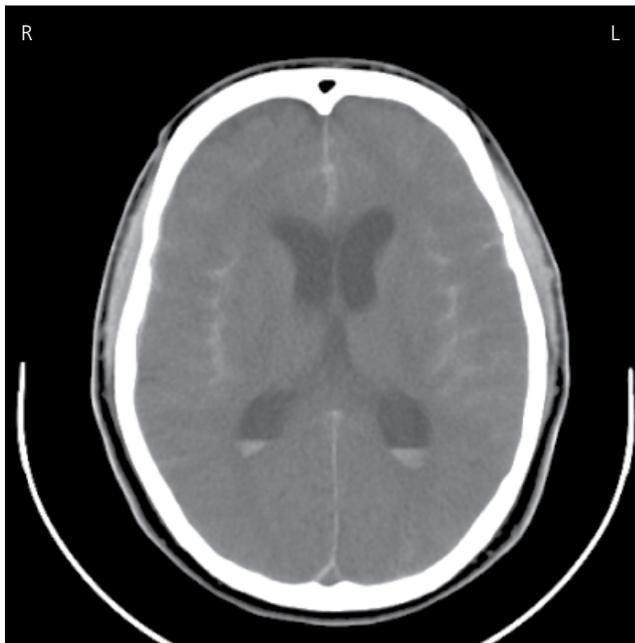

### Investigation

CT is mandatory in those with suspected SAH, generally revealing diffuse blood of a symmetrical distribution around the basal cisterns, Sylvian fissures and cortical sulci (Figure 5.19). Modern generation CT will demonstrate the presence of blood in 95% of patients scanned within 48 hours. However, blood is rapidly cleared from the cerebrospinal fluid (CSF) and the CT pick-up rate gradually decreases to 80% at 3 days, 50% at 1 week and 30% at 2 weeks. When asymmetrical or localised, the distribution of blood may suggest the location of the aneurysm in up to 70%. This is particularly important in the 10–15% of patients who harbour multiple aneurysms, when it may help to guide intervention towards the aneurysm that has bled. Intraventricular haemorrhage is characteristic of ruptured ACOM artery aneurysms; intracerebral haemorrhage is most commonly seen with PCOM artery and MCA aneurysms. Head CT can also demonstrate hydrocephalus, cerebral ischaemia or infarction, midline shift or a rebleed.

If clinical suspicion is strong and the CT is normal, lumbar puncture preferably by an experienced operator should be performed assuming there are no contraindications. If clinically appropriate this should be delayed for 12 hours from the ictus to allow time for xanthochromia (yellow discoloration) to develop. Xanthochromia of the supernatant, which is positive in almost all SAH patients between 12 hours and 2 weeks, is diagnostic. This must be determined by spectrophotometry rather than visual inspection. Negative CSF is very helpful in excluding SAH but bloodstained CSF may result from a traumatic tap. A decrease in the number of red cells from bottles one to three is a very unreliable way of supporting a traumatic tap instead of SAH. It should be remembered that patients may have had both SAH and a traumatic tap.

Conventional MRI is not sensitive to acute haemorrhage as there is too little methaemoglobin for haemorrhage to be easily differentiated from CSF. Visualisation of blood products by MRI improves over 4–7 days following SAH. MRI is therefore excellent for demonstrating subacute and previous SAH, when the diagnostic yield from CT falls.

In patients with either diagnostic CT and/or lumbar puncture, or when results of these tests are equivocal, some form of arterial imaging is necessary to search for a ruptured aneurysm or other lesion. Digital subtraction angiography (DSA) has been the gold standard investigation until recently, but non-invasive alternatives, including CT and MR angiography, are gaining popularity. DSA should demonstrate the aneurysmal site, type, size, orientation,

**Figure 5.19** Unenhanced CT showing diffuse subarachnoid and intraventricular blood.

neck intraluminal calcification and thrombus, the relationship between aneurysm and parent vessel, collateral flow through the circle of Willis, the presence of adjacent perforators and the state of the cerebral vasculature, including other aneurysms. In the case of multiple aneurysms, identification of the ruptured lesion may be difficult. The distribution of blood and location of any focal intraparenchymal haematoma on CT are more useful for identification. In situations where the CT reveals diffuse blood or the haemorrhage had been diagnosed on lumbar puncture, and multiple aneurysms are found subsequently, the aneurysm most likely to have ruptured is usually the largest, has greater irregularity, mass effect or associated local vasospasm.

Recent advances in three-dimensional CT angiography have meant that it now has a sensitivity and specificity approaching that of percutaneous catheter angiography (sensitivity 77–97% and specificity 87–100%). Imaging time is significantly reduced, allowing acquisition of the entire CT volume in 30–45 seconds during the first arterial pass of an intravenous contrast injection, with minimal patient movement artefact. Its non-invasive nature may obviate the need for cerebral angiography with its inherent risks, at least as a first line investigation. MR angiography also reveals most aneurysms greater than 3 mm in diameter. The sensitivity of MR angiography for identification of aneurysms is 85–90%, with a specificity greater than 90% when compared with DSA as the gold standard, with an excellent intra-observer consistency and good-to-excellent inter-observer reproducibility. However, MRI times are significantly longer than CT. This is particularly relevant in this group of patients who are often in great pain and restless.

Despite thorough investigation, 10–15% of SAH cases have a normal angiogram. Of these, 65% will have a distinctive pattern of subarachnoid blood lying in the prepontine or peri-mesencephalic cisterns. These patients tend to be younger, non-hypertensive, of better clinical grade and more often male than SAH patients with angiograms positive for aneurysms. The aetiology of the SAH in these cases is unclear but the cause may be venous haemorrhage.

The overall prognosis tends to be good, partly because rebleeding is rare and few patients develop delayed ischaemic deficit. However, the diagnosis should only be entertained with caution as 10% of vertebrobasilar aneurysms present with a similar distribution of blood. Repeat imaging should be considered carefully because these aneurysms can be obscured by vasospasm, hypoperfusion, poor angiographic technique or thrombosis. Such re-imaging at 2–4 weeks finds previously undetected aneurysms in 2–5% in these cases.

### Initial management

General supportive care should be instituted. Stabilisation of the patient, with optimisation for aneurysm treatment, together with prevention of secondary cerebral insults is achieved by ensuring adequate ventilation and oxygenation, normovolaemia and haemodynamic stability and control of intracranial pressure. Frequent neurological examination is required in order to identify any neurological deterioration requiring further investigation or management.

Bed rest is generally recommended until aneurysm treatment is undertaken. Aspirin should be stopped, if it is being taken. Nimodipine, a calcium-channel antagonist, has been shown to reduce the risk of cerebral infarction by 34% and as a result, poor outcome following SAH by 40%. An oral dosage of 60 mg 4-hourly is currently used. With a ruptured aneurysm prior to surgery or coiling, gentle volume expansion with slight haemodilution may help to return the circulating volume to normal and prevent or minimise the effects of vasospasm; however, hypertension should be avoided. Once the aneurysm has been secured, hypertension is allowed (see later), but there is no agreement on the safe range. Hyperglycaemia and hyperthermia are both associated with a poor outcome and should therefore be corrected. These problems are more often seen in poor grade patients, and their effect on outcome may therefore not be independent of presenting clinical condition. Analgesia is often required.

### Aneurysm treatment

Currently, the two main treatment options for securing an aneurysm are microvascular neurosurgical clipping and endovascular coiling. Traditionally, craniotomy and clipping has been the method preferred, although the optimum timing of surgery has been debated. The rebleeding rate from aneurysms is particularly high during the first 2 weeks, and then declines. This early high rebleed rate, which may have devastating complications, together with more recent improvements in microsurgical techniques, is the reason why early intervention is generally favoured. Securing the aneurysm will also facilitate the treatment of complications such as cerebral vasospasm. The Guglielmi Detachable Coil (GDC) has been available since 1991 and has been increasingly used in clinical practice. Detachable platinum coils are delivered endovascularly into the aneurysm. Once the correct position within the aneurysm has been achieved, the coil is detached from the wire. Multiple coils of various lengths and thicknesses are often packed into the aneurysm to exclude it from the circulation. The results of the International Subarachnoid Aneurysm Trial (ISAT) showed that patients treated by endovascular means have a 24% better chance of survival, free of disability, at 1 year than those treated surgically. The risk of epilepsy was substantially lower in patients who underwent endovascular coiling, but the risk of rebleeding was slightly higher. Also, in patients who underwent cerebral angiography, the rate of complete occlusion of the aneurysm was greater with surgical clipping. ISAT was a landmark study that validated the

technique of endovascular coiling in patients suitable for either treatment method. However, many aneurysms are not equally suitable for either microsurgical clipping or endovascular coiling. In individual cases, several factors – such as patient's age, and overall medical condition and the aneurysm's location, size, morphology and relationship to adjacent vessels – need to be analysed by a multidisciplinary team to decide on the most appropriate treatment.

### Management of complications

Neurological complications are common and include symptomatic vasospasm (46%), hydrocephalus (20%) and rebleeding (7%). Untreated, 15–20% of patients will rebleed in the first 2 weeks, carrying with it a significant mortality (50–75%) and risk of permanent neurological disability. There is an initial peak of rebleeding in the first 48 hours of approximately 4%, which rapidly plateaus to 1–2% per day until 40 days post-haemorrhage. After 6 months there is a long-term risk of further haemorrhage of 3% per year in patients whose aneurysm has not been excluded from the circulation. The risk of rebleed is increased with poor clinical grade, posterior circulation lesions, hypertension, elderly patients and abnormal clotting.

Cerebral vasospasm is multi-factorial in origin. The mechanisms include the liberation of spasmogenic metabolites during clot lysis in the basal cisterns and impairment of cerebral vasodilatation related to endothelial dysfunction and structural changes within the arterial wall. Symptomatic vasospasm, often leading to delayed ischaemic deficit, occurs in 20–30% of patients and is at its worst 3–14 days following the haemorrhage. The severity and distribution of vasospasm are related to the amount and site of subarachnoid blood. Basal subarachnoid blood tends to be a more important risk factor for vasospasm than intraventricular blood or diffuse blood over the cortex. Other predisposing factors include increasing age of the patient, high systolic blood pressure, poor clinical grade, decreased conscious level, the presence of a motor deficit or hydrocephalus, while patients with vertebral aneurysms, predominantly intraventricular haemorrhage or a negative CT, have a lower risk of developing symptomatic vasospasm. Diagnosis of vasospasm can be difficult and is often made after exclusion of other causes of neurological deterioration such as hydrocephalus, electrolyte disturbance, seizures or a rebleed. Elevated velocities on transcranial Doppler can be useful in confirming clinical suspicion. Once identified, patients are treated with hypervolaemia and induced hypertension in an attempt to improve cerebral blood flow. In those patients refractory to medical treatment, transluminal balloon angioplasty at the site of the most severe vasospasm, or vasodilator infusion (e.g. papaverine) can be used to improve both angiographic appearances and the patient's clinical condition.

Symptomatic hydrocephalus caused by diminished CSF absorption is seen in 10–35% of patients. Acutely, hydrocephalus is treated by a period of external ventricular drainage but, in the longer term, 10–15% of patients will require a permanent ventriculo-peritoneal shunt.

The highest risk of seizures is within the first 24 hours of initial bleeding, occurring at presentation in 3–18% of individuals. Epilepsy persists in 6–15% of survivors and is associated with intraparenchymal haematoma, vasospasm, MCA aneurysms, poor clinical grade, systemic hypertension, peri-operative complications, rebleed, early seizures, shunt-dependent hydrocephalus, neurological deficit and blood load.

The most common medical complications of SAH include pulmonary oedema in 23% (either cardiogenic or neurogenic), cardiac

arrhythmias in 35% and electrolyte disturbances in 28% of patients. Hyponatraemia (Chapters 20 and 26), is caused either by cerebral salt-wasting, with low-intravascular volume, or the syndrome of inappropriate antidiuretic hormone (SIADH), with normal or increased intravascular volume; both, if left untreated, have a high morbidity and mortality. The distinction is important because cerebral salt-wasting is treated by aggressive fluid administration and sodium supplements, while treatment of SIADH involves fluid restriction. Fluid restriction of patients with cerebral salt wasting will worsen their hypovolaemia and will predispose them to vasospasm (Chapter 20).

### Outcome

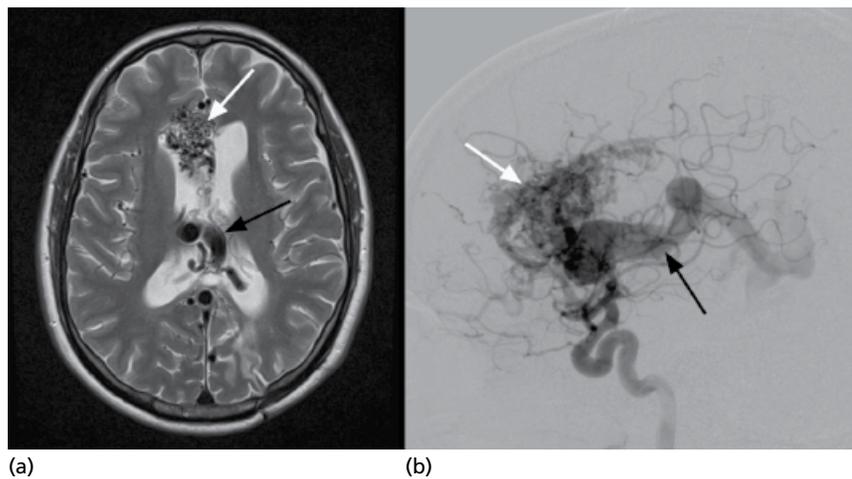

Pre-hospital mortality is 3–26%, with an overall mortality of 45–60% in the first 30 days following SAH. Overall morbidity is some 25–33%, caused in the majority of patients by vasospasm, although initial deficits and intervention also contribute. The major predictive factors for a poor outcome are level of consciousness on admission, age and amount of blood on presenting CT. More than 50% of survivors report problems with memory, mood or neuropsychological function. Despite this, half to two-thirds of patients surviving SAH are able to return to work 1 year after presentation. Prompt physical and neuropsychological assessment for rehabilitation are important. The recent National Confidential Enquiry Audit into the management of patients with SAH, shows significant improvements in care over the last decade but there are still ongoing issues with misdiagnosis of this patient group in primary and secondary care, delay and poor organisation of care transfers, and variability in radiological practice.

### Arteriovenous malformations

Arteriovenous malformations (AVMs) form part of the larger group of structural cerebral vascular malformations (CVMs). Also included within this group of developmental vascular anomalies of the CNS are cavernous malformations, developmental venous anomalies and capillary telangiectasia. AVMs are characterised by a complex tangle of abnormal arteries and veins that lack a capillary bed but are linked either by one or more direct fistulas creating an arteriovenous shunt, or through a mass of dysplastic vessels within the nidus. Although considerably less common than intracranial aneurysms, with a prevalence of 0.14–0.5%, AVMs are an important cause of haemorrhage in patients under 40 years old. They are thought to arise from developmental derangements of the cerebral vascular system during the 40–80 mm stage of embryogenesis.

### Presentation

Some 65% of individuals with AVMs present with haemorrhage at a peak age of 25–40 years. These figures may under-represent the true incidence of haemorrhage as clinically silent haemorrhage is diagnosed by imaging or at surgery in as many as 10% of patients: haemosiderin staining is seen surrounding the lesion. It has been postulated that episodes of acute headache, seizures or other acute neurological symptoms may also represent episodes of otherwise silent haemorrhages. Risk factors for haemorrhage include increasing age, previous haemorrhage (particularly in the preceding 12 months), deep site (basal ganglia and posterior fossa especially), small size, diffuse nidus, deep venous drainage, a single draining vein and associated aneurysms. Haemorrhage may be intracerebral, subarachnoid or intraventricular. Most supratentorial haemorrhages are lobar in location, but they also occur in the basal ganglia

**Figure 5.20** Arteriovenous malformation (AVM). (a) T2-w and (b) digital subtraction angiography (DSA) images of an arteriovenous malformation highlighting the nidus (white arrow) and dilated draining vein (black arrow).

or thalamus. In the posterior fossa, AVMs are the cause of most cerebellar haemorrhages in normotensive patients less than 40 years old. Pial-based AVMs may cause direct SAH. In most instances, however, SAH results from the rupture of an intraparenchymal bleed through the pial surface. In contrast to aneurysms, SAH from an AVM is rarely associated with vasospasm and recurrent haemorrhage within the first 2 weeks of AVM rupture occurs in only 1% of patients.

Alternative presenting symptoms in patients with AVMs include seizures in 20–30%, particularly if the lesion is large, involves the cortical surface or temporal lobe or there has been previous haemorrhage or surgery. Frontal lobe AVMs commonly present with generalised seizures, motor strip AVMs can cause Jacksonian seizures and medial temporal lobe AVMs are often associated with complex partial seizures. Patients may also present with non-haemorrhagic focal neurological symptoms. Most commonly seen in lesions within the MCA distribution, the focal symptoms are dependent on the location of the AVM. Large basal ganglia lesions may present with slowly progressive dementia, hemiparesis or visual field defect, while occasionally brainstem AVMs produce motor or sensory deficit with or without cranial nerve involvement, sometimes with patterns resembling multiple sclerosis. The cause of neurological deficit is often uncertain: recurrent haemorrhages, multiple micro-infarcts, decreased perfusion because of arterial stenoses, venous hypertension and steal phenomena have all been noted as mechanisms. Patients with AVMs often complain of headaches although, as a primary presentation, they are unusual (12%). Pain tends to be well localised, unilateral and throbbing and is often difficult to distinguish from other types of vascular headache or migraine. Headaches occur more frequently in AVMs that have a significant dural or pial component and despite treatment of the lesion, they often persist following treatment. Cranial bruits are present in as many as 25% of cases and again are more common with dural AVMs. With widespread MRI, many asymptomatic AVMs are now discovered coincidentally.

### Natural history

Knowledge of the natural history of a disease is a prerequisite for evaluating the influence of any treatment on the course of that disease. This is especially true when the risks of therapy may be

profound. Advances in treatment for AVMs are developing more rapidly than advances in our knowledge of their natural history. It has become increasingly difficult to identify large groups of untreated patients with AVMs for prospective study because of the availability of so many treatment options. Although it is possible to quote expected mortality and morbidity figures for AVMs on the basis of size, location and angioarchitecture, estimating the risks associated with a specific AVM is much more difficult. It is therefore important that the management of any patient with an AVM should be evaluated and planned carefully by an experienced multidisciplinary team of neurosurgeons, neuroradiologists and neurologists.

The treatment of AVMs is primarily intended to eradicate or lessen the risk of future haemorrhage. Untreated AVMs do have a significant risk of mortality and morbidity, most commonly associated with haemorrhage. In one prospective study, the annual mortality rate was 1% and that of severe morbidity 1.7%, these rates being constant over some 24 years. The long-term risk of AVM rupture for patients with symptomatic AVMs is estimated to be 2–3% per year. The risk appears higher in children and probably in those patients who have had a previous haemorrhage. Factors associated with AVM haemorrhage include small size, deep location, intranidal aneurysms, deep venous drainage and draining vein stenosis. A single haemorrhage is associated with 10–13% mortality and 30% serious morbidity. There is controversy whether or not treatment of high risk components within an incurable AVM (e.g. venous aneurysms) modifies the bleeding risk.

### Management

In any patient where treatment is considered, MRI and formal angiography in expert hands is performed to define the angioarchitecture and to give precise anatomical localisation (Figure 5.20). This allows the risks of treatment or conservative management to be defined as accurately as possible. A variety of anatomical and physiological factors such as AVM size and location, number and distribution of arterial feeders, pattern of venous drainage and flow through the AVM nidus influence the technical difficulty and consequent risk of surgical, endovascular or radiosurgical treatment. The Spetzler–Martin AVM grading is commonly used (Table 5.12). This stratifies surgical risk specifically in association to the size,

**Table 5.12** Example of surgical risks according to Spetzler–Martin grade.

Grade	No deficit (%)	Minor deficit (%)	Major deficit (%)
I	100	0	0
II	95	5	0
III	84	12	4
IV	73	20	7
V	69	19	12

venous drainage and eloquence of surrounding brain and is frequently used in this decision-making process.

Many factors influence whether or how an AVM should be treated including age and co-morbidity, presentation, AVM location, size, morphology and complexity, expected natural history and treatment risks. Management plans for these lesions should only be made by a multidisciplinary team that can balance risk of treatment against expected natural history. Following rupture of an AVM, the risk of early rebleeding is significantly lower than that observed in aneurysmal rupture. Consequently, AVM treatment should be considered carefully and can often be delayed to allow the patient to recover and undergo treatment under optimal conditions.

Treatment modalities include operative resection, endovascular embolisation and stereotactic radiosurgery, either alone or in combination. Surgical removal of an AVM is the most definitive treatment offering the best chance of lasting cure. Surgery for accessible lesions, particularly if small with single arterial supply and venous drainage, is the treatment of choice. Nevertheless, surgery carries significant mortality and morbidity. Patients should be carefully selected. Complete surgical resection should be confirmed by formal angiography postoperatively.

Endovascular embolisation of AVMs is a rapidly evolving technique. The present agent of choice is *N*-butyl cyano-acrylate (NCBA) which is a medical glue. It is successful in eradicating approximately 20% of lesions. Procedural risk can be high. Between 2% and 17% have major or minor morbidity and mortality is 1–4%. The overall risk of an ischaemic complication per procedure is around 10%. Inadvertent glue deposition in normal cerebral vessels can cause infarction. Catastrophic AVM rupture from glue placement in a draining vein (raising intranidal pressure) is also a significant complication. However, endovascular treatment can be an extremely useful adjunct to surgery and radiosurgery, by reducing blood flow and eliminating surgically inaccessible arterial feeders pre-operatively. Sequential endovascular treatments can incrementally reduce the size of an AVM, making it amenable to definitive surgical or radiosurgical treatment. In some patients, endovascular treatment is useful in palliation, particularly for refractory headaches or progressive neurological deficit. However, recanalisation of previously embolised segments can certainly occur in the long-term.

Stereotactic radiotherapy (Chapter 21), in particular LINAC or gamma knife radiosurgery can be used in selected patients to provide a single high dose of stereotactically localised radiation to the AVM nidus. The usual radiation dose is 20 Gy. This is administered to the margin of the nidus. This radiation causes endothelial

damage, smooth muscle cell proliferation, progressive sclerosis and subsequent thrombosis of nidus vessels over time. The success of stereotactic radiosurgery depends on AVM size and radiation dose delivered. Several studies have demonstrated AVM obliteration in 80% with nidus size less than 2–3 cm diameter or 10 mL volume by 2 years. A small percentage will go on to thrombose between 24 and 36 months. The patient remains at risk of haemorrhage during this time. Delayed radiation injury, such as radiation necrosis of cortical tissue or cranial nerve palsy, is related to the radiation dose, volume treated, patient age and AVM flow characteristics. Radiation-induced tumours are very rare and generally occur many years after treatment. Radiation-related complications are correlated with the volume of normal brain tissue that receives greater than 12 Gy.

Conservative management (i.e. no intervention whatever) may be the best option in those patients with a low life-long risk of haemorrhage (e.g. asymptomatic older patients), given that all available treatment modalities have risks and the uncertainty about their benefits. Younger patients with a history of haemorrhage are now almost always offered some form of treatment. AVM cases should probably not take aspirin, nor probably non-steroidal anti-inflammatory drugs unless there is good reason. A recent trial into the benefits of interventional treatment in unruptured AVMs was suspended as a result of excess morbidity in the treatment arm, though this is not surprising given the low but cumulative risk of rupture. Many years follow-up will be needed to see there is a point at which the risk is reversed.

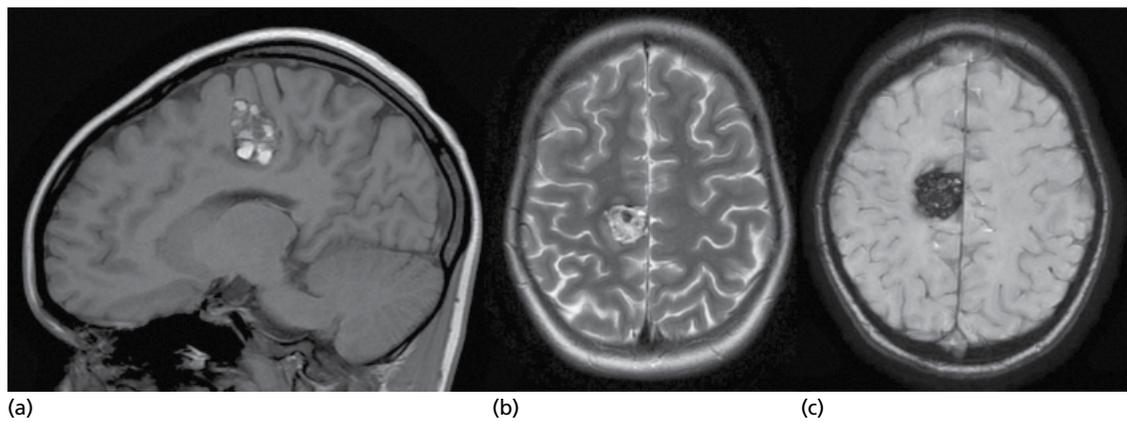

## Cavernous malformations

Cavernous malformation (CM), also called cavernous angiomas, cavernomas or cavernous haemangiomas, have a prevalence around 0.5% in the population (Figure 5.21). A retrospective review of MRI scans reported a detection rate of 0.4–0.9%. They are uncommon in children and have a peak incidence in the fourth and fifth decades of life. Overall, they account for 10% of all symptomatic intracranial vascular abnormalities. They can be familial and are often multiple.

Grossly, CMs are well-circumscribed, lobulated, raspberry-like lesions that vary from a few millimetres to several centimetres in diameter. Microscopically, they consist of a tangle of intertwined cluster of sinusoidal vascular channels that have one layer of endothelial lining and a variable layer of fibrous adventitia. Radiological evidence of previous haemorrhage, usually silent, is common, and there is often thrombosis within the dilated venules.

CMs are commonly asymptomatic but they may present with seizures or haemorrhage. Occasionally there is a progressive development of a neurological deficit, most likely to be caused by recurrent small bleeds. The frequency of haemorrhage among those who present either incidentally or with seizures is 0.4–2% per year. Among those presenting with symptomatic haemorrhage, the annual recurrent risk of haemorrhage is higher: 4–5% in the subsequent year. The risk of haemorrhage does appear to be dependent on location; there is a higher risk associated with deep lesions – brainstem, cerebellum, thalamus and basal ganglia. CMs are most readily seen on MRI as a combination of high and low T1 and T2 signal with surrounding haemosiderin (Figure 5.21). They are angiographically occult.

Surgery is usually considered only in patients with multiple haemorrhagic episodes and sometimes in those with poorly controlled seizures. Most surgeons have a high threshold for advising surgery for CMs; but excision, even for those CMs in critical

**Figure 5.21** Cavernoma. From right to left: (a) T1 sagittal, (b) T2 axial and (c) susceptibility weighted (SWI) images showing a lobulated lesion in the right frontal lobe typical of a cavernoma. Note the central regions of T1 and T2 hyperintensity, hypointense margins and internal septations and marked hypointensity on SWI.

**Figure 5.22** Dural fistula. Axial MRA and lateral common carotid digital subtraction angiography (DSA). Enlarged occipital arteries (white arrows) are seen contributing to the occipital arteriovenous fistula with shunting into the transverse sinuses (black arrows).

locations, often has an acceptable morbidity. Radiosurgery has also been carried out but it is unclear whether it alters the natural history. The concept that CMs tend to bleed in clusters supports the decision to treat CMs with stereotactic radiosurgery. Some studies suggest a reduced haemorrhage rate, usually after a 1–3 year latent period.

### Dural fistulae

Dural arteriovenous fistulae (DAVF) are rare and can be found from adolescence to old age. They are most common in young adult women. They consist of an arteriovenous fistula with multiple arteries converging on a single venous structure. They are primarily fed by dural arteries but high-flow lesions can recruit pial branches. Different patterns of venous drainage are seen, for example drainage into a sinus with or without flow restriction or drainage into cortical veins either directly or by reflux from a venous sinus.

DAVFs are thought to be acquired lesions probably a result of venous thrombosis, usually silent, with development of collaterals. They may be located anywhere within the intracranial dura, although most are found adjacent to major dural venous sinuses, particularly the transverse sinus. Symptoms and signs differ greatly

but are in the main caused by the pattern of venous drainage. Significant symptoms include haemorrhage, neurological deficit and intracranial hypertension. The overall risk of haemorrhage is approximately 2% per year; much depends on site and haemodynamics of the lesion. Rather than bleeding, common features are audible bruits, cranial nerve palsies and ocular signs such as papilloedema.

Head CT rarely detects a DAVF, although dilated veins may suggest its presence. MRI may demonstrate dilated feeding vessels and veins but is neither sensitive nor specific. Six vessel catheter angiography (i.e. including the external carotid arteries) is necessary to detect and delineate a fistula accurately and is the optimal investigation (Figure 5.22).

Treatment of DAVFs has evolved over the last three decades. Cortical venous drainage is a risk factor for haemorrhage. Action is required in these cases. Patients without cortical venous drainage and without threat of visual loss from papilloedema have a benign natural history and may require no therapy. Treatment of these patients is justified only if the risk of complication is low. Sometimes palliation is necessary. The primary treatment has been surgical disconnection of the fistula and resection of the dural segment and

venous sinus. Not surprisingly, this carries a high risk of substantial blood loss and morbidity. Recently, there has been less emphasis on resection of the venous sinus. This has proved as effective as sinus resection and the risk of venous infarction is lower. Therapeutic embolisation can be used for either palliation or attempted cure. This can be achieved via transarterial and/or transvenous routes. DAVFs can also be treated with stereotactic radiosurgery with or without endovascular embolisation of accessible feeding vessels. Partial prior endovascular treatment aims to reduce the risk of haemorrhage prior to the later obliteration of the DAVF by stereotactic radiosurgery.

## Investigation of stroke and TIAs

Stroke investigation is aimed at identifying risk factors and confirming or refuting the clinical diagnosis. Investigation nearly always improves the clinician's understanding of the pathophysiology of the stroke or transient ischaemic syndrome. This then guides acute treatment and secondary preventative measures. It is facile to separate completed stroke from TIAs when considering appropriate investigation. The aetiological spectrum is identical, although management may be very different.

### Basic investigations for all: simple tests

In all patients, basic blood screening should include full blood count to look for anaemia, polycythaemia, thrombocytopenia and thrombocytopenia. Polycythaemia is an important risk factor for stroke and care should be given to clarify marginal results. Anaemia of chronic disease may be a marker for endocarditis. Exceptionally, haematological malignancies may be complicated by stroke. Basic coagulation analysis should be undertaken in patients with haemorrhage and is especially important in those receiving anticoagulants or any other medication. Urea and electrolytes guide homeostatic management in the acute phase and may also reveal end-organ damage from hypertension. Patients with significant electrolyte disturbance may present with global or focal dysfunction. Plasma glucose is an essential triage test; diabetes is common and hypoglycaemia can cause focal signs. Hyperglycaemia is also associated with severe stroke. Rarely, hyperosmolar non-ketotic diabetic coma presents as a stroke. Basic lipid analysis for cholesterol and fasting triglycerides should be performed in all. Syphilis and HIV serology should be performed if the patient has been at risk at any time. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are non-specific screening tests for inflammatory arterial disease and endocarditis. Serum proteins and immunoglobulins are necessary to exclude myeloma or other gammopathy. Multiple blood cultures and repeated urine examinations should be carried out if there any question of endocarditis. Thyroid function tests should be performed in all patients especially those with atrial fibrillation. In all patients, chest X-ray and electrocardiography (ECG) should also be carried out. The principal point of chest radiology is to establish the presence of a normal cardiac silhouette and look for consolidation. The ECG changes of note are left ventricular hypertrophy secondary to hypertension, previous or acute coronary syndrome (possible cardiogenic embolus) and, most importantly, atrial fibrillation or other unsuspected dysrhythmia.

### Imaging

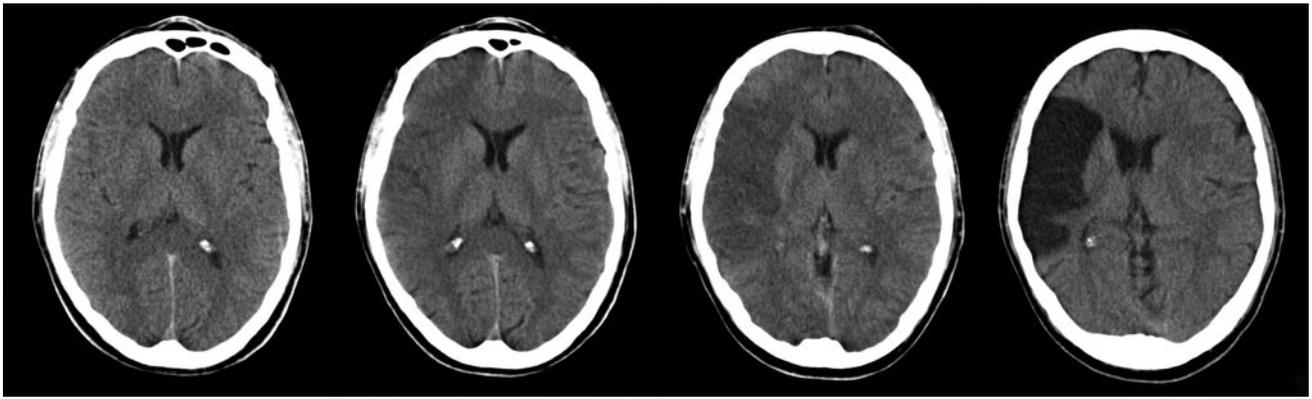

Neuroimaging is essential. Although MRI is greatly superior to CT, it is not currently widely available as a routine acute investigation. Initial CT is performed to distinguish infarction from

**Figure 5.23** Early partial right hemisphere infarction on unenhanced CT following right MCA occlusion. There is effacement of right temporal sulci, obliteration of the Sylvian fissure, with slight hypodensity of the cortex, right temporal lobe and of the insula.

haemorrhage or reveal mimics of the stroke syndrome such as tumour or subdural haematoma. In the early stages, depending partly on time interval, the size of infarction and the skill of the radiologist, CT may be negative. Only 50–70% of infarcts are ever visible with CT. It has become generally accepted that CT can diagnose a haemorrhage >0.5 cm accurately (i.e. exclude it) and indeed it is preferable to conventional MRI in the acute phase. However, patients with microhaemorrhage on susceptibility weighted MRI may present with minimal impairments when CT and conventional MRI are normal. The very early CT changes of stroke are subtle, but the ability to read these is crucial in making decisions about the suitability of a patient for thrombolysis. The very early stages of cytotoxic oedema in the MCA territory are indicated by loss of the insular ribbon, and effacement of the sulci with obscuration of the lentiform nucleus, shown in Figure 5.23. The evolution of CT changes following MCA infarction is shown in Figure 5.24.

CT can indicate clearly large vessel occlusions (e.g. a dense outline of the MCA), pointing to a central cause for embolism, or multiple haematomas suggestive of amyloid angiopathy or vasculitis. The size of the infarct or haemorrhage will provide useful information relating to prognosis and the presence or likelihood of subsequent brain swelling. A small infarct in the territory of a lenticulo-striate penetrating vessel suggests a completed vascular syndrome, but if the anatomy suggested a more proximal MCA source then this would indicate the whole MCA territory is at risk. The role of CT in the diagnosis of SAH is discussed earlier.

**Figure 5.24** Evolving MCA infarct. Serial CT illustrating typical evolution of a right MCA infarct (from right to left: 3 years prior, day 1, day 2 and 3 months after symptom onset). The earliest features are loss of normal grey–white matter differentiation affecting the right insular ribbon and cortices of the adjacent frontal and temporal lobes with local sulcal effacement. On day 2 the infarct has a lower attenuation and is better defined with increased mass effect. After 3 months it has matured to encephalomalacia with associated volume loss and ex vacuo dilatation of the adjacent frontal horn.

MRI is a far more sensitive investigation than CT for both stroke and non-stroke pathology. It is especially superior in the posterior fossa and for revealing small areas of infarction secondary to penetrating vessel occlusion. Sophisticated multimodal imaging can also be used to distinguish acute from chronic infarction and may demonstrate microhaemorrhage. These techniques are likely to become critical to safe delivery of hyperacute treatments such as thrombolysis. MRI has high sensitivity to detect cerebral venous thrombosis and can be used in conjunction with MR angiography to detect dissections of the carotid and vertebral arteries. The two most useful MR sequences are diffusion weighted imaging and blood sensitive sequences such as T2\* and susceptibility weighted imaging. Diffusion weighted imaging (DWI) maps the constant diffusion of water. This rapidly becomes abnormal after ischaemia returning a 'light bulb signal' indicative of restricted diffusion resulting from cytotoxic oedema. This usually indicates completed infarction but this is not absolute; some reversible diffusion changes have been demonstrated. Older infarcts may also appear bright on DWI ('T2 shine-through'), but these can be distinguished from acute infarcts by examining the apparent diffusion coefficient (ADC) images that show acute infarcts as dark. DWI can be matched with clinical examination, MR perfusion imaging and MR angiography to ascertain whether there are salvageable areas of brain. In addition, DWI commonly refines the pathophysiological diagnosis of stroke, by separating into time intervals different areas of infarction and demonstrating acute multi-territory changes suggestive of cardiac embolus, not apparent on conventional MRI.

MR susceptibility weighted sequences help demonstrate areas of microhaemorrhage not visible on conventional MR or CT. The distribution of these microhaemorrhages may point to amyloid (superficial location) or severe hypertensive arteriopathy (deep location). Patients with microhaemorrhage are at higher risk of primary intracerebral haemorrhage and have a more severe form of small vessel disease than those without haemorrhage.

In patients with haemorrhage in whom a non-hypertensive aetiology is suspected, it is necessary to exclude an AVM. In some this can be adequately achieved with MRI and/or MR angiography delayed until resolution of the haematoma. However, many such patients will require catheter angiography.

Conventional MR sequences are also useful in the diagnosis of cervical artery dissection (see carotid and vertebral dissection). MRI

**Table 5.13** Recommendations for immediate imaging in stroke based on National Institute for Health and Care Excellence (NICE) guidance 2008.

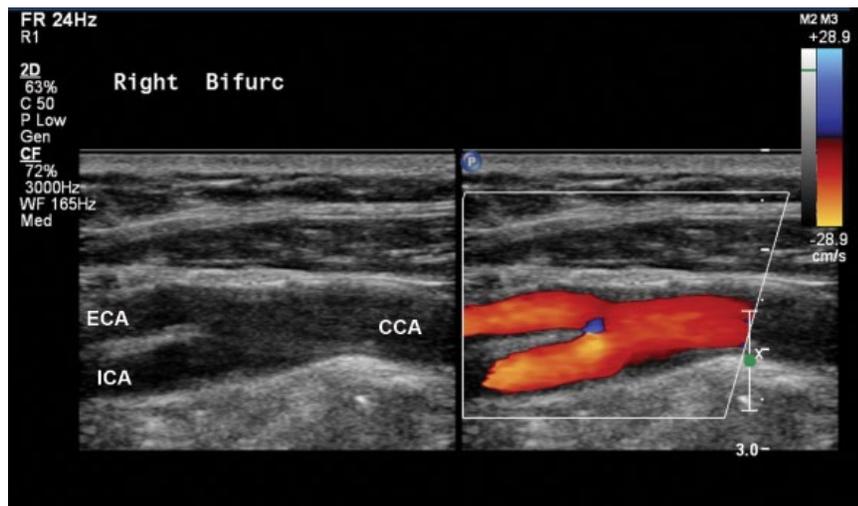

Indications for thrombolysis or early anticoagulation treatment
On anticoagulant treatment
A known bleeding tendency
A depressed level of consciousness (Glasgow Coma Scale below 13)
Unexplained progressive or fluctuating symptoms
Papilloedema, neck stiffness or fever
Severe headache at onset of stroke symptoms

Source: National Institute for Health and Clinical Excellence 2008. Reproduced with permission of NICE.

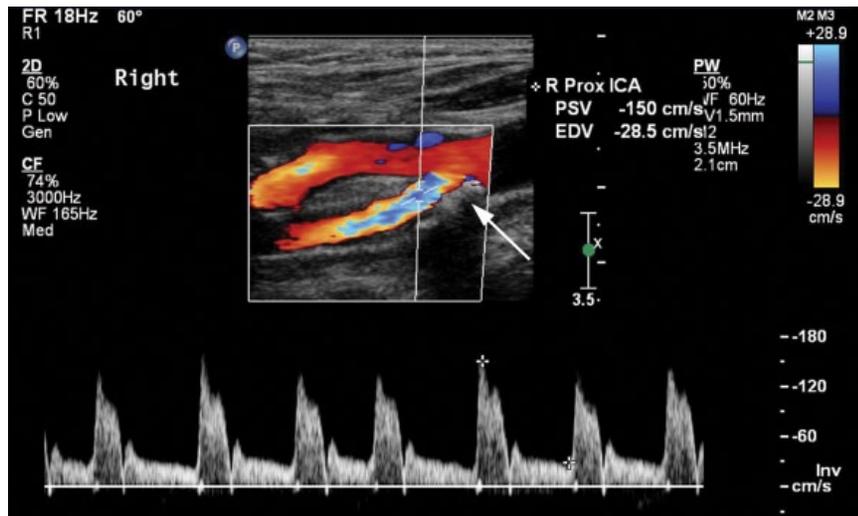

is sensitive and specific when used to image in cross-section the carotid artery from the bifurcation to the skull base. The vertebral artery is harder to image accurately and false positives are common and secondary to the vertebral venous plexus returning a 'dissection type' signal. Contrast enhanced MR angiography is also helpful here.

Whatever imaging modality is available, information derived should be used to build up the pathophysiological profile and to guide management. Most importantly, the imaging abnormalities must be concordant with the clinical picture. For example, the presence of acute or old infarction in non-symptomatic vascular territories should focus further investigation toward a central embolic source. Also, extensive asymptomatic small vessel disease is a risk factor for cerebral haemorrhage and helps refine a decision away from anticoagulation in a patient in atrial fibrillation.

Imaging also has a critical role in managing patients with stroke who may benefit from neurosurgical intervention. Imaging for stroke should happen at presentation as accurate diagnosis is a key component of a range of interventions that improve outcome. For pragmatic reasons in some services this has been delayed up to 24 hours. In all situations immediate (i.e. at 3 a.m.) imaging is recommended in a number of circumstances (Table 5.13).

**Figure 5.25** Carotid Doppler. Colour Doppler ultrasound image of a normal carotid artery bifurcation. The greyscale image on the left is labelled to show the common carotid (CCA), internal carotid (ICA) and external carotid (ECA) arteries. The colour Doppler image on the right demonstrates flow within the vessel, depicted red.

**Figure 5.26** Carotid Doppler stenosis. Colour Doppler image showing stenosis of the internal carotid artery due to atheroma (arrow). Elevated peak systolic velocities of 150 cm/s are shown on the spectral trace below the colour image.

Many of these recommendations relate to the simple yet important principle that any patient with a depressed level of consciousness may need urgent neurosurgical intervention. One of the most important recommendations is that patients on anticoagulants should be imaged immediately.

#### Guided investigations following basic profile

Imaging, simple tests and the clinical profile should build up the pathophysiological diagnosis sufficiently to direct further investigation. Ischaemic stroke within the carotid territory should prompt the search for carotid stenosis. This is obviously essential in those in whom secondary preventative surgery would be considered. The emphasis is on non-invasive imaging, in preference to invasive techniques such as catheter angiography. MR angiography, CT angiography and duplex imaging are all useful. If any of these is completely normal then the screen is adequate with regard to

stenosis at the carotid bifurcation. If any suggests carotid stenosis greater than 50% or occlusion then it is very useful to carry out a confirmatory non-invasive test. If they are concordant one can assume that the information is accurate. In patients in whom the information is non-concordant it may be necessary to perform a third non-invasive modality before formal catheter angiography. It should be appreciated that catheter angiography carries the risk of causing stroke, fatal or severely debilitating, especially in those with severe atherosclerosis, and it has other hazards (see later).

Ultrasound of the neck vessels in real time 'B' mode provides images in several arterial planes, as well as allowing measurement of blood flow velocity and wave patterns by utilising the Doppler shift (Figure 5.25 and Figure 5.26). It is accurate in experienced hands, at the carotid bifurcation, the major area of interest in patients with carotid territory stroke or TIA. It has a good sensitivity and specificity for occlusive lesions, but has limitations. It only visualises the

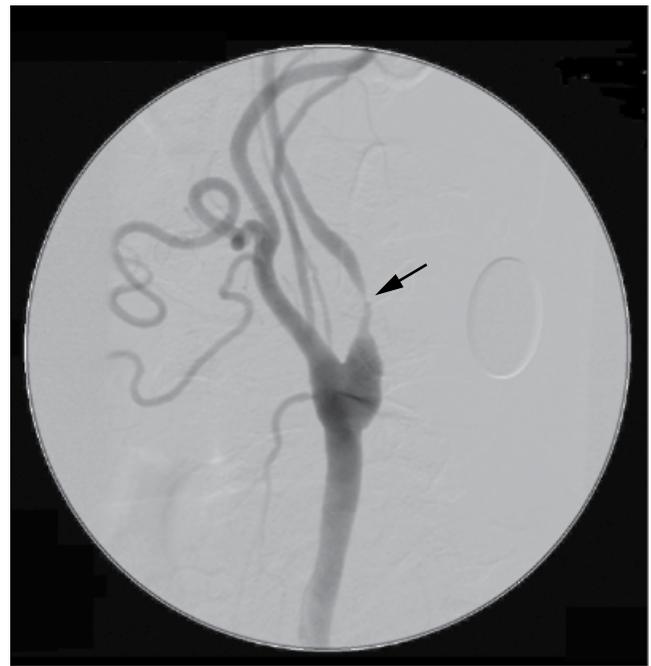

mid-cervical portions of the carotid and vertebral arteries. It is not possible to see the distal internal carotid artery, although distal stenosis can be suspected from changes in spectral patterns. Often the vertebral origin is difficult to image and small clots, localised dissection and ulcers are difficult to image at any site. Calcification may obscure the visualisation of a stenosis. Arteries may be misidentified. For example, a carotid occlusion may be reported as trickle flow by mistaking a small branch of the cervical artery for the carotid. The combination is better than either alone. B-mode imaging allows individual arteries to be identified and provides information about the arterial wall (e.g. intimal-media thickness or composition of an area of atherosclerosis). Duplex can highlight areas of stenosis by combining B mode imaging with colour-flow. The severity of the stenosis of an artery above a certain threshold can then be determined from increases peak systolic and diastolic blood flow velocity measured by analysis of the Doppler signal. Duplex is widely available and non-invasive but there are some difficulties. It is operator dependent and requires considerable experience. It is not completely sensitive or specific for high-grade stenosis and does not always correlate with measurements of stenosis made by angiography.

Doppler can also be applied transcranially (TCD) through the temporal 'window' and the foramen magnum and has significantly advanced the study of stroke. TCD can accurately detect atherosclerotic lesions in the intracranial ICA, MCA, intracranial vertebral artery and the mid and proximal basilar artery. TCD may be used to detect emboli, acutely image intracranial vessel thrombosis and in some centres it has been used in combination with thrombolysis as a mechanical aid to clot dissolution. TCD may also be used to detect systemic right to left shunts (e.g. through a PFO). Agitated saline can be injected into a vein and the MCA insonated for arrival of small bubbles with a Valsalva manoeuvre.

Another safe sensitive non-invasive technique is MR angiography (MRA). MRA can accurately visualise the carotid bifurcation but may overestimate the degree of stenosis. MRA of the vertebral origin from the subclavian is subject to artefact in many cases, but the portions of the vertebral artery within the neck and within the intravertebral foramina are well shown. MRA of the intracranial circulation is providing a useful screening tool both for aneurysms and occlusive disease.

CT angiography (CTA) is rapidly taking over as a primary vascular imaging technique at admission of a patient to hospital. It is rapid and can be obtained at the time of emergency initial imaging. This aids immediate decisions with regard to acute treatments and is an accurate technique to detect acute intracranial occlusion by thrombus and is also sensitive to underlying stenosis throughout the cervical and intracranial vessels, including the vertebral artery not well seen on Duplex imaging. CTA has a sensitivity of 92–100% in the diagnosis of intracranial stenosis when compared with catheter angiography, and is a very accurate method for the detection of severe carotid atheroma, dissection and occlusion. CTA requires a significant contrast dose and hence impaired renal function is a relative contraindication.

The advent of MRA, CTA and duplex has led to a steady decrease in the indications for catheter angiography but this technique is still useful in selected circumstances. Intra-arterial angiography carries a small but definite risk of causing a stroke. The commonly quoted figure is 1% but inexperienced operators have a higher risk. The catheter or contrast can dissect the femoral artery and/or cause 'trash foot' as a result of dislodging aortic or arterial atheroma. Contrast medium can occasionally precipitate renal failure

**Figure 5.27** Severe left internal carotid artery stenosis (catheter angiogram).

and provoke allergic reactions. Some patients develop alarming but usually temporary blindness after vertebral injections. The decision for angiography should be made carefully in a multidisciplinary setting. The non-invasive tests must have been carried out first and usually a therapeutic decision must follow catheter angiography if this is to be performed. It is necessary to perform angiography in a number of vascular situations. In occlusive carotid disease, angiography may clarify discordant results from non-invasive tests (e.g. MRA suggests a 90% stenosis but duplex 50%). It may clarify sites not visible on non-invasive testing or subject to artefact (Figure 5.27). Catheter angiography is able to detect smaller aneurysms than MRA and is necessary following SAH when MRA is negative. It can be used to screen for underlying vascular malformations when MRI and MRA are normal and is often the only way of detecting dural fistulae. Despite the sophistication of MR venography, the venous phase of a catheter angiogram is superior and can clarify anatomic variants less clearly interpretable on MR. Currently, as CT angiography continues to improve it is taking over from catheter angiography in an increasing number of cases.

The degree of carotid stenosis is defined currently by three different methods and it is important to know which method is being discussed as the values differ; so does the evidence on which intervention is based. All three methods measure the diameter of the stenosis at the site of the maximal narrowing of the artery but the proportional stenosis that they produce is then calculated from different estimates of what the normal artery should have measured at that point, as the denominator. The European Carotid Surgery Trial (ECST) method used an estimate of the normal luminal diameter at the site of stenosis. In the North American Symptomatic Carotid Endarterectomy Trial (NASCET) it is based on comparison with the distal internal carotid artery diameter. In the common carotid method, it is based on the common carotid diameter. These produce different measurements. The NASCET method

produces a lower percentage stenosis than the ECST or common carotid methods for the same lesion at the carotid bifurcation.

Both CT and MR can also be used to measure regional cerebral perfusion after injection of contrast agents, as can PET and SPECT after injection of radioisotopes, while the newer technique of MR arterial spin labelling can be used to measure cerebral blood flow without using injected contrast. However, none of these techniques have entered routine practice except in a small number of enthusiastic units. The use of these techniques in selecting patients for therapy is discussed later.

### Cardiac investigations

In patients with suspected cardiogenic embolus, transthoracic echocardiography can define wall motion abnormalities or the presence of atrial or ventricular thrombus. In selected patients with prosthetic valves, suspected aortic root disease and right to left shunts TOE provides better visualisation than the transthoracic mode. If cardiogenic embolus is still strongly suspected despite normal chest X-ray, ECG and echocardiogram, then sometimes Holter monitoring may be useful to reveal paroxysmal atrial fibrillation; monitoring may need to be prolonged and implantable rhythm monitoring devices are increasingly being used to pick up infrequent episodes of paroxysmal atrial fibrillation. Echocardiography has a high yield in patients with known cardiac disease, with systemic embolic phenomena and when the stroke pathophysiology points to cardiac embolism (e.g. PCA occlusion). TOE is undoubtedly superior to transthoracic insonation, particularly as the left atrium is directly anterior to the oesophagus. TOE also visualises the proximal aorta (e.g. for atherosclerosis). If previous blood cultures have been negative, consider repeating them to exclude bacterial endocarditis.

### Special investigations

Thrombophilia assessment is rarely useful in arterial stroke with the exception of antiphospholipid antibodies. It should be noted that antiphospholipid antibodies can be associated with many sorts of vasculopathy and they are not uncommonly seen coincidentally in patients with atherosclerosis. Venous thrombophilia may be relevant in the rare circumstance of a positive family history of thrombosis associated with embolic stroke through a PFO. Autoantibodies may mark a systemic vasculitis. In appropriate circumstances, screening for common mitochondrial and NOTCH III (CADASIL) mutations, leukocyte galactosidase A for Fabry's disease, homocysteine, syphilis and HIV serology should be carried out. Very occasionally, if a vasculitic or an infective aetiology is suspected it will be necessary to examine the CSF. Urine toxicology screening should be carried out if drug misuse is suspected.

## Management of acute stroke

Over the last two decades, stroke has changed from being seen as untreatable, to a condition where there is now a range of options for acute interventions, shown conclusively to improve outcome. In the first few hours after ischaemic stroke, measures are designed to restore blood flow (reperfusion), preserve the ischaemic penumbra (neuroprotection) and prevent early recurrence (antiplatelet treatment). Admission to a stroke unit and multidisciplinary rehabilitation are vitally important and are complementary to medical treatments. It is now well-recognised that rehabilitation should start as soon as possible after onset of stroke (Chapter 18), aiming to optimise recovery, enhance neural plasticity and facilitate

functional adaptation to any residual impairments as far as possible. Active rehabilitation consists of measures designed to facilitate and enhance recovery from impairments, such as task specific training and measures to improve independence (e.g. the provision of walking aids or modified utensils). Key to successful rehabilitation requires the setting of achievable goals as in any learning or relearning exercise. Successful stroke unit care also pays critical attention to the prevention of complications and the prevention of recurrent stroke.

An early accurate diagnosis of the underlying pathological cause and mechanism of stroke should have been made to guide appropriate therapy. At the most basic level it is essential to distinguish between haemorrhage and infarction by brain scanning. Therefore, CT or MRI scan should be performed immediately on admission of the patient to hospital. The more that is understood about the pathophysiology of the stroke at admission, the more the effectiveness of the interventions. Some initial supportive treatment remains generic (e.g. assessment of swallowing and prevention of aspiration). If initial treatments are given without clear knowledge of the underlying pathology, apart from the distinction between haemorrhage and infarction, then it should be borne in mind that interventions such as thrombolysis, designed to lyse a clot, are unlikely to be effective if the cause of ischaemia is arterial occlusion by atheromatous debris or a dissecting haematoma. On the other hand, identification of the mechanism of stroke may lead to specific therapies (e.g. antibiotics for bacterial endocarditis or intra-arterial clot retrieval), in addition to more generic treatments.

### Organised care in a stroke unit

One of the most important aspects of stroke treatment is quite simple. It is to treat patients in an organised stroke unit. The trials of stroke unit care show that about 1 in 12 patients are saved from death or being dependent by being cared for on an organised stroke unit rather than in a general medical ward. The same benefits cannot be achieved by providing a mobile stroke team visiting general medical wards in hospital, nor by visiting patients in their own homes. More patients are discharged from stroke units to their own homes without increasing average length of stay. The benefits of stroke unit care appear to apply equally to elderly and young patients, to both genders and irrespective of whether the stroke is mild, moderate or severe. All patients should therefore be admitted to an acute stroke unit as soon as possible after onset, irrespective of age, gender or clinical severity, for multidisciplinary assessment and treatment. It is likely that all patients benefit from the provision of information, the positive attitudes to stroke and the organised provision of care on an organised stroke unit. From a public health perspective, the benefits of stroke unit care arising from the overall prevention of death, reduction in disability and need for institutional care are considerable when compared with individual pharmacological treatments. Also, organised stroke care is unlikely to harm anyone.

The reasons why organised stroke care benefits patients are complex. Factors identified that characterise stroke unit as opposed to general medical ward care (e.g. a discrete geographical area, multidisciplinary team meetings) are to some extent epiphenomena of a more fundamental difference. This simply is having an effective team that has ownership of the patient's problems and a responsibility to address them. The complex problems of patients with stroke go far beyond the strict medical issues and cannot be effectively addressed by a disjointed approach. It is likely that the benefits from organised care result first from better care of the acute patient

(e.g. accurate diagnosis, appropriate use of drugs, prevention of swallowing complications/hypoxia/hypovolaemia, appropriate treatment of pyrexia, hyperglycaemia) leading to less secondary brain damage. Secondly, coordinated goal-orientated rehabilitation and discharge planning is a totally different proposition to more fragmented delivery of rehabilitation. Patients with intracerebral haematomas often gain considerably and as much from organised care as patients with ischaemic stroke. In contrast to ischaemic stroke, they take much longer to start to recover and need careful supportive care during this time.

The benefits of stroke unit care in the randomised trials were maximal when patients were admitted within a week of onset. The benefits are likely to be even greater where patients are admitted acutely for monitoring and provision of acute treatment such as thrombolysis. This has been recently evidenced by health reforms in London, UK, where new regional hyperacute stroke units (HASUs) were commissioned in 2010 to provide immediate 'hyperacute' care for the first 1–2 days after stroke. These large units allowed a critical mass of staffing, expertise and infrastructure to be available and responsive 24/7. The units have produced a considerable decrease in mortality following stroke and a considerable increase in the delivery of intravenous thrombolysis. However, the optimal service delivery model depends on many non-clinical factors (e.g. in the mountainous region of Bavaria the use of telemedicine provides population exposure to appropriate expertise). There are several and increasing strong arguments for patients to be admitted to an acute/hyperacute stroke unit directly from the community or from the A&E department. Several models of service delivery of acute stroke care exist, depending on local circumstances. Some acute stroke units keep patients for 2–7 days before discharging those who require further therapy to a rehabilitation stroke unit. Other units combine acute and early rehabilitation care on one ward, keeping patients for up to 6 weeks before discharging them home or to alternative rehabilitation facilities. These facilities include community rehabilitation centres, community stroke teams providing treatment at home, rehabilitation facilities for care of the elderly and specialised neurological rehabilitation units.

## Specific treatments for acute ischaemic stroke

### Thrombolysis

'Time is brain' and early treatment is the most important factor for successful thrombolysis. To deliver this on a public health basis requires a considerable coordination of care across agencies and public awareness of the need for immediate treatment. It is essential that 'stroke' is recognised as a medical emergency.

Thrombolysis is one of the most exciting, controversial and complex recent developments in stroke medicine. The first thrombolytic agent to be tried in acute ischaemic stroke in the 1980s was streptokinase, but this agent was found to cause an unacceptable incidence of cerebral haemorrhage and was abandoned. Later trials showed that alteplase, a recombinant tissue plasminogen activator, was far safer. The most convincing benefits of intravenous alteplase were shown in the National Institute of Neurological Disease and Stroke (NINDS) study, which randomised patients within 3 hours of onset of ischaemic stroke, half within 90 minutes of onset. The trial required a CT before treatment, and blood pressure was carefully controlled in those with raised readings, using intravenous drugs if necessary. One in eight patients treated benefited in terms

of making a full, or nearly full, recovery and the proportion of patients in Part 2 of the study achieving a Rankin grade 0 or 1 score at 3 months follow-up was 39% after alteplase treatment, compared to 26% after placebo. This benefit was accompanied by a significant risk of symptomatic intracranial haemorrhage after alteplase of 6%, compared to less than 1% in the placebo group. However, this did not lead to a significant difference in mortality rates between the two groups. Most benefit from alteplase was demonstrated in the group recruited within 90 minutes from stroke onset and in those with moderately severe stroke.

Subsequent trials of alteplase randomised patients up to 6 hours after onset of ischaemic stroke, but failed to show the striking benefits of the NINDS 3-hour study. Subsequent meta-analysis, combining the results of all previous major trials of intravenous thrombolysis with alteplase, has shown that there is a clear relationship between the time to treatment and the chances of benefit: the earlier patients are treated the better such that the odds ratio (OR) for a good outcome with alteplase at 3 months (mRS 0/1) is 2.55 for treatment started within 90 minutes of onset when compared with an OR of 1.6 for treatment started between 90 and 180 minutes. These results led to alteplase receiving a licence for use in North America, Europe and elsewhere. The European Union licence has strict conditions, initially limiting use to 3 hours from onset of stroke (now extended to 4.5 hours) and insists that only experienced teams with neurological training should administer the drug. Beyond 4.5 hours from onset, the benefit remains uncertain. The IST-3 trial found a non-significant trend favouring alteplase in the group treated between 4.5 and 6 hours and a 2012 updated meta-analysis of randomised controlled trials comparing treatment with alteplase with placebo given within 6 hours of stroke onset reported a significant benefit of alteplase with an OR of 1.29 in this time window. Although the IST-3 trial did not demonstrate significant benefit of alteplase between 0 and 6 hours compared with placebo it did demonstrate that patients over the age of 80 years benefited from thrombolysis when treated within 3 hours and that this treatment was not associated with increased rates of treatment-related haemorrhage in this older population.

Intravenous thrombolysis should only be offered to patients according to established protocols if they satisfy the inclusion criteria (Table 5.14). Patients treated with thrombolysis outside the strict protocol have an unacceptable rate of complications, especially intracranial haemorrhage. Training and experience are required to diagnose stroke, exclude stroke mimics and interpret CT appearances in acute ischaemic stroke. Established infarction shows on the CT as a well-defined area of low attenuation. However, the early changes of infarction are often subtle. In the MCA territory infarction, these include loss of distinction of the lentiform nucleus and insular ribbon cortex, loss of cortical definition between grey and white matter, and effacement of the sulci. Although not part of the NINDS protocol, most experts would exclude patients with early signs of infarction involving a large proportion of the MCA territory, because such signs imply that ischaemia has already progressed to irreversible infarction (Figure 5.11). Patients and relatives need to accept that although thrombolysis provides a chance of some real benefit, there is also a risk of harm from cerebral haemorrhage. Patients should not be denied thrombolysis if consent cannot be obtained (e.g. because of aphasia). It is essential that the timing of symptom onset should be well established, so that patients are only treated within the guidelines, currently within 4.5 hours of onset. For example, patients who wake from sleep with deficit from an ischaemic stroke are not eligible for thrombolysis with alteplase

**Table 5.14** Guidelines for intravenous alteplase in acute ischaemic stroke.

<b>Eligibility</b>
Age 18 years or older
Clinical diagnosis of acute ischaemic stroke
Assessed by experienced team
Measurable neurological deficit
Glasgow Coma Score >8
Timing of symptom onset well established
CT or MRI and blood tests results available
CT or MRI consistent with diagnosis
Time since onset <4.5 hours at start of infusion
<b>Exclusion criteria</b>
Symptoms only minor or rapidly improving
Haemorrhage on pre-treatment CT (or MRI)
Suspected subarachnoid haemorrhage
Active bleeding from any site
Recent gastrointestinal or urinary tract haemorrhage within 21 days
Platelet count less than 100 000/mm <sup>3</sup>
Recent treatment with heparin and APTT above normal
Recent treatment with warfarin and INR elevated
Recent major surgery or trauma within the previous 14 days
Recent post-myocardial infarction pericarditis
Neurosurgery, serious head trauma or previous stroke within 3 months
History of intracranial haemorrhage (ever)
Known arteriovenous malformation or aneurysm
Recent arterial puncture at non-compressible site
Recent lumbar puncture
Blood pressure consistently above 185/110 mmHg
Abnormal blood glucose (<3 or >20 mmol/L)
Suspected or known pregnancy
Active pancreatitis
Epileptic seizure at stroke onset
<b>Cautions and limitations</b>
Severe neurological deficit (NIHSS >22)
Visible changes on pre-treatment CT of infarction > one-third of MCA territory
Diabetic retinopathy

APTT, activated partial thromboplastin time; CT, computerised tomography; INR, international normalised ratio; MCA, middle cerebral artery; MRI, magnetic resonance imaging; NIHSS, National Institutes of Health Stroke Scale.

unless they are known to have been gone to sleep without symptoms within the 4.5 hour time window.

Only a proportion of patients will be suitable for thrombolysis, especially because many patients will not reach hospital within

4.5 hours of onset. Nevertheless, changes in service delivery are required to institute thrombolysis (e.g. development of acute stroke teams and protocols to ensure that patients are scanned with alacrity). The proportion of patients reaching hospital in a timely fashion can be increased by joint hospital and ambulance service protocols, involving training of ambulance personnel in the recognition of stroke, so that patients with suspected stroke are taken directly to an acute stroke centre. Education of the public to recognise stroke symptoms and to summon emergency ambulance services immediately is also required.

In the future, selection of patients with persisting penumbra may play a part in selecting cases for thrombolysis. For example, a mismatch between a small volume of infarction shown on DWI and a larger volume of impaired cerebral blood flow shown on perfusion MRI may be an indication of salvageable penumbra, and this could allow the extension of the window for thrombolysis beyond 4.5 hours in patients who arrive late and have persistent mismatch. Alternative thrombolytic agents may also allow the time window to be prolonged. For example, desmoteplase shows promise as an intravenous thrombolytic agent when administered within 3–9 hours of ischaemic onset in patients with MRI perfusion–diffusion mismatch, but the agent needs to be tested in larger randomised trials. CT perfusion imaging is an alternative to perfusion MRI, and may become more widely applicable in the future.

Another experimental approach to improving the effectiveness of thrombolysis is to combine intravenous alteplase with therapeutic transcranial ultrasound applied to the skull and focused on the site of arterial occlusion. Experimental studies have shown that ultrasound improves the activity of clot lysis, presumably by facilitating access of the thrombolytic drug to the core of the thrombus. Clinical trials have suggested an improvement in recanalisation rates with continuous transcranial Doppler ultrasound given for a 2-hour period after administration of intravenous alteplase. Again, larger trials are required to demonstrate the benefit of this approach.

The majority of evidence in favour of thrombolysis relates to the intravenous route of administration. This reflects the ease and rapidity with which an intravenous transfusion can be administered. On the other hand, local arterial infusion of thrombolytic agents has the advantage that a preliminary angiogram can be performed to confirm arterial occlusion, and that the agent can be infused exactly where it is needed. Case series and the PROACT II randomised trial suggest that intra-arterial thrombolysis can be highly effective, even up to 6 hours after onset in selected patients. However, intra-arterial thrombolysis requires specialised facilities and experienced neuroradiologists, limiting its widespread applicability. Moreover, the need to establish arterial access increases the delay to treatment compared with the intravenous route. The idea of giving intravenous thrombolysis first followed by intra-arterial thrombolysis ('bridging' therapy) was therefore introduced, but the dose of intra-arterial agent that can then be used is limited by the increased risk of haemorrhage from the thrombolytic agent. In practice, intra-arterial thrombolysis as a catheter-based approach has been largely replaced by mechanical thrombectomy, which appears to be more effective than intra-arterial therapy.

### Mechanical recanalisation

For patients presenting with stroke secondary to proximal intracranial artery occlusion it is becoming clear that a good outcome following treatment will depend on whether this vessel is rapidly recanalised. Control data from the PROACT II study identified that only 22% of untreated stroke associated with proximal MCA

(M1 segment) stenosis was associated with a good outcome (mRS 0–2) and from the SENTIS control group that presentation with terminal ICA occlusion is associated with good outcome in only 5% of occasions. Early recanalisation appears to be the key to recovery and meta-analysis of the available data has shown that good recovery may be twice as likely with demonstrated recanalisation compared with persistent occlusion and that mortality reduces from 42% of patients with proximal occlusion to 14%. As a consequence of such data and the demonstration of only modest efficacy of intravenous alteplase in improving outcomes in the presence of proximal MCA occlusion, there has been substantial interest in the potential benefits provided by mechanical clot retrieval procedures that aim to physically remove persisting clot in proximal intracranial vessels.

In 2013, the results from three randomised controlled trials, MR RESCUE, IMS3 and SYNTHESIS EXPANSION, were reported in the same edition of the *New England Journal of Medicine*. All three studies evaluated the efficacy of endovascular treatments when compared with standard intravenous alteplase treatment for hyper-acute ischaemic stroke associated with proximal intracranial artery occlusion. Endovascular treatment was not associated with excess treatment-related risk but did not demonstrate benefit compared to standard treatment. Proponents of endovascular treatment have pointed out that these data may be misleading because of poor patient selection, delayed treatment in the endovascular group or the use in the trials of endovascular technology that has already been superseded. In particular, very few patients were treated in these trials with removable stent systems ('stent retrievers'), which appear to be more effective than earlier devices, perhaps because expansion of the stent across the occluded segment of the artery results in more rapid reperfusion even before the clot is pulled out by stent. Subsequent to these trials five new randomised controlled trials (MR CLEAN, ESCAPE, SWIFT PRIME, EXTEND-IA and REVASCAT) have now clearly demonstrated that early intra-arterial treatment with second-generation mechanical thrombectomy is superior to conventional intravenous thrombolysis in large artery occlusion of the proximal anterior circulation. The largest of these trials, MR CLEAN, enrolled 500 adults within 6 hours of acute ischaemic stroke onset caused by a proximal anterior circulation large artery occlusion and randomly assigned them to treatment with intra-arterial therapy or to usual care. Intra-arterial therapy involved mechanical thrombectomy with retrievable stents in 82%, and 90% of subjects in both groups received intravenous thrombolysis prior to randomisation. Compared with conventional therapy, the group assigned to intra-arterial treatment had improved outcomes at 3 months, including functional independence. There was no significant difference between the groups in the rates of symptomatic intracranial haemorrhage or death. When these results were announced the remaining trials were stopped early. Undoubtedly, this will now become the standard of care, though the relative numbers of patients suitable are very small. However, advanced logistics and concentration of expertise are required to deliver and replicate these trial benefits in a clinical setting, and certainly in the United Kingdom this will mean further centralisation of specialised services, as attempts by the non-expert will rapidly negate any possible benefit.

#### Antiplatelet therapy in acute stroke

Two very large randomised trials have shown that aspirin, given within 48 hours of onset, has a small but significant benefit in reducing the rate of recurrent ischaemic stroke. About 1/100 patients treated with aspirin avoid death or disability without a significant

increase in the risk of symptomatic cerebral haemorrhage. Although this benefit seems small, it translates into a substantial cost effectiveness, given the commonness of stroke and the low cost of aspirin. For example, in the United Kingdom it is estimated that if everyone with stroke were given aspirin within 48 hours of onset, preferably after a CT scan to exclude cerebral haemorrhage, then more than 1000 patients would be saved from death or disability every year. Aspirin has not been extensively studied in patients with cerebral haemorrhage, but the majority of experts and emergency physicians consider aspirin contraindicated in any cerebral haemorrhage or if there is substantial acute haemorrhagic transformation within an ischaemic stroke.

Evidence is accumulating that the addition of clopidogrel to aspirin may be more effective in secondary prevention immediately after minor stroke or TIA than aspirin alone. In 2013, a large trial of 5170 patients recruited within 24 hours of minor stroke or high risk TIA and randomised to clopidogrel plus aspirin or aspirin alone was reported. The dual therapy group experienced 30% fewer ischaemic strokes and demonstrated an absolute risk reduction of 3.5% at 90 days and no excess haemorrhage. These data are consistent with the degree of risk reduction reported in the Canadian-based FASTER trial reported in 2007 and are likely to lead to widespread change in practice for those with minor stroke and TIA in the acute phase. Antiplatelet therapy for longer term prevention is discussed later.

#### Anticoagulation in thrombo-embolic stroke

A large number of randomised trials have failed to demonstrate any overall benefit of early anticoagulation (i.e. within the first 2 weeks) with standard heparin, or with low molecular weight heparins, either routinely in acute stroke or in patients with progressive stroke or acute cardioembolic stroke associated with atrial fibrillation. The latter is in contrast to the clear benefit of warfarin in the long-term prevention of stroke from atrial fibrillation. In the acute stroke trials, any reduction in the rate of recurrent ischaemic stroke related to anticoagulation was matched by an increased rate of symptomatic intracranial haemorrhage. The evidence shows that there is no place for the routine use of anticoagulation or subcutaneous heparin in acute stroke. Best practice for preventing immobility-induced venous thromboembolism (VTE) has become clearer since the publication of the CLOTS3 (Clots in Legs Or sTockings after Stroke) trial results. This trial followed on from two earlier trials – CLOTS and CLOTS2, which had demonstrated that below knee or above knee stockings fitted soon after acute stroke made no difference to the risk of development of VTE and in some cases created harm by damaging the skin and impairing distal circulation. Prior to the completion of CLOTS3 these findings left stroke clinicians with difficult and often arbitrary decisions to make about when to start VTE prophylaxis in patients who were immobile but had had a recent large territory stroke or haemorrhage. However, CLOTS3 has provided a clearer pathway for all stroke inpatients. This study recruited 2876 patients with acute stroke and randomised them to placebo or intermittent pneumatic compression stockings. Follow-up lower limb Doppler ultrasound found proximal deep venous thrombus in 12.1% of the placebo patients and only 8.5% of patients wearing the stockings. Early mobilisation (e.g. sitting the patient up the day after stroke) and active physiotherapy will continue to play an important part in limiting the risk of VTE.

There may also be a role for the use of heparin in selected patients who are thought to be at high risk of early stroke recurrence. We use low molecular weight heparin in patients with demonstrated

thrombus in the heart, or in some patients with acute vertebral or carotid artery occlusion, so long as the patient does not have a large infarct (more than one-third of MCA territory by volume). In these latter cases the risk of symptomatic haemorrhagic transformation may be increased. Anticoagulation is sometimes recommended in patients with carotid and vertebral artery dissection (see later), so long as the dissection is limited to the extracranial portions of the artery. However, this treatment has not been shown to be superior to antiplatelet therapy in small randomised trials. In patients in whom there is a good indication for long-term anticoagulation (e.g. atrial fibrillation), we delay anticoagulation for 2 weeks if the infarct is large.

### Neuroprotection

Many neuroprotective drugs, designed to block various components of the biochemical cascade leading to cell death after an ischaemic insult, have been shown to reduce the size of infarction in animal models of ischaemic stroke. To date, none of these agents has fulfilled their promise in randomised trials in human stroke. A number of factors may be responsible for this failure to translate animal research to the bedside, including inability in clinical trials to replicate experimental conditions and inclusion of patients too late – up to 24 hours after onset of stroke. In animal studies of neuroprotection, agents are usually only effective if given within an hour or two after induction of ischaemia.

The only licensed drug with an apparent protective benefit is nimodipine, given after recent SAH. In the British Aneurysm Trial, nimodipine reduced the incidence of cerebral infarction and the proportion of patients with a poor outcome by about 10%. Nimodipine has been shown to have no effect, or even to be harmful, in patients with ischaemic stroke and it is therefore possible that the benefits in patients with SAH arose because the patients can be pre-treated before the onset of ischaemia from vasospasm, or because nimodipine reduces severity of vasospasm.

### Maintenance of homeostasis

Although drug therapy to protect the brain against the effects of ischaemia may not be beneficial, it is still logical to maintain the brain's physiological and biochemical environment in normal homeostatic balance, to preserve the penumbra and take all steps to prevent secondary deterioration. However, there is no trial evidence that the measures we recommend below to maintain homeostasis improve final outcome. Oxygen saturation should be monitored routinely and hypoxaemia treated appropriately.

Blood sugar levels are elevated in about one-quarter of all stroke admissions and elevated blood glucose on admission is a risk factor for haemorrhagic transformation of the acute infarct. This includes patients with known and undiagnosed diabetes, and patients in whom elevation in blood glucose appears as a stress response. Mortality, poor outcome and infarct size are increased in patients with raised blood glucose, but whether the larger size of infarction contributes to the high blood glucose, or vice versa, is uncertain. Nevertheless, we recommend avoiding administering intravenous glucose in patients with acute stroke, and we institute insulin therapy on a graded scale when the blood glucose is  $>10$  mmol/L, to maintain optimal levels within 6–9 mmol/L. Equally, hypoglycaemia should be avoided.

The majority of patients with acute stroke have raised blood pressure on admission, often because of pre-existing hypertension and an invariable hormonal or autonomic response to the stroke itself.

The blood pressure readings usually fall over the course of the first week. It is not clear whether hypertension in the acute stage is harmful (because it might reduce blood flow in already maximally dilated blood vessels) or beneficial (by reducing oedema and the risk of haemorrhagic transformation). However, the recent large INTERACT-2 trial showed that intensive lowering of blood pressure (target systolic level of  $<140$  mmHg) in patients with spontaneous intracerebral haemorrhage was not harmful and might have been beneficial. However, the situation may be different in ischaemic stroke where the adequacy of collateral blood flow is a critical determinant of outcome. Some trials have shown no benefit but treatment was often started late in these studies and one trial suggested harm from blood pressure lowering. Further trials are therefore in progress. Until the results of these trials are available, we recommend continuing any previously prescribed antihypertensive agents, but do not intervene to lower blood pressure unless the patient is a candidate for thrombolysis, has hypertensive encephalopathy, malignant hypertension or the blood pressure readings are persistently above an arbitrary threshold of 200 mmHg systolic pressure or 110 mmHg for diastolic readings. Over-vigorous lowering of blood pressure in acute stroke can certainly lead to extension of the infarct. In most cases, blood pressure should therefore be lowered using oral agents, although in patients in whom thrombolysis is appropriate, intravenous medication with labetalol is used. This should be given at a dose titrated against the blood pressure. The latter should be closely monitored in any patient receiving hypotensive therapy to avoid precipitous falls in blood pressure, aiming for systolic readings of 150–185 mmHg. Intramuscular agents should be avoided because of their unpredictable effect on blood pressure. In other cases, we would recommend that the institution of medication to treat hypertension should be delayed for 48 hours or more after onset.

Spontaneous hypotension after stroke is rare, but may occur if the patient develops cardiac problems or becomes dehydrated. Hypotension should be corrected promptly by raising the foot of the bed, fluid replacement and stopping hypotensive medication. Occasionally, inotropic medication may be required. A very small number of patients, usually with carotid occlusion or a severe intracranial stenosis, can be very sensitive to blood pressure levels to the extent that they may develop a new symptoms or increase in severity of their signs (e.g. worsening hemiparesis) if their blood pressure falls (e.g. when sitting or standing up). Such patients may benefit dramatically from measures to correct hypotension. Similarly, patients with intracranial vasospasm after SAH may develop focal deficits that respond to measures to increase blood pressure.

Pyrexia is associated with poor outcome of stroke, while animal studies show that even a small fall in body temperature is associated with smaller infarct volumes. Hence, we recommend that all patients should have fever treated vigorously (e.g. with paracetamol) and infections should be treated promptly with antibiotics. In clinical practice, therapeutic hypothermia is difficult to achieve, requires intensive care and is associated with significant complications on rewarming, and has therefore not entered routine clinical practice. However, a large European trial of hypothermia has been started which might affect practice in the future.

### Treatment of cerebral oedema

Cerebral infarction is associated with failure of membrane pumps and influx of water into the cells. Cytotoxic oedema is therefore an

inevitable consequence of cerebral infarction, and it is this feature that allows infarcts to be seen on CT. All infarcts are associated with a degree of swelling of the ischaemic tissue, which is manifest in larger infarcts on imaging by compression of the sulci and ventricles. The swelling of the infarct may last up to 4 weeks before the oedema resolves. In large hemispheric infarcts, this mass effect can cause transtentorial herniation with compression of the brainstem and is the most common cause of death in the first week after cerebral infarction. Typically, in patients with symptomatic cerebral oedema, the patient appears stable after the onset of symptoms for the first 24–48 hours, and then deteriorates on the second or third day, with progressive impairment of consciousness, coma and respiratory failure. This most often occurs in a patient with a large infarct caused by MCA occlusion, which is then sometimes known as malignant MCA infarction because it is an important cause of death from ischaemic stroke. Direct brainstem compression may also occur in patients with large cerebellar infarcts.

Cytotoxic cerebral oedema secondary to infarction tends to be unresponsive to steroids, but mannitol may provide a temporary respite pending surgical treatment. Paralysis and hyperventilation are rarely of benefit. Instead, decompressive neurosurgery with a large craniectomy should be considered.

Consideration for decompressive hemicraniectomy is National Institute for Health and Care Excellence (NICE) guidance for patients with large territory (>50% of total territory) anterior circulation acute infarction with developing ‘malignant’ mass effect. This treatment has been demonstrated in recent trials to save life (number needed to treat = 4) if treatment is initiated within 48 hours of stroke onset. Current guidance recommends that eligible patients will be aged 60 years or younger, have a National Institute of Health Stroke Scale (NIHSS) score of above 15, and have reduced level of alertness to give a score of 1 or more on item 1a of the NIHSS (Table 5.15). Trial data suggest that infarct volume of more than 145 mL will inevitably lead to the development of the ‘malignant’ mass effect syndrome in patients aged 60 years or younger and acute stroke with infarct volumes greater than 145 mL should be actively considered for proactive decompression even before malignant swelling starts to develop. Most recently, data presented from the DESTINY 2 trial has suggested that decompressive surgery is also beneficial for patients of good pre-morbid function and aged >60 years. Our practice is to proactively transfer patients at risk of developing significant mass effect secondary to a large volume ischaemic stroke to our high dependency unit and work closely with neurosurgical colleagues to plan the best time for the procedure in appropriate cases. Such patients will require daily interval brain imaging pending a decision regarding surgery and there is no doubt that unnecessary delay in these patients can lead to secondary infarction resulting from direct pressure effects.

Patients with cerebral haemorrhage may also deteriorate because of oedema and transtentorial herniation, or direct brainstem compression. Occasionally, cerebral infarction, usually in the cerebellum, is associated with the development of hydrocephalus from compression of the aqueduct, although this is much more common following intracranial haemorrhage. Hydrocephalus may require shunting, or evacuation of the infarct or haemorrhage (see earlier).

### Management of progressive stroke

About one-third of patients with ischaemic stroke progress in the first day after onset. Acute progression is even more common in patients with cerebral haemorrhage because of continued bleeding

**Table 5.15** National Institute of Health Stroke Scale (NIHSS).

Scale	Grade	Observations
1a Level of consciousness (LOC)	0	Alert
	1	Not alert, but arousable with minimal stimulation
	2	Not alert, requires repeated stimulation to attend
	3	Coma
1b LOC questions – Month? Patient's age?	0	Answers both correctly
	1	Answers one correctly
	2	Both incorrect
1c LOC commands: Open/close eyes Grip (non-paretic hand)	0	Obeys both correctly
	1	Obeys one correctly
	2	Both incorrect
2 Best gaze	0	Normal
	1	Partial gaze palsy
	2	Forced gaze palsy
3 Visual field testing	0	No visual field loss
	1	Partial hemianopia
	2	Complete hemianopia
	3	Bilateral hemianopia (blind, including cortical blindness)
4 Facial palsy	0	Normal symmetrical movement
	1	Minor paralysis (effaced nasolabial fold, asymmetry on smiling)
	2	Partial paralysis (total or near total paralysis of lower face)
	3	Complete paralysis of one or both sides (absence of facial movement in the upper and lower face)
5 Motor function arms (R & L)	0	Normal (extends arm 90° or 45° for 10 s without drift)
	1	Drift
	2	Some effort against gravity
	3	No effort against gravity
	4	No movement
	U	Untestable (joint fused or amputated – scores 0)

and enlargement of the haematoma. In ischaemic stroke, the causes of early progression are often unclear, but may include extension of the area of ischaemia from thrombus propagation, recurrent embolism, failure of initially adequate collaterals or enlargement of the penumbra from release of cytotoxic chemicals and the local effects of cytotoxic oedema. In patients who deteriorate after a period of stability, a number of other causes need to be considered:

- Metabolic disturbances (e.g. low or high blood sugar, or hyponatraemia)
- Hypotension, or severe hypertension
- Cardiac arrhythmias or MI
- Pyrexia and infections
- Dehydration
- Hypoxia (e.g. from aspiration, infection or silent pulmonary embolism)
- Cerebral oedema or hydrocephalus
- Haemorrhagic transformation of infarction
- Vasospasm after subarachnoid haemorrhage,
- New infarction (often from cardiac embolism) or haemorrhage in a new location.

Patients who deteriorate should therefore be investigated for these possibilities by repeat CT or MRI, chest imaging, search for infection and appropriate blood tests. Management will depend on the findings.

### Common medical complications of stroke

- Frank dysphagia, or an unsafe swallow with the risk of aspiration, is very common and occurs in about one-third of patients with hemispheric stroke and two-thirds of those with brainstem stroke. This can easily cause aspiration pneumonia, leading to hypoxia and stroke progression. All patients with acute stroke should therefore have their swallowing assessed as soon as possible, using an agreed protocol. They should be kept nil-by-mouth until their swallowing has been assessed as safe. It is very likely that dehydration and starvation are harmful in the acute stages of stroke and fluid replacement should commence as soon as the patient is admitted if swallowing is not safe. It also makes sense to start feeding patients immediately. Even if a patient can swallow safely, the spontaneous intake of food and liquid is often inadequate because of poor appetite, cognitive impairment, neglect or physical difficulties in feeding. Nurses and carers should therefore have adequate time to help a patient to eat and drink sufficiently. When the oral route is not safe or practical, it is essential to establish other routes. In the short term, it is often convenient to replace fluids via an intravenous line, but this has the disadvantage of immobilising the patient. A nasogastric tube is therefore preferred, with the advantage of allowing feeding as well as fluid replacement, with less risk of cardiac overload or line infection. If nasogastric tube feeding is likely to be required for more than 2 weeks, consideration should be given to inserting a percutaneous endoscopic gastrostomy (PEG) tube. This is usually preferred by patients and has the advantage that a large tube can be used. However, there are some risks of tube insertion, including peritonitis. Overall, there is little difference to the outcome after early PEG feeding compared with a nasogastric tube. It should be borne in mind that nasogastric tubes may increase the risk of gastrointestinal haemorrhage.
- Deep vein thrombosis is usually seen in severely hemiparetic limbs and is very common on radiographic studies. Pulmonary embolus is a rare but important cause of death after stroke. The prevention of venous thromboembolism is discussed in the section on anticoagulation.
- Pressure sores should only occur in those patients who have lain at home undiscovered and immobile for some hours before admission to hospital. In all hospital patients sores should be avoided by frequent turning, careful positioning and the use of appropriate bedding (e.g. an air mattress). Early mobilisation and sitting the patient out of bed as soon as possible after onset also play a part in preventing pressure sores and other complications of immobility.
- Shoulder pain is a common complication of stroke, largely preventable by good positioning of the shoulder and early physiotherapy. In particular, a paralysed upper limb should not be allowed to hang unsupported at the side of the patient, because the weight of the limb leads to subluxation of the shoulder joint and subsequently a painful frozen shoulder. The correct position of a patient in a bed or chair, with the weak limb supported at all times by a comfortable pillow or similar support, is essential. Patients who do experience shoulder pain may benefit from standard rheumatological treatments, including local steroid injections. The paralysed upper limb must never be neglected from motor therapy as it will contract and become dysfunctional and painful.
- Limb swelling of the hand or foot of a hemiparetic limb is common and is partly explained by excessive sympathetic activity.

The patient often complains that the limb is cold, because vasodilatation results in heat loss, even though the limb may feel warm to touch. This type of oedema should be distinguished from oedema secondary to a deep venous thrombosis. Elevation of the limb may help. Diuretics are not indicated.

- Spasticity is a common but not universal feature of the upper motor neurone lesion resulting from infarction or haemorrhage. The increase in tone often develops several days or weeks after the onset of stroke. In the upper limb, the pattern of spasticity usually leads to flexion at each joint, and in the lower limb to extension. Early mobilisation and appropriate physiotherapy probably play an important part in limiting the development of severe spasticity, and particularly the development of contractures. Oral drug treatment has a limited role in treating spasticity in stroke. The problem is that drug treatment often results in generalised muscle weakness and function is rarely improved. However, local injections of botulinum toxin into individual muscles may benefit patients in whom spasticity is causing focal problems.
- Depression is very common after stroke and may reflect a direct neurophysiological cause, as well as reaction to the illness and persistent disability. Depression is associated with poor outcomes and should therefore be treated vigorously and expert psychiatric advice sought if necessary.
- Post-stroke pain (Chapter 23) is characteristically associated with infarction in the thalamus and often develops weeks or even months after the onset of stroke. The pain is often described as a deep burning pain throughout one side of the body, which limits the patient's activities and may lead to severe depression. Standard analgesics are often ineffective, but relief may be obtained with tricyclic antidepressants, particularly amitriptyline taken at night, or anticonvulsants (e.g. gabapentin). Occasionally, transcutaneous nerve stimulation is helpful.
- Dystonia is a rare complication of stroke involving the basal ganglia and usually develops some months after the initial event. Chorea is occasionally seen in patients with the Moyamoya syndrome (see Moyamoya angiopathy), and is also a rare acute manifestation of basal ganglia lacunar infarction.

## Secondary prevention

Secondary prevention implies specific evidence-based measures that reduce the risk of future stroke following a defined clinical event. In the case of TIA, this implies preventing, to some degree, the risk of subsequent stroke. Following a stroke, secondary prevention means recommending and adopting measures that have been shown to prevent stroke recurrence. Advice that is not based upon evidence, nor widely agreed, is frequently given to patients in these clinical settings. Much of the evidence related to primary prevention, such as the control of hypertension, also applies to secondary prevention.

### Secondary prevention after TIA and stroke

Patients who have had a TIA are at high risk of stroke and those who have had a stroke are at high risk of recurrent stroke. Both are at risk of MI. As a general figure, following either of these events, the risks of stroke or a recurrent stroke are about 5% per annum, but can be as high as 30% in patients with severe carotid stenosis. In general, the older the patient, and the more risk factors present, the greater the risk of recurrence. However, with appropriate management, the risks can be reduced substantially. The EXPRESS study performed by the Oxford Group demonstrated an 80% relative risk

**Table 5.16** The ABCD2 score for transient ischaemic attack (TIA). A TIA is judged to be high risk if the ABCD2 score is 4 or more and as low risk if the score is 3 or less. National guidance in the United Kingdom recommends review by a stroke specialist within one working day of all patients with TIA and ABCD2 score greater than 3.

ABCD2 risk factor	Values	Score
Age	>59 years	1
Blood pressure	Systolic blood pressure >140 mmHg or diastolic blood pressure >90 mmHg	1
Clinical symptoms	Unilateral weakness	2
	Isolated speech disturbance	1
Duration of symptoms	Other	0
	>60 minutes	2
	10–59 minutes	1
	less than 10 minutes	0
Diabetes mellitus	Present	1

reduction when patients with TIA were seen within the 24 hours of referral and commenced immediately on secondary prevention treatments. Scoring systems to grade risk with TIA have been developed (most notably the ABCD2 score; Table 5.16) once the diagnosis of TIA has already been made. High risk patients (ABCD2 >3) should be seen within 24 hours of referral while low risk patients (ABCD2 ≤3) might be seen within 5 working days. Many stroke services have been reorganised around this scoring system, which has the vulnerability that the score and hence the risk stratification are only valid *after* an informed evaluation of the patient, which is the first task of the clinician running the TIA service. Studies have shown that the score is often poorly measured when done outside an expert context. The accuracy of the score can be improved in TIA patients if the findings on CTA or MRI are incorporated in the score, because acute infarction on DWI and the finding of arterial occlusion or stenosis on CTA both independently increase the risk of early stroke.

Evidence from EXPRESS and the FASTER trial performed in Paris demonstrates that for patients with TIA or minor stroke there is much to be saved by effective measures to prevent recurrence. Treatment should be based on addressing risk factors and the results of investigations, together with an assessment of the degree of risk and benefits of treatment in individual patients.

Targets for preventive measures include the following:

- Lifestyle risk factors
- Lowering blood pressure
- Lowering cholesterol by statin therapy and diet
- Optimising treatment of other conditions that promote vascular disease (e.g. diabetes)
- Prevention of cardiac embolism (e.g. valve surgery or anticoagulation for atrial fibrillation)

- Targeted treatment for atherosclerotic stenosis by carotid endarterectomy or stenting,
- Inhibition of platelet aggregation with antiplatelet agents.

In patients with a history of cerebral haemorrhage, prevention should be targeted only at the first four issues and, in general, antiplatelet therapy and anticoagulation are contraindicated. Sources of cerebral haemorrhage, particularly aneurysms and AVMs may require specific treatment as previously described.

Following cardiogenic thrombo-embolism, formal anticoagulation treatment to prevent recurrence should start immediately after a TIA or rapid recovery from a minor stroke. In patients with more severe stroke, we start anticoagulation with warfarin at around 2 weeks after onset. Several trials have shown no benefit to anticoagulation within the first 2 weeks after onset, because any reduction in the numbers of recurrent ischaemic stroke is balanced by cerebral haemorrhage secondary to the therapy in the hyperacute setting. In patients who are very disabled, some preventive measures may need to be delayed, for example for stroke secondary to a symptomatic internal carotid artery stenosis the decision on whether to perform a carotid endarterectomy will usually be deferred until the risks of reperfusion injury in the damaged cerebral hemisphere are reduced and the potential benefit of protective surgery for the remaining anterior circulation territories can be evaluated against the primary injury and associated persisting clinical deficit. Anticoagulants and antiplatelet therapy have a rapid effect at reducing risk in appropriate patients and it is also possible that there is a rapid impact of statins in the stabilisation of acute symptomatic atheromatous plaque disease. However, in general, statin therapy and lowering of blood pressure appear to take several months to be effective at reducing risk, and the maximum benefits are not achieved for up to 1–2 years.

There is much to be gained by effective secondary prevention of stroke: the patient who stops smoking will halve their risk of stroke; a patient with atrial fibrillation taking warfarin will reduce their risk of stroke by two-thirds; antihypertensive therapy will reduce the risk by about 40%, and a patient with stroke secondary to arterial disease taking simvastatin 40 mg/day will have their stroke risk reduced by 30%. Carotid endarterectomy in patients with recent symptoms and severe carotid stenosis may reduce the risk of recurrence by as much as 80%. Antiplatelet therapy is the least effective of these measures and only reduces the risk of recurrent stroke by about 15%. Each of these treatment modalities acts independently. Thus, patients with multiple risk factors stand to benefit considerably from multimodal intervention.

### Lifestyle modification

Patients with the relevant risk factors should be strongly advised to stop smoking, eat healthily to reach and maintain a normal weight, to take regular exercise and to reduce excessive alcohol consumption.

### Lowering blood pressure

Epidemiological studies have established clearly that the lower an individual's blood pressure, the lower the risk of stroke, even within the normal range. In patients with hypertension, it is therefore likely that the lower the blood pressure is reduced with treatment the better, so long as the patient does not develop unwanted effects. Thus, we suggest that if the patient is at any risk of recurrence and can tolerate the medication, the British Hypertension Society (BHS) guidelines (optimum targets: below 140/90 mmHg in general and below 130/80 mmHg for patients with diabetes) should be followed closely (i.e. the blood pressure maintained at levels lower than

these). This may require the use of three or four antihypertensive agents. At one time, there was concern that lowering the blood pressure in patients with prior stroke might be harmful, but the PROGRESS trial established that even patients with a relatively normal blood pressure after a stroke (often achieved with prior medication), benefited from further reduction in their blood pressure using a combination of an angiotensin converting enzyme (ACE) inhibitor and a diuretic.

Most experts believe that the benefits of lowering blood pressure in preventing stroke are related to the degree in reduction of blood pressure, not the drug class used to lower it. However, there is some evidence that  $\beta$ -blockers are less effective than other classes of antihypertensive agent.

### Diabetes mellitus

Both type 1 and type 2 diabetes are well-recognised risk factors for stroke, probably because of the association of atherosclerosis and hypertension with diabetes. In keeping with this assumption, vigorous control of hypertension has more benefit in reducing the incidence of stroke in patients with diabetes than tight control of blood sugar levels. However, it is important to maintain HbA<sub>1c</sub> levels at less than 7%.

### Lowering cholesterol

There is now convincing evidence from the Heart Protection Studies and the SPARCL study that lowering cholesterol with a statin after ischaemic stroke dramatically reduces the risk of recurrent stroke and MI. The lower the achieved level of cholesterol the lower the risk, with an approximately 30% reduction in the risk of recurrent ischaemic stroke and MI associated with a reduction in LDL cholesterol of 1.0 mmol/L. The benefits of statin therapy are therefore greater than those of antiplatelet therapy. All patients with stroke and TIA should therefore be considered for statin therapy, unless they have a total cholesterol of <3.5 mmol/L or LDL cholesterol <1.8 mmol/L.

### Anticoagulation

Anticoagulation in acute stroke has been discussed earlier. In contrast to the lack of benefit of heparins in acute stroke, there is good evidence that anticoagulation with warfarin prevents recurrent stroke in patients with cardio-embolic sources of thrombus (Table 5.17). The evidence is best for atrial fibrillation, which is associated with a very high rate of recurrent stroke. In the European Atrial Fibrillation Trial, warfarin reduced the rate of recurrent TIA and stroke from 12% per annum down to 4% per annum, a two-thirds reduction in risk. In contrast, aspirin was much less effective, reducing the rate of recurrence by only about one-sixth. It is likely that warfarin works more effectively than aspirin because it affects the formation of thrombin-based clots in the heart, whereas antiplatelet agents are more effective at preventing thrombus starting with platelet aggregation on atheromatous clots. Thus, warfarin is the treatment of choice in patients with atrial fibrillation following stroke or TIA to prevent recurrence. In the elderly, the risks of intracranial haemorrhage (including subdural haematoma), the need for regular monitoring and the issue of compliance, especially if there is cognitive impairment, need to be considered but the benefits of anticoagulation in these patients is usually so substantial that significant problems with the treatment should be identified before anticoagulation is considered to be contraindicated. Occasional falls or one single fall with injury should not be automatic reasons for long-term withdrawal of anticoagulation. Antiplatelet treatments are not as effective as warfarin, even when

**Table 5.17** Indications for anticoagulation in secondary stroke prevention.

Established indications
Cardiac embolism
• Atrial fibrillation
• Mechanical valve prosthesis
• Recent myocardial infarction
• Left ventricular aneurysm
• Dilated cardiomyopathy
Cerebral venous and venous sinus thrombosis
Possible indications
Recent major vessel occlusion
• Internal carotid artery occlusion
• Basilar artery occlusion
Recent extracranial cervical arterial dissection
Severe carotid stenosis prior to surgery or stenting
Crescendo TIAs despite antiplatelet therapy
Thrombophilia and prothrombotic states
Paradoxical embolism

**Table 5.18** The CHA<sub>2</sub>DS<sub>2</sub>-VASc scoring system for assessing risk of stroke in the presence of atrial fibrillation. Maximum total score = 9. The presence of congestive heart failure, hypertension, age 65–74 years, diabetes mellitus, stroke/TIA, or female sex score 1 point each while age >74 years and history of previous thromboembolism score 2 points each.

CHA <sub>2</sub> DS <sub>2</sub> -VASc score	Risk category	Adjusted stroke risk (%/per year)
0	Low	0
1	Intermediate	1.3
2	High	2.2
3	High	3.2
4	High	4.0
5	High	6.7
6	High	9.8
7	High	9.6
8	High	6.7
9	High	15.2

used in intensive combinations of aspirin and clopidogrel, and these treatments can be associated with similar levels of non-CNS-related haemorrhage. Fixed or low dose warfarin therapy is not effective in preventing embolism in patients with atrial fibrillation.

Several novel oral anticoagulant treatments have now been licensed in Europe and in the United States. These medications have the benefit of requiring no blood level testing, fixed dosing and reduced risk of over or under-treatment complications. Rivaroxaban and apixaban are inhibitors of factor Xa while dabigatran is a direct thrombin inhibitor. To date, most vascular networks have adopted a position that recommends these medications for patients with atrial fibrillation only after they have failed with a trial of warfarin for some reason (e.g. because of non-compliance or poor management of International Normalised Ratio [INR] levels.) From the trial data, these drugs have similar efficacy and when compared with warfarin are all non-inferior to warfarin with reported reduction in intracranial haemorrhage rates. They have not been tested in patients with metallic valves or with other prothrombotic conditions such as antiphospholipid syndrome and for these patients warfarin will remain the treatment of choice.

Several scoring systems have been developed to assist clinicians in planning anticoagulation treatment. The CHA<sub>2</sub>DS<sub>2</sub>-VASc scoring system is widely used to assess risk of stroke in the presence of atrial fibrillation while the HAS.BLED tool may be useful in estimating treatment haemorrhage risk in patients prescribed warfarin (Table 5.18 and Table 5.19). A criticism of these scoring systems is that neither requires evaluation of the contemporary brain imaging and it is likely that incorporation of information from MRI (e.g. prior silent cortical infarcts) and sequences sensitive to haemorrhage (e.g. susceptibility weighted imaging) may add value to risk assessment. Standard practice is to offer anticoagulation for all

**Table 5.19** Clinical characteristics comprising the HAS.BLED bleeding risk score.

H - Hypertension	Hypertension' is defined as systolic blood pressure >160 mmHg	1
A - Abnormal renal and liver function (1 point each)	Abnormal renal function is defined as serum creatinine ≥200 mmol/L Abnormal liver function is defined as chronic hepatic disease (e.g. cirrhosis) or biochemical evidence of significant hepatic derangement	1 or 2
S - Stroke	Previous stroke	1
B - Bleeding	Bleeding refers to previous bleeding history and/or predisposition to bleeding (e.g. bleeding diathesis or anaemia)	1
L - Labile INR	Labile INRs refers to unstable/high INRs or poor time in therapeutic range (e.g. 60%)	1
E - Elderly	Age >65 years	1
D - Drugs or alcohol (1 point each)	Drugs/alcohol use refers to concomitant use of drugs, such as antiplatelet agents, non-steroidal anti-inflammatory drugs, or alcohol abuse, etc.	1 or 2
Total (maximum)		9

INR, International Normalised Ratio.

those with  $\text{CHA}_2\text{DS}_2\text{-VASC}$  scores  $>1$  and to consider anticoagulation or antiplatelet agents for those with a  $\text{CHA}_2\text{DS}_2\text{-VASC}$  score of 1. Consideration of the HAS.BLED score in conjunction with the  $\text{CHA}_2\text{DS}_2\text{-VASC}$  score is most useful in patients with high risk of bleeding. In practice, anticoagulation should be introduced with caution in patients with very frequent falls or a HASBLED score of  $>2$  but anxiety about bleeding, particularly in patients who fall frequently, may become less of an issue in the future when the novel oral anticoagulants are more widely used because these new agents appear to guarantee a therapeutic dose without excessive anticoagulation and with reduced risk of intracranial bleeding.

Anticoagulation is indicated as a life-long treatment for patients who have had heart valves replaced with mechanical prostheses. If such patients have a cerebral haemorrhage while on warfarin, the treatment can be stopped relatively safely empirically, but should in most cases be restarted after 7 days. Other cardiac conditions associated with a high likelihood of the development of cardiac embolism listed in Table 5.17 should be considered for anticoagulation.

Possible indications for anticoagulation after stroke are also listed in the Table 5.17. Evidence that anticoagulation is superior to aspirin in all these disorders is lacking. It needs to be borne in mind that there are significant long-term risks of warfarin therapy, including a risk of intracranial haemorrhage of 1–2% per annum. We therefore usually only recommend anticoagulation for short periods in patients with uncertain indications to cover the period of time when their risk of recurrence is highest (e.g. for a maximum of 6 months after an acute ischaemic event).

The usual target INR for the treatment of atrial fibrillation is 2.5 (range 2.0–3.0). For patients with mechanical prosthetic valves, a higher INR target of 3.5 (range 3.0–4.0) is usually chosen. A target INR of 2.5 is appropriate for most other indications. Analysis of the Atrial Fibrillation Trials suggests that an INR of 2.0 or less is insufficient to prevent thrombo-embolism, while the risk of haemorrhage rises substantially with an INR of  $>4.0$ . It is important that anticoagulant clinics, and the patients themselves, are aware of these recommended levels.

The management of patients who are found to have a patent foramen ovale (PFO), in association with TIA or stroke, remains controversial. There appears to be an association between PFO and cryptogenic stroke (i.e. those patients in whom no other cause is evident after full investigations). However, whether the mechanism of stroke in these patients is paradoxical embolism from cryptic deep vein thrombosis, embolism of thrombus formed in the PFO itself, or some unrelated mechanism, is not clear. Nevertheless, careful observational studies have suggested that the rate of recurrent stroke in patients with PFO treated with aspirin alone is as low, as the rate in patients with cryptogenic stroke without PFO, except if the PFO is associated with atrial septal aneurysm, when the risk may be increased. There appears to be little consistent relationship between the risk of stroke treated with aspirin and the size of the PFO. In patients where the PFO is thought to be relevant to the mechanism of their stroke, the PFO can be closed using percutaneous techniques and mechanical devices. The risks of this treatment are low, but not zero, and the long-term consequences of having a prosthesis in the heart are uncertain. None of the three randomised trials completed to date has conclusively shown PFO closure to be of benefit on an intention to treat basis, though subgroup analysis has suggested potential benefit in high risk groups, particularly younger patients with a large PFO. We therefore favour medical management with

optimised antiplatelet treatment in the majority of cases but value a multidisciplinary approach to the decision-making process to assist in the identification of patients more suitable for PFO closure. The evidence suggests that warfarin is no more effective than aspirin in these patients provided a full thrombophilia screen is negative.

For non-cardioembolic stroke, a number of randomised trials have shown that warfarin is no more effective than aspirin in preventing recurrent stroke in patients who have had TIA or stroke that has not been attributed to atrial fibrillation or a cardiogenic source (i.e. patients with stroke attributable to atherosclerosis, small vessel disease or cryptogenic mechanisms). Antiplatelet therapy is therefore preferred to anticoagulation in patients with this type of stroke, sometimes known as athero-thrombotic stroke. The danger of warfarin therapy in this group of patients was emphasised by the results of the Stroke Prevention in Reversible Ischaemia Trial (SPIRIT), which was stopped prematurely because of an excess of brain haemorrhage in patients who did not have atrial fibrillation or cardiac embolism randomised to warfarin compared with those randomised to aspirin after a recent TIA or stroke. Most of the haemorrhages occurred in patients over the age of 75 and in those who had moderate or severe small vessel disease (leukoaraiosis) on CT. This trial used a high target range for INR of 3.0–4.0, which may have increased the risk of cerebral haemorrhage; nevertheless, extensive leukoaraiosis should be considered a relative contraindication to warfarin therapy.

Warfarin treatment has been recommended in the past as an option in patients with recurrent stroke or TIA symptoms on antiplatelet agents but perhaps more appropriately recurrent events despite apparently optimal treatment should result in detailed re-evaluation for causation. These further investigations should be determined by the pattern of the recurrence, for example TOE, aortic arch imaging and implantable rhythm monitoring investigations are useful in evaluating unexplained recurrent embolic stroke; up-to-date high resolution intracranial arterial imaging is important for recurrent single territory events; and a wider survey of uncommon causes of small vessel arteriopathy (e.g. CADASIL or Fabry's disease) for progressing small vessel disease.

This process of re-evaluation on the mechanism for stroke despite optimised treatment is particularly important for patients who have recurrent symptoms on warfarin with apparently good INR control. The range of options here is wide. It may be that warfarin control is less good than thought and needs to be optimised, perhaps with a higher target INR. Other possibilities might be that the recurrent events relate to a different vascular process (e.g. large artery disease or small vessel arteriopathy) and for these patients intensification of the warfarin treatment is unlikely to be helpful. It is mandatory in these cases to exclude a symptomatic carotid artery event that might be treated with carotid surgery. For patients with new small vessel events blood pressure and cholesterol control should be optimised but there is a theoretical option to add in an antiplatelet treatment (e.g. low dose aspirin 75 mg/day). In general we would avoid this option wherever possible because there is clear evidence of significant increase in haemorrhage risk in patients on this dual agent combination but in exceptional cases where these options are being considered primarily from a stroke prevention position blood sensitive MRI sequences are increasingly helpful in guiding the evaluation of risk–benefit. In some cases, dual therapy (warfarin plus an antiplatelet) or even triple therapy with warfarin plus two antiplatelet agents is necessary to cover recent stroke in the context of cardiogenic thrombo-embolism and acute coronary

artery disease requiring coronary artery stenting and dual antiplatelet cover. In these situations there is no one correct treatment strategy and best practice is for stroke and cardiology clinicians to determine the minimum duration of the antiplatelet treatments, the optimal stent device and to ensure that the patient is aware that there will be an unavoidable period of increased risk of haemorrhage.

### Antiplatelet therapy

Aspirin has been the mainstay of treatment to prevent recurrent stroke for many years in patients who are not anticoagulated, and has the advantage of being very cheap. However, it should be borne in mind that antiplatelet therapy has less relative benefit in reducing the risk of vascular events than lowering blood pressure or lowering cholesterol. In a meta-analysis looking at the overall benefit of aspirin after stroke or TIA, the overall relative risk reduction in the combined outcome of stroke, MI or vascular death in different trials was only 13%. Aspirin also has the disadvantage of frequent side effects, particularly at high doses, including gastrointestinal haemorrhage and intracranial haemorrhage, which have incidences of approximately 27 and 5 per 1000 patients per year, respectively. The most common side effect is gastrointestinal irritation, and as many as 25% of patients discontinue aspirin treatment within a year or so of starting. Gastrointestinal side effects are less troublesome at lower doses. There is little evidence for a significant difference in effectiveness at any dose above 30 mg/day, and we therefore recommend using the lowest easily available convenient dose, which in the United Kingdom is 75 mg once daily.

There has been considerable interest in developing alternative, more effective antiplatelet agents than aspirin. The first widely used alternative to aspirin was dipyridamole. Initially, there was doubt about the effectiveness of dipyridamole in preventing stroke, but the Second European Stroke Prevention Study (ESPS-2) showed that dipyridamole in a modified released preparation at a dosage of 400 mg/day had a similar effectiveness to aspirin in preventing recurrent stroke in patients with recent stroke or TIA. The combination of low dose aspirin and dipyridamole was significantly superior to aspirin or dipyridamole alone, with a relative reduction in stroke recurrence, compared with placebo, of 37%. These results have recently been confirmed by the ESPRIT trial. Dipyridamole is a very safe antiplatelet agent, and does not appear to significantly increase the risk of bleeding, even when combined with aspirin. However, it is not well tolerated by a significant proportion of patients because of side effects, particularly headache. These side effects may be minimised by starting with a low dose of dipyridamole and increasing the dose gradually, and may work in some patients over a few weeks, if they persist in taking the tablets. In ESCS-2, nearly 30% of patients discontinued combination therapy because of side effects.

NICE in England, in its 2010 appraisal of antiplatelet agents for the prevention of thrombosis in patients with stroke, recommended that all patients with recent stroke and TIA should be started on clopidogrel with the combination of aspirin and dipyridamole being an option. Clopidogrel is an antiplatelet agent that was developed as a replacement for ticlopidine, an older antiplatelet agent that had the disadvantage of a 1% incidence of neutropenia. Clopidogrel 75 mg/day was compared with aspirin in the CAPRIE trial, and was shown to be slightly better than aspirin in the prevention of the combined outcome of all vascular events in patients with recent stroke, MI or peripheral vascular disease. However, the absolute reduction in vascular events attributed to clopidogrel over and

above the benefit of aspirin alone was only 0.5% (i.e. the number needed to prevent one additional event was 200 patients over 2 years). Clopidogrel is slightly better tolerated than aspirin in terms of gastrointestinal symptoms, but has a slightly higher rate of rash and diarrhoea as side effects. The rate of haemorrhage associated with clopidogrel is similar to that of aspirin.

The combination of clopidogrel and aspirin may be more effective than either drug alone in preventing recurrent stroke. In the MATCH trial, clopidogrel plus aspirin was compared with clopidogrel alone in patients with recent stroke considered at a high risk of recurrence. In this trial, there was a significant increase in the risk of life-threatening haemorrhage in patients treated with the combination, without any significant reduction in the rate of ischaemic stroke. In contrast, in 2013, the CHANCE study, a randomised double-blind placebo controlled trial comparing clopidogrel plus aspirin with aspirin alone started within 24 hours of minor stroke or TIA in 5000 Chinese patients, reported a relative risk reduction of 43% in stroke occurrence within 90 days for the dual agent combination compared with aspirin alone. The combination treatment was not associated with excess haemorrhage compared with aspirin as monotherapy. Similarly, in the EXPRESS study, patients with TIA judged to be at high risk of recurrence (e.g. early presentation post index TIA) appeared to benefit from combination therapy with aspirin and clopidogrel without excess haemorrhage at 90 days. If these findings are repeated in the planned Platelet-Orientated Inhibition in New TIA and Minor Ischaemic Stroke (POINT) trial, a rationale for short-term dual agent treatment in the immediate period post minor stroke or TIA will be established. Pending further clarification on the safety and efficacy of combination treatment with aspirin and clopidogrel in stroke patients, dual agent treatment is already used in some departments for high risk TIA, patients post coronary or carotid artery stenting, and in high risk patients planned for carotid endarterectomy secondary to symptomatic significant carotid disease.

### Management of carotid stenosis

#### Symptomatic carotid stenosis

The large randomised trials comparing carotid endarterectomy with medical treatment alone completed over 20 years ago demonstrated that selected patients with recent ipsilateral TIA or non-disabling stroke, who are fit for surgery and have significant carotid stenosis, benefit from carotid endarterectomy to remove the stenosis (Table 5.20). The benefit of surgery is strongly related to the severity of the stenosis and the recentness of symptoms. The risk of recurrent stroke in patients with recent TIA who do not have carotid endarterectomy and are treated medically increases substantially

**Table 5.20** Indications for carotid surgery.

History of ipsilateral carotid TIA or stroke with reasonable recovery
Severe stenosis ( $\geq 70\%$ , NASCET method, excluding near-occlusion) and symptoms within 6 months
Moderate stenosis (50–69%, NASCET method) and symptoms within 2 months and male gender
Patients must be fit for surgery and an experienced, skilled surgical team available

NASCET, North American Symptomatic Carotid Endarterectomy Trial; TIA, transient ischaemic attack.

above 50% stenosis with increasing deciles of stenosis over the next 5 years. Carotid endarterectomy has a risk of causing a stroke or death at the time of the surgery, in good hands, of 4–6% in recently symptomatic patients, but thereafter removing the stenosis surgically almost abolishes the risk of ipsilateral recurrence, with a subsequent annual rate of stroke of only about 1%. The risks of surgery bear little relationship to the severity of internal carotid artery stenosis. Hence, the benefits of surgery increase with increasing degrees of stenosis above 50% or so, in patients with recently symptomatic stenosis. However, patients with very severe stenosis in which the distal internal carotid artery has collapsed (an appearance referred to as pseudo-occlusion or near occlusion on angiography) have a low risk of recurrent stroke and do not benefit from surgery. Patients with complete carotid occlusion were not included in the endarterectomy trials, but previous studies suggested that surgery for carotid occlusion was hazardous.

The benefits of surgery for carotid stenosis decline with time from symptoms to the operation. Patients with moderate degrees of stenosis (50–69%, measured using the NASCET method) benefit from surgery if it is performed within the first few weeks after recent symptoms, especially if they are male, but not if the surgery is delayed beyond a month or two. Patients with more severe stenosis may benefit from surgery performed up to 6 months after symptoms, but any delay in surgery in these patients will mean that some patients will already have had a stroke while awaiting surgery. It is therefore essential that patients should be referred as soon as possible after TIA and stroke for carotid investigations, and operated on as soon as possible if significant stenosis is detected, the patient is neurologically stable and the patient is at high risk of recurrent stroke on medical therapy alone. Very early surgery can be hazardous and the optimum time to operate is between days 2 and 14 after symptoms.

A number of other clinical features apart from stenosis severity and time from symptoms alter the risk of recurrent stroke: the nature of the symptoms, the sex and age of the patient, their vascular risk factors and whether or not the carotid plaque is ulcerated on angiographic imaging. There are tools available that use these features to calculate the risk of recurrent stroke in recently symptomatic patients and these should be used to select patients for surgery. One issue is that medical therapy has improved substantially since the data that are used to calculate the risks and benefits of endarterectomy in symptomatic patients were collected. The current evidence suggests that medical therapy is now so effective that the benefits of removing the narrowing may not justify the risk of surgery in as many as 60% of patients with a lower risk of stroke currently receiving endarterectomy. The Second European Carotid Surgery Trial (ECST-2) has recently started with the aim of establishing whether these patients should be managed by drug therapy alone or should be referred for surgery. There is also ongoing research examining whether methods of imaging the composition of carotid plaque, including various ultrasound, MRI and PET techniques, are effective at identifying the 'vulnerable' plaque likely to cause future symptoms. It is likely that in the future, one or more of these techniques will prove useful in selecting patients for endarterectomy.

The main hazard of carotid endarterectomy is stroke during the procedure itself. There is also a small incidence of stroke in the first 2 weeks after endarterectomy, probably resulting mostly from a thrombus formed on the endarterectomy site. Surgery also risks MI, pulmonary embolism and the development of a haematoma at the wound site. Up to 10% of patients develop a cranial nerve palsy,

usually a unilateral hypoglossal nerve palsy, but these usually recover and only rarely cause disability (Chapter 13). Performing the operation under local anaesthesia has been shown in a randomised clinical trial to be no safer than operating under general anaesthesia. About 1% of patients develop hyperperfusion syndrome, which usually follows endarterectomy (or stenting) for a very tight stenosis, and may be more common in patients who develop postoperative hypertension. Patients with hyperperfusion syndrome complain of headache and may develop seizures and/or cerebral haemorrhage. Treatment of the hyperperfusion syndrome includes the urgent lowering of blood pressure. In patients with large acute infarcts, there may be a risk of causing reperfusion haemorrhage if the artery is operated on immediately, and it may be wise to wait 2 weeks or more before operating on these patients

### Asymptomatic carotid stenosis

Patients investigated for TIA, stroke or other vascular conditions may be found to have a stenosis of one or more internal carotid arteries that is asymptomatic. A number of randomised trials have established that patients found to have carotid stenosis who have never had ipsilateral symptoms, or have had symptoms more than 6 months prior to randomisation, have a very low rate of ipsilateral stroke during follow-up of around 2% per annum. Carotid endarterectomy for asymptomatic carotid stenosis is less hazardous than in symptomatic patients, but carried a risk in these trials of around 3% within 30 days of the operation. Surgery then reduces the risk of ipsilateral stroke to about 1% per annum. The 5-year risk of any stroke or surgical death in the Asymptomatic Carotid Surgery Trial (ACST) fell from about 12% in patients in whom surgery was deferred until a more definite indication appeared (e.g. the stenosis became symptomatic), down to 6.4% in patients who had early endarterectomy. Subgroup analysis of ACST showed that patients over the age of 75 did not benefit from surgery, and the benefit in women was doubtful. The low rate of stroke in patients treated medically means that operating on asymptomatic carotid stenosis as a policy would result in a very large number of patients having unnecessary surgery, while some would be harmed from the operation, and only a small proportion (5%) would gain some benefit by avoiding stroke over the next 5 years. The majority of neurologists have concluded that this does not justify a policy of endarterectomy for asymptomatic stenosis, although exceptions may be made for young patients who are particularly anxious. The earlier carotid endarterectomy trials did not incorporate state-of-the-art medical treatment. It is likely that in asymptomatic patients who are treated with high dose statins, have vigorous control of hypertension and stop smoking, the benefits of endarterectomy will be even less than those demonstrated in the trials. The evidence from non-randomised studies suggest that the risk of stroke in asymptomatic patients has fallen in the last few years to around 1% or even lower in those receiving intensive medical therapy and risk factor modification. However, the risks of endarterectomy have also fallen to around 1%. There are therefore arguments supporting the need for new trials studying the effects endarterectomy compared with medical therapy in patients with asymptomatic stenosis. Several have started recently.

There does not appear to be a close relationship between stenosis severity and risk of future stroke in patients with asymptomatic carotid stenosis. There is therefore no benefit to following up asymptomatic stenosis with regular ultrasound examinations.

The benefits of carotid endarterectomy or stenting for patients with asymptomatic carotid stenosis who require major surgery,

especially coronary artery bypass grafting (CABG), is uncertain. Severe carotid stenosis increases the risk of stroke during CABG, but the risk is not necessarily reduced by prior carotid endarterectomy or stenting, and the risk of stroke during treatment of the carotid artery is similar to the risk of stroke during CABG. Hence, a routine policy of screening and treatment of carotid stenosis prior to CABG is probably not justified. Patients who are symptomatic from both their carotid and coronary arteries should have the carotid treated prior to treatment of the coronary arteries.

### Carotid stenting

Carotid stenting has become an alternative treatment to carotid endarterectomy for symptomatic carotid artery stenosis (Figure 5.28). Carotid stenting has the advantage of avoiding any incision in the neck and is usually performed under local anaesthesia. It appears less invasive and is therefore often preferred by patients to carotid endarterectomy, given the choice. However, carotid endarterectomy remains the treatment of choice for most patients. Randomised trials comparing endarterectomy with stenting for symptomatic carotid stenosis have consistently shown higher rates of procedural stroke in patients treated by stenting compared with endarterectomy. Stenting appears to be particularly hazardous in elderly patients, contrary to what might have been expected. However, subgroup analysis of the trial data has shown that patients younger than 70 years of age have a similar risk of procedural stroke comparing stenting with surgery, as do patients with less than average severity of white matter lesions on brain CT or MRI. Long-term follow-up in the trials have shown that stenting has a similar effectiveness compared with endarterectomy at preventing recurrent ipsilateral stroke after the periprocedural period. On the basis of this evidence carotid endarterectomy should remain the treatment of choice for symptomatic carotid stenosis in patients suitable for surgery except in younger patients and those with little white matter disease in whom stenting can be considered if appropriate carotid stenting expertise is available. Stenting remains an option in specific situations such as cases where surgery is not

**Figure 5.28** Left carotid stenosis; stent passes from CCA into ICA (catheter angiogram).

appropriate or particularly risky (e.g. ‘hostile neck’ secondary to previous radiotherapy) or in patients with significant cardiac risk. There are currently insufficient data concerning the safety of stenting compared with endarterectomy for asymptomatic carotid stenosis to form firm conclusions, but trials specifically examining this question are in progress.

### Vertebral stenosis

Posterior circulation stroke secondary to vertebrobasilar stenosis is not usually treated by surgical methods because of difficulty with access and then stenting is the only available treatment other than medical therapy. In the same way that stroke recurrence in the anterior circulation is highest in the presence of a symptomatic internal carotid artery stenosis so the recurrence rate for posterior circulation events is higher when a vertebrobasilar stenosis is demonstrated. The risk of recurrence is highest with intracranial stenosis and has been shown in one pooled analysis to be 33% at 90 days compared to 16.2% for extracranial vertebral artery stenosis and 7.2% when no stenosis is demonstrable. Current evidence suggests that stenting for proximal vertebral artery stenosis is relatively safe.

### Intracranial artery stenosis

Angioplasty and stenting are occasionally used to treat proximal MCA stenoses but treatment at this site has considerable hazards and is usually regarded as a last resort for patients with severe stenosis and recurrent symptoms unresponsive to other treatments. The Stenting versus Aggressive Medical Management for Preventing Recurrent Stroke in Intracranial Stenosis (SAMMPRIS) study compared stenting using the Wingspan stent system against intensive medical therapy for recently symptomatic intracranial artery stenosis and was terminated early because of excess stroke and death at 30 days in the stented group (14.7% versus 5.8%). The final results of the trial showed that even with longer follow-up, the patients who were treated with intensive medical therapy alone still had a significantly lower rate of stroke than those allocated stenting. With time, better methods of dilating intracranial stenosis will become available but SAMMPRIS is also notable for the relatively low rate of recurrent stroke in the medically treated group when compared to previous reports of very high recurrence rates in such patients. This low rate of recurrence has been attributed to the intensive blood pressure and cholesterol reduction, short-term dual antiplatelet treatment with aspirin plus clopidogrel and frequent follow-up to encourage compliance with medication and lifestyle measures. The risks for recurrent stroke are highest in the immediate period post stroke or TIA referable to the stenosis, for high grade stenosis and in cases where there is poor collateral supply to the distal territory.

## Non-atherosclerotic vascular disease and other rarer causes of stroke

Although the majority of patients with ischaemic arterial stroke and primary intraparenchymal haemorrhage have atherosclerosis, there are several important non-atherosclerotic vasculopathies, including extracranial arterial dissection and conditions associated with vasculitis.

### Carotid and vertebral artery dissection

Cervicocephalic dissections of the vertebral or carotid arteries should be especially considered in young patients. Although many disease processes that may be associated with dissection (e.g. Marfan’s syndrome, Ehlers–Danlos syndrome and fibromuscular

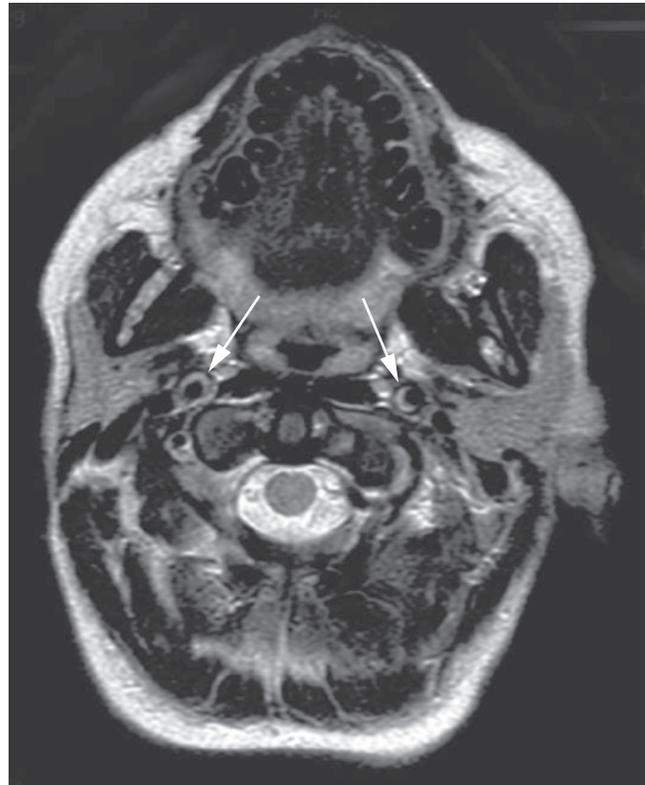

dysplasia), the vast majority occur in apparently normal subjects after trivial neck trauma (e.g. minor whiplash injuries) or apparently spontaneously. The incidence of dissection resulting from major head and neck trauma is surprisingly low at around one case per 10 000 patients with head or neck trauma of sufficient severity to be admitted to hospital. In otherwise spontaneous dissection, hyperextension of the neck during hair washing in the salon or when painting a ceiling, are common preceding events. Whether these apparent precipitants are relevant or not is unclear. In particular, dissection is often attributed to manipulation of the neck, but epidemiological evidence suggests that in many cases it may be neck pain from the dissection that has taken the patient to a chiropractor or other therapists in the first place. New evidence is emerging that many of these patients probably have subtle underlying collagen defects that may make them particularly vulnerable to even normal neck movement. These patients may have fragments of Marfanism. For example, they may be entirely double-jointed, or they may have a relative with Marfan's syndrome.

Fibromuscular dysplasia, a non-atheromatous condition that may involve all three arterial wall layers, can affect many systemic arteries. It is most commonly described in middle-aged women. Bilateral ICA involvement is common, sparing the bifurcation and intracranial carotid artery. In fibromuscular dysplasia, dysplastic fibrous tissue and proliferating smooth muscle cause constricting areas interspersed with areas of dilatation. This is responsible for the characteristic sign on angiography – the 'string of beads' sign. Many of these lesions are benign or present with benign symptoms (e.g. pulsatile tinnitus) but stroke may occur from embolism or occlusion. The recurrence rate of stroke is low. However, patients with fibromuscular dysplasia have a high incidence of intracranial aneurysms and SAH.

Dissection is produced by the subintimal penetration of blood and subsequent extension between the vessel layers resulting in an intramural haematoma, which expands the artery. This may narrow the lumen and lead to occlusion of the vessel but more often the dissection exposes a thrombogenic surface on which intraluminal haematoma develops. This haematoma may then embolise and produce stroke. Occasionally, a free flap of intima may protrude into the lumen of the artery without an evident mural haematoma or there may be only a small tear of the intimal surface leading to thrombosis. The latter mechanism is very difficult to demonstrate in life. The vast majority of cases of dissection affect the extracranial carotid and vertebral arteries and usually start at the level of C1/2, probably because the vertebral and carotid arteries lie close to the transverse process of C1 and are injured during neck rotation. Dissection appears to be less common in older patients, perhaps because atherosclerosis renders the cervical arteries less flexible. Intracranial dissection is much rarer but usually leads to SAH because of the thinness of the muscular wall of the intracranial arteries, which is sometimes catastrophic. Occasionally, intracranial dissection cuts through perforating vessels and present as stroke.

The classic clinical scenario is of the precipitating event to be followed shortly by the development of neck pain and headache. There may be a delay of several days, sometimes weeks before embolisation causes stroke. Patients more often present when stroke has occurred. In some, dissection may never give rise to symptomatic embolisation but in others dissection may be instantly associated with devastating cerebral infarction. Asymptomatic dissection may be recognised by chance during imaging for another indication and is sometimes bilateral in a patient with unilateral symptoms. Although any stroke syndrome may occur as a complication of dissection, the

presence of a Horner's syndrome may be particularly alerting. In the carotid circulation, this will be caused by involvement of the ascending sympathetic fibres surrounding the ICA in the neck. In the vertebral-basilar circulation this may result from embolic occlusion of the posterior inferior cerebellar artery with resultant infarction of the dorsolateral medulla where the descending sympathetic tracts lie (lateral medullary syndrome). Some patients present with a painful Horner's syndrome alone brought about by carotid dissection. Occasionally, carotid dissection causes compression of a lower cranial nerve or nerves within the jugular foramen (e.g. a unilateral XIIth nerve lesion causing deviation of the tongue). MRI or CTA provides a sensitive and non-invasive means to confirm dissection. MRI fine-cut axial imaging with sequences that suppress signal from fat through the neck may reveal the characteristic crescentic vessel wall haematoma and flow-related MRI (Figure 5.29). Catheter angiography may show tapering luminal compromise or, rarely, an intimal flap. Carotid imaging is easier to interpret than vertebral imaging; as the vertebral artery is wrapped at some points in a venous plexus this sometimes give the artificial appearance of crescentic haematoma on cross-sectional MRI. The dissection should be followed on MRI and/or CT because about 50% show recanalisation (allowing anticoagulation or antiplatelet therapy to be discontinued) and rarely a false aneurysm develops. These are usually asymptomatic but exceptionally rarely may expand resulting in a retropharyngeal mass effect. Carotid ultrasound may show the characteristic features of a distal stenosis beyond the site of intonation, but is not as sensitive as other techniques. If the artery is completely occluded it may be difficult to confirm a suspicion of

**Figure 5.29** Axial T2 MRI through the skull base showing bilateral ICA dissection. Flow voids indicate patency of each arterial lumen; the crescent-shaped hyperintensity is the intramural thrombus on each side (arrows).

dissection – ultrasound does not visualise the site of the mural haematoma, and dissection can only be inferred on MRI if the occluded distal carotid or vertebral artery appears expanded.

There is no agreed protocol for prevention of (further) stroke events associated with a demonstrated acute dissection. Antithrombotic therapy with either anticoagulation or antiplatelet drugs has long been used but the two treatments were only recently compared in the CADISS trial, which enrolled subjects with extracranial carotid or vertebral dissection and randomly assigned them to either antiplatelet or anticoagulant treatment for 3 months. There was no significant difference between the two groups in terms of stroke recurrence, which occurred in 2% of the antiplatelet group and 1% in the anticoagulant group. There were no deaths in either group but one major bleeding occurred in the anticoagulant group.

Because of the very low rate of recurrence, this trial cannot establish which treatment is superior. However, the data are reassuring, and most physicians now use antiplatelets in preference to anticoagulation for secondary and/or primary prevention of stroke following cervical artery dissection, as it is much less complicated to administer and possibly safer. Anticoagulation should definitely be avoided in those with a volume of infarction exceeding one third of the MCA territory, large territory cerebellar infarction and in intradural dissection. Stenting in the acute phase is hardly ever necessary but may have a role for recurrent events especially when brought about by haemodynamic and/or perfusion failure. In patients with false aneurysm formation, follow-up to ensure stability with MRI and/or CT angiography or ultrasound is recommended for 2 years. Progressive expansion may need stenting but is rare. The risk of recurrence of symptomatic dissection in the absence of any underlying collagen disorder or obvious precipitant is around 1% per annum.

### Vasculitis

Vasculitis is believed by some in the differential diagnosis of stroke. Although vasculitis may result in stroke (usually from uncontrolled hypertension), it is exceedingly rare for vasculitis to present simply as stroke. Vasculitis may be of infective origin, necrotising, associated with collagen vascular disease, other systemic disease, hypersensitivity, giant cell or miscellaneous. Neurological investigations, other than the occasional cerebral biopsy, are not particularly helpful in the diagnosis of cerebral vasculitis. If MRI is requested with the words: ‘Stroke – ? vasculitis’, the report is likely to indicate: ‘Vasculitis cannot be excluded.’ Despite this opinion, contrast enhanced MRI can be helpful in suggesting an inflammatory arteriopathy if there is enhancement of both the meninges and parenchyma and MRI sequences sensitive to blood breakdown products may reveal microhaemorrhagic sequelae of active vessel wall disease. Other clues for a vasculitic process on MRI are that the pattern of acute infarction indicates pathology in vessels of a similar caliber, that there is multi-territory and sequentially appearing signal change, or that there is evidence of both acute ischaemia and parenchymal haemorrhage. In systemic and other vasculitides, the diagnosis is based on the extracranial features and typical serology. It is only when the vasculitis is confined to the nervous system (isolated angiitis) that the diagnosis will require more detailed investigation (see also Chapters 9 and 26).

### Infective vasculitis

Infective vasculitis associated with meningitis can occur acutely in the appropriate setting of severe bacterial, fungal, tuberculous or herpes zoster infection. There is nearly always an appropriate preceding history suggestive of a meningo-encephalitis syndrome.

After primary syphilis infection, an obliterative endarteritis affecting the small vessels of the brain may occur with a usual latency of 7 years. Headache and encephalopathy predominate in the prodrome before stroke occurs. Evidence of previous infection is easy to screen for in the blood and those with neurological involvement usually have pleocytosis and positive serology in the CSF (Chapter 9). Enhanced MRI may show chronic syphilitic pachymeningitis with thickening of the meninges. Lyme borreliosis can mimic syphilis.

Viral infection may well be responsible for some cases of vasculitis previously considered idiopathic. Hepatitis B and C and herpes zoster are proven examples. Zoster is the most well-described form of viral arteritis to affect the CNS. The classic scenario is of V<sub>1</sub> shingles followed by brain infarction several weeks later. The infarct is usually ipsilateral to the rash and some patients may have encephalitis. The carotid territory is most commonly involved with occlusion at the siphon or MCA. In children, stroke may follow primary zoster infection (chickenpox). Patients with HIV have higher rates of cerebrovascular disease but there are many mechanisms underpinning this, including atherosclerosis secondary to HIV therapy and hypercoagulability.

Parasites may also be associated with endarteritis. Cysticercosis may be complicated by stroke when cysts lodge in the subarachnoid space leading to meningeal inflammation. The major basal arteries may be affected by this process and asymptomatic angiographic stenosis is more common than stroke.

In cerebral malaria caused by *Plasmodium falciparum*, haemorrhagic stroke may accompany the diffuse brain injury, particularly in children.

### Systemic vasculitides

Systemic vasculitis has been classified immunopathologically, by the nature of the vessel involved or clinically. Most strokes associated with systemic vasculitis are brought about by uncontrolled hypertension, not cerebral involvement, and patients have usually been unwell for a considerable time. When looking at vasculitis through stroke spectacles, vessel size is a good starting point. Issues relevant to stroke are discussed here.

**Large vessel vasculitis** These are Takayasu and giant cell arteritis. Both are granulomatous vasculitides. In giant cell arteritis (Chapter 26), the internal elastic lamina of the extracranial medium sized arteries becomes fragmented and invaded by inflammatory cells. It virtually always occurs in those aged over 50 and in 90% is accompanied by an elevated ESR. Patients complain of headache with scalp tenderness associated with malaise, depression, myalgia and sometimes claudication of the jaw muscles while eating. Examination usually reveals thickened tender temporal arteries. Stroke is a very rare complication of the disease but may occur from involvement of the extradural vertebral artery leading to brainstem infarction. A far more common complication without treatment, or at presentation, is anterior ischaemic optic neuropathy (Chapter 14). Diagnosis is established by temporal artery biopsy. Treatment is with high dose prednisolone, and if the diagnosis is correct the response of the systemic symptoms is dramatic and usually occurs within 1 day. Occasionally, the intracranial ICA may be involved.

Takayasu's arteritis was originally described in Japanese girls and women and is often called pulseless disease. There may be a prodromal phase associated with anaemia and raised ESR followed by severe occlusive disease of the aortic arch and its branches, leading to absent neck and limb pulses. Stroke is not a common feature

but headache, dizziness and syncope are more frequent. The diagnosis of Takayasu's arteritis may be made by ultrasound showing occluded or stenotic large neck vessels at their origin from the aorta with thickened walls. Characteristic sites of involvement include the proximal common carotid artery, subclavian artery and the innominate artery.

**Medium vessel vasculitis** Polyarteritis nodosa (PAN) is the principal medium vessel vasculitis. It is important to remember that PAN is usually ANCA negative. PAN affects medium and small arteries. The most common neurological feature is mononeuritis. CNS involvement may occur in 20%, but it is often late in the disease. Presenting features include cerebral infarction, cerebral haemorrhage and SAH.

**Small vessel vasculitis** Microscopic polyarteritis is usually ANCA positive and affects small vessels, as do Wegener's granulomatosis and Churg–Strauss syndrome. Encephalopathy and peripheral manifestations are common but stroke rare. Exceptional patients have presented with SAH as the first sign of vasculitis.

### Collagen vascular disease

Systemic lupus erythematosus (SLE) commonly causes neurological problems. These often have a neuropsychiatric component and are rarely caused by the vasculitis. Encephalopathy, psychosis, seizures, stroke-like focal deficits, myelopathy and neuropathy are all encountered. At pathological examination the histology is often one of non-specific gliosis although thrombosis may be observed especially in those with a lupus anticoagulant and antiphospholipid antibodies. Echocardiography shows a high frequency of valvular disease in SLE, particularly Libman–Sacks endocarditis, which may lead to cerebral embolism. Myocarditis is also a feature of SLE. Response to immunosuppression of florid neurological involvement is often poor. Lupus may also cause a terminal carotid occlusive syndrome leading to a Moyamoya angiopathy.

### Other vasculitis

Very rarely, true necrotising arteritis can be seen in association with rheumatoid resulting in encephalopathy or small infarcts. Brain infarcts have also been reported in systemic sclerosis along with SAH, but there is a high incidence of hypertension in systemic sclerosis. Sarcoid may occasionally cause a cerebral vasculitis or focal infarction, usually in association with meningeal involvement.

### Isolated angiitis of the central nervous system

This rare condition affects small and medium sized intracranial vessels. It may cause a combination of infarcts and haemorrhages. Presentation is usually chronic with prominent headache, leading to encephalopathy and then stroke-like focal dysfunction. Any age may be affected and there is a male predominance. The disorder may be acute over weeks or subacute. Angiography may reveal segmental narrowing of intracranial vessels but this is neither sensitive nor specific. Many patients have normal angiography. The CSF often shows a pleocytosis with oligoclonal immunoglobulin on electrophoresis. Brain imaging may show multiple small vessel infarcts and sometimes haemorrhages, if advanced. Diagnosis is by meningeal and brain biopsy, which typically shows a granulomatous vasculitis. If patients have neither headache nor CSF

pleocytosis then biopsy rarely shows vasculitis. Treatment is with steroids and cyclophosphamide.

### Thrombotic thrombocytopenic purpura

This is characterised by microangiopathic haemolytic anaemia, thrombocytopenia and systemic microinfarction from platelet-rich thrombi. Renal failure, fever and transient neurological signs, or diffuse encephalopathy, are common. Large vessel infarction and cerebral haemorrhage may also occur. Posterior leukoencephalopathy has been described. The mainstay of treatment is plasma exchange but anticoagulation is sometimes necessary and the decision to do this has to be finely balanced against the risk of haemorrhage.

### Behçet's disease

The common neurological manifestations of Behçet's disease are meningitis, encephalitis with multifocal signs, stroke-like events and dural sinus thrombosis. The lesions of Behçet's disease do not conform to arterial territories, suggesting a venous origin, and usually angiography shows no abnormalities. The brainstem is frequently involved.

### Susac's syndrome

Susac termed this condition a microangiopathy of the brain and retina. The cochlea is also involved. There is always obliteration of the large retinal arteries causing focal scotomata and stepwise visual loss. Tinnitus and sudden hearing loss are common and the principal neurological features are dementia, pyramidal and cerebellar dysfunction. The disorder usually affects young women.

### Sneddon's syndrome

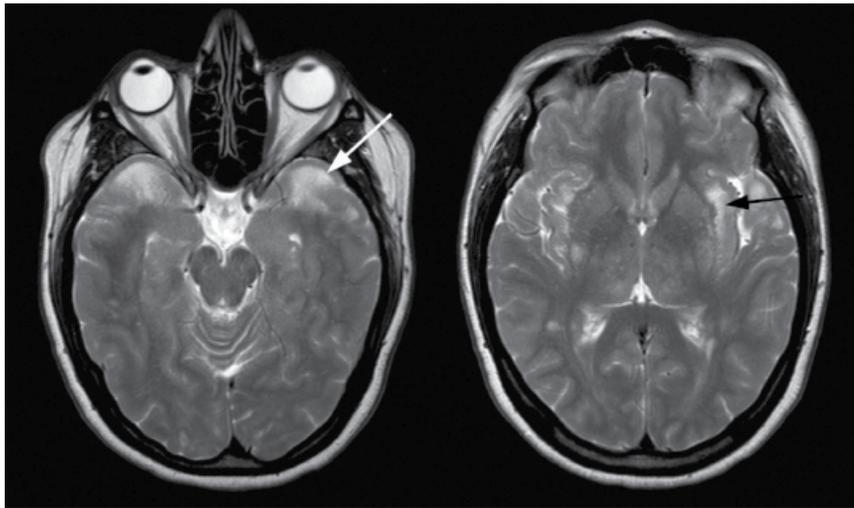

This is characterised by chronic skin lesions, livedo reticularis and stroke. The most important feature is the livedo. Skin biopsy may show distinctive abnormalities in small and medium arteries. Cerebral angiography may show branch intracranial occlusions. Some cases have been attributed to the antiphospholipid antibody syndrome.

### Mitochondrial disease

MELAS syndrome (mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes) is sometimes considered as a differential diagnosis under the young stroke umbrella. Imaging may show multifocal abnormalities most often in the parieto-occipital and temporal lobes. Although the ischaemic lesions affect cortex and underlying white matter, these often cross arterial territories and the arteries supplying these areas are normal on investigation. Other features of a mitochondrial cytopathy are usually present (Chapter 10).

### Fabry disease

Fabry disease is an X-linked liposomal disorder in which there is deficiency of  $\alpha$  galactosidase A. Typical clinical manifestations include painful neuropathy, stroke and renal failure, but young stroke may be the presenting feature. Angiography shows branch artery occlusion caused by the diffuse arteriopathy associated with sphingolipid accumulation. Imaging usually shows features of small vessel disease with a bias towards infarction in the brainstem and posterior circulation territories.

**Figure 5.30** CADASIL. T2-weighted images showing multiple small subcortical infarcts in the deep grey nuclei and white matter with confluent high signal in the temporal poles (white arrow) and external capsules (black arrow) typical of CADASIL.

### CADASIL and CARASIL

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is the most common genetic vascular disorder of the brain and, although rare, does crop up from time to time in vascular clinics. The disorder is characterised by migraine headache often with aura and extensive white matter abnormalities and lacunar infarction. Patients may present with depression, migraine, dementia and/or progressive gait difficulty. MRI often shows characteristic involvement of the temporal white matter (Figure 5.30). Although dominantly inherited, many cases appear to present as new mutations. The diagnosis can be obtained through skin biopsy and genetic testing for the underlying mutation of the NOTCH III gene (Chapter 8). CARASIL is the acronym for same descriptor except that for the inheritance being recessive, not dominant. CARASIL is a very rare disorder and has similar neurological symptoms to CADASIL, but is also characterised by premature alopecia and attacks of back pain secondary to vertebral disc degeneration.

### Hypertensive encephalopathy

This condition, which is now rare, develops if systemic blood pressure exceeds the upper limit of cerebral autoregulation. Oedema develops in the hyperperfused intracerebral circulation. Patients present with headache, fits, focal TIA-like events, stroke and depressed consciousness. In addition, examination may reveal optic disc swelling and microscopic haematuria characteristic of malignant or accelerated hypertension. The blood pressure is usually very high (e.g. 250/150 mmHg) but may be lower. In these patients the rate of blood pressure elevation has often been rapid and brought about by renal disease. Slower elevation allows autoregulatory mechanisms to compensate to some extent. Brain imaging may show a posterior reversible leukoencephalopathy, as well as focal infarcts or haemorrhage. Eclampsia in pregnancy and the puerperium has similar features.

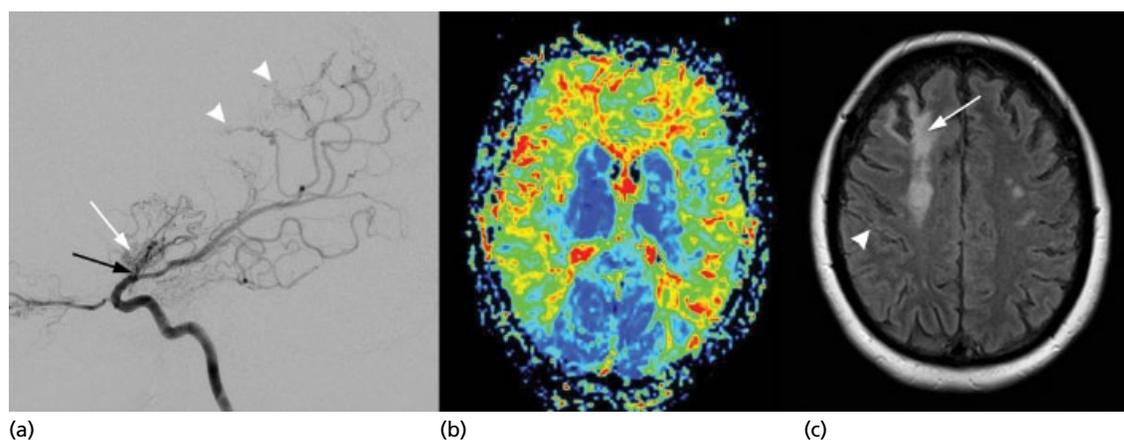

### Migraine and stroke

There is a small but definite increase in stroke incidence in patients with migraine. However, this needs to be interpreted with caution as vascular disease predisposes to migraine headaches and aura.

In particular, carotid artery dissection may precipitate a classic migraine attack with visual aura. There are links between antiphospholipid syndrome, sickle cell disease and possibly PFO with migraine, all of which can cause stroke. Other associations include mitochondrial disease and CADASIL. There remain very rare patients who develop infarction at the peak of a typical migraine attack, for which no other reason can be found. The symptoms of these migrainous strokes mimic the features of the patient's aura, and the associated infarction usually involves the occipital cortex. Hemiplegic migraine is a very rare familial channelopathy. Almost all young patients with migraine-like headache who suffer a hemiplegia have had the stroke from a cause unrelated to migraine. Migraine without aura but particularly migraine with aura are independent risk factors for stroke (Chapter 12). This risk appears to be substantially increased in female migraineurs who smoke, are hypertensive and take the oestrogen-containing contraceptive pill.

### Moyamoya angiopathy

The term Moyamoya ('puff of smoke') angiopathy refers to an angiographic appearance in which terminal carotid occlusion is associated with the development of a fine and friable network of basal collateral vessels. Moyamoya disease is a distinct condition, prevalent in Japan but also occasionally seen in the West, in which a symmetric progressive and obliterative intracranial arteriopathy develops, causing stenosis and occlusion of the basal vessels, usually the termination of both internal carotid arteries and the M1 segment of the MCA (Figure 5.31). Early or arrested cases may show involvement of only one side, but this can progress to bilateral involvement. The basilar and vertebral arteries are very rarely affected and never in isolation. The term Moyamoya syndrome is used when similar appearances occur in association with identifiable causes such as radiotherapy and sickle cell disease. Moyamoya disease presents most often in children with TIA, ischaemic stroke, chorea, severe migrainelike headaches or seizures. Some patients appear to stabilise clinically in late adolescence, although long-term follow-up studies are lacking. Adults may present with similar symptoms and the likelihood is that the condition starts in childhood and those presenting in adulthood either have a slower rate

**Figure 5.31** Moyamoya. (a) Internal carotid artery digital subtraction angiogram showing occlusion of the vessel just distal to the posterior communicating artery (black arrow) and typical Moyamoya collateral vessels (white arrow). Pial collaterals arise from posterior cerebral artery branches (white arrowheads). (b) Perfusion MRI shows abnormal mean transit time throughout the middle and anterior cerebral artery territories with sparing of the basal ganglia and tissue supplied by the posterior cerebral arteries (blue voxels). (c) Right anterior border-zone infarcts (white arrow) and sulcal hyperintensity ('ivy sign') (arrow head) representing distended pial vessels are seen on FLAIR.

of progression or they develop better collateralisation that only fails when they develop additional vascular disease from smoking, hypertension or atherosclerosis. Adults can also present later in life with ICH from rupture of the friable collaterals. Treatment options include surgical revascularisation, either extracranial–intracranial bypass or synangiosis, a procedure in which vascularised omentum or muscle is juxtaposed to the brain. Children are usually prescribed aspirin, but this should be stopped in adults because of the risk of haemorrhage. Intensive and early control of vascular risk factors, including mild hypertension and elevated cholesterol levels, is key to preventing deterioration in adults.

### Cerebral venous thrombosis

Cerebral venous thrombosis is often considered under the umbrella of stroke but is a condition with diverse manifestations that mimic many other neurological disorders. It is increasingly recognised because of enhanced awareness and the use of MRI. Venous thrombosis may be septic or non-septic. Septic causes are increasingly rare but cavernous sinus thrombosis secondary to facial cellulitis and lateral sinus thrombosis secondary to purulent otitis media or mastoiditis are still seen. Septic thrombophlebitis of the cortical veins may also be associated with severe bacterial meningitis.

Aseptic thrombosis can affect the cortical veins, dural sinuses and deep veins. There are numerous potential causes. The most common are raised oestrogen levels in women, associated with pregnancy, the puerperium and the contraceptive pill. There are no reliable estimates of incidence although venous thrombosis may complicate 11/100 000 deliveries. Other factors include dehydration in association with systemic disease, thrombophilia (particularly the factor V Leiden polymorphism), activated protein C resistance and Behçet's syndrome. It has become clear that such external factors pose far more significant risk for recurrent thrombosis than inherited thrombophilias (Table 5.21). In 20% of cases of venous thrombosis no aetiology is uncovered.

The clinical syndrome that results from cerebral venous thrombosis may be acute or subacute. The most frequent manifestations are headaches, seizures, altered consciousness, focal signs and

optic disc swelling. Hence, cerebral venous thrombosis should be considered in the differential diagnosis of patients presenting with severe headache, seizure disorders, coma, stroke, acute meningoencephalitis syndromes or isolated intracranial hypertension, mimicking idiopathic intracranial hypertension. Venous sinus thrombosis can cause headache, sometimes thunderclap, as the only feature. Only 50% of patients have papilloedema.

Venous thrombosis results in venous hypertension that leads to raised intracranial pressure. This may give rise to a syndrome of headache with papilloedema and normal CT imaging, initially identical to idiopathic intracranial hypertension. However, as the venous pressure rises, forced local arterial hypertension can lead to cerebral haemorrhage. Alternatively, or in addition, spread of the thrombus to cortical veins results in venous infarction, which is often haemorrhagic and results in focal neurological deficit and depression of consciousness.

Patients with venous sinus thrombosis may be severely ill and such patients often present to neurosurgeons as cases of primary intracerebral haemorrhage in coma. However, the radiological findings are usually distinct from both arterial ischaemic stroke and intracerebral haemorrhage. Venous infarction is characterised on imaging by vasogenic as opposed to cytotoxic oedema. These areas do not confine themselves to vascular territories and are often haemorrhagic. The thrombus in the venous sinuses may be visible on plain MRI although false negatives occur in the hyperacute (first few days) and chronic phases (1–2 months) necessitating flow-related imaging (Figure 5.32). Sometimes, the flow-related imaging can be difficult to interpret, especially whether the transverse sinus on the left is hypoplastic (a common variant) or thrombosed. If sufficient clinical suspicion exists and MR/MRV are negative, we recommend CT angiography or, if necessary, catheter angiography. Depending on local practice, CT angiography may be the investigation of choice. Rarely, venous sinus thrombosis is the result or the cause of dural fistulae and this often needs full intra- and extracranial angiography to diagnose.

The most common sinus involved is the sagittal sinus, followed by the lateral sinuses. Cortical veins may rarely be involved in isolation (Figure 5.33). Imaging proof of isolated cortical venous thrombosis is difficult. Often one has to embark on treatment on the basis

**Table 5.21** Causes of cerebral venous thrombosis.

Prothrombotic disorders	Polycythaemia Paroxysmal nocturnal haemoglobinuria Sickle cell Haemolytic anaemia Factor V Leiden Protein C and S deficiency Antothrombin III Prothrombin gene mutation DIC Antiphospholipid syndrome
Malignancy	Visceral carcinoma Carcinoid Lymphoma Myeloproliferative disease
Drugs	Combined contraceptive pill Hormone replacement therapy Heparin-induced thrombocytopenia Ovarian hyperstimulation
Pregnancy and the puerperium	
Systemic inflammatory disease	Behçet's Systemic lupus erythematosus Sarcoidosis Giant cell arteritis Granulomatosis with polyangiitis (Wegener's) Thrombangitis obliterans Inflammatory bowel disease (Crohn's disease and ulcerative colitis)
Severe dehydration	Any cause including exercise
Systemic infection	Septicaemia Endocarditis TB Malaria Aspergillosis
Cardiac	Congenital, CCF
Vascular malformation	Dural AV fistulae
Others	Nephrotic syndrome Head injury Low CSF pressure
Local cranial causes	Extradural infection: facial cellulitis, mastoiditis, sinusitis Intradural: abscess, meningitis Tumour: metastasis, meningioma
Idiopathic	Intravenous cannula

CCF, congestive cardiac failure; CSF, cerebrospinal fluid; DIC, disseminated intravascular coagulation; TB, tuberculosis.

of the clinical presentation and MRI of a presumed venous infarct. Thrombosis of the deep venous system is rare in adults and gives rise to thalamic venous infarction with prolonged coma.

Cavernous sinus thrombosis should be considered a separate entity as it is most commonly caused by local sepsis rather than primary or secondary non-septic hypercoagulable states. It is a

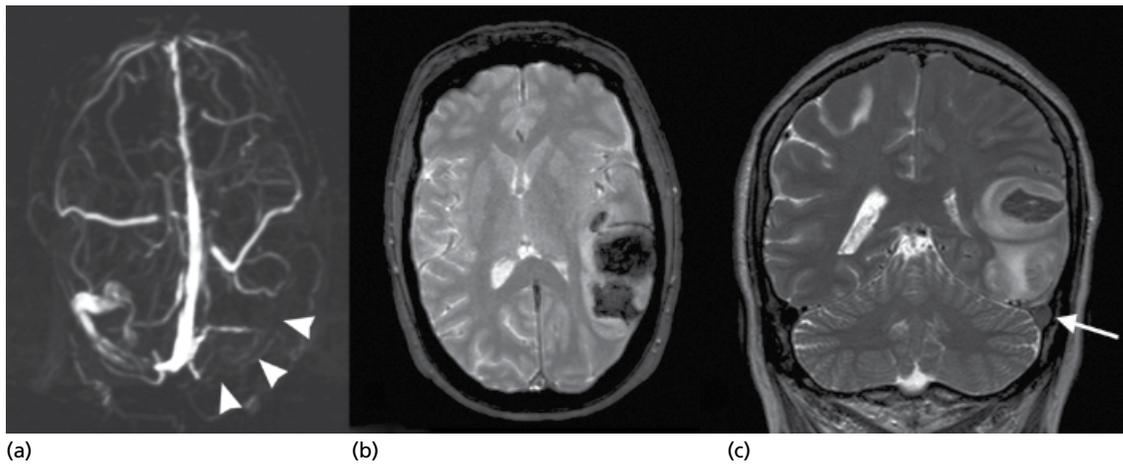

serious disease with a high mortality. The veins draining the face are the common portals, hence the view that facial cellulitis is also a very serious condition. The early symptoms are pain, headache, fever, facial oedema then proptosis and ophthalmoplegia (Chapter 14). The principal treatment is antibiotics. Non-septic cavernous sinus thrombosis may follow head injury and thrombosis within dural cavernous arteriovenous fistulae. Cavernous sinus thrombosis rarely presents to stroke neurologists, but is seen more commonly in ophthalmological and emergency medical practice.

The accepted treatment of intracranial venous thrombosis is anticoagulation, whether haemorrhage is present or not. The evidence for this is controversial. Anticoagulants were first given to prevent pulmonary embolism from intracranial thrombosis. Early studies suggested that patients treated with anticoagulants had a 7% mortality compared with 37% if untreated. A small prospective trial and retrospective analysis also suggested a significant survival benefit with anticoagulation and also the safety of heparin in the presence of haemorrhage. Later studies have suggested no advantage to heparin but were weighted toward less sick patients with indolent intracranial hypertension presentations, and better than expected outcomes in the placebo arm. It is the general view from clinical practice that anticoagulation is an essential treatment for these patients. The favoured method is subcutaneous low molecular weight heparin rather than intravenous heparin unless surgery is contemplated. The literature supports the safety of heparin in haemorrhage. In addition to anticoagulation, sepsis must be identified and treated with antibiotics and drainage where appropriate (e.g. mastoiditis). Patients with significant intracranial pressure will need ventilation and occasionally consideration for craniotomy. Our policy following venous thrombosis is to anticoagulate for 6 months, or for longer terms if a persisting reason for hypercoagulability persists. In patients with disc swelling, vision should be monitored using a visual field screen (e.g. Goldmann) at regular intervals. Visual obscuration (Chapter 14) is a sign of incipient optic nerve infarction. Optic nerve fenestration, therapeutic lumbar puncture, lumbo-peritoneal shunting and acetazolamide all have their place in management. Recently, thrombolytic agents delivered by a transvenous endovascular route have been used to treat patients with sinus thrombosis and may be safe with haemorrhage. Early studies show promising results, but our current policy is to reserve this for patients not responding to, or worsening on, heparin.

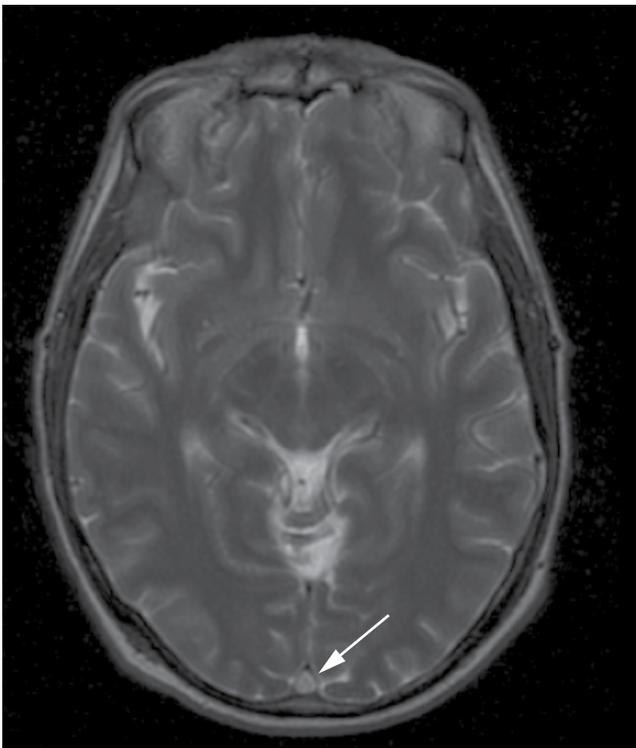

The outcome of venous thrombosis tends to be polarised. Usually, patients either make a good recovery or die. Good outcome may be seen in up to 85%, death in 12% and the remainder have an intermediate outcome. Mortality is higher with age and in association with infection or cancer. Seizures occurring during the acute phase have a good long-term prognosis with low rate of recurrence. Recurrent thrombosis may be seen in 10–20%, usually in the first year. The necessity for long-term anticoagulation after the first thrombosis is based on identifying ongoing active risk factors and the strategy is identical to that applied to limb venous thrombosis.

## Reversible cerebral vasoconstriction syndrome

Reversible cerebral vasoconstriction syndrome (RCVS) is characterised by transient dysregulation of cerebral vascular tone leading to prolonged but reversible constriction of intracranial arteries, with resolution within 3 months. It is an increasingly recognised

**Figure 5.32** Venous infarct. (a) MR venogram viewed as if looking from above the patient towards the feet. No flow is visible in the occluded left transverse sinus (arrowheads). (b,c) T2\*-w axial and T2-w coronal images showing a haemorrhagic venous infarct in the left temporal lobe. Note abnormal signal in the thrombosed left transverse sinus (arrow) immediately below the infarct.

**Figure 5.33** Absence of flow in the superior sagittal sinus on T2 MRI due to thrombosis (arrow).

syndrome, and a common medical condition transferred to neurosurgeons.

The most common clinical presentation is with severe acute headache (typically thunderclap), with or without additional neurological symptoms including focal neurology and seizures. Most patients (>90%) will present with recurrent thunderclap headaches. The syndrome may be spontaneous (idiopathic), or may occur secondary to a precipitant (25–60%). Reported precipitants include vasoactive substances, pregnancy or puerperium, catecholamine-secreting

tumours, and immunosuppressants or blood products. The most commonly reported precipitants are serotonin selective re-uptake inhibitors, cannabis and cocaine, and over-the-counter nasal decongestants. A trigger immediately prior to the onset of headache is recounted by 80% of patients, including sexual intercourse, straining, physical exertion, urination, high emotional state, showering and head movements.

Complications of RCVS include seizures, SAH and intracerebral haemorrhage during the first 7 days after headache onset when small calibre vessels are affected, followed by ischaemic infarcts during the second week when medium and larger calibre arteries are affected. SAH is of small volume and tends to be localised, overlying the cortical surface.

CT/MR brain imaging at presentation is frequently normal. Angiography shows multifocal segmental narrowing and dilatation, in a 'string of beads' pattern. Serial angiography has found peak involvement of arterial segments 16 days after headache onset, with unsynchronised progression and regression of vasoconstricted arterial segments. Complete reversal of angiographic abnormalities is apparent between 1 and 3 months after presentation. The differential diagnosis for a single thunderclap headache includes primary headache syndromes, aneurysmal SAH, intracranial haemorrhage, cervical or intracranial dissection, hypertensive encephalopathy, post-partum vasculopathy, venous thrombosis, giant cell arteritis and pituitary apoplexy. Recurrent thunderclap headaches are much more likely to be RCVS or primary headache syndromes.

The following diagnostic criteria for RCVS have been proposed:

- 1 Acute severe headache with or without neurological signs or symptoms
- 2 Multifocal segmental vasoconstriction of cerebral arteries demonstrated by angiography
- 3 No evidence for aneurysmal SAH
- 4 Normal or near-normal CSF analysis (protein <1 g/L, white cells <15 mm<sup>3</sup>, glucose normal)
- 5 Reversibility of angiographic abnormalities within 12 weeks after onset.

Initial management includes cessation of potential precipitants, blood pressure control and medical management of seizures.

There have been no clinical trials evaluating pharmacotherapy in RCVS and open studies have not found any significant clinical benefit with calcium channel blockers or glucocorticoids. Calcium channel blockers (particularly nimodipine) are frequently used as vasodilators, but care must be taken to avoid hypotension and subsequent border-zone infarction in areas perfused by the constricted artery.

The prognosis in RCVS is favourable, with excellent recovery in uncomplicated cases.

## Vascular disease of the spinal cord

The spinal cord is most often affected by occlusion of the anterior spinal artery which supplies the anterior two-thirds of the cord. The blood supply is most tenuous in the upper thoracic region of the cord, which is a border-zone region. Although the anterior spinal artery is vulnerable to aortic dissection, most patients with anterior spinal artery occlusion presenting to a neurologist have atherosclerosis secondary to multiple risk factors, especially hypertension and diabetes. The dorsal columns are spared (because of a rich plexal supply) after the anterior spinal artery occludes. The resultant clinical picture is that of acute areflexic paraplegia characterised by dissociated sensory loss, with striking preservation of joint position and vibration sense but marked loss of pinprick and temperature sensation. Paraplegia is also well recognised following aortic surgery. There is a vogue still for anticoagulation of these patients and placement of a lumbar drain but little evidence to support these measures.

The spine can also be affected by AVMs and dural fistulae. Dural fistulae present with symptoms resulting from venous hypertension and cord ischaemia. Bleeding does not occur from spinal dural fistulae, unlike their cranial counterparts. They often present in elderly men with step-wise cauda equina symptoms with prominent exercise exacerbation. MRI virtually always shows dilated draining veins and treatment may be possible with embolisation or surgery. The remainder of spinal AVMs are mostly intramedullary; they present in younger men with cord syndromes, cord or epidural bleeding. Treatment is often difficult, and unsatisfactory. Other features of vascular cord disease are discussed in Chapters 16 and 26.

## Stroke: overall conclusions

Stroke is a varied and challenging speciality. There is a diverse age range at presentation and a multitude of systemic issues that need to be dealt with. It is a speciality for those who enjoy multidisciplinary working, both within a medical context and across professions. Stroke is also high risk, patients can become unwell very quickly, and re-admission is common after minor stroke or TIA, because of deterioration and even when all risk factors have been adequately addressed. Well-planned intervention can also go wrong, but the discipline is underpinned by a rich evidence base to guide practice and new trials to answer unknowns are always being constructed.

## CHAPTER 6

# Movement Disorders

Kailash Bhatia<sup>1</sup>, Carla Cordivari<sup>2</sup>, Mark Edwards<sup>1</sup>, Thomas Foltynie<sup>1</sup>, Marwan Hariz<sup>1</sup>, Prasad Korlipara<sup>2</sup>, Patricia Limousin<sup>1</sup>, Niall Quinn<sup>1</sup>, Sarah Tabrizi<sup>1</sup> and Thomas Warner<sup>1</sup>

<sup>1</sup>UCL Institute of Neurology

<sup>2</sup>National Hospital for Neurology & Neurosurgery

Movement disorders are common causes of disability, especially in older people. They either cause poverty of movement or unwanted, involuntary movements. Much early work in the field was pioneered by Kinnier Wilson and Purdon Martin at The National Hospital, and many others elsewhere. David Marsden, in London and Stanley Fahn (the Neurological Institute, New York) founded the Movement Disorder Society and its journal *Movement Disorders*. This chapter provides an overview of the different forms of parkinsonian and dyskinesic disorders.

### Parkinsonian (akinetic-rigid) syndromes

#### Cardinal motor features of parkinsonism

Akinesia is the defining and principal disabling feature of parkinsonism (Table 6.1). It is a symptom complex, comprising slowness of movement (bradykinesia), poverty of movement and small amplitude of movements (hypokinesia), difficulty initiating movement or with simultaneous motor acts and, most specifically, fatiguing and decrementing amplitude of repetitive alternating movements, which distinguish true akinesia from pyramidal or cerebellar slowing. Almost all individuals with parkinsonism also display muscular rigidity to passive movement across a joint. Unlike spasticity, it is fairly equal in flexors and extensors, and may feel like bending a lead pipe; the presence of additional tremor (which may not be visibly evident) can add a ratchety 'cogwheel' feel to the rigidity (tremor alone can cause cogwheeling, but without rigidity).

Tremor is an optional feature of parkinsonism, and indeed of Parkinson's disease (PD) itself. Up to 80% of PD patients will display a tremor at some stage. Classically, this is in the form of a 4–6 Hz rest tremor which, in the hand, is 'pill-rolling' with flexion of the thumb. It typically subsides or lessens with movement, to reappear after an interval when a new static position (e.g. arms outstretched) is achieved ('re-emergent tremor'). A number of patients can additionally, or instead, display a faster postural tremor. A classic rest tremor, particularly if accompanied by a jaw tremor, is a strong pointer to PD or drug-induced parkinsonism, but this combination can also be seen in dystonic tremor. Classic rest tremor is uncommon, and jaw tremor rare, in other degenerative forms of parkinsonism. To the above triad a fourth 'cardinal' motor feature of parkinsonism is sometimes added – postural abnormality. Flexed posture may or may not be evident early in the disease, and postural

instability is typically a late feature in PD, so this item is not usually useful for diagnosing PD, although if present early on can point to alternative causes of the syndrome.

Molecular advances have revealed helpful schemata for classifying the principal degenerative parkinsonisms into alpha-synucleinopathies, including PD, dementia with Lewy bodies (DLB) and multiple system atrophy (MSA), and tauopathies, including progressive supranuclear palsy (PSP) and corticobasal degeneration (CBD).

#### Parkinson's disease

PD has traditionally been, and continues to be, defined as a clinicopathological entity, in which progressive levodopa-responsive parkinsonism, without atypical features (see later), is associated, at postmortem, with neuronal loss and the presence of intracytoplasmic, eosinophilic, alpha synuclein containing inclusions known as Lewy bodies in specific central and autonomic nervous structures. These include particularly the pigmented brainstem monoaminergic nuclei, the substantia nigra (dopaminergic) and locus caeruleus (noradrenergic). However, the pathology is usually much more widespread, also involving serotonergic raphe nuclei, dopaminergic mesolimbic, mesocortical and tubero-infundibular pathways, the cholinergic nucleus basalis of Meynert (NBM), the cerebral cortex, the hypothalamus, the dorsal motor nucleus of vagus, the olfactory tract and sympathetic ganglia. The pathological criteria have been correlated in detail with the classic clinical PD phenotype lending support to the continued use of diagnostic criteria as elaborated in 1988 by the Queen Square Brain Bank (Table 6.1).

The prevalence of PD in most countries is around 180/100 000. Overall, incidence rises steadily with age with an average age at onset of about 60 years, and fewer than 5% of cases starting before age 40. Despite modern treatment, life expectancy is still reduced, with a standardised mortality ratio of about 1.9.

Clinical heterogeneity has long been recognised within 'PD', and the concept of PD as a single entity has been turned upside down with the identification of individuals and familial kindreds carrying any of a variety of genetic mutations now known to be causally related to PD pathogenesis. For example, mutations in two genes (*alpha-synuclein* and *LRKK2*), or duplications or triplications of *alpha-synuclein*, can cause dominantly inherited or sporadic parkinsonism accompanied by Lewy bodies in the brain. On the other hand, mutations of three recessive genes (*parkin*, *DJ1* and *PINK1*)

**Table 6.1** UK PDS Brain Bank diagnostic criteria for Parkinson's disease.**STEP 1. Diagnosis of a parkinsonian syndrome**

Bradykinesia (slowness of initiation of voluntary movement with progressive reduction in speed and amplitude of repetitive actions) – obligatory

And at least one of the following:

- Muscular rigidity
- 4–6 Hz rest tremor
- Postural instability not caused by primary visual, vestibular, cerebellar or proprioceptive dysfunction

**STEP 2. Exclusion criteria for Parkinson's disease**

History of repeated strokes with stepwise progression of parkinsonian features

History of repeated head injury

History of definite encephalitis

Oculogyric crises

Neuroleptic treatment at onset of symptoms

More than one affected relative

Sustained remission

Strictly unilateral features after 3 years

Supranuclear gaze palsy

Cerebellar signs

Early severe autonomic involvement

Early severe dementia with disturbances of memory, language and praxis

Babinski sign

Imaging evidence of a cerebral tumour or communicating hydrocephalus

Negative response to large doses of levodopa if malabsorption excluded.

MPTP exposure

**STEP 3. Supportive prospective positive criteria for Parkinson's disease**

(Three or more required for diagnosis of definite Parkinson's disease)

Unilateral onset

Rest tremor present

Progressive disorder

Persistent asymmetry affecting the side of onset most

Excellent response (70–100%) to levodopa

Severe levodopa-induced chorea

Levodopa response for 5 years or more

Clinical course of 10 years or more

can present mainly in younger individuals with clinical PD without Lewy bodies. The list of *PARK* genes and loci is increasing exponentially, with more still to be identified. How many of these should still be called PD is a moot point. The phenotypes of these monogenic

'PDS', especially of *LRKK2* cases, can be indistinguishable from typical sporadic PD. However, patients with *alpha-synuclein* mutations or triplications have somewhat younger onset, shorter survival and a higher incidence of dementia. Although *alpha-synuclein* mutations are rare, excessive levels of otherwise normal *alpha-synuclein*, as a result of gene duplications or triplications, are sufficient to cause dominantly inherited Lewy body parkinsonism. Furthermore, in meta-analyses of thousands of apparently 'sporadic' PD patients, the strongest whole genome association is with common variation in the *alpha-synuclein* gene. Evidence is emerging that exogenous fibrils of *alpha-synuclein* can enter neurones (by a form of endocytosis), and promote recruitment of endogenous *alpha-synuclein* leading to the formation of Lewy bodies. This reinforces the theory that Lewy body pathology is potentially 'transmissible' from one neurone to the next, as has been observed in the clinical trials of fetal cell transplantation for PD. Another rare cause of monogenic autosomal dominant PD are mutations in the *VPS35* gene.

The recessive forms have younger onset, slower disease progression and present with leg tremor more often than sporadic PD. In independent populations mutations in the glucocerebrosidase (*GBA*) gene can cause either familial or seemingly sporadic PD. A mutation in a single copy is associated with an increased risk of PD, and of dementia within PD. Table 6.2 lists the currently identified *PARK* genes and loci. Overall, monogenic PD accounts for about 6–8% of all PD. However, different genetic causes vary in frequency in different populations (e.g. both *GBA* and *LRKK2*-related parkinsonism is particularly common in Ashkenazi Jews and *LRKK2*-related parkinsonism in North Africans). Overall, incidence rises steadily with age, although recessive forms become less frequent with age.

Molecular advances have introduced alternative schemata for classifying the principal degenerative parkinsonisms into *alpha-synucleinopathies* (Lewy body diseases and MSA), *tauopathies* (including PSP and CBD), and others (e.g. cases with parkin mutations). Table 6.3 summarises causes of parkinsonism and other conditions sometimes confused with PD.

PD has been traditionally defined as a motor disorder, but the frequency and importance of premotor and non-motor features is increasingly recognised.

**Premotor features of PD**

All neuronal systems have built-in reserves which allow a degree of neuronal loss to be tolerated, and which can be compensated for by up-regulation of surviving neuronal function before a threshold is reached at which point symptoms become apparent. Thus, 60–80% of nigrostriatal dopaminergic reserve is lost before the motor features of parkinsonism emerge. Brains with 'subclinical' nigral Lewy bodies have been called 'incidental Lewy body disease'. Sequential fluorodopa positron emission tomography (PET) scans have been used to estimate, by back-extrapolation, the duration of the presymptomatic phase of PD, with estimates varying between 3 and 6 years. However, a number of pathological and clinical observations have questioned this. Thus, Braak *et al.* (2006), based on examination of Lewy body pathology in a large number of brains of individuals with and without clinical parkinsonism in life, postulated 6 'stages' of PD. In stages 1 and 2, Lewy bodies are restricted to the medulla, pontine tegmentum and anterior olfactory structures, and it is only in stage 3 that the nigrostriatal tract is first involved. Thus, back-extrapolation from fluorodopa PET scans can only, at best, tell us when stage 3 might begin. Clinically, constipation, dysphagia, olfactory impairment, cardiovascular autonomic involvement and REM sleep behaviour disorder (RBD) can

AD, autosomal dominant; AR, autosomal recessive; EOPD, early onset Parkinson's disease; YOPD, young onset Parkinson's disease (usually before 40 years).

\**PARK4* is an erroneous locus; the family was subsequently proven to have an *SNCA* triplication (i.e. *PARK1*).

precede, by many more years, the appearance of the motor disorder in PD. In RBD there is loss of the usual muscle atonia that accompanies dreaming, such that the individual is able to 'act out' usually frightening dreams, often striking or injuring their bed-partner, and often with vocalisations. In one sleep laboratory study, 38% of 29 men with (at that time idiopathic) RBD went on to be diagnosed with a parkinsonian disorder an average of 3.7 years after the diagnosis and 12.7 years after the onset of their RBD.

The identification of premotor PD features has led to great interest in the detection of cohorts of individuals with premotor features of sufficient sensitivity and specificity for predicting the future

development of PD. The main purpose is to enable trials of candidate neuroprotective agents to be applied as early in the disease process as possible, when they may be most likely to modify the neurodegenerative process.

#### 'Typical' motor presentation of PD

Most patients with PD only present to medical attention following the onset of the well-known motor features of the disease. PD is classically an asymmetric disease, remaining so throughout its course. It more commonly starts in the arm, with impaired dexterity on fine tasks, and often with a tremor at rest (e.g. holding a

\* Often misdiagnosed as Parkinson's disease even though fatiguing/decrement of repetitive movements not present.

newspaper). Other patients present with a tendency to drag one leg or shuffle. The spouse may have noticed a general slowing down, a change in facial expression or impaired arm swing. Direct questioning may reveal a change in voice or micrographia, but these symptoms as presenting complaints are less common, and raise the possibility of atypical disease. The patient may admit to aching or sometimes pain in the affected limb, and presentation with or

development of a frozen shoulder or worsening back discomfort is well recognised.

Examination will reveal akinesia, usually with rigidity and often tremor, which can be difficult to bring out. The patient should be asked to relax their hands in their lap or over the arms of a chair, and deliberately put under stress by being asked to count backwards with the eyes closed, then repeated with the arms outstretched, then with the fingers in front of the nose. Often the earliest tremor to be observed may be an adduction–abduction tremor of the fingers. Sometimes, the only time a rest tremor is observed is on walking, when reduced arm swing, flexed posture (initially of one arm) and gait abnormality can be seen.

Atypical features should also be sought. The 'bedside' examination of eye movements should be normal (except for some limitation of convergence or of up-gaze with normal saccadic velocity), and there should be no evidence of limb or gait ataxia or dysidiadochokinesis, no apraxia and no pyramidal signs. The so-called striatal toe can mimic a Babinski response, but is often present spontaneously or on walking and is not accompanied by other pyramidal features. Sometimes (particularly younger) patients may present with 'dystonic claudication' (exercise-induced leg dystonia) on prolonged walking. Early postural stability or freezing of gait, although sometimes seen in PD, should raise other possibilities. Of note, patients who are unsteady for whatever reason may not swing their arms, and abnormal arm swing is also common in patients with dystonia.

Unilateral PD (stage 1 on the non-linear Hoehn and Yahr scale) progresses, through stage 2 (bilateral), which typically lasts for 5–10 years, until postural instability (stage 3) appears. Over time, fully developed disease (stage 4) develops, and after many years the patient may eventually become chair- or even bed-bound (stage 5). However, this progression is influenced by treatment, so that a patient on chronic levodopa treatment can fluctuate between stage 4 or even 5 when 'off', to stage 2 or 3 when 'on'. Freezing of gait is usually a late feature.

### Non-motor features of PD

Beyond the premotor symptoms, a host of other non-motor features occur in, and can be the most disabling features of PD so should be routinely enquired about:

- Sialorrhoea is particularly a problem in later disease; only a few patients can tolerate centrally acting anticholinergics such as scopolamine because of the risk of confusion, but some can be helped by peripherally acting drugs, or botulinum toxin injections. As this is caused by reduced frequency of swallowing rather than excessive saliva production, simple tricks such as chewing gum to promote swallowing can be effective in controlling this problem.
- Drenching sweats usually occur in levodopa-treated patients, often as wearing off or 'off' phenomenon. They are poorly understood and no effective pharmacological treatment exists, other than adequate dopaminergic replacement. Anxiety, and sometimes panic, can also be a major problem, and can occur acutely in the wearing off or off state.
- Urinary urgency and frequency are common, as a result of detrusor hyper-reflexia, and can be helped by a peripherally acting anticholinergic such as trospium.
- Depression, usually minor rather than major, affects about 40% of patients before, at, or after diagnosis. The symptomatology of this minor depression overlaps with abulia, and lack of initiative and drive, which is also common in PD. In numerous studies,

depression has been shown to be the most important factor correlating with impaired quality of life, so it should be actively sought, and treated if found. Clinical depression can be treated with nortriptyline, with an SSRI such as citalopram, or with a serotonergic noradrenergic re-uptake inhibitor (SNRI) such as mirtazapine or venlafaxine.

- Pain is also common in PD. It may be a presenting feature or can arise in established disease, often as a wearing off or off phenomenon, sometimes in conjunction with dystonia. It is usually lateralised to the side more affected by PD.
- Cognitive impairment can occur early in PD but is usually a very mild dysexecutive syndrome which is detectable only when specifically sought using neuropsychological tests. As the disease progresses, other cognitive problems can emerge including more obvious disturbances of memory and attention, and presence of hallucinations and visuospatial deficits. After surviving 20 years of disease, 80% of PD patients will have developed dementia (see Dementia in association with Lewy body pathology).

Many of these non-motor features appear only when the patient's dose of levodopa is wearing off, or in the off state, but can represent the patient's biggest problem. Appropriate management is to take measures to minimise time 'off' (e.g. by appropriate adjustment of dopaminergic medications), rather than necessarily resorting to antidepressants or analgesics. A whole range of neuropsychiatric disturbances resulting from the disease or its treatment can also occur (see later).

### Ancillary investigations

Young onset (less than 40 years) patients should always be screened for Wilson's disease with serum copper and caeruloplasmin and slit-lamp examination. Routine magnetic resonance imaging (MRI) of the brain is normal in PD and not necessary in typical cases. A dopamine transporter (DaT) single photon emission computerised tomography (SPECT) scan can sometimes be useful to confirm a nigrostriatal lesion, particularly in those with rest tremor when there is some doubt about the presence of bradykinesia, but in a typical case of PD is unnecessary.

### Treatment of PD

No drug has so far been proven to be neuroprotective in PD. When the patient is first diagnosed they may not yet feel in need of symptomatic treatment, and the doctor may not wish to rush into treatment at the first visit. There have been recent suggestions that early initiation of treatment might preserve or restore healthy behaviours such as exercise, and thus have long-term benefit, even without a neuroprotective action, but this is not yet proven. Commonly, PD clinicians still wait until the patient's symptoms are beginning to affect their daily life before starting symptomatic treatment.

Discussion of treatment options has been greatly influenced over the years by what is known about the long-term levodopa syndrome of fluctuations and dyskinesias among patients started on treatment with levodopa as first line, often in high dosages. As a result, many patients and clinicians had developed a form of 'levodopa phobia' which can lead to marked under-treatment. In fact levodopa remains the most effective symptomatic treatment for PD and is therefore discussed first.

### Levodopa

Preparations of levodopa combined with the peripheral dopa decarboxylase inhibitors (DDIs) carbidopa or benserazide (co-careldopa, Sinemet; co-beneldopa, Madopar) are still the most potent and

effective symptomatic treatment for PD, and remain the 'gold standard'. Levodopa, in competition with other large neutral amino acids, is transferred across the wall of the proximal small bowel, and again across the blood-brain barrier, by an active transport system. Some patients find that protein in meals impairs the effect of a dose of levodopa close to meals, so that timing or size of the dose, or the protein intake, may need adjustment. Once in the brain, no longer protected from the peripheral DDI that cannot follow it, levodopa is metabolised in the surviving presynaptic dopaminergic terminals to dopamine, which is released physiologically (with both tonic and phasic bursts) to stimulate dopamine receptors in striatum.

It is usual to start with half a tablet of 25/100 (DDI/levodopa) strength twice or three times daily for a couple of weeks, then doubling the dose and waiting to judge the effect. If ineffective or insufficiently effective, the dosage can then be increased to 1½ or 2 tablets three times daily, although the ELLDOPA trial showed increasing rates of dyskinesia and wearing off, particularly as the dose increased from levodopa 300 to 600 mg/day. Almost all PD patients will show marked improvement at this dose but, if ineffective, the total daily dosage of levodopa should be further increased to 1–1.5 g/day (if tolerated) before concluding that it has no benefit in a given patient. Lack of response of all of the motor signs to levodopa should prompt the clinician to reconsider the accuracy of the diagnosis.

One should note that there are long duration effects of levodopa, such that a treatment change can take at least 2 weeks for its effect to equilibrate in the brain, and similarly one can see late deterioration up to 2 weeks after discontinuing or reducing the dosage. Initially, benefit is smooth throughout the day, even if a dose is late or missed – the so-called honeymoon period. Over time, however, patients start to notice early morning akinesia, or wearing off of their doses, and around the same time may develop an 'overshoot' from akinesia to dyskinesia when the dose is working. A very rough rule of thumb is that these problems develop in 10% of patients per year of treatment, so that after 5 years about 50% of patients will have them, and after 10 years almost all patients will ultimately experience them, to a greater or lesser degree. In general, younger onset patients develop them earlier and to a more severe degree. Rates reported from clinic-based series are higher than those in community-based studies.

Gradually, a 'threshold' level of dopaminergic transmission in the striatum develops, so that the doses work in an all-or-none fashion, and the patients fluctuate, from on and mobile, to off with recurrence of their parkinsonian features, sometimes over minutes or even seconds. On periods are usually associated with the development of involuntary dyskinesic movements likely as a result of levodopa being taken up by non-dopaminergic neurones and released inappropriately as a false transmitter, and to supersensitivity of postsynaptic dopamine receptors and changes in synaptic plasticity in the striatal output pathways occurring as a result of prolonged non-physiological dopaminergic replacement.

Mobile dyskinesias can be peak dose (occurring mainly at the peak of action of each dose), square wave (occurring throughout the period of benefit) or diphasic (being much more severe at the beginning or at the end of action of a dose of levodopa). Most on period dyskinesias are usually a mixture of chorea and dystonia, but when diphasic (usually in young onset patients) they can be violent and disabling stereotyped or ballistic movements. Some patients develop off period dystonia, which is relatively fixed, usually painful, most commonly affects one leg, and relates to falling, low or intermediate levels of dopaminergic stimulation; paradoxically, this

is both caused and relieved by levodopa, disappearing when the patient turns 'on'. Levodopa-induced dyskinesias in PD typically involve limbs more than neck and face, and are more severe on the initially, and more, affected side.

Attempts to treat levodopa-induced dyskinesias by fractionation of doses to give smaller amounts frequently lead to dose failure or unpredictability of effect. Relative to standard preparations, bioavailability of controlled release (CR) levodopa is only 70%; moreover, although providing a longer tail at the end of the dose, CR is absorbed more slowly than standard, leading to delayed 'on' and sometimes only a short on period because the threshold is only briefly exceeded. CR formulations have therefore been disappointing in managing daytime fluctuations, but remain useful at bedtime to improve nights. A (very expensive) levodopa-carbidopa gel (Duodopa) delivered continuously into proximal jejunum via a gastrostomy and jejunal extension tube (PEG-J) can give stable plasma levels and improve fluctuations in patients who are unsuitable for, or unable to tolerate, apomorphine or surgery.

**Other side effects of levodopa** Levodopa can also cause nausea or vomiting, mainly by stimulating dopamine receptors in the chemoreceptor trigger zone in the area postrema in the floor of the fourth ventricle, functionally outside the blood-brain barrier. It can also cause or aggravate postural hypotension, mainly through a central action. Overall, levodopa is far better tolerated than the alternative symptomatic agents.

### Monoamine oxidase B inhibitors

Selegiline and rasagiline are irreversible inhibitors of monoamine oxidase B (MAO-B), the iso-enzyme responsible for catabolising dopamine to homovanillic acid (HVA). Unlike MAO-A inhibitors, they can safely be given together with levodopa. Used alone in early disease, selegiline has been shown, probably through a mild symptomatic effect, to delay the need for levodopa by about 9 months. Symptomatic effects are modest. Oral selegiline is partly metabolised to metamphetamine, so should be given in the morning to avoid insomnia. Zelapar, a buccally absorbed preparation of selegiline, avoids first-pass metabolism and hence this problem. Otherwise, these drugs have very few side effects when given alone, but can potentiate any of the symptomatic side effects of levodopa. Safenamide, a new MAO-B inhibitor (but also dopamine reuptake and glutamate inhibitor), has recently been licensed for use in the United Kingdom and the EU.

Great publicity surrounded the publication of the DATATOP (selegiline) and the TEMPO and ADAGIO trials (rasagiline) which sought to evaluate whether these agents can have neuroprotective properties. The rasagiline trials adopted a delayed start design deliberately to try to disentangle the known symptomatic effects of these drugs (observed in DATATOP) from possible disease-modifying effects. Although small benefits appeared to emerge as a result of earlier introduction of rasagiline at a dose of 1 mg, the data on the 2-mg dose were negative, casting doubt on the overall reliability of the trial findings, and prompting the US Food and Drug Administration (FDA) to conclude that no neuroprotective effects had been demonstrated.

### Catechol-O-methyl transferase inhibitors

Entacapone (peripheral) and tolcapone (peripheral and central catechol-O-methyl transferase [COMT] inhibitor) block the conversion of levodopa to 3-O-methyldopa, its principal metabolite. They both extend the elimination half-life of levodopa, and

thereby often extend the duration of action of individual doses. They are of no use if given without levodopa, and in the case of entacapone should be given simultaneously with levodopa. Tolcapone is generally the more effective of the two, but is only used as a second line treatment because of a (low) risk of potentially fatal hepatotoxicity, necessitating frequent liver function test monitoring. Both drugs can cause gastrointestinal upset, particularly diarrhoea, and a harmless orange discoloration of the urine. A combined tablet containing levodopa, carbidopa and entacapone (Stalevo) is available.

### Dopamine agonists

Dopamine agonists stimulate dopamine receptors directly. Five oral agonists (three ergoline: bromocriptine, pergolide and cabergoline; and two non-ergoline: ropinirole and pramipexole) and one transdermal non-ergoline agonist (rotigotine) have been introduced. Apomorphine is the only dopamine agonist that can be administered subcutaneously and has a rapid time to onset of action. While the oral and transdermal agonists are commonly given before levodopa is introduced, in an attempt to reduce or delay the development of fluctuations and dyskinesias, they undoubtedly have a weaker antiparkinsonian effect. Apomorphine on the other hand is generally reserved for people who have already experienced levodopa-induced complications.

**Adverse effects** Dopamine agonists stimulate both peripheral and central dopamine receptors.

Peripheral side effects include nausea and, rarely, aggravation of existing cardiac disease or peptic ulceration. The risk of nausea and vomiting (particularly problematic with initiation of apomorphine) can be reduced by the peripherally acting dopamine receptor antagonist domperidone. However, the Medicines and Healthcare products Regulatory Agency (MHRA) has recently determined that because of its potential for causing cardiac problems, not more than 30 mg/day domperidone should be given, for a maximum period of 1 week. Other antiemetics that do not block dopamine receptors are cyclizine, promethazine and ondansetron. Tolerance to nausea usually develops rapidly over 10 days or so, and there is cross-tolerance between levodopa and agonists, and between different agonists. Covering the introduction of an agonist is therefore most important with *de novo* treatment, optional when adding an agonist to levodopa, and unnecessary when switching between agonists (except to switch to apomorphine).

All agonists can cause ankle swelling, sometimes extending to the knees, or higher. In most cases the mechanism is unknown, but evidence of cardiac failure should always be sought. The ergot derivatives, particularly, can cause a tense angry erythematous rash called erythromelalgia. It has long been recognised that ergot agonists can (rarely) cause lung fibrosis, pleuro-pulmonary effusions or (even more rarely) retroperitoneal fibrosis. More recently, they have also been found to cause fibrosis of heart valves (most commonly the tricuspid), analogous to what is seen with carcinoid tumours and fenfluramine treatment. This reaction is thought to be mediated by stimulation of 5HT<sub>2B</sub> receptors, and to be wholly, or mostly, restricted to ergoline agonists. The vast majority of patients found on echocardiography to be affected are asymptomatic, but because of these problems the ergoline agonists are no longer recommended.

Central side effects include postural hypotension (mainly central), excessive daytime somnolence and a variety of neuropsychiatric manifestations.

While any antiparkinsonian medication can cause neuropsychiatric adverse effects, the oral agonists definitely cause more problems than levodopa. At the milder end of the spectrum, levodopa, agonists and anticholinergics can cause vivid dreams or nightmares, illusions, extracampine hallucinations (delusions of presence) or (typically visual) pseudohallucinations (with retained insight), of animals or people, sometimes Lilliputian, often non-threatening. More problematic are true hallucinations (with loss of insight) and delusions (often paranoid). So-called impulse control disorders (ICDs) are much more common with agonists, and include hypersexuality, pathological and compulsive gambling, shopping or eating. Agonists can also cause morbid jealousy (Othello syndrome). 'Punding' (defined as repeated stereotyped pointless complex behaviours, for instance sorting, or assembling and disassembling items) is more common with patients 'addicted' to excessive doses of levodopa in the 'dopamine dysregulation syndrome'.

All patients considering or taking dopamine agonists must be warned and interrogated about these possible neuropsychiatric effects.

**De novo use of dopamine agonists** The main advantage of *de novo* agonist monotherapy is that it rarely causes significant motor fluctuations or dyskinesias until, almost inevitably, levodopa is later added. However, over recent years the relative merits of starting treatment with an agonist versus starting with levodopa have gradually altered. Long-term studies have shown that, despite delaying the onset of levodopa-related complications (fluctuations and dyskinesias) by using an agonist first, these problems often start much sooner after levodopa is started, and at the end of 10–15 years there is no difference in outcome irrespective of which treatment was started first. Moreover, if fluctuations and dyskinesias cannot be adequately controlled medically, deep brain stimulation (DBS; see later) can now usually control them very effectively. In addition, the 1 in 8 risk of agonists provoking one or more ICDs has to be factored in. Therefore for many neurologists and patients the pendulum is now swinging back in favour of levodopa.

When first introduced, at low dosage, dopamine agonists can also have a paradoxical effect of worsening parkinsonism by shutting down endogenous dopamine release, before higher dosages that stimulate the postsynaptic D2 receptors are reached. Agonists are often used in suboptimal dosage, commonly because the patient stops increasing the dosage at the end of a 'starter pack', or because of confusion about what is meant by 'minimum effective dose' – this can be construed as the dose that is effective, but is usually the minimum dose that has any useful effect.

If one oral agonist fails to have any useful effect at maximum dosage, there is usually little to be gained by switching to another. If one agonist is poorly tolerated because of somnolence, one may switch to another, although risking the same problem again. If an agonist is poorly tolerated because of hallucinations, delusions or confusion, there is a significant risk of the same with another agonist.

**Add-on use of dopamine agonists** Dopamine agonists have longer clinical and pharmacological half-lives than levodopa. Hence, when added, they can help to minimise 'troughs' of dopaminergic stimulation and increase on time. Dyskinesias will usually increase, unless the dose of levodopa is reduced to compensate. In general, the less a patient's dopaminergic stimulation is obtained from levodopa and the more from an agonist, the less severe their dyskinesias tend to be.

Apomorphine is the oldest and most effective agonist and has a definite role as 'add-on' therapy to levodopa. It can be given via pen injections to rescue unpredictable off periods, or via continuous infusion to reduce them. The effect of single injections (usually 3–5 mg) is rapid (within 10–15 minutes) and reliable. Infusions (usually 3–6 mg/hour) can be supplemented by on-demand boluses. Apomorphine causes more drowsiness, particularly initially, and less psychiatric morbidity than oral agonists. It can very rarely cause an autoimmune haemolytic anaemia, so periodic haemoglobin, reticulocytes and Coombs testing is mandatory. Patients may also develop tender, inflamed or infected subcutaneous nodules or panniculitis which may cause them to abandon treatment. Infusions are usually given for about 12 hours during the day, but some patients use apomorphine infusions just at night, or 24 hours/day, with a lower rate at night.

Any oral agonists can usually be tailed off and levodopa dosage often reduced, which usually improves dyskinesias.

### Anticholinergics

Anticholinergics such as benzhexol were the first drugs used to treat PD. They usually have only a mild symptomatic effect, often restricted to reducing tremor, although when abruptly discontinued patients can dramatically worsen. Because of cortical pathology, and the cholinergic deficit caused by NBM pathology, older PD patients are particularly susceptible to develop hallucinations and organic confusional states when given centrally acting anticholinergics. These agents should be avoided in elderly patients and their use restricted to younger, cognitively intact, usually tremor-dominant patients. Peripheral side effects of anticholinergics are common and predictable; they can cause blurred near vision because of mydriasis (so are contraindicated in narrow angle glaucoma), delayed gastric emptying and constipation. However, they can help sialorrhoea, and also reduce the detrusor hyper-reflexia commonly responsible for frequency and urgency in PD, but can precipitate retention of urine if there is also an element of prostatic obstruction.

### Amantadine

This drug was originally used as an anti-influenza medication. Its use in PD was discovered serendipitously. It has several actions: an amphetamine-like effect (releasing presynaptic dopamine stores); a mild anticholinergic effect; a mild dopamine re-uptake inhibition effect; finally, it is also an *N*-methyl-D-aspartate (NMDA) glutamate receptor antagonist. Traditionally, amantadine was used as a mild early treatment. Often the effect would wane, at least in part, after 6 weeks or so. The drug commonly causes ankle oedema and livedo reticularis. It can cause hallucinations or confusion, and is excreted by the kidneys, so should be used with caution in renal failure. More usefully, amantadine has also been recognised to have a (sometimes dramatic) antidyskinetic effect in at least some patients on levodopa, without worsening parkinsonism, presumed to be mediated by its NMDA antagonist property. It can also help freezing, even on freezing, in a minority of patients.

### Surgery for PD

For some patients with more or less advanced PD, with motor fluctuations, dyskinesias or troublesome tremor, and who are difficult to manage despite the combination of available drugs, functional neurosurgery is an option, and can be most valuable. Lesioning procedures such as thalamotomy and pallidotomy were applied for many years but have been largely replaced in most countries by

deep brain stimulation (DBS). DBS uses permanently implanted electrodes in the brain in conjunction with a neurostimulator implanted in the chest wall that delivers high frequency electrical impulses. The three established brain targets for the treatment of PD with DBS are the ventrolateral thalamus, the internal pallidum (GPi) and the subthalamic nucleus (STN). DBS on each target improves a different range of symptoms.

**Thalamic deep brain stimulation** Thalamic stimulation was developed in 1987 to treat tremor related to PD or essential tremor, initially contralateral to a previous thalamotomy. In view of the benefits on tremor and the low rate of side effects, bilateral thalamic stimulation was then performed. However, thalamic DBS does not allow reduction in drug dosage. Balance problems and dysarthria are possible side effects, especially after bilateral surgery. Patients are usually asked to stop the stimulation at night to reduce the risk of tolerance and rebound. Benefits on tremor can be maintained for more than 10 years. Nevertheless, some long-term studies have shown that in many patients other symptoms such as gait difficulty, akinesia and dyskinesia progress and are not helped by thalamic DBS. This has led to the search for other brain targets in which DBS can help those symptoms and there has been a decrease in the indications for thalamic DBS. Thalamic DBS still has a place for elderly patients with tremor dominant disease.

**Subthalamic nucleus deep brain stimulation** Subthalamic nucleus deep brain stimulation (STN DBS) was developed in 1993, following basic research in the MPTP monkey model of PD. Hyperactivity of the STN was identified in their parkinsonian condition and an improvement of symptoms after STN lesions. In patients with PD, STN DBS can improve a large range of off-phase symptoms: limb bradykinesia, rigidity, tremor and gait difficulty including balance and freezing (if they are also dopa-sensitive). Levodopa-induced dyskinesias also improve over time, largely because of drug dosage reduction. 'Off' dystonia improves as well. Dopa-refractory symptoms are not helped and the effect on speech is variable, and it is not infrequent that speech intelligibility deteriorates over time. Medications are usually reduced after STN DBS. In the early stage, stimulation is increased slowly in parallel with drug reduction to avoid increase of dyskinesias. After 5 years of STN DBS, benefits on appendicular symptoms are maintained; however, the effect on axial features (gait, balance, speech) and the on-phase scores often declines. Side effects are not infrequent: speech problems, possible neuropsychiatric problems (in particular mood changes) and more rarely eyelid opening apraxia and dyskinesias induced by the stimulation.

**Internal pallidum deep brain stimulation** Internal pallidum (GPi) DBS was developed in parallel with STN DBS but a smaller number of patients have received surgery because most teams opted for STN DBS. The effect on 'off' symptoms is more variable than with STN. The most reliable effect of GPi DBS is on dyskinesia. Nevertheless, although results of a US randomised blinded comparative study have shown only a moderate difference between the results of GPi and STN DBS, another similar Dutch study has shown superiority for STN DBS over GPi DBS. However, GPi DBS seems to be more lenient with the advantage of a lower rate of side effects, and it remains useful particularly for older patients or patients with severe dyskinesias who are at higher risk for adverse effects with STN DBS.

**Patient selection for surgery** Patient selection aims at identifying those patients likely to benefit from surgery and unlikely to have severe adverse effects. Therefore, it is important to identify the disabling symptoms and assess if they are dopa-sensitive or dopa-induced and how they impact on the patient's daily life. A levodopa challenge is very helpful to assess in detail 'off' symptoms, the response to medications and the severity and type of dyskinesias. Cognitive functions and mood should also be carefully assessed. Brain MRI is carried out to exclude contraindications such as severe atrophy, extensive white matter change and focal lesions. The patient's general condition has to be considered. Patients treated by platelet anti-aggregants or anticoagulants should be able to stop them for 2 weeks before and 2 weeks after surgery. Speech and swallowing have to be considered, because of the risk of deterioration. Patients and their family should be given detailed information about the procedure, its risks and potential benefits, as well as its limitations. Patient and family expectations have to be addressed. The choice of brain target for DBS depends on the profile of symptoms and the risk factors.

**Surgery** Surgery is performed under stereotactic conditions. The implantation of the electrodes was usually carried out under local anesthesia, but thanks to better imaging modalities it is increasingly carried out in general anaesthesia, especially on brain targets that can be readily visualised pre- and postoperatively, such as the STN and GPi. Brain atlases can provide some guidance, in particular when the target cannot be visualised on MRI, for example the subnuclei of the ventrolateral thalamus (ventral oral posterior [Vop], and ventral intermediate [Vim] nuclei). During awake surgery, different electrophysiological methods can be used, Microelectrode recording techniques are used by many surgeons, although it has been shown that their use can result in higher risk for hemorrhage. In awake patients, intraoperative stimulation allows one to confirm the benefits and to observe side effects. The neurostimulator and the connectors are always implanted under general anaesthesia. The general risk of surgery includes haemorrhage in 0–4% of patients, according to the technique and the surgeon, and infections of the system occur in about 2–3% of patients.

**Stimulator adjustment and long-term management** Patients implanted with DBS need life-long follow-up by a specialist team. Stimulation parameters have to be adjusted from time to time, as well as medication. Electrical parameters are similar for all targets: voltage is usually between 2 and 4 V, pulse width usually 60  $\mu$ s, occasionally 90  $\mu$ s, but tends to be higher in GPi, and frequency is typically 130 Hz or above. Monopolar stimulation is preferred unless side effects limit the increase in voltage. Adjustment of thalamic DBS is usually straightforward. However, adjustment of STN DBS has to be progressive, in parallel with adjustment of medications. Adjustment of GPi DBS does not have the same immediate effect on the symptoms. The neurostimulator has to be changed approximately every 3–7 years.

Some side effects, in particular neuropsychiatric problems such as depression, apathy and mania, can occur even a long time after surgery. Infections or skin erosions can also occur late. Some medical equipment, in particular diathermy and monopolar coagulation, should not be used in DBS patients. Brain MRI after implantation can only be performed under restricted conditions of energy delivery and using a receiver–transmitter head coil.

**The future** Existing DBS procedures, although very helpful, have limitations. They only allow symptomatic improvement, they do not appear to change the progression of the disease and they are ineffective against dopa-refractory symptoms, with the exception of tremor. There is no real alternative at present, although preliminary albeit conflictual reports of DBS in the area of the pedunculo-pontine nucleus have suggested that it might improve gait. There is a renewed interest in stereotactic lesional procedures, and pilot trials are underway using non-surgically invasive techniques such as gamma knife or focused ultrasound to perform thalamotomy or pallidotomy in patients with PD or essential tremor. Dopaminergic cell transplants and intraputamina delivery of glial derived neurotrophic factor (GDNF) have shown apparent improvement in a minority of patients, and these procedures are under renewed investigation after having been halted previously because of side effects. Further development of potentially disease-modifying and restorative procedures is the challenge for the future.

### Dementia in association with Lewy body pathology

It has long been recognised that patients with PD have a higher risk of developing dementia than age-matched controls. Longitudinal studies have found cumulative dementia risks between 42%, and up to 80% with follow-up as long as 20 years. Dementia starting more than 1 year after the onset of parkinsonism is arbitrarily called Parkinson's disease dementia (PD-D).

In contrast, the development of parkinsonism and dementia within 1 year of each other, or a similar type of dementia without spontaneous parkinsonism is termed dementia with Lewy bodies (DLB), and is the most common cause of dementia in the elderly after Alzheimer's disease (AD; see Chapter 8). Mean survival of both DLB and PD-D cases after the development of dementia is only 5 years. Postmortem pathological examination reveals the presence of Lewy body pathology (often accompanied by varying numbers of senile plaques and sometimes of both senile plaques and neurofibrillary tangles) in both cerebral cortex and brainstem. On a pathological basis, it is usually impossible to distinguish patients with a clinical diagnosis of PD-D from patients with a clinical diagnosis of DLB.

Progressive disabling cognitive impairment is a mandatory requirement for the diagnosis of both PD-D and DLB. For probable DLB two, and for possible DLB, one of the following three core features are required:

- 1 Fluctuating cognition with pronounced variations in attention and alertness
- 2 Recurrent visual hallucinations, and
- 3 Spontaneous features of parkinsonism.

Other supportive features of DLB are RBD and, in the absence of spontaneous parkinsonism, severe neuroleptic sensitivity and impaired dopamine transporter uptake in striatum on PET or SPECT scanning.

The management of confusion and hallucinations and of cognitive impairment in PD, PD-D and DLB is challenging. Intercurrent illness should be sought and treated (including infection, constipation, metabolic disturbance or head injury). The number and type of psychoactive (mostly antiparkinsonian) drugs taken should be rationalised, starting with reduction of anticholinergics, then dopamine agonists and amantadine, then MAO-B inhibitors, then COMT inhibitors, leaving the patient on monotherapy with a levodopa preparation in the lowest dose possible. If hallucinations or delusions persist, an antipsychotic drug may be needed. Quetiapine is well tolerated, but not of proven efficacy in this indication. The only

drug with class 1 evidence of antipsychotic efficacy, while not worsening underlying parkinsonism, is clozapine. However, because of the risk of bone marrow suppression and the consequent stringent monitoring requirements, it is little used in the United Kingdom in this indication, for which it is considered a second line drug.

The cortical cholinergic deficit in demented, and even in non-demented, PD patients and in DLB, is greater than that in AD. Therefore, the cholinesterase inhibitors are also effective in these indications. Rivastigmine, started at a dose of 1.5 mg twice daily and gradually increased to 6 mg twice daily, or donepezil, started at a dose of 5 mg once a day and increased to 10 mg once a day, can be very helpful in some patients, although responses can be disappointing in others. However, these drugs can worsen any urinary frequency or urgency.

### Multiple system atrophy

This sporadically occurring alpha-synucleinopathy was also previously described as Shy-Drager syndrome, striato-nigral degeneration, or (some cases) sporadic olivo-ponto-cerebellar atrophy (sOPCA). It causes varying combinations of parkinsonism (MSA-P, usually poorly responsive to levodopa), cerebellar dysfunction (MSA-C), autonomic failure (orthostatic hypotension, male erectile dysfunction and urinary incontinence or incomplete bladder emptying) and pyramidal signs. Pathology involves varying combinations and locations of neuronal loss and oligodendroglial pathology (ubiquitin and alpha-synuclein positive intracytoplasmic inclusions; GCIs) in striatum (especially posterior putamen), substantia nigra, locus caeruleus, inferior olive, pons and cerebellum, and in the intermediolateral cell columns and Onuf's nucleus of the spinal cord. It is almost invariably sporadic. Prevalence is about 4/100 000, mean age at onset is 57 years (never starting before age 30) and mean survival is about 7 (1–16) years. Often autonomic failure (AF) antedates the other neurology. If isolated AF persists for more than 5 years the term pure autonomic failure is used – such patients usually have Lewy body pathology in autonomic ganglia, and also in substantia nigra, but not enough to cause parkinsonism. Rare cases of MSA or of PD 'convert' from a label of pure autonomic failure after the arbitrary 5-year period.

Other clinical features of MSA include RBD and sleep apnoea (also common, but less so, in PD), increased snoring, nocturnal or daytime stridor, emotional incontinence, myoclonic jerks of the fingers, impaired sweating and heat intolerance, Raynaud's phenomenon, cold dusky hands, disproportionate fixed antecollis, postural instability, dysphagia and a characteristic dysarthria – high-pitched, quivery, strained and hypophonic in MSA-P or slurring cerebellar-type in MSA-C. Frank dementia is rare, and an exclusion criterion for the diagnosis, because patients (usually more elderly) with the combination of dementia, parkinsonism and autonomic failure are much more likely to have Lewy body pathology, and dementia, when it does occur in MSA, is a late feature. Consensus diagnostic criteria for MSA were recently revised. Treatment of MSA is symptomatic. Levodopa can be of minor benefit in the early stages, but can exacerbate postural hypotension and can also cause atypical orofacial dyskinesias. Amantadine is useful in some patients. Symptomatic treatment of the autonomic aspects can be of greater help.

### Progressive supranuclear palsy

Progressive supranuclear palsy (PSP) is a tauopathy, usually sporadic, rarely familial. It classically causes axial (hence symmetrical) akinesia and rigidity, early falls (classically backwards without warning),

dysarthria (lower pitch, growling, with late groaning), dysphagia, personality change, frontal cognitive deficits and eye features. These include frontalis overactivity, levator inhibition, sometimes blepharospasm, and a characteristic supranuclear gaze palsy (or, more correctly, paresis) which is necessary for the clinical diagnosis and which gives the disease its name. Often the earliest feature is slowing of vertical voluntary saccades, followed by supranuclear limitation of up-gaze (non-specific) or down-gaze (always pathological), followed by similar abnormalities on horizontal saccades. The supranuclear cause of any limitation of voluntary gaze is identified when a complete range of automatic reflex eye movements is demonstrated by the oculocephalic, or doll's head, manoeuvre, such automatic-voluntary dissociation indicating that the oculomotor pathway from the nucleus distally is intact. The latency to initiate saccades is typically normal in PSP, in contrast to CBD (see later).

The pathology of PSP involves neuronal loss and gliosis, with straight neurofibrillary tangles and tufted astrocytes particularly in substantia nigra, dentate nucleus, pallidum, subthalamic nucleus and, to a variable degree, cerebral cortex. An increase in the concentration of the 4 repeat isoform of tau is present.

The prevalence of PSP is about 5/100 000, mean age at onset is 63 years, never starting before 40, and mean survival is 7 years. Although about half of patients with pathologically proven PSP show the classic clinical picture (Richardson's syndrome) with mean survival of 6 years, about one-third have a longer course averaging 9 years (PSP-P) with more PD-like features, including some levodopa response and resting tremor, with falls and gaze palsy developing later on. Other clinical features include emotional incontinence, frontal release signs, a memory retrieval deficit, palilalia and palilogia, other motor perseveration, sitting down 'en bloc' and prominent sialorrhoea. Despite severe postural instability, patients usually fail to widen their base which, combined with 'motor recklessness', causes frequent falls, with injury. Unlike MSA and PD, cardiovascular AF is not a feature of PSP. However, urinary disturbance is common. A small percentage of individuals present with an isolated phenotype of 'pure akinesia and gait freezing', with little other evidence for parkinsonism or gaze palsy, and rarely PSP patients can present with a corticobasal syndrome or with speech apraxia. Treatment of PSP is symptomatic, and minor benefits can be seen with levodopa and/or amantadine. The mainstay of treatment is supportive and patients should be seen by the multidisciplinary team including dietitians, speech therapists, occupational therapists and physiotherapists.

### Corticobasal degeneration

This tauopathy is also largely sporadic, with only very rare familial cases. Nevertheless, it shares with PSP over-representation of the H1/H1 tau haplotype, and consequent excessive concentration of the 4 repeat tau isoform, indicating some shared genetic susceptibility. Many with the disease present to movement disorder specialists with the asymmetric and progressive evolution, usually starting in one arm (but sometimes in a leg), of 'difficulty' using the limb, which progressively becomes useless because of a combination of akinesia, rigidity, fixed dystonia, myoclonus, jerky tremor, cortical sensory loss and, above all, apraxia. Sometimes there is an additional 'alien limb' phenomenon, when the limb wanders off 'with a mind of its own'. Progression is then to the opposite limb or the other limb on the same side, ultimately to all four limbs, and a supranuclear gaze palsy (paresis) gradually develops which classically is the 'mirror-image' of PSP. Thus, there is great difficulty initiating voluntary saccades, with prolonged latency (oculomotor

apraxia), but when the eyes finally move they do so with normal velocity. The pathology of CBD includes swollen ('ballooned') cortical neurones predominantly in frontal and parietal areas and neurofibrillary tangles and astrocytic plaques. The prevalence of CBD is unknown, but it is rarer than MSA or PSP. Mean age at onset is 63 years and mean survival is 8 years.

However, the classic clinical picture described can be misleading. Thus, those with CBD can present to dementia specialists with apraxia or a progressive non-fluent aphasia, or disease can present symmetrically, or with falls. Conversely, it may be misdiagnosed in life as PSP. Other diseases can also present with a corticobasal-like syndrome, including vascular lesions, but also prion disease, Alzheimer's disease and disorders with TDP-43 pathology. Some of these are caused by mutations in progranulin, *FUS*, *C9orf72* and other genes. Hence in clinical cases the term corticobasal syndrome is preferred to corticobasal degeneration, as different pathologies can result in same clinical syndrome. New diagnostic criteria have been recently proposed.

### Ancillary investigations to distinguish between PD, MSA, PSP and CBD and other conditions

Brain imaging using MRI in MSA patients may reveal, supratentorially, putaminal atrophy, a hyperintense slit-like lateral rim to the putamen, or posterior putaminal hypointensity (Figure 6.1). Infratentorially, pontine atrophy, a 'hot-cross bun' appearance of the pons in cross-section (Figure 6.2), hyperintensity of the middle cerebellar peduncles or cerebellar atrophy may be seen.

In PSP one may see atrophy of the midbrain, as evidenced by the 'hummingbird sign' and an increased pons to midbrain ratio on sagittal cuts (Figure 6.3), and atrophy of the superior cerebellar peduncles on axial cuts (best demonstrated with voxel-based morphometry). In CBD there can be asymmetrical or unilateral frontal and parietal atrophy.

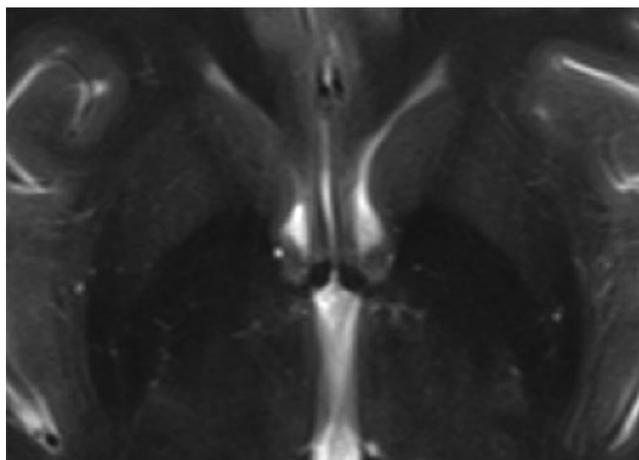

F-dopa PET or dopamine transporter SPECT scans only provide evidence of nigral pathology, so cannot reliably distinguish between these conditions. However, a normal scan can provide useful evidence in favour of psychogenic or drug-induced parkinsonism, or of essential or dystonic tremor, or in distinguishing between dopa-responsive dystonia (normal) and 'juvenile PD' (abnormal). FDG-PET may show a signal void in striatum in MSA (and PSP), and asymmetrical fronto-parietal hypometabolism in CBD. Cardiac  $^{123}\text{I}$  meta-iodobenzyl guanidine (MIBG) scanning usually, but not always, reveals evidence of postganglionic cardiac denervation in PD, whereas such scans are usually normal in MSA, PSP and CBD.

Autonomic function tests can reveal evidence of autonomic failure, but not whether it is caused by Lewy body pathology or MSA or be brought about by drug treatment.

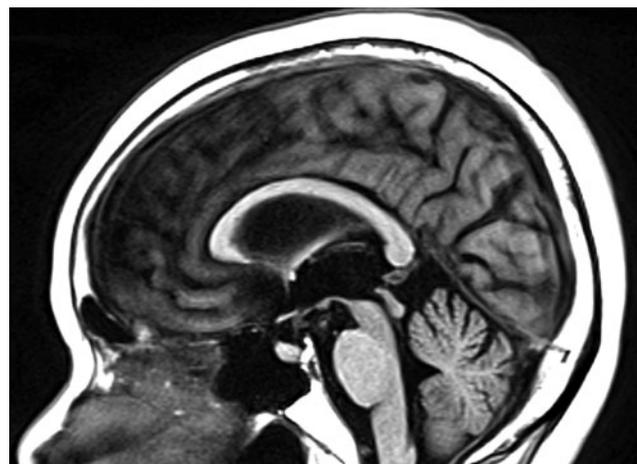

Urethral or anal sphincter electromyography (EMG) can show evidence of denervation and reinnervation (increased amplitude, duration and polyphasia) consequent on loss of anterior horn cells in Onuf's nucleus at S2–3. A normal result would argue against MSA, but abnormal results occur also in PD and PSP.

### Vascular parkinsonism

Subjects with multiple infarcts or, more commonly, multiple basal ganglia lacunes or deep white matter vascular changes, can present with what is often a poor mimic of PD, or even of true parkinsonism. Typically, spontaneous movements and facial expression are good, posture upright, and while there may be pyramidal slowing of finger movements, there is no classic fatiguing or decrement, and no tremor. The gait can be wide-based or unsteady, and

**Figure 6.1** Hypointensity in the posterior putamen in multiple system atrophy (MSA) (T2-weighted magnetic resonance imaging; MRI T2W).

**Figure 6.3** Coronal MRI section showing the 'hummingbird' appearance due to midbrain atrophy in progressive supranuclear palsy (PSP) (MRI T2W).

**Figure 6.2** 'Hot cross bun' appearance (arrow) in the pons in MSA (MRI T2W).

small-stepped (*marche à petits pas*) rather than shuffling. Start hesitation or gait initiation failure, freezing, and some fatiguing of alternating ankle movements are often present, leading to terms such as lower body parkinsonism or parkinsonian ataxia. True parkinsonism involving upper as well as lower body, in the presence of cerebrovascular disease (CVD) is usually brought about by the co-occurrence of PD – the patient's upper body has levodopa-responsive parkinsonism while their lower half behaves differently, and gait problems and falls often appear or worsen suddenly or

subacutely. However, some cases of apparent true parkinsonism resulting from CVD, with no Lewy body pathology, have been reported, and some of these have responded to levodopa, so that a trial of this drug is probably justified in all cases of CVD with convincing 'parkinsonian' features.

#### Ethnic or region-specific parkinsonism

X-linked dystonia-parkinsonism ('Lubag') with striatal mosaicism is essentially limited to Filipinos and is caused by a mutation in the *TAF1* gene. Patients may respond to levodopa, and beneficial effects have been seen with DBS. The parkinsonism–dementia–ALS complex in Guam, a disease characterised by tangle pathology rather than Lewy bodies, may be of environmental, rather than genetic, origin, as it is fast disappearing. Atypical parkinsonism on Guadeloupe may be heterogeneous, and at least partly environmentally determined.

#### Other causes of parkinsonism

Other genetic causes of parkinsonism include the Huntington's disease Westphal phenotype, seen mostly in juvenile onset cases; Wilson's disease; SCAs 1–3, in which tremor and levodopa-responsiveness can be seen; FTDP-17; and other rarer causes (Table 6.2).

Environmental causes include toxins (MPTP, CO, methanol and manganese) and drugs (dopamine receptor blockers, presynaptic dopamine depletors); post-infectious, particularly after Japanese B encephalitis and encephalitis lethargica (which still occurs rarely, with positive antibasal ganglia antibodies); post-traumatic encephalopathy in boxers and other sportspeople; and hydrocephalus and tumour.

The coexistence of parkinsonism and dystonia should prompt imaging looking for the presence of metal deposition in the basal ganglia. A range of conditions can cause neuronal degeneration with brain iron accumulation (NBIA) – listed in Table 6.3 and also discussed in section on dystonia. These can be distinguished using genetic tests. Iron deposition is best revealed during T2\* sequence MRI, while CT imaging usefully demonstrates basal ganglia calcification. The presence of abnormal deposition in the absence of

evidence to suggest iron, calcium or copper deposition, and especially with the coexistence of cirrhosis, should raise the suspicion of hypermanganesaemia, and can be associated with mutations in the SLC30A10 manganese transporter.

## Tremor

Tremor is defined as rhythmic sinusoidal alternating movement. It can be described in several ways (e.g. rest; postural; action or terminal; or intention). Tremor in PD, MSA and PSP has been discussed earlier.

### Benign essential tremor

This is commonly inherited as an autosomal dominant trait. Most people with essential tremor (ET) have little or no disability, so never see a neurologist. Published community prevalence figures vary hugely, but an average of studies is 3–400/100 000. Interestingly, despite being very common and inherited with a high penetrance, no gene has been identified to cause the majority of ET. There are a few families linked to some genetic loci and some families carry a genetic disorder restricted to them (e.g. the Lingo gene). Typically, ET involves both arms first, fairly symmetrically, and to a greater degree than any other body parts (neck, legs, voice) which may be subsequently involved. The tremor is usually vertical (flexion–extension) rather than pronation–supination. It often worsens slowly over many years, but even then often does not cause marked functional impairment, although in some cases it does. It often improves after alcohol, and may be helped by  $\beta$ -blockers, primidone, gabapentin and topiramate in some cases. There are a number of other tremor disorders often mistaken as ET: dystonic tremor, enhanced physiological tremor and other conditions that cause postural tremor.

### Dystonic tremor

The authors' view of dystonic tremor is that it is poorly defined, under-recognised and often misdiagnosed as ET or as benign tremulous PD. This view is controversial, and not yet generally accepted. The Movement Disorder Society Consensus Statement on Tremor restricts the term dystonic tremor to a tremor in a body part also displaying overt dystonia (e.g. tremulous torticollis). When someone with spasmodic torticollis, for example, also has a tremor of one or both arms, without overt dystonia in those limbs, it is called tremor associated with dystonia. Such an arm tremor usually displays other characteristics: it may be unilateral or asymmetrical, relatively slow, pronation–supination, coming in 'flurries', jerky, position-specific or markedly worsened by certain tasks (e.g. attempting to write), and therefore more commonly disabling than ET; it can be associated with abnormal or reduced arm swing, or a jaw tremor, and about one-third of these patients also display a dominant family history (in taking a family history of tremor it is always useful to ask what shook [e.g. neck] as well as who shook). We would also call this tremor dystonic tremor. Where the patient has tremor with these characteristics, but (as yet) no evident dystonia, we currently label this as atypical tremor, while recognising that many of these subjects may later turn out to have dystonic tremor. Drug treatment is disappointing in older patients, but levodopa and anticholinergics are worth trying in younger subjects.

Both ET and dystonic tremor can be helped by botulinum toxin injections or, in severe cases, thalamic deep DBS or pallidal DBS (if dystonic).

### Neuropathic tremor

Some neuropathies, particularly immunoglobulin M dysgammaglobulinaemic neuropathy, can cause a postural (and if severe, even a resting) tremor. The severity of the tremor does not necessarily correlate with the severity of the neuropathy or the degree of deaf-ferentation. In patients with unexplained tremor it is always important to search for any clinical evidence of neuropathy.

### Fragile X tremor ataxia syndrome

It has recently been recognised that individuals (usually males) with premutations (55–200 CGG repeats) in the fragile X mental retardation 1 (*FMR1*) gene can, as they get older, present with a relatively slowly (compared with MSA-C) progressive syndrome combining postural or action tremor and ataxia, sometimes with additional parkinsonism, peripheral neuropathy, cognitive impairment and dysautonomia. There can be a family history of, and an increased risk, especially to males, of mental retardation, and premature ovarian failure can occur in females. MRI commonly shows hyperintensity of the middle cerebellar peduncles or of subcortical white matter, and cerebellar atrophy.

### Cerebellar (pathway) tremor

#### Intention tremor

This is caused by brainstem or cerebellar outflow pathway lesions, the most common cause being multiple sclerosis (MS). The tremor is not just action or terminal (features common to many postural tremors), but worsens steadily throughout the whole trajectory of the movement. Symptomatic drug treatment is unhelpful. DBS may transiently help, but its benefits are usually overwhelmed by the progression of MS lesion load.

#### Holmes tremor

This form of tremor, previously called midbrain tremor or rubral (red nuclear) tremor, is a tripartite tremor incorporating tremor at rest, postural tremor and intention tremor. It is caused by a combination of damage to the cerebello-rubrothalamic and nigro-striatal pathways.

#### Palatal tremor

This comprises rhythmic (1–2 Hz) contractions of the soft palate, presumably resulting from a dysfunction (essential palatal myoclonus, EPM) or a lesion (symptomatic palatal myoclonus, SPM) involving the connections between dentate nucleus, red nucleus and inferior olivary nuclei (the Guillain–Mollaret triangle). EPM consists of rhythmic contractions of the tensor veli palatini, innervated by the trigeminal nucleus. In SPM, the main muscle involved is the levator palatini, innervated by the facial nucleus and the nucleus ambiguus. EPM is typically associated with clicking, whereas SPM usually persists during sleep and is often associated with hypertrophy of the inferior olive. SPM is often associated with vertical ocular movements (oculopalatal myoclonus) or rhythmic and oscillatory limb movements at a rate of 1–3 Hz. Important causes of SPM include Wilson's disease, stroke and/or tumour and Alexander's disease. A number of EPM cases are of functional (non-organic) origin. Oculomasticatory myorhythmia or oculo-facial-skeletal myorhythmia are believed to be pathognomonic of Whipple's disease. Clonazepam sometimes helps.

#### Orthostatic tremor

This is a rare condition in which subjects feel unsteady, and often tremulous, while standing still, but not on walking, so that they like to either sit down or to keep moving. It is characterised by 13–16 Hz

tremor of the leg muscles, easily recorded on surface EMG which can often be felt or auscultated, but not usually seen. Some cases have additional features of parkinsonism or restless legs. Clonazepam sometimes helps.

**Drug and toxin-induced tremor**

Tremor can be caused by a number of different drugs or toxins including dopamine-depleting or receptor-blocking drugs, cinnarazine, some calcium-channel blockers, diltiazem (mostly rest tremor), sodium valproate (rest or postural), or beta-agonists, theophylline, caffeine, nicotine, lithium, amiodarone, SSRIs and tricyclic antidepressants, ciclosporin, thyroxine excess, and intoxication with marijuana, cocaine, amphetamines or mercury (postural).

**Psychogenic tremor**

This is dealt with in Other movement disorders.

**Dystonia**

Dystonia is a heterogeneous and common movement disorder typically characterised by involuntary muscle spasms leading to abnormal postures of the affected body part. Typically, the spasms in dystonia are mobile and this often leads to a slow writhing of the affected body part as described by the older term ‘athetosis’. Co-contraction of agonist and antagonist muscles is the underlying reason for the abnormal posturing in dystonia, and this can be obvious clinically or more easily on simple EMG assessment. Dystonia can be variable in its presentation and in some cases tremor or jerks can be the predominant feature with the abnormal postures being subtle. In fact the recent 2013 consensus statement on classification and definition of dystonia recognises tremor as an integral part of dystonia and includes it within the definition. Dystonia can also often be task, or position-specific (e.g. present only on writing or playing a musical instrument but not with other tasks). Another characteristic feature of dystonia, particularly focal dystonia, is the presence of a sensory trick or *geste antagoniste*, whereby applying a sensory stimulus to a particular area will cause the abnormal posture to resolve. Some non-motor aspects of dystonia have been recognised including abnormalities in specialised sensory function such as spatial and temporal discrimination and psychiatric features such as anxiety and depression.

**Epidemiology**

There have been few epidemiological studies of dystonia. Most studies have provided estimates based on few cases. A European prevalence study with pooled data from eight countries undertaken to provide more precise rates of dystonia found the crude annual period prevalence rate (1996–1997) for all primary dystonia was 152 per million, with focal dystonia having the highest rate of 117 per million (108–126) of which cervical dystonia was most common (57 per million), followed by blepharospasm (36 per million) and writer’s cramp (14 per million). However, the authors pointed out that because of under-ascertainment of cases, these rates were probably an underestimate of the true prevalence of dystonia.

**Classifying dystonia**

Dystonia can be classified in a number of ways including by age of onset, by distribution and aetiology (Table 6.4). With regard to aetiology there have been major advances in the genetic causes of the dystonias and this list keeps growing. Clinically, however, the most important and useful division is classifying patients broadly into

**Table 6.4** Classification of dystonia.

By aetiology	By distribution	By age at onset
Primary (no neurodegeneration; dystonia only ± tremor)	Focal Segmental	Young onset (<28 yrs) Adult onset (>28 yrs)
Dystonia-plus syndromes	Multifocal	
Dopa-responsive dystonia	Hemidystonia	
Myoclonus dystonia		
Secondary		
Symptomatic		
Hereditary		
Paroxysmal		

**Table 6.5** Clinical clues in the history and examination suggesting a secondary cause of dystonia.

Abnormal birth/perinatal history
Developmental delay
Continued progression of symptoms
Unusual distribution of dystonia given age of onset (e.g. leg dystonia in an adult, hemidystonia)
Unusual nature of dystonia (e.g. fixed dystonic postures)
Prominent bulbar involvement by dystonia
Additional neurological symptoms (pyramidal signs, cerebellar signs, cognitive decline)
Seizures
Other systems affected (e.g. organomegaly)
Previous exposure to drugs (e.g. dopamine receptor blockers)

two categories: those with ‘primary dystonia’; and those with ‘secondary/hereditary’ dystonic conditions. Dystonia is the only clinical sign (with the exception of tremor) in primary dystonia, and there is no neurodegeneration. The age of onset (below or above age 28), and distribution (focal, segmental, generalised) can be very useful to decide whether the patient fits into the well-defined phenotypes of primary dystonia (see later), and for picking up patients with unusual phenotypes (e.g. an adult presenting with generalised dystonia, which would be incompatible with typical primary dystonia) and to investigate these patients further to find out the likely secondary/hereditary cause. Clinical features or ‘red flags’ that should make one consider secondary dystonia rather than primary dystonia are listed in Table 6.5. A new consensus classification has proposed that dystonia be classified by two axes. Axis 1 clinically defines dystonia as either ‘isolated’ or ‘combined’ (when associated with other features). Those with combined features may

further be characterised into a syndrome and particular etiologies are to be considered in Axis II. Psychogenic dystonia is dealt with later in this chapter.

### Primary dystonia

In patients with primary dystonia, age at onset appears to be very important in determining the clinical phenotype. Young onset dystonia (before the age of 28 years) most commonly manifests with limb onset dystonia, followed by subsequent generalisation and was referred to in the older literature as dystonia musculorum deformans or Oppenheim's dystonia. It is now known that about 70% of patients presenting in this way will carry a single GAG deletion in the *DYT1* gene on chromosome 9. This condition is more common in Ashkenazi Jews, with a possible founder in Eastern Europe about 3 centuries ago. It has an autosomal dominant inheritance, but a very low phenotypic penetrance such that only 30–40% of gene carriers will ever develop dystonia, and in those who do this will almost always happen before the age of 30 years.

When dystonia appears in adult life, a focal or segmental distribution is commonly seen and the condition does not generalise. These presentations, in order of frequency of occurrence, include cervical dystonia (spasmodic torticollis), cranial dystonia (e.g. blepharospasm, Meige syndrome [blepharospasm and oromandibular dystonia]), writer's cramp, laryngeal dystonia (sometimes called spasmodic or, inappropriately, spastic dysphonia) and other task-specific dystonias. Cranio-cervical dystonia is more common in women than men, with the opposite pattern seen in task-specific writing dystonia. The adult onset focal dystonias are not a forme fruste of the early onset *DYT1* gene-related dystonia, and this gene has been excluded in these disorders, most of the patients being sporadic. Apart from *DYT1* a number of genes have now been identified causing primary dystonia but also some forms of combined dystonia (where there are other associated features; Table 6.6) and the list is growing. Amongst these is one causing isolated primary cranio-cervical dystonia with onset in the early adulthood is *DYT6*, caused by mutations in the *THAP1* gene. Patients with *THAP1* often have marked laryngeal with cervical or oromandibular dystonia often with spread to the limbs. Other rare causes of cervical/segmental dystonia are due to rare genetic forms due to *CIZ1*, *GNAL* and *ANO3* gene mutations. *DYT7* and *DYT13* have been described in rare families with cranio-cervical segmental dystonia but the genes are yet to be discovered (Table 6.6).

### Dystonia-plus syndromes

This category refers to two diseases without evidence of neurodegeneration whose motor manifestations are restricted to dystonia, plus parkinsonism or myoclonus. Some would consider it reasonable to include them with *DYT1* under the heading of primary dystonias.

### Dopa-responsive dystonia

Dopa-responsive dystonia (DRD; *DYT5*), previously also called Segawa disease, typically presents in childhood, purely with lower limb dystonia, and parkinsonism may rarely be associated, although the latter can be a presenting feature when onset is at an older age. A diurnal fluctuation in symptom severity with a gradual worsening of symptoms throughout the day was said to be typical of the condition, but is present in only 60% of cases. This condition is inherited in an autosomal dominant manner, with reduced penetrance, and is caused by mutations in the GTP cyclohydrolase 1 gene (*GTPCHI*; *DYT5*), a rate-limiting step in the production of

dopamine from tyrosine. Although rare, it is of critical importance to the practising neurologist as it is entirely treatable by small doses of levodopa. This typically leads to complete resolution of symptoms, which is sustained without the development of long-term complications as seen in PD.

It is increasingly recognised that DRD can present with unusual phenotypes such as spastic diplegia, writer's cramp and other focal dystonias including predominant cervical dystonia and even ataxia. In view of this, an adequate trial of levodopa (ideally up to 100–200 mg according to age/weight plus peripheral decarboxylase inhibitor, three times daily), for at least 2 months is strongly recommended in all those with young onset dystonia, especially as genetic diagnosis is time-consuming and not generally available. A phenylalanine loading test and cerebrospinal fluid (CSF) pterin studies can be helpful. It is also important to differentiate patients with DRD from those with young onset Parkinson's disease, who may present with foot dystonia, and in whom the early use of levodopa is not recommended. A DaT SPECT or a fluorodopa PET scan (both normal in DRD) can be useful in this regard. Other inherited defects of the dopamine synthesis pathway (e.g. the recessively inherited tyrosine hydroxylase deficiency) can also cause DRD, but usually as part of a more severe neurological syndrome.

### Myoclonus dystonia

Patients with myoclonus-dystonia (*DYT11*), caused by autosomal dominantly inherited mutations in the  $\epsilon$ -sarcoglycan gene on chromosome 7q21, present with early onset dystonia in combination with myoclonic 'lightning' jerks. The jerks respond quite dramatically to alcohol. The condition typically starts in childhood, and is mostly inherited through the father because of maternal genomic imprinting. The myoclonus or dystonia mainly affects the head, neck and arms, with the legs usually being spared. The myoclonus worsens during movement (action myoclonus) and is often more prominent than the dystonia. It had been suspected that hereditary essential myoclonus (when myoclonus is prominent) and dominantly inherited myoclonic dystonia, with lightning jerks and dramatic response to alcohol, might often be the same disease, and this has now been confirmed with the discovery of the causative mutations, although other broadly similar cases are mutation-negative. Psychiatric features such as anxiety, depression and obsessive-compulsive disorders are also a feature of the condition in a fair proportion of cases.

Figure 6.4 shows the breakdown of dystonia classification scheme according to clinical presentation and its genetic correlations.

### Symptomatic dystonia

Dystonia can be secondary to a number of environmental causes, many of which affect the basal ganglia. Dystonia is commonly seen following brain injury (e.g. perinatally: dystonic/dyskinetic/athetoid cerebral palsy) or following stroke. In such patients a static deficit is commonly seen, although onset can be delayed for months or even years after injury, and progression and late worsening of symptoms is sometimes seen.

Tardive dystonia is dealt with in Other movement disorders.

### Heredodegenerative dystonias

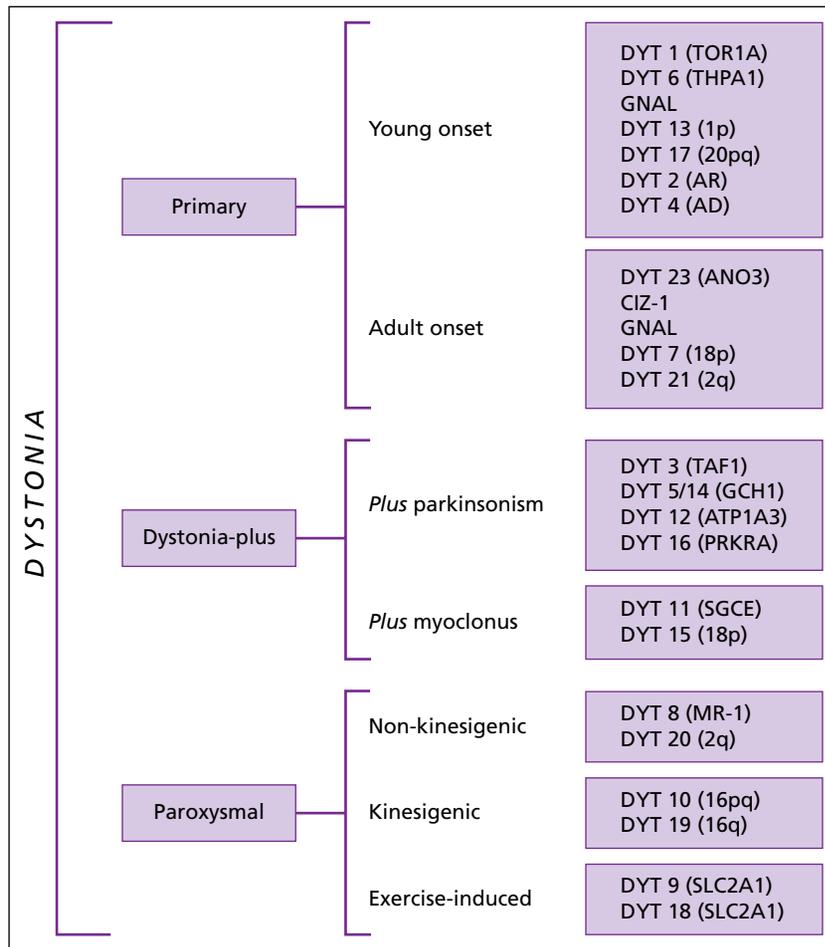

Dystonia can be a feature of a wide range of neurodegenerative conditions, which can make selection and prioritisation of the appropriate investigations and reaching the correct diagnosis a difficult task. One aspect of such conditions that can be helpful is that many

have syndromic associations which can help guide the investigating clinician. For example, peripheral neuropathy in association with dystonia would make one think of neuro-acanthocytosis or metachromatic leukodystrophy as more likely diagnoses. Prominent facial dystonia or flapping tremor would make one consider Wilson's disease and associated ataxia can point to spino-cerebellar degenerations such as SCA2 or SCA3. Prominent bulbar or severe tongue involvement by dystonia is a strong pointer to secondary dystonia and would favour certain conditions including neurodegeneration with brain iron accumulation (NBIA; formerly known as Hallervorden–Spatz syndrome) and also neuro-acanthocytosis and Lesch–Nyhan syndrome. Appropriate investigation should be carried out. Brain MRI is very important as it may show characteristic changes; for example, the 'eye of the tiger sign' characteristic of NBIA caused by mutations of the pantothenate kinase 2 gene (*PANK2*) (Figure 6.5). A list of some of these conditions, with their associated clinical symptoms, is given in Table 6.7, and the investigations to be carried out as suggested by the syndromic association are given in Table 6.8.

### Wilson's disease

Of all the causes of hereditary degenerative dystonia, Wilson's disease (WD) is the most important because it is treatable, and fatal if left untreated. It is an autosomal recessive disorder of copper

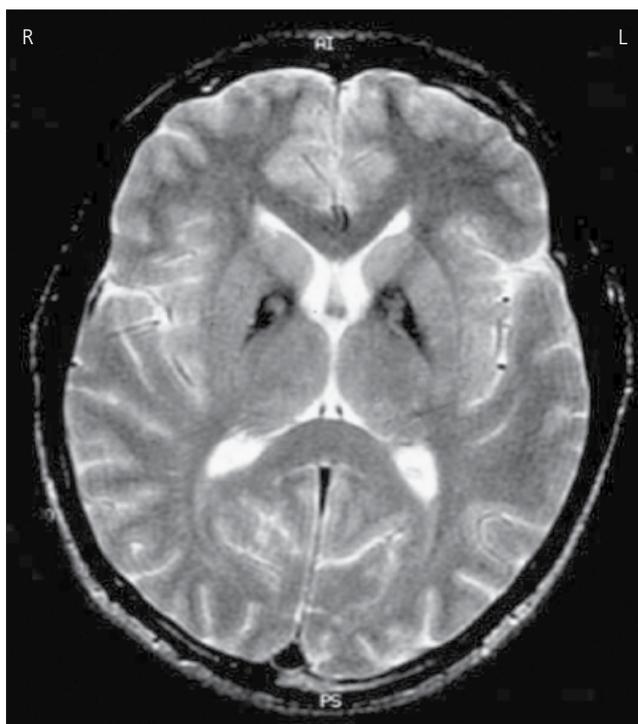

metabolism that most commonly presents in the first two decades of life. It occurs worldwide with prevalence of 1–3/100 000. More than 300 different mutations have been identified distributed across the responsible gene, *ATP7B* on chromosome 13, which encodes a copper-dependent transmembrane protein P type ATPase. The most common in patients of European origin is the H1069Q mutation. The heterozygote carrier rate is 1%.

### Clinical presentations

Patients may present with acute liver failure, chronic hepatitis or cirrhosis, most commonly in the first decade of life, and a few present with an acute haemolytic anaemia. Other features include joint and bone abnormalities, azure lunulae of the finger nails, aminoaciduria and cardiomyopathy.

Most cases of neurological WD present with slurred speech and a movement disorder in adolescence, often in association with behavioural disturbances. Approximately half of all cases present with neuropsychiatric symptoms, usually between 14 and 20 years of age.

The 'pseudosclerotic' neurological variant is perhaps the most common, with the onset of a Holmes or wing-beating tremor and some ataxia and dysarthria; in other patients dystonia or an akinetic-rigid syndrome may dominate. Early gait abnormalities are frequent and a mixed movement disorder is common,

**Figure 6.5** Classic ‘eye of the tiger sign’ (central hyperintensity with surrounding hypointensity in globus pallidus) in a patient with neurodegeneration with brain iron accumulation (NBIA) caused by a *PANK2* mutation (MRI T2W).

**Table 6.7** Examples of common hereditary degenerative causes of dystonia and associated syndromic clinical features.

Wilson’s disease	Kayser–Fleischer rings, ataxia, cognitive decline
Neurodegeneration with brain iron accumulation ( <i>PANK2</i> , Hallervorden–Spatz syndrome)	Retinal degeneration, pyramidal signs, oromandibular/bulbar involvement
Neuro-acanthocytosis	Peripheral neuropathy, oromandibular dystonia, epilepsy
Metachromatic leukodystrophy	Peripheral neuropathy, frontal dementia
GM1/GM2 gangliosidosis	Cognitive decline
Glutaric acidaemia	Cognitive decline
Huntington’s disease	Cognitive decline, personality change, depression, supranuclear eye movement abnormalities
Ataxia telangiectasia	Supranuclear eye movement abnormalities
Niemann–Pick type C	Vertical gaze palsy, cognitive decline

sometimes with associated risus sardonicus and pseudobulbar palsy. Dysarthria is the most common sign, whereas chorea and athetosis affect only about 10%. If left untreated, fronto-limbic cognitive dysfunction may develop and seizures, myoclonus and

MRI brain/spine (structural lesions, leukodystrophies, ‘eye of tiger’ sign in NBIA)
Nerve conduction studies (neuro-acanthocytosis, metachromatic leukodystrophy)
Copper studies, slit-lamp, gene test, ?liver biopsy (Wilson’s disease)
White cell enzymes (GM1, GM2, metachromatic leukodystrophy)
Alphafetoprotein, immunoglobulins (ataxia telangiectasia)
Lactate/pyruvate, mitochondrial mutations, muscle biopsy (mitochondrial disease)
Fresh thick blood smear for acanthocytes (neuro-acanthocytosis)
Plasma amino acids, urinary organic acids, aminoacids, oligosaccharides (glutaric academia, GM1, GM2)
Skin biopsy-fibroblast culture, bone marrow biopsy/axillary skin biopsy (Niemann–Pick type C, Kufs)
Phenylalanine loading test/CSF pterin assessments (DRD)
ERG, retinal examination, <i>PANK2</i> gene test (positive in some cases of NBIA)

DRD, dopa-responsive dystonia; ERG, electroretinogram; MRI, magnetic resonance imaging; NBIA, neurodegeneration with brain iron accumulation.

pyramidal signs have been reported. Cases presenting later than age 40 are exceptionally rare. Virtually every patient with WD presenting with neurological dysfunction has Kayser–Fleischer (K-F) rings on slit-lamp examination. These are caused by copper deposition on the inner surface of the cornea in Descemet’s membrane and have a golden brown or greenish appearance. They can occur in other forms of chronic liver disease but in the context of a neurological presentation in adolescence can be considered pathognomonic for WD.

The histopathological findings in the brain include swollen glia and an increase in astrocytes within the grey matter, often with spongiform change.

### Diagnosis

The emergence of parkinsonism, dystonia or a tremor in an adolescent or young adult with slurred speech should always raise the possibility of WD, particularly if there is a family history of hepatic, psychiatric or neurological disorder in childhood. Consanguinity should be enquired about. Suspected cases should be referred to an experienced ophthalmologist for slit-lamp examination.

The combination of a movement disorder with emotionalism, a risus sardonicus and a K-F ring makes the diagnosis highly likely but biochemical confirmation is required. Unfortunately, there is still no one single fail-safe test.

A low serum caeruloplasmin level is consistent with WD and is diagnostic when K-F rings are present. Low levels of caeruloplasmin also occur in hereditary acaeruloplasminaemia and Menkes’ disease. Some WD heterozygotes have a reduced caeruloplasmin level, while a few WD patients with decompensated liver disease can have normal levels. In females, the oral contraceptive pill can raise an otherwise low level to within the normal range. In WD, a hepatic copper concentration greater than 250 µg/g dry weight is usual. Serum aminotransferase levels are also usually abnormal. However, a lower hepatic copper value does not absolutely exclude

WD and long-standing cholestasis can also cause high copper levels. The biochemical results therefore need to be taken in the context of the clinical picture and the histological changes. Although genetic testing is not available as a routine service test, in ambiguous cases it can be extremely helpful to at least screen for the more common mutations. Urinary copper, derived from the free non-caeruloplasmin-bound copper circulating in plasma, is elevated in WD. An excretion rate greater than 100 µg/24 hours (0.6 mmol/L in 24 hours) is considered diagnostic but levels above 40 µg/24 hours can be significant in a neurological presentation. Wide-necked bottles with copper-free disposable polyethylene liners are recommended. Urinary copper excretion after penicillamine loading can be a useful ancillary test.

In neurological cases, brain MRI can show high signal abnormalities on T2-weighted images and low intensity lesions on T1 in the putamen, globus pallidus, thalamus, midbrain, pons and cerebellum. White matter abnormalities are also common and cortical atrophic changes also occur. Proton density MRI sequences can be particularly sensitive. Once WD has been diagnosed, screening of all first degree relatives is essential.

### Treatment

The first chelation treatment, parenterally administered British anti-Lewisite (BAL), was introduced in 1951. In 1956, John Walshe first reported clinical benefit with penicillamine and half a century of use has confirmed its efficacy in most cases. However, some patients cannot tolerate the drug and about 20% of patients with neurological presentations can deteriorate markedly on its introduction. Regular monitoring with a full blood count and renal function tests is recommended. Adverse events include fever, rash, lymph gland enlargement, neutropenia, thrombocytopenia and proteinuria. Nephrotoxicity, a lupus syndrome, bone marrow suppression, skin changes including elastosis perforans serpiginosa and a myaesthetic syndrome are late complications. Children and pregnant women should be given weekly pyridoxine.

In 1969, Walshe discovered another chelator, trientine, which has proved to be a well-tolerated alternative. It is still generally used as a second line drug, but some now recommend it as the initial treatment of choice in neurological cases, although deterioration can also occur on starting treatment. Pancytopenia has been reported and sideroblastic anaemia may occur if copper deficiency develops.

Oral elemental zinc, which induces intestinal metallothionein which binds copper within the enterocyte, has also been recommended, particularly for asymptomatic and presymptomatic patients and as maintenance therapy after a period of initial chelation.

Tetrathiomolybdate forms a complex with copper and protein and prevents copper absorption when given with food, and has been claimed to be highly effective, but remains investigational. Whichever drug is chosen, regular lifelong monitoring to ensure compliance is essential.

Chocolate, liver, nuts, mushrooms and shellfish contain high levels of copper, so are best avoided. Anticholinergics may modestly help dystonia and some patients with an akinetic-rigid syndrome may have some improvement with levodopa. In patients with hepatic disease who deteriorate despite optimum therapy, liver transplantation, which corrects the underlying pathophysiology, can be life-saving. For refractory or deteriorating neurological disability despite other treatments, a course of intramuscular BAL injections is worth trying. The use of liver transplantation for

patients with progressive neurological impairment despite adequate chelation is controversial. Patients with WD surviving into middle age have an elevated risk of hepatic carcinoma.

### Paroxysmal dyskinesias

Paroxysmal dyskinesias are defined as intermittent attacks of involuntary movements, usually dystonia, chorea or ballism, with normal neurological examination between attacks. Episodes are induced by trigger factors including sudden movements (paroxysmal kinesigenic dyskinesia; PKD), prolonged exercise (paroxysmal exercise-induced dyskinesia; PED) or alcohol and coffee (paroxysmal non-kinesigenic dyskinesia; PNKD) or sleep (paroxysmal nocturnal dyskinesia; PND). The duration can be seconds to hours. Recently, genetic mutations for all three forms of the primary paroxysmal dyskinesias have been identified. PRRT2 gene mutations underlie the majority of sporadic and familial PKD cases. Mutations of the myofibrillogenesis regulator gene (*MR-1*) on chromosome 2q33-35 have been identified in patients with PNKD. The encoded protein appears to have a role in the detoxification pathway of methylglyoxal, a compound present in coffee and alcoholic beverages, both of which can induce attacks. About 40% of PED cases are caused by mutations of the glucose transporter 1 gene (*Glut1*). In PND, nicotinic acetylcholine receptor gene mutations occur and this is an example of a ligand-gated channelopathy. For the other forms, various loci have been proposed but genes have not yet been identified. Secondary paroxysmal dyskinesias have also been described and possible causes include demyelination, vasculopathy, infectious disease (HIV, cytomegalovirus), cerebral and peripheral trauma, neurodegenerative disease, hormonal and metabolic dysfunction, neoplasm and cerebral palsy. Anticonvulsants (first choice carbamazepine in PKD), benzodiazepines, barbiturates or acetazolamide can bring relief. PED related to *Glut1* gene mutations can benefit by changing to a ketone diet or modified Adkins diet. Triggering factors should be avoided.

### Investigation of dystonia

Following a careful history (in particular, drug and family history) and examination, investigation of patients with dystonia should be tailored to the presentation of the patient, and in particular whether the clinical picture suggests primary or secondary dystonia. Common clinical situations are of children or adolescents presenting with a primary focal, segmental or generalised dystonia, or adults presenting with a primary focal or segmental dystonia. For the former category, investigations should include copper studies and slit-lamp to exclude WD, brain imaging (preferably MRI), the *DYT1* or another gene test as appropriate and an adequate trial of levodopa. For adult onset primary dystonia, copper studies and slit-lamp to exclude WD should be performed if presentation is under 50 years of age; brain imaging is not generally required, but if there is fixed or painful cervical dystonia an MRI of the spine should be carried out to exclude structural lesions. More extensive investigations are needed in patients with presumed secondary dystonias (Table 6.5) but this list can be narrowed down by considering pertinent aetiological possibilities according to the presence of associated clinical features as shown in Table 6.7, and an outline of the investigations is given in Table 6.8.

### Treatment of dystonia

Drug treatment of dystonia is most appropriate in those with younger onset generalised and/or segmental dystonia for whom botulinum toxin (see later) would be unlikely to control the full

extent of the dystonia. First line treatment is with anticholinergics such as trihexyphenidyl. Slow introduction of the drug is very important to avoid side effects, but some, particularly younger, patients can ultimately tolerate very high doses (100 mg/day or more) with good effect. Clonazepam can be useful for the treatment of tremor, jerks and pain associated with dystonia. Other drugs that are sometimes useful include tetrabenazine, baclofen and even dopamine receptor blocking drugs. As mentioned above, all patients with young onset dystonia should receive an adequate trial of levodopa. The treatment of WD has been detailed above.

Botulinum toxin has revolutionised the treatment of patients with focal dystonia. Botulinum toxin cleaves specific proteins involved in vesicular fusion at the presynaptic terminal, thereby blocking the release of acetylcholine, the principal neurotransmitter at the neuromuscular junction. The affected nerve terminals do not degenerate, but the blockage of acetylcholine release is irreversible. Neuromuscular transmitter release recovers by sprouting of new nerve terminals and formation of new synaptic contacts, which takes about 3 months. Transmission is also inhibited at gamma neurones in muscle spindles, which can alter reflex overactivity.

A number of randomised double-blind clinical trials have established the efficacy of botulinum toxin injection treatment for focal dystonia. Treatment is required every 3–4 months, and is expensive, but a 70–80% improvement in symptoms is common in most patients, particularly those with blepharospasm and cervical dystonia. Treatment of those with limb dystonia, in particular writer's cramp, is often more difficult and benefit can be inconsistent. Main side effects of treatment are excessive weakness of the treated muscle or spread of effect to nearby muscles (e.g. paralysis of pharyngeal muscles following sternomastoid injections). Immune-mediated resistance to botulinum toxin is seen in a small proportion of chronically treated patients, particularly those who receive high doses, 'top-up' doses or injections more frequently than every 12 weeks. An alternative toxin, botulinum toxin type B, is available, but antibodies to the commonly used type A toxin can be cross-reactive with type B toxin, and, in addition, a primary immune response to type B toxin can also occur. Botulinum toxin can be helpful for those with generalised dystonia where a particular functional problem can be linked to dystonia in a single or a small group of muscles.

### Surgery for dystonia

Although the primary treatment for dystonia is medical, a number of patients, particularly those with generalised dystonia, remain severely disabled and can benefit from surgery. Ventrolateral thalamotomies, and to a lesser degree pallidotomies, were performed from the 1950s for alleviation of dystonia. The results were not consistent and some patients had initial benefit that wore off over time, necessitating several operations. Complications, including dysarthria and dysphagia, were not uncommon, especially in bilaterally operated patients.

Concerns about potential side effects of bilateral lesions, and the beneficial effect of globus pallidus internus (GPi) DBS on dyskinesias in PD patients, led the group of Coubes in France to propose the use of GPi DBS in dystonia. Their early report of successful treatment has been confirmed in larger series of patients and multi-centre controlled trials.

Primary generalised dystonia is recognised as being the indication giving the best results and both *DYT1* positive and negative patients can obtain a good effect – up to 70% improvement of the clinical score has been reported. The improvement is gradual and follows a complex time course; the mobile aspects of the dystonia

tend to improve more rapidly than the fixed aspects that can take up to 6 months. In consequence it is difficult to adjust stimulation parameters according to acute changes of symptoms. The outcome in those with focal dystonia such as cervical dystonia or writing dystonia is mixed although tremor and jerks associated with cervical dystonia can respond quite well.

Beneficial effect on quality of life has also been reported, while there was little change on cognitive scores and neuropsychiatric measures, in particular on depression. The presence of fixed orthopaedic deformities limits the potential beneficial effect of DBS. Sudden interruption of the stimulation can lead to severe dystonic state in these patients, who may need urgent or prophylactic battery replacement.

Myoclonus dystonia (*DYT11*) can also benefit from GPi DBS. Some forms of secondary dystonia may benefit, but usually not to the same extent as primary dystonia. Neuroleptic-induced tardive dystonia may show major benefit with GPi DBS and some forms of hereditary degenerative dystonias such as PANK2-related brain iron accumulation disorders, neuracanthocytosis and others may have some benefit for a limited period of time. In Lubag-related status dystonicus pallidal DBS may be life-saving.

The surgical procedure is similar to that used for PD and is usually carried out in one session under general anaesthesia. Side effects are rare and usually reversible by adjustment of electrical parameters.

## Chorea

Chorea is derived from the Greek word *choreia* meaning a dance. Chorea is a state of excessive spontaneous movements, irregularly timed, randomly distributed and abrupt. Severity can range from restlessness with mild intermittent exaggeration of gesture and expression, fidgety movements of the hands or unstable dance-like gait to a continuous flow of disabling and violent movements. Chorea has many causes which can be simply divided into acquired and inherited. This section summarises the assessment and investigation of the choreic patient and focuses on the important causes of chorea seen in clinical neurological practice (Table 6.9).

### Assessment of chorea

Assessment of the choreic patient depends on directed history and examination (Figure 6.6; Table 6.10), which will determine the appropriate investigations to consider (Table 6.11). Onset and nature of progression are important features. Abrupt or subacute onset is more suggestive of acquired causes. It is important to take a detailed drug history, to ask about recent throat infections (Sydenham's chorea or PANDAS), pregnancy (chorea gravidarum), rashes or joint aches (systemic lupus erythematosus; SLE), and metabolic history (hyperthyroidism), and to note the symmetry of the chorea, as asymmetric onset suggests a structural or vascular lesion in the contralateral basal ganglia (Figure 6.7). Most inherited causes of chorea have a slow and insidious onset, most commonly noticed by friends or relatives rather than patients themselves. A detailed family history is crucial and particular attention should be paid to a parent who died at a relatively young age.

### Huntington's disease

Huntington's disease (HD) is a slowly progressive autosomal dominant neurodegenerative disorder and the most important inherited cause of chorea. Onset is usually in adult life with a mean age of about 40 years, although juvenile and elderly onset are well described.

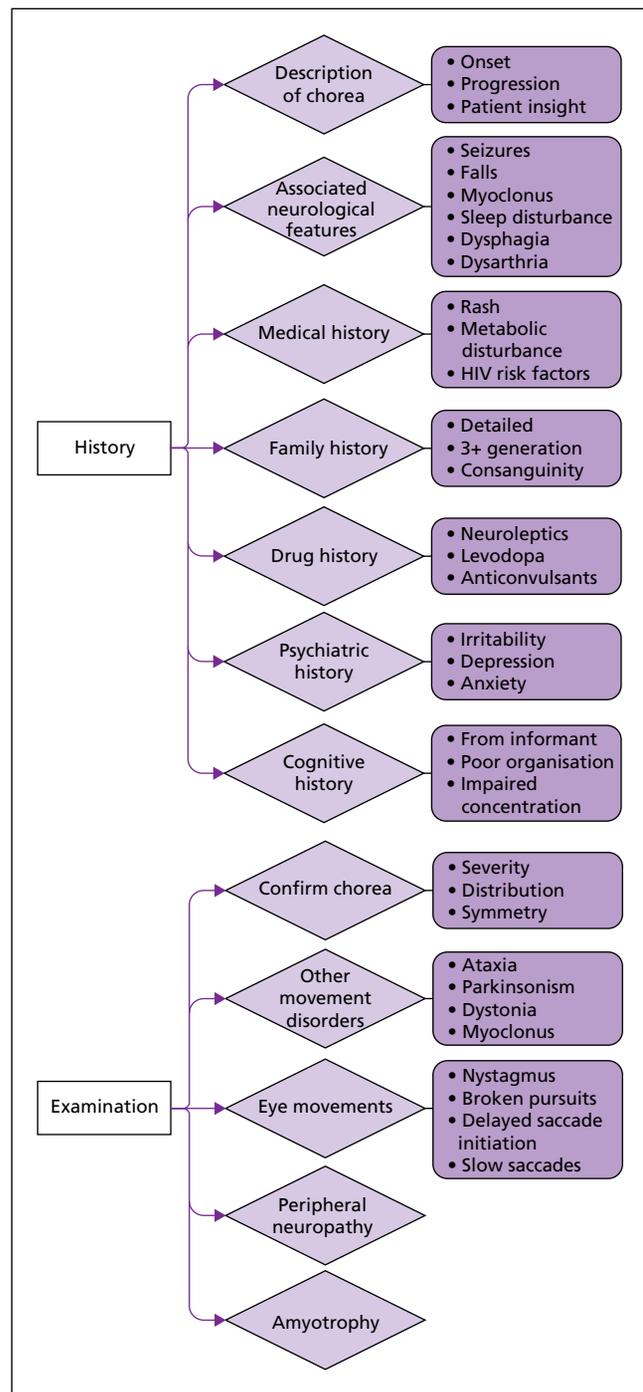

**Table 6.9** Inherited and acquired causes of chorea.

Inherited causes	Acquired causes
Huntington's disease*	Focal striatal pathology:
Neuro-acanthocytosis	Stroke
McLeod syndrome	Hyperglycaemia
Dentatorubro-pallidoluysian atrophy	Space-occupying lesions
Benign hereditary chorea	Drug-induced
Spinocerebellar ataxia types 1, 2, 3 and 17	Chorea gravidarum
Mitochondrial disorders	Thyrotoxicosis
Inherited prion disease	Systemic lupus erythematosus/antiphospholipid syndrome
Huntington's disease-like 2	Post-infective:
Wilson's disease	Sydenham's chorea (group A streptococcal infection)
Friedreich's ataxia	Paediatric autoimmune disorders associated with streptococcal infections (PANDAS)
Neurodegeneration with brain iron accumulation type 1	Herpes simplex encephalitis
Ataxia telangiectasia	Polycythaemia rubra vera
Neuroferritinopathy	Infective:
Lysosomal storage disorders	AIDS
Amino acid disorders	New variant Creutzfeldt–Jakob disease
Tuberous sclerosis	

\* The most common cause of inherited chorea – the remainder of these disorders are rare.

It progresses inexorably, with death occurring 15–20 years from onset. Prevalence is 4–10/100 000 in populations of Western European descent, but HD has been described throughout the world. HD is named after George Huntington who originally described it in 1872. In 1993, the causative gene defect was identified as a CAG repeat expansion, encoding polyglutamine repeats within a novel protein huntingtin. This highly polymorphic CAG repeat is located in exon 1 and ranges between 10 and 28 copies on normal chromosomes, but is expanded to a range of 36–121 on HD chromosomes. Adult onset patients usually have 40–55 repeats, with juvenile onset patients having over 60. CAG repeats above 40 are fully penetrant, although there is a borderline repeat range between 36 and 39 repeats with reduced penetrance.

CAG repeat lengths vary from generation to generation, with both expansion and contraction, but there is a tendency for repeat lengths to increase, particularly when transmitted through the paternal lineage. The instability of the CAG expansion with the tendency to expand during transmission underlies the phenomenon

**Figure 6.6** Clinical assessment of the choreic patient.

of anticipation. Genetic anticipation describes increasing severity and earlier onset of an inherited disease during intergenerational transmission and is a hallmark of HD and the other trinucleotide repeat disorders. CAG repeat instability during paternal transmission is important in the development of large expansions associated with juvenile HD; approximately 80% of juvenile HD patients inherit the HD gene from their father. There is a correlation between CAG repeat size and age at onset, such that the larger the repeat, the earlier the onset. Most individuals with more than 50 repeats develop the disease before the age of 30 years. CAG repeat number

also appears to govern the development rate of neuropathological changes. However, CAG repeat length does not completely explain variations in age of onset, clinical phenotype or rate of clinical progression, so that other modifying genes obviously have an important role.

Neuropathologically, in the early stages of disease, the brain can look macroscopically normal, but later there is marked cortical atrophy with ventricular dilatation, severe atrophy of the caudate more than the putamen, with atrophy of the internal segment of the globus pallidus and substantia nigra pars reticulata.

### Clinical features

HD can produce a varied clinical phenotype. It is important to realise that as the disease progresses, the signs and symptoms change, so disease duration can markedly modify the clinical presentation.

**Motor features** The onset of HD is often difficult to discern clearly. Many patients report psychiatric problems or mild cognitive symptoms before developing any motor problems. However, the defini-

tive diagnosis of HD is usually made when motor abnormalities are noted on examination. Subtle motor abnormalities seen early in the disease include general restlessness, abnormal eye movements, hyper-reflexia, impaired finger tapping, and fidgety movements of fingers, hands and toes during stress or when walking. Oculomotor abnormalities are a cardinal feature of the disease, and often the earliest motor sign. Saccadic abnormalities are characteristic and include gaze impersistence and distractibility and delayed initiation or slowing of voluntary saccades (vertical worse than horizontal).

As the disease progresses, more obvious extrapyramidal signs develop; chorea is seen in 90% of adult onset patients but can decrease in the late stages, whereas dystonia, rigidity and parkinsonism may dominate the clinical picture in late disease. A key motor abnormality in HD is impaired voluntary motor function with clumsiness, motor impersistence and disturbances in fine motor control and motor speed. Gait disturbance is common, with impaired postural reflexes making patients more prone to falling. Dysarthria and dysphagia are common and should be asked about.

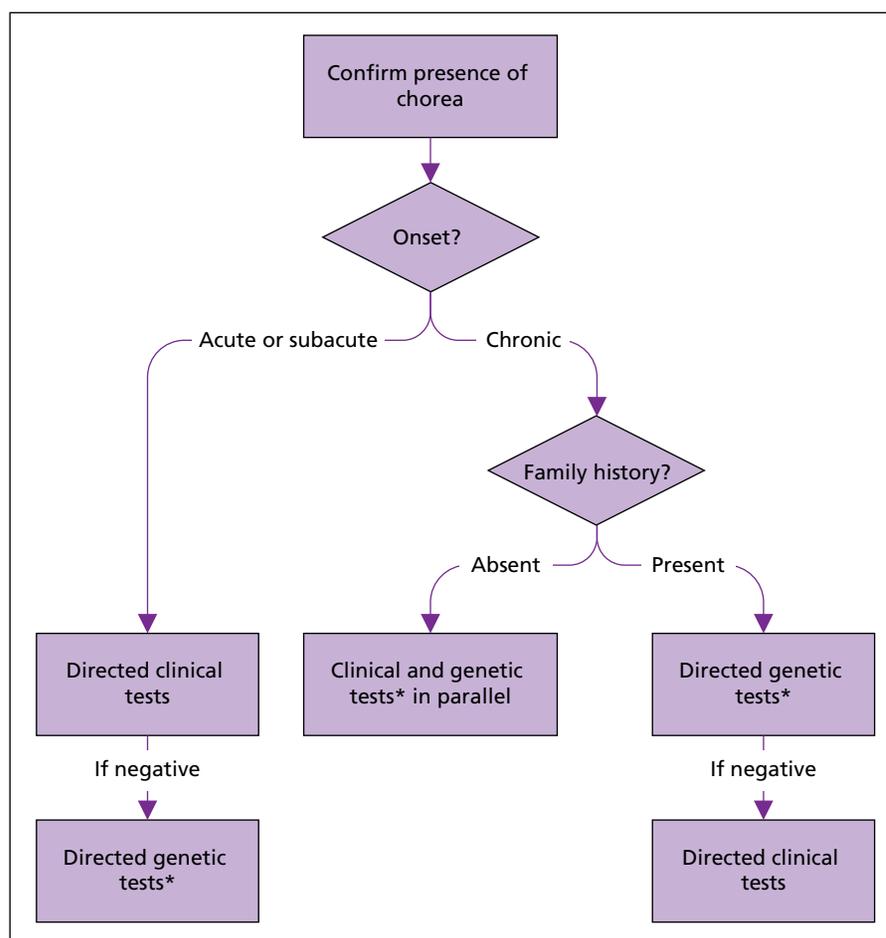

**Table 6.11** Investigations to consider in the choreic patient.

Test	Notes
MRI imaging	Stroke or other focal basal ganglia pathology T2* imaging abnormal in iron accumulation disorders T1 basal ganglia hyperintensities in hyperglycaemia FLAIR imaging abnormal in prion disease  Deep brain T2 hyperintensities in Wilson's disease
Full blood count	Haematocrit can be elevated in PRV
Red cell mass	Sensitive test required for diagnosis of PRV
Blood film	3 × fresh thick blood films necessary to exclude neuro-acanthocytosis
Erythrocyte membrane chorein levels (western blot)	Neuro-acanthocytosis
Serum caeruloplasmin	Reduced in Wilson's disease
Urinary copper level	Elevated in Wilson's disease
Liver biopsy	Sometimes required to diagnose Wilson's disease
Pregnancy test	Chorea gravidarum in first trimester
HIV test	(Hemi) chorea/ballism can be presenting feature of AIDS
Erythrocyte sedimentation rate and antinuclear antibody	Sensitive tests to reveal SLE
Anti-dsDNA	Relatively specific to SLE
Anticardiolipin and lupus anticoagulant	Antiphospholipid syndrome is risk factor for chorea
Thyroid function tests	Thyrotoxicosis
Antistreptolysin O (ASO) titre	Recent streptococcal infection suggests Sydenham's chorea/PANDAS
Antibasal ganglia antibodies	Associated with post-infective chorea, chorea gravidarum and OCP-induced chorea
Muscle biopsy	Ragged red fibres or respiratory chain abnormalities in mitochondrial disease
Cerebrospinal fluid analysis	Can reveal inflammatory/neoplastic causes

MRI, magnetic resonance imaging; OCP, oral contraceptive pill; PANDAS, paediatric autoimmune disorders associated with streptococcal infection; PRV, polycythaemia rubra vera; SLE, systemic lupus erythematosus.

**Cognitive features** Cognitive abnormalities are variable but universal in HD. The key cognitive abnormalities seen are impaired executive function with poor planning and judgement, impulsive behaviour, disorganised actions and difficulty coping with multiple tasks. Many patients exhibit psychomotor slowing with apathy, lack of self-care and loss of initiative which can make caring for them difficult. Patients often complain early on of visual and verbal memory problems, in addition to poor concentration and attention.

**Psychiatric features** The combination of psychiatric and cognitive features causes the greatest disability, functional decline and distress to relatives and HD patients. Psychiatric symptoms are common, particularly depression and anxiety. Irritability is also very common and some patients become aggressive. As the disease progresses, obsessions and compulsions often make life difficult for carers. Psychosis, despite being well-recognised, is relatively rare. The suicide rate in HD is much higher than in the general population. Psychiatric symptoms often cause great

**Figure 6.7** Approach to the investigation of the choreic patient. \*Genetic testing must always be preceded by detailed expert genetic counselling.

distress to patients and relatives and should be actively managed with the same drugs used in standard psychiatric practice.

### Juvenile Huntington's disease

Juvenile HD cases are defined as onset before age 20 years, usually associated with repeat lengths greater than 60. They have more severe disease and shorter life expectancy. The akinetic-rigid form of the disease (Westphal variant) is more common in juvenile HD: patients typically have little chorea and are predominantly rigid and dystonic. Juvenile HD patients also have a higher incidence of seizures and myoclonus than adult onset patients. Younger adult-onset patients with HD (<40 years) can also present with a predominantly parkinsonian phenotype similar to the juvenile HD cases.

### Differential diagnosis of Huntington's disease

**Huntington's disease phenocopies** Before the advent of genetic testing for HD, diagnosis was based on clinical evaluation and neuropathological examination. Now, genetic diagnosis allows definitive confirmation of the disease. Genotype-phenotype studies have increased our understanding of disorders that can present like HD (HD phenocopies) with similar cognitive, psychiatric and motor features, but are HD gene negative (Table 6.12). HD phenocopies occur in approximately 1% of large genetic screens of individuals

with clinical signs of HD. An approach to genetic testing of HD phenocopies is suggested in Figure 6.8.

HDL2 (HD-like 2) is caused by a CAG/CTG expansion in the *Junctophilin-3* gene and is very rare, and moreover only reported so far in individuals with African ancestry. In one consanguineous family, a phenocopy syndrome (HDL3) was mapped to 4p16.3, but no causative mutation has been identified. Other dominantly inherited diseases mimicking HD are dentatorubro-pallidoluysian atrophy (DRPLA), another polyglutamine disorder caused by a CAG repeat expansion in the atrophin-1 gene, and spinocerebellar (SCA) 17 – also called HDL4 – caused by a CAG repeat expansion in the TATA-binding gene (*TBP*). SCA1 and SCA3 (Chapter 17) may also mimic HD. Inherited prion disease can cause HD phenocopies: one mutation causes HDL1, an early onset prion disease with prominent psychiatric features. Recently, *C9ORF72* mutation, which is known to cause frontotemporal dementia, was also found to be an important cause of HD phenocopy. Neuroferritinopathy, a very rare, dominantly inherited disorder, caused by mutations in the ferritin light chain, has clinical features overlapping with HD.

### Neuro-acanthocytosis

There are several conditions (the neuro-acanthocytoses) in which chorea and other movement disorders are associated with the presence of acanthocytosis of the red blood cells in the peripheral blood.

**Table 6.12** Differential diagnosis of Huntington's disease (HD phenocopies).

Condition	Cause
HDL1	Octapeptide repeat insertion in gene encoding prion protein
HDL2	Triplet repeat expansion in gene encoding junctophilin-3
Frontotemporal dementia	Mutations of the C9orf72 gene
SCA17 (HDL4)	Triplet repeat expansion in gene encoding TATA-box binding protein
Inherited prion disease	Mutations in gene encoding prion protein
SCA1	Triplet repeat expansion in gene encoding ataxin-1
SCA3	Triplet repeat expansion in gene encoding ataxin-3
DRPLA	Triplet repeat expansion in gene encoding atrophin-1
Neuro-acanthocytosis	Mutation in gene encoding chorein
Neuroferritinopathy	Mutations in gene encoding ferritin light-chain
NBIA	Mutations in the <i>PANK2</i> gene

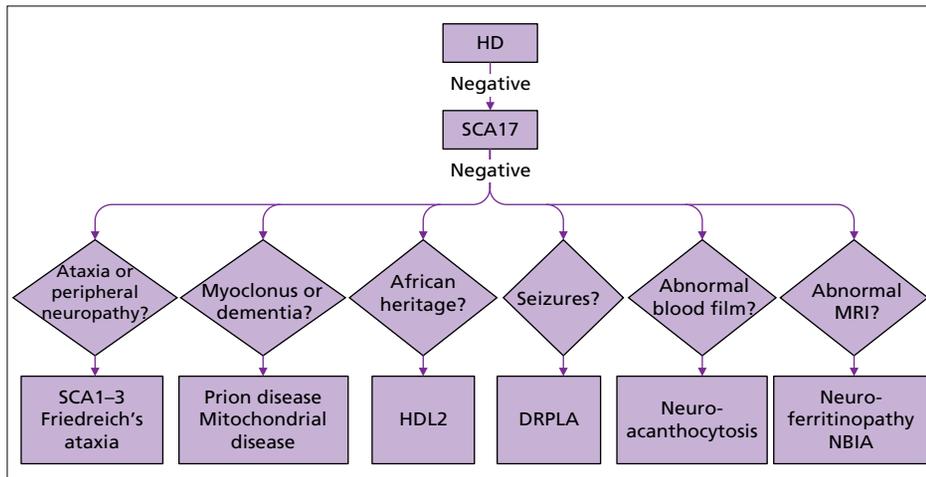

DRPLA, dentatorubro-pallidoluysian atrophy; NBIA, neurodegeneration with brain iron accumulation.

Autosomal recessive neuro-acanthocytosis is rare, and associated with mutations in the *CHAC* gene leading to production of a truncated protein termed chorein. Onset is typically in the fourth decade with a progressive movement disorder, psychiatric and cognitive changes which mimic HD. The movement disorder comprises chorea, dystonia and tics, with prominent eating dystonia, dystonic tongue protrusion and tongue and lip biting and also sudden head/trunk flexion or extension drops. Psychiatric and cognitive features are similar to HD. Unlike HD, seizures are seen in 50% of patients, and there is commonly a distal amyotrophy or axonal neuropathy with a high creatine kinase. Investigations include analysis of fresh blood films for >3% of acanthocytes. More than one blood film may be necessary to identify these. Genetic testing for mutations in the *CHAC* gene is difficult, so confirmation relies on demonstration of low erythrocyte membrane chorein levels in the blood. McLeod syndrome is a very rare X-linked recessive disorder linked to mutations in the *XK* gene, which encodes the Kell antigen. It usually begins around the age of 45 years and is slowly progressive, with limb chorea and facial tics. Dystonia is less common than in chorea-acanthocytosis and subcortical dementia and psychiatric features tend to occur later in the disease. Axonal neuropathy, cardiomyopathy and haemolytic anaemia can be seen, CPK is often elevated, and acanthocytes are usually found in fresh thick peripheral blood films.

Acanthocytes have also been described in pantothenate kinase-associated neurodegeneration (PKAN, or NBIA type 1) and HDL2 and all these disorders are encompassed under 'core neuro-acanthocytosis syndromes'.

**Post-streptococcal autoimmune disorders**

Sydenham's chorea and PANDAS (paediatric autoimmune disorders associated with streptococcal infection) can both present with chorea and neuropsychiatric manifestations. Sydenham's chorea is one of the major manifestations of rheumatic fever. It occurs in children, mainly girls, between 5 and 15 years of age and is now rare in the developed world. Widespread chorea, behavioural disturbance and obsessive-compulsive symptoms are common. It is self-limiting and usually resolves within 6 months, with about 20% of cases being

**Figure 6.8** Suggested approach to genetic testing in chorea.

recurrent. Antibasal ganglia antibodies can be detected. The mechanism of damage is thought to be molecular mimicry with cross-reaction between anti-streptococcal antibodies and neurones in the basal ganglia. PANDAS is also discussed under tics.

### Benign hereditary chorea

Benign hereditary chorea (BHC) is a very rare, dominantly inherited disorder caused by mutations in the gene encoding thyroid transcription factor 1 (*TITF1*). It is usually of early onset and is characterised by very slowly progressive chorea without cognitive decline or other neurological features, but there is clinical heterogeneity within and between families. Some cases of BHC also display dystonia, myoclonic jerks, mild dysarthria, gait disturbances or low-average intelligence, and many cases can also have hypothyroidism or pulmonary abnormalities of varying degrees, leading to the recent application of the term 'brain-thyroid-lung syndrome'. Some cases of BHC are caused by mutations in another gene, *ADCY5*, encoding adenyl cyclase 5.

### Drug-induced chorea

Many different medications can cause chorea. The main ones include neuroleptics (tardive dyskinesia), levodopa/dopamine agonists/anticholinergics (most often, but not exclusively, in patients being treated for parkinsonism), anticonvulsants (phenytoin, carbamazepine, valproate, gabapentin), CNS stimulants (amphetamines, methylphenidate, cocaine), benzodiazepines, oestrogens (oral contraceptive pill or, rarely, hormone replacement therapy) and lithium (although this more commonly causes myoclonus or jerky tremor).

### Drug management of chorea

Chorea can cause cosmetic embarrassment to some patients but many do not notice the severity of their chorea. Indeed, it is often relatives, rather than patients, who request treatment. Best agreed practice is to use antichoreic medication sparingly as no drug is particularly efficacious, and a balance has to be struck between benefits and side effects. For functionally disabling chorea, drugs such as sulpiride, olanzapine, risperidone and tetrabenazine can be useful by non-specifically damping down movements in general, but they can worsen speech, swallowing and gait and balance, so need careful monitoring.

## Tics

Tics are typically relatively brief rapid intermittent stereotyped involuntary movements (motor tics) or sounds (vocalisations). In a sense tics are caricatures of normal movements; the common motor tics being eye blinking, elevation of a shoulder, a facial grimace, and vocal being a sniff or grunt which are all part of our repertoire of normal movements or sounds. Classically, they can be suppressed, at least temporarily, by an effort of will, but at the expense of rising inner tension, often followed by a rebound exacerbation. Most tics are abrupt in onset and duration (clonic tics), but can also be slow and sustained, either dystonic (associated with more sustained muscle contractions) or tonic (if muscle contractions are not associated with any movement, e.g. arm or abdominal tensing).

### Gilles de la Tourette syndrome

Gilles de la Tourette syndrome (GTS) is a common and widely recognised variety of tic. The diagnostic criteria for GTS include multiple motor tics and one or more phonic and/or vocal tics,

which must last longer than a year. The motor and phonic tics do not necessarily occur together, characteristically wax and wane over time, occur in bouts and are suggestible and suppressible. The maximum age at onset is 18 years. The mean age at onset of motor tics is about 7 years, and vocal tics 11 years. The worst severity is at 10–12 years, and the majority of symptoms disappear in half of the patients by the age of 18 years. Associated behaviours such as obsessive-compulsive behaviour or obsessive-compulsive disorder (OCB/OCD) can be more evident later.

Tics in GTS can be simple (e.g. blinking, eye rolling, head nodding, facial grimacing) or complex (e.g. touching, squatting). Premonitory sensations (also referred to as premonitory urges, mental urges or inner tension) precede both motor and phonic tics in up to 80% of patients; these can be localised (burning feeling in the eye before an eye-blink, or a sensation similar to nasal stuffiness before a sniff – the sensation has been likened to that which occurs before a sneeze). They can be localised (around the area of the tic) or generalised (covering a wide area of the body). New tics appear in response to a new somatosensory sensation, such as a cough (phonic tic) persisting after an upper respiratory tract infection. Tics usually begin in the head and face, and blinking is one of the most common first tics. Simple phonic tics include sniffing, throat clearing, gulping, snorting and coughing. Complex vocal tics include barking, the making of animal noises, inappropriate voice intonations and uttering strings of words. Tics characteristically are suggestible, suppressible, there is rebound after suppression and they have a waxing and waning course. Other important and characteristic features of GTS include echolalia (copying what other people say), echopraxia (copying what other people do) and palilalia (repeating the last word or part of sentence said by the individual). Coprolalia (inappropriate involuntary swearing, often disguised by the patient) is uncommon, occurring in only 10–15%, starting at around 15 years. Many clinicians are under the misapprehension that coprolalia must be present in order to make the diagnosis. Instead of the whole swearword, many individuals say only parts of the word and disguise it (by coughing, saying something, covering their mouths). Copropraxia (e.g. the V sign) also occurs but is rare.

### Epidemiology, history and prevalence

GTS has been described worldwide but with apparent different prevalence rates. The male : female ratio is 3 : 1. Clinical characteristics are similar irrespective of the country of origin. In some instances it seems that within families, the affected males have tic symptoms, whereas the females often have OCB. GTS was once considered to be uncommon. However, studies report a prevalence of 0.4–3.8% for youngsters aged 5–18 years, and a figure of 1% worldwide overall prevalence has been calculated. The prevalence of GTS in individuals with learning difficulties or autistic spectrum disorders can be as high as 6–10%. It is important to note that GTS individuals identified in community settings have more behavioural, mental health and educational difficulties than their peers. Many people with GTS never come to medical attention. Among those who do, the correct diagnosis is often missed as many clinicians remain under the misapprehension that coprolalia is necessary for the diagnosis.

### Psychopathology and associated co-morbidity

About 90% of GTS individuals have psychiatric co-morbidity. The most common is attention deficit hyperactivity disorder (ADHD), followed by OCB and OCD. Checking rituals, 'evening up', counting

rituals and compulsions to touch objects or people may be present, but are not often volunteered and need to be asked about. Anger control problems, sleep difficulties, coprolalia and self-injurious behaviours are more common in those with co-morbidity. Patients with GTS have more depression, anxiety, hostility, obsessional symptomatology and personality disorders than controls.

### Assessment

GTS is a clinical diagnosis. Standardised schedules are available to describe the phenomenology, and quantify and qualify associated behaviours and psychopathology, and to monitor response to treatment. Investigations are usually not necessary, but may be helpful in diagnosing alternative causes of tics (see later).

### Current aetiological theories

Various causes have been postulated including genetic influences, neuro-immunological reactions to infections, and prenatal and peri-natal difficulties. Complex segregation analysis suggested that GTS was genetic, consistent with a single major gene and autosomal dominant transmission, but with incomplete penetrance. However, much of the genome has been excluded, so the genetics of GTS is much more complicated than previously thought. The term PANDAS (paediatric autoimmune neuropsychiatric disorders associated with streptococcal infections) was coined for children with post-streptococcal OCD and tics. This pathogenic mechanism is somewhat controversial but most centres that have sought them have also found anti-basal ganglia antibodies (ABGAs) in a subgroup of patients with GTS. Streptococcal infection (with group A beta-haemolytic strains) probably does not cause GTS, but individuals can inherit a susceptibility to GTS and to the way they react to some infections.

### Multiple phenotypes of GTS

Some clinicians prefer not to make a diagnosis of GTS when the patient presents with only simple motor and phonic tics, when they simply call it a 'tic disorder'. However, several recent studies have demonstrated by hierarchical cluster analysis or principal component factor analysis that there is more than one type of GTS. Moreover one factor (phenotype), replicated by several centres, consists almost solely of simple motor and phonic tics. Other factors include complex tics and associated psychopathologies, as well as aggressivity and self-injurious behaviour. There have been initial suggestions that the varying phenotypes can have different aetiologies.

### Other forms of tic disorder

Tic disorders, usually referring to motor tics, are much more common than GTS, although prevalence figures differ, depending on the population studied. They have been reported to occur with a point prevalence of 1–29% of young people. The most common tic disorders can be divided into the following:

- 1 Transient tic disorder (TTD), in which there are single or multiple motor and vocal tics occurring for at least a month but for no longer than a year
- 2 Chronic motor or vocal tic disorder (CMTD), in which motor or vocal but not both have been present in excess of a year, or
- 3 Tic disorder not otherwise specified, such as adult onset tic disorder with an age at onset after 18 years.

Once again, tics are more frequent in those individuals with behavioural difficulties, learning difficulties, and those requiring special education placement or those seen as 'problem children'.

### Other diseases that can cause tics

Tics can also be seen in WD, neuro-acanthocytosis, Lesch–Nyhan syndrome, neuroferritinopathy, autism spectrum disorders, and in association with acquired lesions of the caudate nucleus and after chronic neuroleptic drug intake. However, they are usually only a part of the clinical picture, so should not be confused with primary tic disorder. Not all vocalisations are tics – they can be seen in dystonia, HD and tardive dyskinesia, for example.

### Investigation of tics

In the typical case (the vast majority) no investigations are necessary. If the presentation is unusual, the following could be helpful: serum copper and caeruloplasmin and slit-lamp examination for WD; ASO titre, throat swab, anti-DNA antibodies and ABGAs for post-streptococcal tics; fresh thick blood films (×3), creatine phosphokinase, nerve conduction studies, MRI, chorein and ChAc gene testing for neuro-acanthocytosis.

### Management of GTS and tics

In mild cases, explanation, reassurance and psycho-education may be the only interventions required. When the condition is causing problems, supportive psychotherapy, cognitive-behavioural therapy (CBT) and habit reversal training (HRT) may be useful: HRT specifically targets tics. Ideally, management should be multidisciplinary and treatment should be targeted at symptoms.

In many patients, medication may be required for the treatment of the tics and psychopathologies. The main agents for the tics are the typical and atypical neuroleptics, given in small doses (relative to treating psychosis), for example haloperidol 0.5–3 mg/day or sulpiride 100–400 mg/day. The older 'typical' neuroleptics such as haloperidol, pimozide, sulpiride and tiapride, and the newer 'atypical' neuroleptic such as risperidone have all been shown to be superior to placebo in double-blind trials. Tetrabenazine can also be effective but can often cause depression. Clonidine or guanfacine can help tics, impulse control or ADHD. If these agents are used, baseline ECG is advisable, as is regular monitoring of pulse and blood pressure. Recently, the newer 'atypical' neuroleptics (risperidone, quetiapine, aripiprazole) as well as sulpiride and tiapride have become more popular because of the unacceptable side effects of the older agents. The response to medication in GTS patients is idiosyncratic. Importantly, individuals with this often life-long, generally benign, condition should be warned of the possibility of developing a superimposed tardive movement disorder after chronic treatment with neuroleptic drugs.

Antidepressants, especially SSRIs, are useful for depression (using the standard dose, e.g. 20 mg fluoxetine), whereas the dose for OCB/OCD is higher (e.g. 40–60 mg). Clomipramine (a tricyclic) can be useful in OCB/OCD, but usually has more side effects than the SSRIs and is dangerous in overdose. SSRIs have been reported to cause suicidal ideation and there are now strict guidelines for the use of SSRIs in young people. In some patients, botulinum toxin injections to the affected areas (e.g. vocal cords if loud distressing vocal tics/coprolalia) can improve the tics and the urge to tic. DBS of internal capsule, GPi or thalamus in some carefully selected, severely affected and treatment-resistant patients has apparently helped.

When a patient has GTS + ADHD, one should assess which symptoms are most problematic, and attempt to treat these. Clonidine helps tics, ADHD and sleep. It was once thought that stimulants (e.g. methylphenidate) that improve ADHD increased

tics, and were therefore contraindicated, but this is now known not to be the case in most patients. Newer once-daily slow-release preparations can increase compliance. If the ADHD and tics pose equal difficulties, try clonidine; if ADHD is the greatest problem, try stimulants. The next option is to use stimulants with clonidine. Stimulants can also be given with neuroleptics.

## Myoclonus

Myoclonus is defined as a sudden brief shock-like involuntary movement caused by muscular contraction or inhibition. Muscle contraction produces positive myoclonus and muscle inhibition causes negative myoclonus or asterixis (e.g. liver flap). Myoclonus can be focal, multifocal, generalised, spontaneous or reflex. It can occur at rest, when maintaining a posture or during action. Myoclonus can be classified as cortical, subcortical, spinal or peripheral, based on the presumed physiological mechanism underlying its generation. Alternatively, based on its aetiology, it can be classified as physiological, essential, epileptic or symptomatic (Table 6.13).

### Physiological myoclonus

This includes hypnic jerks (initial phases of sleep), hiccup (physiological myoclonus of diaphragm) and startle response (commonly exacerbated by anxiety).

### Essential myoclonus

See Myoclonus dystonia (DYT11).

### Epileptic myoclonus

This term is used to denote conditions where myoclonic jerks are part of an epileptic syndrome (see Neurophysiological assessment of movement disorders and Chapter 7). Generalised myoclonus can occur in the syndromes of idiopathic generalised epilepsy or in the secondarily generalised epilepsies which include the progressive myoclonic epilepsies or the static epileptic encephalopathies. Epileptic myoclonus is accompanied by generalised epileptiform discharges, but the myoclonus itself can be focal, segmental or generalised. Focal myoclonus can occur in secondary symptomatic epilepsy as a result of infection, inflammation, vascular disease, trauma or tumours.

### Familial cortical tremor (also called benign autosomal dominant familial myoclonic epilepsy)

Clinically, this superficially resembles essential tremor. It is associated with infrequent or rare generalised seizures. It is an autosomal dominant, benign condition characterised by fine shivering-like 'tremor'. It usually presents in the third or fourth decade of life and there is no significant clinical progression. The myoclonus usually responds to valproate, carbamazepine or primidone, and has been mapped in Japanese families to chromosome 8q and in Italians to chromosome 2p.

### Epilepsia partialis continua

This is spontaneous, regular or irregular muscle twitching of cortical origin confined to one part of the body and continuing for a period of hours, days or weeks. This condition is further described in Chapter 7.

### Secondary myoclonus

This occurs in the context of an underlying neurological or non-neurological disorder brought about by trauma, brain hypoxia or progressive myoclonic encephalopathies. Often there

is clinical or pathological evidence of diffuse or focal nervous system involvement.

### Non-progressive myoclonic encephalopathies

It is important to recognise metabolic causes (renal or hepatic failure, vitamin E deficiency, increased level of antithyroid autoantibodies), toxic causes (bismuth, methyl-bromide, tetraethyl, chloralose poisoning) or drugs (levodopa, lithium, tricyclic antidepressants, morphine, antibiotics, SSRIs, MAOIs, antipsychotic and anaesthetic agents) that can cause myoclonus. Usually, such myoclonus is multifocal and often stimulus-sensitive, and can include negative myoclonus.

### Post-anoxic action myoclonus (Lance-Adams syndrome)

This is a distinct condition secondary to severe cerebral hypoxia (usually after respiratory rather than cardiac arrest) characterised by action myoclonus, usually without other neurological disturbances, after a latent interval of 24–28 hours (Chapter 19). Myoclonus can be positive, triggered by movement, or negative when the limbs are outstretched against gravity. The voice may be fragmented by the myoclonic jerks. It can be multifocal or generalised. It is most commonly cortical reflex myoclonus, but reticular reflex myoclonus and exaggerated startle may also occur. With treatment using clonazepam, sodium valproate or piracetam or lev-etiracetam, distal myoclonus can be greatly improved, but asterixis in proximal leg muscles ('bouncy legs') may continue to render the patient wheelchair-bound.

### Opsoclonus myoclonus

This is a well-delineated syndrome that most often occurs in children with neuroblastoma (a tumour that can remit without treatment) or medulloblastoma, or in adults in association with small cell carcinoma of the lung, breast carcinoma or melanoma. It also can be post-infectious or metabolic (coeliac disease) or drug-related. This syndrome is characterised by rapid involuntary saccadic eye movements (opsoclonus) and sudden involuntary muscle contractions (myoclonus). Ataxia is quite often also present. This syndrome is thought to be mediated by autoantibodies directed against onconeural antigens that are expressed by the tumours and also by neurones. Treatment of the underlying cause often leads to an improvement in the syndrome. In idiopathic cases, steroids and/or immuno-modulatory treatment have been used with some success.

### Myoclonus in neurodegenerative disorders

Cortical myoclonus is present in about 15% of patients with DLB or PD-D but is uncommon in PD patients without dementia.

Patients with MSA often display irregular small-amplitude myoclonic movements (mini-polymyoclonus) of the hands and/or fingers on posture (jerky postural tremor) that are stimulus-sensitive, or occur during voluntary movements. A cortical origin can often be demonstrated by back-averaging techniques, and somato-sensory evoked potentials (SSEPs) are sometimes 'giant'.

Myoclonus occurs in most patients with CBD, usually appearing focally in the arm and less commonly in the legs, together with other manifestations such as apraxia, rigidity, dystonia and alien limb phenomenon. It can occur in repetitive rhythmic fashion (jerky tremor) at rest and more commonly when attempting to activate the arm or following somato-sensory stimulation (reflex myoclonus). A cortical origin has been postulated. In contrast to CBD, myoclonus is rare in PSP, another tauopathy.

**Table 6.13** Classification of myoclonus.

\*Myoclonus and cerebellar features main problem, perhaps with mild mental impairment and epilepsy.

Source: Caviness and Brown 2004. Reproduced with permission of Elsevier.

HD can rarely be associated with myoclonus, usually in individuals with a juvenile onset and longer CAG repeats. Myoclonus is more common in DRPLA, when it is usually associated with epilepsy.

In Alzheimer’s disease, myoclonus is usually multifocal but can also be generalised. There can be sporadic large myoclonic jerks or repetitive small ones which may occur at rest, during action or be stimulus-sensitive. Commonly, myoclonus appears in middle and late stages of the disease, affecting about 50% of patients. It may occur at the onset of the disease in patients with earlier age of onset, rapid progression and in familial causes of Alzheimer’s disease.

Myoclonus has recently been described in some patients with frontotemporal dementia and parkinsonism linked to chromosome 17 (FTDP-17). Myoclonus is often observed (82–100%) in sporadic, familial and new-variant Creutzfeldt–Jakob disease (CJD) during the course of the disease, in which the jerks are often diffuse, generalised, relatively rhythmic and associated with periodic sharp-wave EEG activity (1–1.5 Hz). They are stimulus-sensitive and can persist during sleep.

### Subcortical myoclonus

Rhythmic myoclonus in a brainstem or spinal segmental distribution suggests a focal lesion at or near that segment of the brainstem or spinal cord. Generalised jerks most commonly reflect an origin in the brainstem reticular formation while axial jerks usually suggest a spinal cord lesion.

### Startle syndromes

The startle reflex is a bilaterally synchronous shock-like set of movements evoked by sudden stimuli. Its most prominent features are forceful closure of the eyes, raising of flexed arms above the head, and flexion of the neck, trunk, elbows, hips and knees. The auditory startle reflex originates in the caudal brainstem, more specifically in the bulbo-pontine reticular formation. The nucleus reticularis pontis caudalis seems particularly important. Startle syndromes occur in three different groups of disorders with abnormal response to startling events: hyperekplexia, neuropsychiatric startle syndrome and startle-induced epilepsy.

The major form of hyperekplexia is characterised by generalised stiffness noticeable soon after birth, but subsiding during the first

years of life, excessive startle to an unexpected stimulus that remains throughout life, and generalised stiffness in response to startle that lasts a few seconds and which commonly produces a fall forwards 'as stiff as a board' while fully conscious. In this form, mutations in the  $\alpha 1$  subunit of the glycine receptor gene, *GLRA1*, or related genes have been identified. A minor form of hyperekplexia is characterised by excessive startle only, with latencies of muscle activation longer than in the major form. No definite genetic substrate for this form has been found. Excessive startle also occurs in the context of neuropsychiatric conditions such as anxiety, panic attack, post-traumatic stress disorders or culture-specific disorders such as the jumping Frenchmen of Maine.

Startle epilepsy is an asymmetric tonic epileptic seizure typically induced by a sudden stimulus, mostly observed in young patients with infantile cerebral hemiplegia or those with a structural lesion in the central cortex. Startle is a transient phenomenon in these cases disappearing in adulthood.

### Palatal myoclonus

See Palatal tremor.

### Spinal myoclonus

Segmental myoclonus involves one or two contiguous spinal segments, whereas in proprio-spinal myoclonus several segments are involved because electrical activity spreads upwards and downwards from a spinal generator via slower proprio-spinal pathways. Spinal myoclonus has been reported in association with spinal cord trauma, vascular disease, disc herniation, drugs and infection. It is usually rhythmic or periodic, involving muscles belonging to one or two spinal segments.

Proprio-spinal myoclonus may also be rhythmic or arrhythmic but is characterised by axial jerks with flexion of the trunk and limbs. It occurs mainly when the patient is relaxed, predominantly when lying on a bed or falling asleep, and may be a cause of insomnia. Jerk duration is usually longer and more variable (50–1000 ms) than in cortical myoclonus. Some reports suggest that a number of those presenting with proprio-spinal myoclonus may have a functional disorder.

### Peripheral myoclonus

Peripheral myoclonus is rare and characterised by rhythmic or semi-rhythmic myoclonus secondary to nerve, root or anterior horn cell disease. Hemifacial spasm is the most common example. Peripheral myoclonus can be also multifocal in anterior horn cell disease (as in post-polio syndrome).

### Psychogenic myoclonus

Psychogenic myoclonus can occur spontaneously or following an external insult. It may be focal (restricted to a few muscles or limb) or generalised. Jerks usually have an inconsistent character over time, occasionally associated with other unusual neurological symptoms, with sudden onset and offset. There is often underlying psychopathology, the jerks are commonly distractible and can respond to placebo or psychotherapy (see Other movement disorders).

### Drug-induced myoclonus

Many different drugs can cause myoclonus. These include antidepressants (especially SSRIs), opiates, antiparkinsonian medications, some antibiotics (especially quinolones), lithium, bismuth,

neuroleptics, anaesthetic agents (especially propofol), cholinesterase inhibitors and, perhaps surprisingly, anxiolytics (especially benzodiazepines) and anticonvulsants.

### Treatment of myoclonus

The treatment of myoclonus depends upon the underlying disorder. Depending upon its aetiology, myoclonus can be partially or totally reversed, as in drug-induced or metabolic myoclonus, or surgically treatable lesions. Unfortunately, treatment of the underlying disorder is not always feasible.

Most causative conditions are poorly responsive to pharmacological treatment and often require polytherapy but this can cause side effects such as ataxia and drowsiness.

In cortical myoclonus, sodium valproate is particularly effective. This can be combined with piracetam or levetiracetam and both have been shown to be very useful agents. Benzodiazepines and barbiturates are also effective and believed to facilitate GABAergic transmission: clonazepam can be combined with valproate and levetiracetam as polytherapy with these three agents is often successful for cortical myoclonus. Lamotrigine and phenobarbital can also be effective in some cases.

Myoclonus dystonia responds partially to clonazepam, which is also particularly useful in hyperekplexia and in spinal myoclonus. Bilateral pallidal DBS can help severe myoclonus dystonia. Injection of botulinum toxin can help in palatal myoclonus and in hemifacial spasm.

## Other movement disorders

### Psychogenic (functional) movement disorders

Psychogenic movement disorders (PMD) can take any form although dystonia and tremor are the most common manifestations and psychogenic parkinsonism and chorea are rare. PMD represent 4–25% of all new cases seen in specialist movement disorders clinics.

The diagnosis of a PMD is primarily clinical, although investigations to exclude alternative or additional diagnoses, and specific electrophysiological tests for certain forms of PMD, can have an important role. However, PMD is not simply a diagnosis of exclusion, and positive features suggesting the diagnosis should be sought: marked fluctuations during examination; distractibility; increase with attention or suggestion; incongruence with patterns of recognised movement disorders; the presence of other non-organic signs; discrepancy between objective signs and disability; abrupt onset with rapid progression to maximum severity; inconsistency over time; a history of previous somatisations; and a sustained and substantial response to placebo or psychotherapy. While none of these features is pathognomonic, they allow a classification based on degree of diagnostic certainty (Table 6.14).

Specific PMDs may have additional clinical and investigational features that support the diagnosis. In psychogenic tremor these include co-activation of antagonist muscles; pause in tremor or entrainment of tremor frequency with externally paced tapping movements of the contralateral hand or foot, pause with ballistic movement of the other limb and a significant increase of amplitude or change of tremor frequency when the limb is loaded with a weight or the limb is restrained. Subjects may display an excessive attention to self in carrying out simple tasks. In psychogenic myoclonus the presence of a Bereitschaftspotential (premovement potential) preceding myoclonic movements, of prolonged

**Table 6.14** Diagnostic criteria for psychogenic dystonia. As only the first two categories provide a clinically useful degree of diagnostic certainty they have been combined to one category of 'Clinically definite'.

#### Documented

Persistent relief by psychotherapy, suggestion or placebo has been demonstrated, which may be helped by physiotherapy, or the patient was seen without the dystonia when believing him or herself unobserved

#### Clinically established

The dystonia is incongruent with classic dystonia or there are inconsistencies in the examination, plus at least one of the following three: other psychogenic signs, multiple somatisations or an obvious psychiatric disturbance

#### Probable

The dystonia is incongruent or inconsistent with typical dystonia, or there are psychogenic signs or multiple somatisations

#### Possible

Evidence of an emotional disturbance

or variable duration EMG-bursts, and of long latency and variable recruitment in stimulus-sensitive myoclonus all support the diagnosis.

However, in some cases investigations can exclude a psychogenic cause. Thus, in myoclonus, consistent duration of myoclonic bursts less than 70 ms or latency to stimulus-sensitive myoclonus of less than 70 ms or the presence of giant SEPs or cortical correlates of myoclonic jerks on back-averaged EEG exclude a psychogenic aetiology. Similarly, an abnormal DaT SPECT scan excludes a diagnosis of psychogenic parkinsonism. However, the specificity of many tests that are reported to be abnormal in certain movement disorders (e.g. reciprocal inhibition in dystonia) is currently unknown and these tests cannot therefore be relied upon to differentiate them from PMD. In addition, many classic features of movement disorders (e.g. *geste antagoniste* in dystonia or treatment-induced dyskinesias in PD) can be seen in PMD. The perceived difficulty of imitating a movement disorder is not sufficient to exclude this diagnosis, and this is exemplified in rare cases of psychogenic palatal tremor. A diagnosis of PMD should not be made simply because the movement disorder is bizarre. Sometimes it is necessary to observe the patient over time to reach a diagnosis. Clinicians should also be aware of overlay of functional symptoms on a typical organic movement disorder.

The prognosis of long-standing PMD is generally poor, although patients with PMD presenting soon after onset appear to have a better prognosis. Management of PMD should include thorough initial investigations followed by discussion of the diagnosis in a clear but un confrontational manner emphasising the unconscious origin of PMD. Where appropriate, exploration of psychiatric disorders or psychological factors underlying the disorder, appropriate referral for diagnosis and treatment, initiation of pharmacological and physical therapy, and continued follow-up by a multidisciplinary team (including the neurologist) should be considered. Avoiding both unnecessary drug treatment and perpetuating illness beliefs are clearly important management goals, particularly in complex and long-standing cases.

### Movement disorders associated with dopamine receptor blockade or dopamine depletion

Dopamine receptor blocking drugs are commonly used for psychiatric indications (neuroleptics) but also in the treatment of nausea, vomiting, vertigo, unsteadiness and migraine. Dopamine depletors originally included reserpine (for hypertension), but now only tetrabenazine (for hyperkinetic movement disorders) is licensed. All of the following types of movement disorder can be produced by any of these drugs, except that tetrabenazine does not cause tardive movement disorders.

Drug-induced parkinsonism (DIP) occurs frequently. Often mild, it can nevertheless sometimes be severe, and can be asymmetrical. It is reversible, the vast majority of cases remitting within weeks to 3 months, and a dwindling residual between 3 and 12 months of stopping the offending drug. The longer the duration of parkinsonism after withdrawal of the causative drug, the greater the chance that the individual was already in the early stages of PD (or other parkinsonian disorder). Management is to withdraw the causative agent if possible, and if not, to substitute an atypical neuroleptic drug with less anti-D2 dopaminergic effect. Anticholinergics can help. So too can levodopa, but this risks psychiatric relapse, and has limited effectiveness until the causative drug is withdrawn. DaT SPECT scan is normal in pure DIP.

Acute dystonic reactions affect about 2% of individuals exposed to these drugs. They arise within hours of starting the medication and predominantly affect head and neck, with oculogyria and jaw and neck dystonia, sometimes painful. They spontaneously subside over hours, but within seconds to minutes after IV administration of a centrally acting anticholinergic.

Akathisia ('not sitting') can occur early or late in treatment (the latter, tardive akathisia, can persist after drug withdrawal). The patient has an inner compulsion to move, a 'motor restlessness' that causes them to pace up and down or shift from one foot to the other, with rather stereotyped movements. Treatment is unsatisfactory.

Tardive dyskinesia arises after weeks, months or years of treatment, but persists for a variable time period, sometimes permanently. It can begin, or worsen temporarily, after discontinuing the offending drug. Most cases display relatively rapid, predominantly choreiform buccolinguomasticatory movements, with lip-smacking and sometimes tongue protrusion. These are more common with increasing age and female sex.

Tardive dystonia, more common in younger male subjects, phenomenologically resembles idiopathic dystonia, so can take the form of torticollis or axial dystonia for example. However, retrocollis, or opisthotonic trunk movements, are more common than in idiopathic torticollis or axial dystonia, as are 'copulatory' pelvic thrusting movements. Tardive dystonia can often be functionally, as well as socially disabling. The remission rate for this condition is very low – only 14% even 8 years after discontinuation of the offending drug, which nevertheless remains the best prognostic feature.

Although the newer 'atypical' neuroleptic drugs appear to be safer with regard to the provocation of tardive movement disorders than older drugs, there are no entirely safe dopamine receptor blocking drugs and, at least for tardive dystonia, no safe period of use. Unfortunately, centrally acting dopamine receptor blocking drugs continue to be used inappropriately for depression and anxiety and also for gastrointestinal disorders such as nausea or vomiting (e.g. metoclopramide).

Anticholinergics can worsen choreiform tardive dyskinesia, but may improve tardive dystonia. Tetrabenazine can sometimes help both. Paradoxically, just as tardive dyskinesia can present when the offending neuroleptic drug has its dose reduced, or is discontinued,

an increase in the dose of the offending drug can improve the movements, but only in the short term, before further aggravating the problem.

Tardive tics, myoclonus and tremor have been described, but are very uncommon.

The neuroleptic malignant syndrome (NMS) is a potentially fatal reaction to the introduction, increase or change of dosage of dopamine receptor blocking drugs (Chapter 19). In its fully developed form it involves the subacute appearance of severe muscle rigidity (sometimes with necrosis and myoglobinuria, leading to renal failure), akinesia, diaphoresis, agitation progressing to stupor and coma, and hyperpyrexia. CPK levels are elevated, often markedly, and a polymorphonuclear leukocytosis is common. Management includes stopping the offending drug, intensive care, cooling, antipyretics, and traditionally the administration of dantrolene and bromocriptine. Mortality in severe cases can still be up to 20%, but is much less in milder cases. The underlying mechanism is thought to be a combination of hypothalamic and striatal dopamine receptor blockade. Rarely an NMS-like syndrome can occur in PD after acute reduction or withdrawal of dopaminergic drugs.

### Restless legs syndrome

Restless legs syndrome (RLS) is probably the most common movement disorder, affecting to some degree 3–10% of the population, with most of those needing treatment being over the age of 50 years. It causes unpleasant sensations or an urge to move in the legs (and sometimes other body parts), classically on retiring to bed at night, which is only, and almost instantly, relieved by getting up and walking about. It can also occur when trying to relax when sitting or lying down during the day. Some (younger onset) cases are dominantly inherited. There are associations with iron deficiency, uraemia, pregnancy, peripheral neuropathy and possibly with PD. Serum ferritin is often low (Chapter 19).

Essential criteria for diagnosis are as follows:

- 1 An urge to move the legs, usually accompanied by uncomfortable or unpleasant sensations in the legs.
- 2 These symptoms begin or worsen during periods of rest or inactivity such as lying or sitting.
- 3 Symptoms are partially or totally relieved by movement, at least for as long as the activity continues.
- 4 Symptoms are worse, or only occur, in the evening or at night.

Supportive criteria are as follow:

- 1 Positive response to dopaminergic treatment
- 2 Periodic limb movements during wakefulness or sleep, and
- 3 Positive family history suggestive of autosomal dominant inheritance.

If drug treatment is needed, dopamine agonists (e.g. pramipexole and ropinirole) are currently favoured over levodopa because chronic levodopa treatment can lead to 'augmentation' – spillover of symptoms to the daytime, an increase in severity of symptoms, and involvement of other body parts. Second line drugs that sometimes help are opiates, gabapentin, carbamazepine and clonazepam. If there is iron deficiency or low ferritin, iron supplementation is indicated.

RLS is commonly associated with periodic leg movements of sleep (PLMS). Several gene associations for RLS (with or without PLMS) and for PLMS (with or without RLS) have recently been discovered.

### Painful legs and moving toes

This rare condition (see also Chapter 23) is characterised by slow undulating flexion–extension movements of the toes, accompanied by pain in the legs, usually unilateral. There may be evidence

of peripheral nerve or root lesion involving the affected leg. No treatment is effective.

### Stiff person syndrome, stiff limb syndrome and encephalomyelitis with rigidity

Stiff person syndrome is characterised by axial rigidity at rest involving mainly trunk (causing hyperlordosis) and sometimes also proximal lower limb muscles. A crucial finding is the presence of continuous motor unit activity in the paraspinal muscles that persists even when trying to relax, so that EMG electrical silence cannot be obtained. The rigidity and continuous motor unit activity lessen, or even disappear, during sleep and after spinal or general anaesthesia, indicating a central source.

Exteroceptive or cutaneo-muscular reflexes are enhanced, habituate poorly and spread as reflex spasms into muscles normally not involved in the reflex. These findings point to enhanced spinal interneurone excitability, caused by defects either within spinal interneuronal networks at a segmental level or their descending control. Polysynaptic reflexes are characteristically exaggerated in both upper and lower limbs as well as the axial (paraspinal) muscles.

Most patients have anti-GAD and/or glycine receptor antibodies in serum and CSF, and some have additional diabetes or other autoimmune disturbances or markers. Typically, patients show a useful response to high-dose baclofen and diazepam, and remain ambulant.

The stiff limb syndrome is rarer, and characterised by rigidity, painful spasms and abnormal postures of distal limb/s (more commonly a leg than an arm). Affected patients may show continuous motor unit activity in the affected limb but this may sometime be absent. However, abnormal exteroceptive reflexes can be detected as well as abnormally segmented EMG activity during spasms. Autoimmune markers are infrequent and anti-GAD may be negative but such patients may have antiglycine receptor antibodies. The condition responds poorly to treatment, most patients becoming wheelchair-bound.

A third, even rarer, disorder comprises patients with a rapidly progressive and fatal inflammatory encephalomyelitis with rigidity (PERM), usually with abnormal CSF and additional denervation. Again anti-GAD and glycine receptor antibodies but also amphiphysin and DPPX antibodies should be looked for as well as doing a paraneoplastic screen. There can be an overlap between any of these forms and patients may start with one and change to another form or have combined features.

## Neurophysiological assessment of movement disorders

Neurophysiological investigations in movement disorders are objective methods to investigate and support clinical diagnosis of different abnormal movements, and to monitor their severity and the effects of treatment.

Many methods are available, most of them useful for research purposes, but often of limited clinical utility. All electrophysiological tests should be interpreted in conjunction with clinical features but neurophysiology may disclose information that it is not possible to obtain by clinical observation alone.

### Neurophysiological assessment of tremor

Tremor is the movement disorder most subjected to neurophysiological study. It can be characterised on the basis of its frequency, pattern of muscle activation, and duration and amplitude of the

muscle bursts. Multichannel EMG recording and accelerometer data can be very useful to assess frequency and other characteristics of muscle activation in tremor.

The situation in which tremor occurs (rest, postural, action), and the presence of associated neurological signs, are important to guide the electrophysiological diagnosis of tremor. Tremor frequency can be helpful to some degree. Thus, the upper limit of frequency of physiological or voluntary tremor in healthy subjects is 11 Hz. Tremor above this frequency is always pathological, and most commonly caused by orthostatic tremor with a frequency of 13–18 Hz. Tremor at 5–7 Hz is often seen in patients with PD and essential tremor (ET) and tremor at >9 Hz in patients with enhanced physiological tremor (EPT). Low frequency tremor <4 Hz may be seen in Holmes tremor, dystonic tremor and cerebellar tremor. However, there is considerable overlap in frequency between different tremor disorders. Tremor amplitude is of little value for diagnostic purposes.

Tremor can arise from different sources. External loading (500–1000 g in the hand) typically reduces the tremor frequency in peripheral tremor (physiological tremor, EPT), but not in central tremor (PD, ET).

Cortical tremor (rhythmic cortical myoclonus) can show burst duration as short as 25–50 ms. Otherwise, burst duration is not particularly useful in identifying the anatomical origin of a tremor. Multichannel EMG recording can show a rostro-caudal pyramidal progression of the pattern of muscle recruitment, or rhythmic arrests of muscle tone as in negative cortical myoclonus or asterixis. The pattern of muscle activation between agonist and antagonist muscles (synchronous or alternating) is not very helpful in guiding the diagnosis.

Dystonic tremor is an irregular tremor usually below 7 Hz. It is associated with dystonic postures in the affected extremity or elsewhere, is subject to position- and task-specific worsening, and increases with attempts to move the body part in the opposite direction to the dystonic pattern.

In psychogenic tremor, amplitude often diminishes and frequency can change during distraction (counting, or tapping with the opposite limb). Furthermore, tapping different frequencies with the unaffected hand 'entrains' to the same frequency as that on the tremulous side. Tremor amplitude and frequency usually increase when adding a load to the affected limb.

### Neurophysiological assessment of dystonia

Many neurophysiological abnormalities have been found in patients with dystonia, but these are only partially useful for diagnostic purposes in individual patients. Impaired reciprocal inhibition of forearm flexor muscles at intermediate and long latency, reduced cortical silent period duration, and short- and long-interval intracortical inhibition have been seen in different studies in dystonic patients.

More sophisticated analyses of EMG discharges consider EMG–EMG coherence. This may disclose the character of the descending discharges responsible for the abnormal muscle activity in dystonia. An abnormal 4–7 Hz drive is seen in dystonic muscles in patients with the *DYT1* gene mutation, idiopathic torticollis and myoclonus dystonia. In the arms there is evidence of an abnormal cortico-muscular drive in the 15–30 Hz band leading to co-contraction between antagonistic muscles, with the exception of writer's cramp where a discrete peak in EMG–EMG coherence may be seen at 11–12 Hz.

### Neurophysiological assessment of myoclonus

Myoclonus is classified according to its pathophysiological basis as cortical, reticular or spinal.

### Cortical myoclonus

This is usually arrhythmic but can also be rhythmic (cortical tremor). It is characterised by jerks of short duration (typically <50 ms) involving many muscles and usually synchronously in agonists and antagonists. EMG recording from an extremity can demonstrate spread of jerks from the proximal muscle to distal with velocity corresponding to that of alpha motor fibres.

In cortical myoclonus, the EEG often shows multifocal or generalised spike and wave or multiple spike and wave which is usually time-locked to the muscle jerks. However, in some cases the EEG does not show any time-locked abnormality. EEG back-averaging can disclose myoclonus-related EEG activity that cannot be recognised on the conventional polygraph. This technique can determine the precise time interval from the EEG activity to the myoclonus. It also identifies the scalp distribution of the myoclonus-related EEG activity based on simultaneous multi-channel recordings. Back-averaging analysis shows a positive–negative biphasic spike at the central electrode somatotopically representing the muscle from which the myoclonus is recorded. The initial positive precedes the onset of myoclonic EMG discharge in a hand muscle by approximately 20 ms. The more distal the muscle the myoclonus is recorded from, the longer is the EEG–EMG time interval. Myoclonus-related discharge spreads through the motor cortex within one hemisphere, and also transcallosally to the homologous area of the contralateral motor cortex (10–15 ms). Unfortunately, EEG back-averaging analysis is limited by muscle activity in the scalp and also in cases where the jerks are of high frequency, or are infrequent.

In subjects in whom myoclonic EMG bursts are of small amplitude, or repeat rhythmically at high frequency, frequency analysis has advantages over back-averaging. Frequency analysis of EMG–EMG and also EEG–EMG coherence can detect a pathologically exaggerated common drive in distal limb muscles, showing significant coherence in the physiological range (15–60 Hz) but also, in some cases, at much higher frequencies.

Patients with cortical myoclonus may also show giant sensory evoked potentials; the initial components, a post-central negative peak (N20) and a precentral positive peak (P20), are not enhanced; however, the subsequent components (P25, P30, N35) are 3–10 times as large as normal. Long loop reflexes (C-reflexes) obtained by the motor subthreshold stimulation of the median nerve, recording from both thenar muscles, are also enhanced with a latency in the thenar muscle of around 45 ms, and 10–15 ms longer contralaterally because of the transcallosal transit time. Negative myoclonus is produced by a sudden (50–400 ms) interruption of a tonic muscle contraction, associated with an ictal discharge.

In CJD, myoclonus is not stimulus-sensitive and occurs continuously and quasi-periodically in the resting condition every 600–1500 ms. There may be accompanying dystonic posturing. EMG bursts are similar to, or slightly longer than, those of classic cortical myoclonus. Periodic sharp discharges (PSDs) are usually associated with muscle jerks, but can occur independently. EEG spike-wave and EMG activity correlate loosely. On back-averaging, the negative spike-wave is much smaller than the PSD recorded with raw EEG. The time interval between EEG and jerks is 50–85 ms (much longer than required for conduction through the pyramidal tract). Typical cortical reflex myoclonus can be seen in late stages of disease.

In subacute sclerosing panencephalitis (SSPE) sudden movements, followed by a tonic phase ('hung-up jerks'), can be related to periodic high-amplitude EEG discharges occurring every 4–13 s.

Essential myoclonus, myoclonus dystonia (except for SSPE), palatal and oculo-palatal myoclonus are characterised by EMG

discharges lasting up to 400 ms. In such cases the EEG does not show any specific correlate to the EMG discharge.

### Reticular, or brainstem, myoclonus

This is characterised by generalised jerks with prominent involvement of proximal and flexor muscles. Jerks can be spontaneous or stimulus-induced, particularly with respect to sound.

Jerks originate from the brainstem reticular formation; the first muscle to be activated is trapezius or sternomastoid; subsequently there is spread to the cranial and caudal muscles with different velocities of activation.

Myoclonic jerks can be associated with cortical spikes. However, the lack of correlation between the two suggests that spikes are projected to, but do not originate at the cortex. Evoked potentials are not increased, but there can be an enhanced C-reflex.

The normal human startle response consists of a brief flexion response, most marked in the upper half of the body, elicited by unexpected auditory, and sometimes somesthetic, visual or vestibular stimuli. Conduction of efferent impulses both upwards and downwards from the generator, possibly in the medial reticular formation, is slow. The shortest latencies are 20–50 ms for the orbicularis oculi muscle. In the quadriceps muscle the latencies of the responses are 100–150 ms.

Electromyographic responses in the intrinsic hand and foot muscles are particularly delayed. However, the auditory startle reflex electromyographic latencies are rather variable. The constant reflex EMG activity in orbicularis oculi is the most important event in the normal auditory startle reflex. If one considers the auditory blink reflex in orbicularis oculi as separate from the startle response, then the earliest muscle recorded is the SCM, with a latency of <100 ms. The activity then spreads up the brainstem from the XIth nerve to the Vth cranial nerve and down the spinal cord (reflex brainstem myoclonus). In physiological startle the stimulus-induced response tends to habituate, and disappears after 4–6 stimuli. Exaggerated startle responses are seen in hyperekplexia, in neuropsychiatric startle syndrome and in stimulus-induced epilepsy and stiff person syndrome.

### Spinal myoclonus

Two different patterns of spinal myoclonus are recognised: proprio-spinal myoclonus and segmental myoclonus. Myoclonus is most often positive, but negative myoclonus also occurs.

Proprio-spinal myoclonus is characterised by arrhythmic sequences or runs of axial jerks producing flexion or extension of the trunk. Bursts of muscle activity vary from 50 ms to 4 s. EMG jerks arise from abdominal or cervical spinal segments and slowly spread rostrally and caudally at <10 m/s. Cranial muscles are not involved, with the exception of the neck. It can be stimulus-sensitive. It is important to keep in mind psychogenic myoclonus and look for pre-movement potential in these cases.

Segmental myoclonus is described as regular or irregular repetitive jerks, involving a group of muscles innervated by one or two spinal segments.

### Definitions

A standard definition of epilepsy is as a disorder of brain characterised by an ongoing liability to recurrent epileptic seizures.

An epileptic seizure is defined as the transient clinical manifestations that result from an episode of epileptic neuronal activity. The epileptic neuronal activity is a specific dysfunction, characterised by abnormal synchronisation, excessive excitation and/or inadequate inhibition, and can affect small or large neuronal populations.

In addition to an ongoing liability to recurrent seizures, epilepsy is also associated with neurobiological, cognitive, psychological and social consequences ('being epileptic'), and with co-morbidities. These aspects can be as significant to an individual as are the epileptic seizures themselves, and can also require management in the clinic setting.

### Epidemiology

Epilepsy is a common condition. The incidence of epilepsy is in the region of 80 cases per 100 000 persons per year, with different studies showing rates varying mostly between 50 and 120 per 100 000 per year. Its point prevalence has been found to be 4–10 cases per 1000 persons in most studies, although higher figures are found from settings in resource-poor countries. The frequency of epilepsy is also slightly higher in lower socio-economic classes. The incidence of seizures is age dependent, with the highest rates in the first year of life and a second peak in late life. About 40% of patients develop epilepsy below the age of 16 years of age and about 20% over the age of 65 years. In Western practice, epilepsy accounts for about 20% of all neurological consultations, and in developing countries the proportion is even higher.

An isolated (first and only) seizure occurs in about 20 persons per 100 000 each year. The cumulative incidence of epilepsy – the risk of an individual developing epilepsy in his/her lifetime – is 3–5%. The fact that prevalence is much lower than cumulative incidence demonstrates that in many cases epilepsy remits. In fact, the prognosis is generally good, and within 5 years of the onset of seizures 50–60% of patients will have entered long-term remission. However, in about 20% of cases, epilepsy, once developed, never remits. Fertility rates are reduced by about 30% in women with epilepsy. Standardised mortality rates are also 2–3 times higher in patients with epilepsy than in others in the population. The excess

mortality is caused largely by the underlying cause of the epilepsy. Some deaths are directly related to seizures and there are higher rates of accidents, sudden unexpected death and suicides amongst patients with epilepsy when compared with the general population. The rates of death are highest in the first few years after diagnosis – reflecting the underlying cerebral disease (e.g. tumour, stroke). In chronic epilepsy, the excess mortality is partly a result of sudden unexpected death in epilepsy (SUDEP). The rates of SUDEP range from about 1 death per 2500 persons per year in mild epilepsy to 1 death per 100 patients per year amongst those with severe and intractable epilepsy. About 30% of children and 20% of adults with epilepsy have additional learning or neurological disabilities. Epilepsy occurs in about 20% of those with learning disability.

Of adults with newly diagnosed epilepsy, 18% show additional cognitive impairment, 6% motor disabilities (usually hemiplegia due to stroke) and 6% severe psychiatric disorders. About 1 in 15 persons with epilepsy is dependent on others for daily living because of epilepsy and the associated handicaps.

Epilepsy is associated with significant medical, social and secondary handicap. The World Health Organization (WHO) has estimated that epilepsy causes 6.4 million disability-adjusted life years (DALYs) and 1.32 million years of life (YLL) lost worldwide, and amongst neurological diseases is less only than stroke and dementia in its impact.

### ILAE classification of seizure type

The International League Against Epilepsy (ILAE) classification of seizure type is the most widely accepted classification scheme for epilepsy. It has undergone a series of revisions since it was first proposed and further revisions are under consideration, and are controversial. Here the well-accepted classification and terminology are used.

The current classification divides seizures into generalised and partial categories (Table 7.1). Generalised seizures are those that arise from large areas of cortex in both hemispheres, in which consciousness is always lost, and are subdivided into seven categories. Partial (or focal) seizures are those that arise in specific often small loci of cortex in one hemisphere. They are divided into simple partial seizures which occur without alteration of consciousness and complex partial seizures in which consciousness is impaired or lost. A secondarily generalised seizure has a partial onset (the aura)

**Table 7.1** The International League Against Epilepsy (ILAE) classification of seizure type (1981).

which spreads to become a generalised attack. Simple partial seizures may spread to become complex partial seizures, and either can spread to become secondarily generalised. The classification is based entirely on clinical and electroencephalography (EEG) phenomenology, but some generalised seizure types occur only in specific types of epilepsy. Partial seizures invariably imply focal brain pathology, although this may not necessarily be demonstrated by conventional clinical investigation. About two-thirds of newly diagnosed epilepsies are partial and/or secondarily generalised.

### Partial (focal) seizures

These are defined as partial seizures in which consciousness is not impaired. Complex partial seizures are those in which consciousness is impaired. Both imply focal cerebral disease and seizures can arise from any cortical region, the most common sites being the frontal and temporal lobes.

### Simple partial seizures

The symptomatology depends on the anatomical localisation of the seizures. Motor manifestations include jerking, spasm or posturing, speech arrest, dysarthria, choking sensations, version of the head or eyes or, less commonly, rotation of the whole body can occur in epilepsy arising in many cortical areas. Todd's paralysis can occur after a seizure, and is a reliable lateralising sign of epilepsy arising in

contralateral motor cortex. Sensory manifestations can take the form of tingling or numbness or pain. Visual phenomena such as flashing lights and colours occur if the calcarine cortex is affected. A rising epigastric sensation is the most common manifestation of a simple partial seizure arising in the mesial temporal lobe. Autonomic symptoms occur such as changes in skin colour, blood pressure, heart rate, pupil size and piloerection.

Complex perceptual or affective 'auras' can take various forms, and are more common in complex partial than in simple partial seizures. They can occur in epilepsy arising from temporal, frontal or parietal foci. There are six principal categories:

- *Dysphasic symptoms* can occur if cortical speech areas (frontal or temporoparietal) are affected and should be distinguished where possible from anarthria (speech arrest) which suggests a fronto-central origin.
- *Dysmnestic symptoms* (disturbance of memory) such as flashbacks, déjà vu, jamais vu, or distortions of memory are most common in mesial temporal lobe seizures although also occur in inferior frontal or lateral temporal lobe seizures.
- *Cognitive symptoms* include dreamy states and sensations of unreality or depersonalisation and occur primarily in temporal lobe seizures.
- *Affective symptoms* include fear (the most common symptom), depression, anger, elation, erotic thoughts, serenity or exhilaration. These are encountered most common in mesial temporal lobe epilepsy (TLE). Laughter (without mirth) is a feature of the automatism of seizures (known as gelastic seizures) which arise in frontal areas, and are a consistent feature of the epilepsy associated with hypothalamic hamartomas.
- *Illusions* of size (macropsia, micropsia), shape, weight, distance or sound are usually features of temporal or parieto-occipital epileptic foci.
- *Structured hallucinations* of visual, auditory, gustatory or olfactory forms, which can be crude or elaborate, are usually caused by epileptic discharges in the temporal or parieto-occipital association areas. Hallucinations of taste, usually an unpleasant taste, are a frequent symptom of TLE. Visual hallucinations can vary greatly in sophistication from simple colours or flashing lights in epilepsy arising in calcarine cortex to complex visual perceptual hallucinations in posterior temporal association areas. Auditory hallucinations and changes in auditory perception also vary in complexity, and most commonly occur in seizures arising in Heschl's gyrus.

### Complex partial seizures

These arise from the temporal lobe in about 60% of cases, the frontal lobe in about 30% and from other cortical areas in about 10% of cases. The clinical features reflect the site of onset of the seizures. The complex partial seizure may evolve during its course and in some seizures it is possible to identify three distinct components: the aura, the absence (loss of consciousness) and the automatism. The aura is in effect a simple partial seizure. It is usually short-lived, lasting a few seconds or so, although in rare cases can be prolonged. Many patients experience isolated auras as well as full-blown complex partial seizures. The symptoms in the aura can take any of the forms described above and depend on the anatomical location of the epileptic discharge. Absence is characterised by motor and speech arrest, during which the patient appears vacant (the 'motionless stare').

Automatisms are defined as involuntary motor actions that occur during or in the aftermath of epileptic seizures, in a state of impaired

awareness. The patient is usually totally amnesic for the events of the automatism. Sometimes the actions have purposeful elements, are affected by environment and can involve quite complex activity. Automatisms should be distinguished from post-ictal confusion. Automatisms are most common in temporal and frontal lobe seizures. The most common automatisms are as follow:

- *Oro-alimentary automatisms* in which orofacial movements occur such as chewing, lip smacking, swallowing or drooling. These are characteristic of partial seizures of mesial temporal origin.
- *Gestural automatisms* include fiddling movements with the hands, tapping, patting or rubbing, ordering and tidying movements. Complex actions such as undressing are quite common also as are genitally directed actions. These too are most common in mesial TLE.
- *Ambulatory automatisms* involve walking, circling, running and are most common in frontal lobe epilepsy, but do occur in TLE also.
- *Verbal automatisms* include words and sentences, meaningless sounds, humming and whistling. Speech during the seizure suggests that the seizure is arising from the non-dominant hemisphere and dysphasia after the seizure suggests a dominant hemisphere seizure origin. Verbal automatisms can occur in both frontal and temporal seizures.
- *Violent behaviour* can occur in an automatism, it is best considered as a response in an acutely confused person and is especially likely if the patient is restrained. The violent actions of the epileptic automatism are generally never premeditated, never remembered, never highly coordinated or skilful and seldom goal-directed; these are useful diagnostic features in a forensic context.

Partial (focal) epilepsy can also be classified by anatomical location. This is a phenomenological classification, based largely on the clinical and EEG appearances of the seizures, and is obviously important when considering surgical therapy. The most common schemes divide seizures into those arising in frontal, temporal, parietal and occipital lobes and also in the central region (pre- and post-central gyrus) (Table 7.2). Subdivisions are proposed but, because epileptic seizure discharges spread extensively, anatomical classifications are often not as specific as might be hoped. Sixty per cent of partial epilepsies arise in the temporal lobe.

Partial seizures may spread to become generalised. The partial seizure is often experienced as an aura in the seconds before the generalised seizure. The generalised seizure is usually tonic-clonic, tonic or atonic.

The EEG during a complex partial seizure of mesial temporal lobe onset typically shows, at the onset, a rhythmic (5–7 Hz) discharge localised to the anterior mid temporal lobe. In lateral temporal seizures, the ictal onset EEG changes are more likely to have a spiked or high-frequency pattern. Complex partial seizures of frontal lobe epilepsy show ictal EEG onset patterns that are typically generalised or widespread, comprising high-frequency activity or slow rhythms or attenuation. Ictal onset EEG patterns in parietal and occipital seizures vary, in part dependent on pathways of seizure propagation, and there is a higher rate of false localisation and lateralisation.

### Generalised seizures

Six forms are defined in the ILAE classification although, in practice, transitional forms or manifestations modified by therapy are common. Consciousness is impaired from the onset of the attack, motor changes are bilateral and more or less symmetric, and the

EEG patterns are bilateral and grossly synchronous and symmetrical over both hemispheres.

### Typical absence seizure (petit mal seizure)

The seizure takes the form of an abrupt sudden loss of consciousness (the absence) and cessation of all motor activity. Tone is usually preserved, and there is no fall. The patient is not in contact with the environment, is inaccessible and often appears glazed or vacant. The attack ends as abruptly as it started, and previous activity is resumed as if nothing had happened and there is no post-ictal confusion. The patient is often unaware that an attack has occurred. Most absence seizures (>80%) last less than 10 seconds. Blinking, subtle clonic movements, alterations in tone and/or brief automatisms can occur, particularly in longer attacks. The attacks can be repeated, sometimes hundreds of times a day, often cluster and are often worse when the patient is awakening or drifting off to sleep. Absences may be precipitated by fatigue, drowsiness, relaxation, photic stimulation or hyperventilation.

Typical absence seizures develop in childhood or adolescence and are encountered almost exclusively in the syndrome of idiopathic generalised epilepsy. The EEG during a typical absence is diagnostic, showing high voltage, regular, symmetric and synchronous 3 Hz spike-wave paroxysms. The features useful in differentiating a complex partial seizure from a typical absence are shown in Table 7.3.

### Atypical absence seizure

This, like a typical absence seizure, takes the form of loss of awareness (absence) and hypomotor behaviour (Table 7.4). However, the duration is longer, loss of awareness is often incomplete and much less marked and associated tone changes are more severe than in a typical absence seizure. The onset and cessation of the attacks are not so abrupt. Amnesia may not be complete and the subject may be partially responsive. The ictal EEG shows usually diffuse but often asymmetric and irregular spike-wave bursts at 2–2.5 Hz, and sometimes fast activity or bursts of spikes and sharp waves. The background interictal EEG is usually abnormal, with continuous slowing, spikes or irregular spike-wave activity, and there is overlap of ictal and interictal EEG features.

Atypical absences occur in the symptomatic epilepsies, and are usually associated with learning disability, other neurologic abnormalities or multiple seizure types. These seizures most commonly form part of the Lennox–Gastaut syndrome and occur at any age.

### Myoclonic seizure

This takes the form of a brief contraction of a muscle, muscle group or several muscle groups brought about by a cortical discharge. It can be single or repetitive, varying in severity from an almost imperceptible twitch to a severe jerking, resulting, for instance, in a sudden fall or the propulsion of handheld objects. Recovery is immediate, and the patient often maintains that consciousness was not lost.

Myoclonic seizures occur in idiopathic generalised epilepsy, in the childhood epileptic encephalopathies (e.g. Lennox–Gastaut syndrome) and in epilepsy associated with other forms of learning disability, and in the progressive myoclonic epilepsies. Focal myoclonus can also occur in focal epilepsy of frontal or occipital origin. Epileptic myoclonus needs to be differentiated from non-epileptic myoclonus of spinal and subcortical origin.

**Table 7.2** Partial seizures arising in different brain regions.

Brain region of origin	Clinical features
Mesial temporal lobe origin	<p>Tripartite seizure pattern (aura, absence, automatism), although only one feature may be present</p> <p>Auras are common and include: visceral, cephalic, gustatory, dysmnestic, affective, perceptual or autonomic auras</p> <p>Partial awareness commonly preserved, especially in early stages</p> <p>Slow evolution of seizure</p> <p>Prominent motor arrest or absence (the 'motionless stare')</p> <p>Dystonic posturing of the contralateral upper limb common in the early stages of the seizure</p> <p>In seizures arising in the dominant temporal lobe, speech arrest common during the seizures and dysphasia common post-ictally</p> <p>Seizures longer than frontal lobe seizures (typically &gt;2 min), with a slower evolution and more gradual onset/offset</p> <p>Post-ictal confusion and dysphasia common</p> <p>Autonomic changes (e.g. pallor, redness, and tachycardia)</p> <p>Automatisms: less violent than in frontal lobe epilepsy, and usually take the form of oro-alimentary (lip smacking, chewing, swallowing), or gestural (e.g. fumbling, fidgeting, repetitive motor actions, undressing, walking, sexually directed actions, walking, running) and sometimes prolonged</p> <p>In hippocampal epilepsy, history of febrile seizures, onset in childhood or adolescence, initial early response lost after several years</p>
Lateral temporal lobe onset	<p>Features overlap with mesial temporal lobe onset, with the following differences:</p> <p>Motor arrest and absence less prominent</p> <p>Aura more likely to take the form of complex perceptual changes, visual and auditory hallucinations</p> <p>Tonic posturing more common</p> <p>More frequent secondary generalisation</p>
Frontal lobe origin	<p>Frequent attacks with clustering</p> <p>Brief stereotyped seizures (&lt;30 s)</p> <p>Nocturnal attacks common</p> <p>Sudden onset and cessation, with rapid evolution and awareness lost at onset</p> <p>Absence of complex aura</p> <p>Version of head or eye common</p> <p>Prominent ictal posturing and tonic spasms</p> <p>Prominent complex bilateral motor automatisms involving lower limbs; often bizarre and misdiagnosed as dissociative seizures</p> <p>Absence of post-ictal confusion</p> <p>Frequent secondary generalisation</p> <p>History of status epilepticus</p>
Parietal and occipital lobe origin	<p>Somatosensory symptoms (e.g. tingling, numbness or more complex sensations – may or may not march)</p> <p>Sensation of inability to move</p> <p>Sexual sensations</p> <p>Illusions of change in body size/shape</p> <p>Vertigo</p> <p>Gustatory seizures</p> <p>Elementary visual hallucinations (e.g. flashes, colours, shapes, patterns)</p> <p>Complex visual hallucinations (e.g. objects, scenes, autoscopia, palinopsia, often moving)</p> <p>Head turning (usually adversive, with sensation of following or looking at the visual hallucinations)</p> <p>Visuospatial distortions (e.g. of size [micropsia, macropsia], shape, position)</p> <p>Loss or dulling of vision (amaurosis)</p> <p>Eyelid fluttering/blinking/nystagmus</p>

**Table 7.2** (continued)

Brain region of origin	Clinical features
Central cortical origin	<p>Often no loss of consciousness</p> <p>Contralateral jerking (which may or may not march)</p> <p>Contralateral tonic spasm or dystonia</p> <p>Posturing, which is often bilateral</p> <p>Speech arrest and spasm of bulbar musculature (producing anarthria or a choking, gurgling sound)</p> <p>Contralateral sensory symptoms</p> <p>Short duration and frequently recurring attacks</p> <p>Prolonged seizures with slow progression (and episodes of <i>epilepsia partialis continua</i>)</p> <p>Post-ictal Todd's paresis</p>

**Table 7.3** Differentiation between typical absences and complex partial seizures.

	Typical absence	Complex partial seizure
Age of onset	Childhood or early adult	Any age
Aetiology	Idiopathic generalised epilepsy	Any focal pathology or cryptogenic epilepsies
Underlying focal anatomical lesion	None	Limbic structures, neocortex
Duration of attack	Short (usually <30 s)	Longer, usually several minutes
Other clinical features	Slight (tone changes or motor phenomena)	Can be prominent; including aura, automatism
Post-ictal	None	Confusion, headache, emotional disturbance are common
Frequency	May be numerous	Usually less frequent cluster
Ictal and interictal EEG	3 Hz generalised spike-wave	Variable focal disturbance
Photosensitivity	10–30%	None
Effect of hyperventilation	Often marked increase	None, modest increase

**Table 7.4** Clinical features differentiating typical and atypical absence seizures.

	Typical absence	Atypical absence
Context	No other neurological signs or symptoms	Usually in context of learning difficulty, and other neurological abnormalities
Consciousness	Totally lost	Often only partially impaired
Focal signs in seizures	Nil	May be present
Onset/offset of seizures	Abrupt	Often gradual
Coexisting seizure types	Sometimes tonic–clonic and myoclonic	Mixed seizure disorder common, all seizure types

### Clonic seizure

Clonic seizures are most frequent in neonates, infants or young children, and are always symptomatic.

### Tonic seizure

This takes the form of a tonic muscle contraction with altered consciousness without a clonic phase. Often there is extension of the neck; contraction of the facial muscles, with the eyes opening widely, upturning of the eyeballs, contraction of the muscles of respiration, spasm of the proximal upper limb muscles causing the abduction and elevation of the semi-flexed arms and the shoulders. The ictal EEG may show flattening (desynchronisation), fast activity (15–25 Hz) with increasing amplitude (to about 100  $\mu$ V) as the attack progresses, or a rhythmic 10 Hz discharge similar to that seen in the tonic phase of the tonic–clonic seizure.

Tonic seizures occur in the setting of diffuse cerebral damage, learning disability, are invariably associated with other seizure types and are the characteristic and defining seizure type in the Lennox–Gastaut syndrome.

### Tonic–clonic seizure (grand mal seizure)

This is the ‘convulsion’ or ‘fit’. It is sometimes preceded by a prodromal period during which an attack is anticipated, often by an ill-defined vague feeling or sometimes more specifically, for instance by the occurrence of increasing myoclonic jerking. If an aura then occurs (in fact a simple or complex partial seizure) in the seconds before the full-blown attack, this indicates that the tonic–clonic seizure is secondarily generalised. The seizure takes the form of loss of consciousness, sometimes with the epileptic cry (a loud guttural sound), tonic stiffening (and the patient will fall if standing) initially sometimes in flexion but then in axial extension, with the eyes rolled up, the jaw clamped shut, the limbs stiff, adducted and extended, and the fists clenched. Respiration ceases and cyanosis is common. The eyes remain open and the pupils dilated and unreactive. There are frequently heart rate changes, which are sometimes marked and can take the form of tachycardia or bradycardia and even asystole. This tonic stage lasts on average 10–30 seconds and is followed by the clonic phase, during which convulsive movements, usually of all four limbs, jaw, and facial muscles occur; breathing can be stertorous and arrest of respiration can occur; and saliva (sometimes bloodstained owing to tongue biting) may froth from the mouth. The tongue biting in an epileptic seizure is typically on the lateral aspects of the tongue, and this is said to occur only in an epileptic seizure. The convulsive movements decrease in frequency (eventually to about four clonic jerks per second), and increase in amplitude as the attack progresses. The attack is usually followed by a period of flaccidity of the muscles and consciousness is slowly regained. Confusion is invariable in the post-ictal phase. The patient often has a severe headache, feels dazed and extremely unwell, and often lapses into deep sleep. Petechial haemorrhages around the eyes, lethargy and muscle aching is common. Injuries also occur. Crush fractures of the vertebrae are common. Posterior dislocation of the shoulders is said only to occur in epileptic seizures.

Primary generalised tonic–clonic seizures occur mainly in idiopathic generalised epilepsy. Secondarily generalised tonic–clonic seizures are encountered in many different types of epilepsy including in symptomatic generalised epilepsies, epileptic encephalopathies, various epilepsy syndromes, febrile convulsions and acute symptomatic seizures. They have no pathological or syndromic specificity.

### Atonic seizure

The most severe form is the classic drop attack (astatic seizure) in which all postural tone is suddenly lost causing collapse to the ground like a rag doll. The seizures are short and are followed by immediate recovery. Longer (inhibitory) atonic attacks can develop in a stepwise fashion with progressively increasing nodding, sagging or folding.

The seizures are always associated with diffuse cerebral damage, learning disability and are common in severe symptomatic epilepsies (especially in the Lennox–Gastaut syndrome and in myoclonic astatic epilepsy).

## ILAE classification of the epilepsies and epilepsy syndromes

An epileptic syndrome is defined as ‘an epileptic disorder characterised by a cluster of signs and symptoms customarily occurring together’, and the ILAE classification scheme attempts to categorise epilepsy according to syndrome (Table 7.5). This system is under revision, and may change in the future. Some syndromes have single aetiologies and specific features, but others have multiple causes and heterogeneous clinical features. The syndromes are often age specific, and over time in individual patients one epileptic syndrome can evolve into another (e.g. West’s syndrome commonly evolves into Lennox–Gastaut syndrome). The same seizure type can occur in very different syndromes (e.g. myoclonic seizures in the benign syndrome of juvenile myoclonic epilepsy and the refractory syndromes of the progressive myoclonic epilepsies).

The classification scheme allows a more comprehensive approach to categorisation than simply classifying by seizure type, but is not widely used in routine clinical practice. The following are the most common syndromes.

### Idiopathic generalised epilepsy

This term should be used to denote a common and important category of epilepsy that has a characteristic clinical and electrographic pattern and a presumed genetic basis. Idiopathic generalised epilepsy (IGE) accounts for about 10–20% of all patients with epilepsy. It probably has a strong genetic basis, but no common susceptibility gene has been found, and the occurrence of epilepsy is not simple ‘genetic’, but also involves epigenetic and epistatic factors, and is also dependent on developmental aspects.

The condition is sometimes subdivided into separate syndromes, although this is contentious and there is a great deal of overlap. The core clinical features are shared to a greater or lesser extent by these syndromes (at least those with onset in later childhood or early adult life). The most important subdivisions are as follow.

### Childhood absence epilepsy

This condition, more common in girls, appears in childhood (peak age 6–7 years), and is not associated with learning disability or other neurological problems. It accounts for 1–3% of newly diagnosed epilepsies and up to 10% of childhood epilepsies. The seizures take the form of generalised absence attacks (see earlier). The prognosis is good, and rapid remission on therapy is expected in 80% or more of patients. When followed up after age 18 years, only approximately 20% of previously diagnosed patients are still having seizures.

### Juvenile myoclonic epilepsy

This is the most common subtype of IGE, and accounts for up to 10% of all epilepsies. The characteristic seizures are brief myoclonic jerks, occurring in the first hour or so after awakening, and usually in bursts. These are sudden, shock-like jerks, affecting mainly the shoulders and arms, usually but not always symmetrically. It is often

--	---

not clear whether consciousness was retained or lost. The myoclonus develops between the ages of 12 and 18 years. In about 80% of cases, generalised tonic–clonic seizures also occur, usually months or years after the onset of myoclonus, and it is these that often trigger the diagnosis. About one-third of patients also develop typical absence seizures, again usually on awakening. About 5% of patients exhibit strong photosensitivity. The myoclonic seizures (and other seizures) can be precipitated by photic stimuli, lack of sleep, alcohol, hypoglycaemia and poor compliance with medication. Complete response to treatment can be expected in 80–90% of cases, but lifelong therapy may be needed.

#### **Epilepsy with grand mal seizures on awakening**

This condition overlaps considerably with other generalised epilepsies especially with juvenile myoclonic epilepsy in which most affected people also have generalised tonic–clonic seizures (GTCS) on awakening. The EEG usually has a normal background with bursts of generalised spike-waves or polyspike-waves. Whether this syndrome represents a discrete entity or simply part of the spectrum of other forms of IGE has been the subject of discussion for several decades, without clear resolution.

#### **Benign partial epilepsy syndromes**

There are a number of benign partial epilepsy syndromes. As with the IGEs, there is overlap between syndromes and the subdivision is a matter of some contention.

#### **Benign partial epilepsy with centrotemporal spikes**

Benign partial epilepsy with centrotemporal spikes (BECTS; *syn*: rolandic epilepsy, benign epilepsy with rolandic spikes) is the most common 'idiopathic' partial epilepsy syndrome, accounting for perhaps 15% of all epilepsies. The peak age of onset is 5–8 years and over 80% of cases have onset at 4–10 years. The condition reflects an age-related genetically determined neuronal hyperexcitability in the rolandic area. The characteristic EEG feature is the high-amplitude rolandic spike, and 10% or more of children with the EEG disturbance do not actually have seizures. The seizures are infrequent, and 50% of children experience a total of less than five attacks in all. Fifty per cent of seizures occur only at night, and the daytime seizures usually occur when the child is tired or bored. The complex partial seizures take a characteristic form, usually beginning with spasm and clonic jerking of one side of the face and throat muscles, then speech arrest and guttural vocalisations. The seizures may

evolve to secondarily generalised tonic–clonic attacks. There are no associated neurological disturbances and intellect is normal. The epilepsy ceases in almost all cases, usually by the age of 12 years, without long-term sequelae. There is an excellent response to therapy with carbamazepine or other antiepileptic drugs. The condition is usually quite benign although some children have associated learning difficulties and atypical EEG or clinical features merge into other more severe childhood epileptic syndromes.

### Early onset benign occipital epilepsy (*syn:* Panayiotopoulos syndrome)

This syndrome occurs in those aged between 1 and 14 years (mean 4–5 years). The partial seizures take the form of eye deviation, nausea and vomiting, with subsequent evolution into clonic hemiconvulsions. Typically, the seizures are prolonged, often lasting hours, and are infrequent (mean number three). The interictal EEG shows occipital spikes, with a morphology similar to that in BECTS, often continuous and abolished by eye opening (the fixation-off phenomenon). However, it is misleading to consider these as 'occipital lobe' seizures and the spikes may reflect spread. Some seizures consist only of vomiting, of syncopal symptoms or prominent autonomic symptoms. The prognosis is uniformly excellent, and the epilepsy always remits over time without adverse sequelae. This syndrome is often misdiagnosed as migraine.

### West syndrome

West syndrome has an incidence of 0.25–0.42/1000 live births. It is defined by the occurrence of infantile spasms and the EEG changes of hypsarrhythmia. The infantile spasms take the form of sudden, generally bilateral and symmetrical contractions of the muscles of the neck, trunk or limbs, tend to cluster and may occur hundreds of times a day. In the most common type, the flexor muscles are predominantly affected, and the attack takes the form of sudden flexion with arms and legs held in adduction (the so-called salaam attacks). The peak age of onset is 4–6 months and 90% develop in the first year of life. Most cases have an underlying cerebral pathology. The most common cause is tuberous sclerosis (7–25% of all cases); neonatal ischaemia and infections (about 15% of all cases); lissencephaly and pachygyria and hemimegalencephaly (about 10% of cases); Down syndrome and acquired brain insults. The prognosis is poor, with most cases developing severe epilepsy, intellectual and psychomotor deterioration. About 5% of children die in the acute phase of spasms. A few patients, especially if treated quickly, recover completely.

### Lennox–Gastaut syndrome

This term is used to denote an age-specific epileptic encephalopathy with a characteristic clinical seizure and EEG pattern and learning disability. However, whether it is a specific syndrome or whether the symptoms and EEG changes simply reflect severe childhood epilepsy with learning disability is a source of contention. There are many potential underlying causes and there is no specific histopathological change nor specific treatment. About 1–5% of childhood epilepsies conform to this pattern. The age of onset is between 1 and 7 years and it can develop in patients who earlier had West syndrome, myoclonic astatic epilepsy or neonatal seizures. In one-third of cases no cause is identifiable (cryptogenic Lennox–Gastaut syndrome). About one-third of cases are caused by malformations of brain development. The epilepsy is very severe, with seizures usually occurring many times a day. These take the form of atypical absence, tonic, myoclonic, tonic and tonic–clonic seizures, and later complex partial and other seizure types develop. The most characteristic are tonic attacks, which occur

most often in non-REM (but not REM) sleep and in wakefulness. Non-convulsive status (atypical absence status) may last hours or days and be repeated on an almost daily basis.

The EEG shows a characteristic pattern with the presence interictally of long bursts of diffuse slow (1–2.5 Hz) spike-wave activity, widespread in both hemispheres, roughly bilaterally synchronous but often asymmetrical. The background activity is abnormal with an excess of slow activity and diminished arousal or sleep potentials. Learning disability is the other major feature of the condition.

At least 50% of cases have an intelligence quotient (IQ) below 50. The prognosis for control of seizures and for the development of intellectual impairment is poor, and many patients require institutional care in childhood and in adult life, and are dependent for daily activities. Response to treatment is often poor, and the seizure disorder can be exacerbated by over-treatment or therapy with sedating drugs. Carbamazepine and benzodiazepines may exacerbate tonic or atonic seizures.

### Febrile seizures

Febrile seizures are seizures that occur in the context of an acute rise in body temperature in children between 3 months and 5 years of age, in whom there is no evidence of intracranial infection or other defined cause. About 3–5% of children will have at least one attack, and 19–41/1000 infants with fever will convulse. The first febrile seizure happens in the second year of life in 50%. In over 85%, the seizures are generalised and are usually brief. The seizure usually occurs early in the febrile illness, and in about one-quarter of cases is the first recognisable sign of the illness.

These essentially benign seizures need to be differentiated from the 5–10% of first seizures with fever in which the seizure is in fact caused by viral or bacterial meningitis, and from other cases where the fever lights up an existing latent predisposition to epilepsy.

About 35% of susceptible children will have a second febrile seizure and 15% three or more. Recurrence is more common if the initial convulsion was at a young age or was prolonged. In about 10–20% of children, subsequent neurodevelopment problems are noted, but these usually reflect pre-existing problems and are not brought about by the convulsions. About 2–10% of children with febrile seizures will later develop epilepsy. The risk is higher in those with pre-existing neurodevelopmental dysfunction. It has been proposed that febrile convulsions sometimes cause hippocampal sclerosis, and by this mechanism subsequent TLE, particularly if the febrile convulsion was prolonged or severe; how frequently this occurs is unknown.

## Causes of epilepsy

Epilepsy is a multifactorial condition, and even if there is a predominant cause, genetic and environmental factors often play a part in its development and manifestations. The range of causes differs in different age groups, patient groups and geographical locations. Broadly speaking, genetic, congenital and perinatal conditions are the most common causes of early childhood onset epilepsy, whereas in adult life, epilepsy is more likely to be result from external non-genetic causes, but this distinction is by no means absolute. In late adult life vascular disease is increasingly common. In certain parts of the world, endemic infections such as malaria or cysticercosis are common causes.

A classification of causes is shown in Table 7.6 and the approximate frequencies of different aetiologies in a typical Western population are shown in Table 7.7.

**Table 7.6** Aetiological classification of epilepsy.

Main category	Subcategory	Examples of aetiology
Idiopathic epilepsy	Pure epilepsies due to single-gene disorders	Benign familial neonatal convulsions; autosomal dominant nocturnal frontal lobe epilepsy; generalised epilepsy with febrile seizures plus; severe myoclonic epilepsy of childhood; benign adult familial myoclonic epilepsy
	Pure epilepsies with complex inheritance	Idiopathic generalised epilepsy (and its subtypes); benign partial epilepsies of childhood
Symptomatic epilepsy – of predominately genetic or developmental causation	Progressive myoclonic epilepsies	Unverricht–Lundborg disease; dentato-rubro-pallido-luysian atrophy; Lafora body disease; mitochondrial cytopathy; sialidosis; neuronal ceroid lipofuscinosis; myoclonus renal failure syndrome
	Neurocutaneous syndromes	Tuberous sclerosis; neurofibromatosis; Sturge–Weber syndrome
	Other single-gene disorders	Angelman syndrome; lysosomal disorders; neuro-acanthocytosis; organic acidurias and peroxisomal disorders; porphyria; pyridoxine-dependent epilepsy; Rett syndrome; urea cycle disorders; Wilson’s disease; disorders of cobalamin and folate metabolism
	Disorders of chromosome structure	Down’s syndrome; fragile X syndrome; 4p-syndrome; isodicentric chromosome 15; ring chromosome 20
	Developmental anomalies of cerebral structure	Hemimegalencephaly; focal cortical dysplasia; agyria-pachygyria-band spectrum; agenesis of corpus callosum; polymicrogyria; schizencephaly; periventricular nodular heterotopia; microcephaly; arachnoid cyst
Symptomatic epilepsy – of predominately acquired causation	Hippocampal sclerosis	Hippocampal sclerosis
	Perinatal and infantile causes	Neonatal seizures; post-neonatal seizures; cerebral palsy; vaccination and immunisation
	Cerebral trauma	Open head injury; closed head injury; neurosurgery; epilepsy after epilepsy surgery; non-accidental head injury in infants
	Cerebral tumour	Glioma; ganglioglioma and hamartoma; DNET; hypothalamic hamartoma; meningioma; secondary tumours
	Cerebral infection	Viral meningitis and encephalitis; bacterial meningitis and abscess; malaria; neurocysticercosis, tuberculosis; HIV
	Cerebrovascular disorders	Cerebral haemorrhage; cerebral infarction; degenerative vascular disease; arteriovenous malformation; cavernous haemangioma
	Cerebral immunologic disorders	Rasmussen’s encephalitis; SLE and collagen vascular disorders; inflammatory and immunological disorders
	Degenerative and other neurologic conditions	Alzheimer’s disease and other dementing disorders; multiple sclerosis and demyelinating disorders; hydrocephalus and porencephaly
Provoked epilepsy	Provoking factors	Fever; menstrual cycle and catamenial epilepsy; sleep–wake cycle; metabolic and endocrine-induced seizures; drug-induced seizures; alcohol and toxin-induced seizures
	Reflex epilepsies	Photosensitive epilepsies; startle-induced epilepsies; reading epilepsy; auditory-induced epilepsy; eating epilepsy; hot-water epilepsy
Cryptogenic epilepsies		

DNET, dysembryoplastic neuroepithelial tumour; SLE, systemic lupus erythematosus.

**Table 7.7** Causes of epilepsy and approximate frequency.

Cause	Frequency (%)*
Cryptogenic – unknown presumed symptomatic basis	20–40
Idiopathic – unknown presumed genetic basis	10–20
Provoked – predominate provoking factor	5–20
Symptomatic	
vascular	5–10
perinatal	5–10
neurodegenerative	5–10
hippocampal sclerosis	5–10
neoplasm	5–10
trauma	5–10
infection	1–5
immunological	1–5
developmental anomalies	1–5
neurocutaneous, progressive myoclonic epilepsy, single gene disorders, chromosomal	1–3
Provoked – reflex epilepsy	1–3

\* Indicative prevalent frequency in different general clinical settings.

### Idiopathic epilepsy

Idiopathic epilepsy is defined as an epilepsy of predominately genetic or presumed genetic origin and in which there is no gross neuroanatomic or neuropathologic abnormalities nor other relevant underlying disease. Although the ‘idiopathic’ epilepsies are likely to have a strong genetic basis, in most cases epigenetic and epistatic factors, and developmental aspects are probably as important as any individual genetic change in the clinical expression of the condition. Single gene disorders probably underlie only 1–2% of all epilepsies, and usually in these conditions there are additional neurological or systemic features (Table 7.8).

### Pure epilepsies resulting from single gene disorder

There is a small number of rare conditions in which epilepsy is the main or only manifestation that is Mendelian in its inheritance pattern. These include the following conditions.

Benign familial neonatal convulsions which start in the first 10 days of life and which usually remit spontaneously, although 10% of patients develop subsequent epilepsy. This is an autosomal dominant condition resulting from mutations of voltage-gated potassium channel genes *KCNQ2* and *KCNQ3*.

Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) is caused by mutations in the  $\alpha_4$  and  $\beta_2$  subunits of the nicotinic acetylcholine receptor. In this condition, frontal lobe complex partial seizures occur exclusively during sleep, sometimes each night and sometimes many times during the night. The seizures are brief, lasting less than 1 minute, and are clustered around the onset and end of sleep. The seizures can be misdiagnosed as parasomnias or even dissociative seizures (in spite of the fact that dissociative seizures never arise from sleep), and are not uncommonly resistant to therapy.

Generalised epilepsy with febrile seizures (GEFS+) is a more heterogeneous form of epilepsy, inherited in an autosomal dominant

**Table 7.8** Some single-gene disorders causing epilepsy.

Acute intermittent porphyria
Aminoacidurias (phenylketonuria, maple syrup urine disease, glutaric acidaemia type 1)
Angelman’s disease
Arginino-succinicaciduria
Biotinidase deficiency
Carnitine palmitoyltransferase 11 deficiency
Chorea-acanthocytosis (neuro-acanthocytosis)
Cortical dysplasias (e.g. agenesis of the corpus callosum, agyria pachygyria band spectrum, peri-ventricular heterotopia, schizencephaly)
Creatinine synthetase deficiencies
DRPLA
Familial cavernoma
Gangliosidoses (various subtypes) (infantile GM1, GM2)
Glucocerebrosidase deficiency (Gaucher’s disease)
GLUT-1 deficiency
Hexosaminidase A deficiency
Huntington’s disease
Isovaleric acidaemia
Lafora body disease
Lysosomal storage diseases (e.g. Gaucher’s disease, Niemann–Pick disease, sialidoses)
Menkes disease
Mitochondrial diseases (including MERFF, MELAS, Alper’s disease, MNGIE)
Mucopolysaccharidoses (various subtypes)
Neuronal ceroid lipofuscinoses (NCL, various subtypes)
Non-ketotic hyperglycinaemia
Organic acidurias (e.g. methylmalonic aciduria, glutaric aciduria, propionic aciduria)
Peroxisomal enzyme deficiencies (various types, e.g. Zellweger syndrome)
Pyridoxamine 5’-phosphate oxidase deficiency
Pyruvate dehydrogenase deficiency
Rett syndrome
Sulfite oxidase deficiency
Neurocutaneous syndromes (e.g. tuberous sclerosis, neurofibromatosis)
Unverricht–Lundborg disease
Urea cycle disorders (e.g. ornithine trans-carbamylase deficiency)
Wolf–Hirschhorn syndrome

List excludes the single gene disorders causing ‘pure epilepsy’ – see text. DRPLA, dentato-rubro-pallido-luysian atrophy; MERFF, myoclonic epilepsy with ragged red fibres; MELAS, mitochondrial myopathy, encephalopathy, lactic acidosis and stroke; MNGIE, mitochondrial neurogastrointestinal encephalopathy syndrome; NCL, neuronal ceroid lipofuscinosis.

fashion, with age-specific manifestations and variable penetrance. Febrile seizures are the most constant feature, in which seizures are precipitated by fever and tend to occur throughout childhood, but other afebrile seizures also occur. The phenotype is wide and it is arguable whether this condition deserves to be categorised as a syndrome. Various mutations underlying the epilepsy in these families have been identified in the  $\alpha$  or  $\beta$  subunits of the voltage-gated sodium channel genes *SCN1A* and *SCN1B*, and  $\gamma_2$  subunit of the GABA<sub>A</sub> receptor.

Dravet's syndrome (severe myoclonic epilepsy of infancy, SMEI) is a severe epilepsy, developing in early life and with a poor prognosis. Most cases have mutations in the *SCN1A* gene, the same gene that causes the more benign GEFS+, and indeed there are families in which both phenotypes coexist. Seizures occur between the ages of 2 and 9 months, and are often prolonged clonic or tonic-clonic seizures, and are precipitated by fever or even hot baths. Myoclonic seizures develop later and episodes of non-convulsive status epilepticus are common. The prognosis is generally poor with intractable epilepsy, early death, severe retardation or institutionalisation in most patients, but milder cases do occur and sometimes the Dravet mutation is found in patients with less severe epilepsy presenting in adult life.

### Pure epilepsies with complex inheritance

These are much more common than the single gene epilepsies. These are divided into idiopathic generalised epilepsies and benign partial epilepsies of childhood, and the more common forms (syndromes) were described earlier. Although presumed to have a genetic basis, no common susceptibility genes have yet been identified and almost certainly their clinical forms are dependent on epigenetic and epistatic factors and developmental aspects. To what extent other cryptogenic epilepsies have a genetic basis is less clear (including cryptogenic febrile convulsions, cryptogenic West's syndrome, cryptogenic Lennox-Gastaut syndrome). There is often no strong family history in any of these conditions.

### Symptomatic epilepsy

Symptomatic epilepsy is defined as an epilepsy predominately caused by a gross neuroanatomical or neuropathological abnormality or a relevant systemic disease, which can be acquired or genetic in origin. Almost any condition affecting the cerebral grey matter can result in epilepsy. The epilepsy usually takes a partial or secondarily generalised form and, in most causative conditions, the epilepsy does not have any particularly distinctive features.

Some symptomatic epilepsies are genetic or congenital in origin, for instance congenital and innate causes of epilepsy which are developmental or genetic (examples include some of the cortical dysplasias, neurocutaneous syndromes, monogenic diseases, chromosomal disorders and progressive myoclonic epilepsies). At least 240 single gene and chromosomal disorders result in neurological disorders in which epilepsy is part of the phenotype. Most are rare or very rare and manifest initially in childhood. Many are inborn errors of metabolism.

After an acute cerebral event, the epilepsy is often divided into 'early' (i.e. seizures occurring within a week of the insult) and 'late' (i.e. epilepsy developing later). There is often a 'silent period' between the injury and the onset of late epilepsy, and the nature of the epileptogenic processes occurring during this period is largely unknown. The occurrence of a silent period raises the possibility that neuroprotective interventions to inhibit these processes could prevent later epilepsy, but to date no effective neuroprotectant agent

is available. Antiepileptic drug therapy will prevent early epilepsy but does not reduce the frequency of late seizures. Early seizures are caused by the acute disturbance and have different mechanisms, and are often not followed by late epilepsy – a fact important to emphasise to patients.

### Inborn errors of metabolism

Seizures are sometimes the presenting features of inborn errors of metabolism. There are many examples and an increasing number are treatable, especially if detected early.

Epilepsies resulting from inborn errors of metabolism in the neonatal period or early infancy are pyridoxine deficiency, pyridoxamine 5'-phosphate oxidase deficiency, folinic acid-responsive seizures, biotinidase deficiency, GLUT1 deficiency, non-ketotic hyperglycaemia, series biosynthetase defects, sulfite oxidase deficiencies, Menkes disease, defects of peroxisomal function and beta-oxidation, disorders of glycosylation and infantile neuronal ceroid lipofuscinosis (Chapter 19).

Epilepsies usually presenting in late infancy or early childhood include creatinine synthetase defects, the early causes of progressive myoclonic epilepsy (sialidosis, mitochondrial diseases, neuronal ceroid lipofuscinosis), mitochondrial disease (especially *POLG1* defects), gangliosidoses, disorders of glycosylation, and peridoxine and pyridoxamine 5'-phosphate oxidase deficiencies.

Epilepsies presenting in adolescence or late childhood include causes of progressive myoclonic epilepsy, Lafora body disease, myoclonic epilepsy with ragged red fibres (MERRF), mitochondrial disorders, Unverricht-Lundborg disease, late-onset forms of neuronal ceroid lipofuscinoses, late-onset GM1 gangliosidosis (such as Tay-Sachs disease and Gaucher type III), lysosomal storage disease (e.g. Niemann-Pick) and peroxisomal disorders.

Most of these inborn errors of metabolism are single gene disorders, although sometimes a wide variety of mutations in a gene, or even mutations in different genes, can cause a similar phenotype. Most are associated with mental handicap, often severe, and with regression if untreated. Many have associated clinical signs and other congenital anomalies or dysmorphologies, and many are associated with limited lifespan. As genetic understanding advances it is also clear that the phenotype of many conditions is wider than previously realised, and occasional mild cases can present late.

Some of these conditions are treatable, and early detection and therapy in some will prevent regression and deterioration. The treatable causes include pyridoxine deficiency, pyridoxamine 5'-phosphate oxidase deficiency, folinic acid-responsive seizures, biotinidase deficiency, GLUT1 deficiency, non-ketotic hyperglycaemia, series biosynthetase defects, sulfite oxidase deficiencies, Menkes disease and some aminocidurias.

The investigation of these conditions is discussed in Chapter 19, and also further on in this chapter 'Investigation of epilepsy'.

### Progressive myoclonic epilepsy

This form of epilepsy can be caused by various genetically determined neurological disorders (Table 7.9). In most parts of the world, the four most common are mitochondrial diseases, Unverricht-Lundborg disease, dentato-rubro-pallido-luysian atrophy (DRPLA) and Lafora body disease.

Unverricht-Lundborg disease (Baltic myoclonus) is the most benign form. It is an autosomal recessive disorder resulting from dodecamer repeats in the *EPM1* gene coding for the cystatin B protein, a protease inhibitor. The condition is particularly common in

**Table 7.9** Causes of progressive myoclonic epilepsy (PME).

Most common causes
Baltic myoclonus (Unverricht–Lundborg disease)
Ceroid lipofuscinoses
DRPLA
Lafora body disease
Mitochondrial disease (MERRF)
Sialidoses
Rarer causes
Alper's disease
Alzheimer's disease
Biotin-responsive progressive myoclonus
Coeliac disease
Gaucher's disease
GM2 gangliosidosis (juvenile type)
Hexosaminidase deficiency
Huntington's disease
Juvenile neuroaxonal dystrophy
Menkes disease
Non-ketotic hyperglycaemia
Phenylketonuria
Tetrahydrobiopterin deficiencies

In a significant proportion of patients, no cause can be identified.

DRPLA, dentato-rubro-pallido-luysian atrophy; MERRF, myoclonic epilepsy with ragged red fibres.

Finland (where the incidence is in excess of 1/20 000 persons) and other Scandinavian countries as a result of founder effects. Myoclonus develops, usually between the ages of 6 and 15 years, and the condition slowly progresses. Ataxia and tremor later become major clinical features. There is a very slow intellectual decline.

DRPLA is inherited in an autosomal dominant fashion. It is particularly common in Japan (a frequency of 0.2–0.7/100 000 persons) and northern Europe. It is a triplet repeat disorder involving the *DRPLA* gene which is of uncertain function. The condition presents in childhood or adult life and is slowly progressive. Ataxia, choreoathetosis, dementia and behavioural changes, myoclonus and epilepsy occur.

Lafora body disease is an autosomal recessive condition, most common in southern Europe, and characterised by Lafora bodies, periodic acid–Schiff (PAS) positive intracellular polyglucosan inclusions found in neurones, sweat glands and elsewhere. The age of onset is 6–19 years and patients develop progressive myoclonic, tonic–clonic and partial seizures. There is also a progressive and severe dementia, and ataxia and dysarthria also occur. Death occurs within 2–10 years. Up to 80% of patients have a mutation in the *EPM2A* gene, which codes for Laforin, a tyrosine phosphatase protein. A second gene, *EPM2B*, has been identified, which codes for Malin, a ubiquitin ligase protein.

Mitochondrial cytopathy (MERRF) is one of the phenotypes of mitochondrial cytopathy. In 90% of cases, the genetic defect is

an A–G transition at nucleotide-8344 in the tRNA<sup>lys</sup> gene of mtDNA, and some other cases are caused by *T8356C* or *G8363A* mutations. This is a multi-system disorder with a very variable phenotype in which myoclonic seizures are often the first symptom, followed by generalised epilepsy, myopathy, ataxia and dementia. Heteroplasmy is responsible for some of the phenotypic variation.

### Epilepsies in neurocutaneous syndromes

The neurocutaneous conditions often result in epilepsy. Tuberos sclerosis complex, Sturge–Weber syndrome and neurofibromatosis (type 1) are the most important. Other rare conditions causing epilepsy include hypomelanosis of Ito, epidermal naevus syndrome (Jadassohn's syndrome), hereditary haemorrhagic telangiectasia, midline linear naevus syndrome, incontinentia pigmenti and Klippel–Trenaunay–Weber syndrome.

**Tuberous sclerosis** This is a not uncommon condition (1/5800 live births in some studies) and there is a high spontaneous mutation rate (1/25 000). It is inherited in an autosomal dominant fashion. To date, about 300 unique *TSC1* or *TSC2* mutations have been identified. The clinical features of the condition are variable. Epilepsy is the presenting symptom in 80% or more of patients. It can take the form of neonatal seizures, West's syndrome, Lennox–Gastaut syndrome or as adult onset partial or generalised seizures. About two-thirds of patients present before the age of 2 years, with motor seizures, drop attacks or infantile spasms. About 25% of all cases of West's syndrome are caused by tuberous sclerosis. The skin is abnormal in almost all patients, and skin lesions include hypomelanotic macules (87–100% of patients), facial angiofibromas (47–90%), shagreen patches (20–80%), fibrous facial plaques and subungual fibromas (17–87%). CNS tumours are the leading cause of morbidity and mortality. The brain lesions can be distinguished on the basis of magnetic resonance imaging (MRI) studies and comprise: subependymal glial nodules (90% of cases), cortical tubers (70% of cases) and subependymal giant cell astrocytomas (6–14% of cases). Fifty per cent of patients have developmental delay or mental retardation. An estimated 80% of children with tuberous sclerosis have identifiable renal tumours by the age of 10 years. Lesions also appear elsewhere and cardiac and retinal lesions are common.

**Sturge–Weber syndrome** This is an uncommon sporadic developmental disorder, of uncertain causation. The cardinal features are a unilateral or bilateral port wine naevus, epilepsy, hemiparesis, mental impairment and ocular signs. The port wine naevus is usually but not exclusively in the distribution of the trigeminal nerve. It can cross the midline and spread into the upper cervical dermatomes. In one-third of cases the naevus is bilateral. The epilepsy can be focal or generalised. It is often the earliest symptom, and most patients with Sturge–Weber develop seizures within the first year of life (at least 70%) and almost all have developed epilepsy before the age of 4 years. Adult onset epilepsy can occur occasionally. The early seizures are often triggered by fever. The seizures take the form of partial or multi-focal attacks often with frequent and severe secondary generalisation. Convulsive status occurs in over half of cases. Seizures developing in the neonatal period can be very difficult to control and carry a poor prognosis. The hemiplegia and mental impairment deteriorate in a stepwise fashion following a severe bout of seizures, and this is one of the few situations where clear-cut

cerebral damage results directly from epileptic attacks, presumably by ischaemic or excitotoxic mechanisms. Severe learning disability is now less common because of better control of the epilepsy. Status epilepticus particularly often results in a permanent and significant worsening of the neurological deficit. The epilepsy should be aggressively treated to prevent neurological deterioration. Resective surgery (either lesionectomy, hemispherectomy or lobectomy) should be given early consideration.

### Cortical dysplasia

Cortical dysplasia (*syn*: cortical dysgenesis, malformations of cortical development) is a term that is applied to developmental disorders of the cortex producing structural cerebral change. In some cases the cause is unknown, but others are caused by identifiable genetic abnormalities and some by environmental influences such as infection, trauma, hypoxia, exposure to drugs or toxins. The clinical features vary, but epilepsy and learning disability are the most common manifestations. Cortical dysplasia is the underlying cause of the epilepsy in up to 30% of children and 10% of adults referred to epilepsy centres with intractable epilepsy. It includes the following conditions.

**Hemimegalencephaly** In this condition, one cerebral hemisphere is enlarged and is structurally abnormal with thickened cortex, reduced sulcation and poor or absent laminar organisation. Giant neurones are found throughout the brain and in 50% of cases balloon cells too. The condition can occur in isolation, associated with other cortical dysplasias or as part of other syndromes (notably tuberous sclerosis or other rarer neurocutaneous syndromes). Hemimegalencephaly results in severe epilepsy with learning disability, hemiplegia and hemianopia. Surgical therapy (hemispherectomy or hemispherotomy) can cure the epilepsy.

**Focal cortical dysplasia** There are a variety of subtypes, with different histological appearances influenced by the time of formation at different stages of embryogenesis. In some the cortical lamination is normal, but in others there may be associated widespread macrogyria and polymicrogyria. Epilepsy is the leading symptom, and other clinical features depend on the extent of the lesion and include learning disability and focal deficits.

**Schizencephaly** This term denotes the presence of clefts in the cortex, stretching from the surface to the ventricle. Schizencephaly can be unilateral or bilateral and is often peri-sylvian in location. The causes are heterogeneous, and include germline mutations of the homeobox gene *EMX2* and environmental insults during development including radiation, infection and ischaemia. Epilepsy is the most common symptom (over 90% of cases), associated usually but by no means always with learning disability or cognitive changes. Focal neurological deficit is common in extensive or bilateral cases.

**Agryria pachygyria band spectrum (lissencephaly, pachygyria, agryria and subcortical band heterotopia)** These abnormalities of cortical gyration are grouped together as they show an interconnected genetic basis. In all the gyration is simplified and the cortex is thickened. Lissencephaly (literally, smooth brain) is the most severe form, in which gyration is grossly diminished or even absent. Subcortical band heterotopia (*syn*: double cortex

syndrome) denotes the presence of a band of grey matter sandwiched by white matter below the cortical grey matter. The band may be thin or thick, and can merge with overlying cortex in which case the cortex takes a macrogyric form. It is caused in about 80% of cases by germline deletions in the *DCX* (*XLIS*) gene and occurs almost always (but not exclusively) in females. The pachygyria and bands are anteriorly predominant. The genetic anomaly in the other 20% of cases has not been identified.

Macrogyria refers to thickened cortex, and can occur as an isolated phenomenon, is variable in extent and when focal is indistinguishable on clinical or imaging grounds from some forms of focal cortical dysplasia. Isolated lissencephaly is present in 12 per million live births and results in profound retardation, epilepsy and spastic quadraparesis. In less severe cases, where the lissencephaly is restricted to one region of the brain (albeit usually bilaterally, with an anterior or posterior gradient), the epilepsy and learning disability may be mild. Of cases of isolated lissencephaly, 60–80% are caused by identifiable mutations in the *LIS1* or *XLIS* (also known as the *DCX*) genes, on 17p13.3 and Xq22.3-q24, respectively, and in 40% the entire gene is deleted. Other forms of lissencephaly have more widespread associations. The best known is the Miller–Dieker syndrome, caused by large deletions of *LIS1* and of several other contiguous genes on 17p13.3, in which the lissencephaly is associated with epilepsy, facial dysmorphism, microcephaly, small mandible, failure to thrive, retarded motor development, dysphagia, decorticate and decerebrate postures. All these conditions usually present in children with epilepsy and learning disability. The clinical severity of the syndrome seems to correlate with the extent of the cerebral anomaly.

**Agenesis of the corpus callosum** This anomaly occurs in various genetic and congenital disorders. Epilepsy is invariable and is the leading symptom. In Aicardi's syndrome, the corpus callosum agenesis is associated with peri-ventricular heterotopia, thin unlayered cortex and diffuse polymicrogyria.

**Polymicrogyria** The appearance of small and prominent gyri, separated by shallow sulci, is known as polymicrogyria. It can have a genetic or environmental cause. Epilepsy is the leading clinical feature, associated with learning disability and focal neurological signs and the manifestations vary greatly in severity. Bilateral peri-sylvian polymicrogyria (Kuzniecky syndrome) is a condition in which there is severe upper motor neurone bulbar dysfunction and diplegia as well as severe epilepsy and mental retardation.

**Periventricular nodular heterotopia (syn: bilateral peri-ventricular nodular heterotopia, subependymal nodular heterotopia)** In this condition, subependymal nodules of grey matter are present, usually bilateral and located along the supralateral walls of the lateral ventricles. It is much more common in females, inherited in an X-linked dominant fashion and many (but not all) of the cases have shown mutations in the *FLN1* (filamin-1) gene. Bilateral peri-ventricular nodular heterotopia usually has a genetic origin, but unilateral cases often do not and are presumably caused by intrauterine vascular or other congenital insults. The clinical presentation can vary from mild epilepsy presenting in older children or young adults to severe infantile or childhood partial epilepsy.

### Hippocampal sclerosis

Hippocampal sclerosis is the most common cause of mesial temporal lobe epilepsy which is itself the most common form of partial epilepsy. It is found in over one-third of patients with refractory focal epilepsy attending hospital clinics in whom there is no other structural lesion, but is less frequent in those with mild epilepsy. Hippocampal sclerosis typically is associated with complex partial seizures. There is a clear association with a history of childhood febrile convulsions, and it has been proposed that the febrile convulsions, especially if prolonged or complex, result in hippocampal sclerosis which itself results in subsequent TLE. Serial MRI studies have demonstrated that status epilepticus also can result in hippocampal sclerosis and there is clear evidence from animal experimentation that prolonged partial seizures can cause hippocampal damage and in some cases progression of the hippocampal atrophy and worsening seizures. In other cases, hippocampal sclerosis may be a congenital lesion, and hippocampal sclerosis can also occur after severe brain trauma or vascular damage.

### Cerebral palsy, perinatal and prenatal injury

Cerebral palsy is a non-specific term that covers many prenatal and peri-natal pathologies. It is strongly associated with epilepsy. In the US National Collaborative Perinatal Project, a prospective cohort study of infants followed to the age of 7 years, epilepsy was found to occur in 34% of children with cerebral palsy, and cerebral palsy was present in 19% of children developing epilepsy. In the same cohort, the risk of learning disability (associated with cerebral palsy) was 5.5 times higher among children developing epilepsy following a febrile seizure than in children with a febrile seizure alone. Learning disability (IQ <70) is present in 27% of children with epilepsy, and seizures are present in about 50% of children with mental retardation and cerebral palsy. In case-controlled studies, only severe perinatal insults have been found to increase the risk of subsequent epilepsy (examples are perinatal haemorrhage and ischaemic hypoxic encephalopathy). Factors such as pre-eclampsia, eclampsia, forceps delivery, being born with the 'cord round the neck', low birth weight or prematurity have only a very modest association, if any, with the presence of subsequent epilepsy.

### Post-vaccination encephalopathy

The role of vaccination (notably pertussis vaccination) in causing a childhood encephalopathy and subsequent epilepsy and learning disability has been the subject of intense study. The UK National Childhood Encephalopathy Study found that children hospitalised with seizures and encephalopathy were more likely to have received DTP (diphtheria, tetanus, pertussis) vaccination in the previous 7 days than control children. Although potential methodological biases of this study have been severely criticised, the results from this and other studies have led many authorities to accept that there is a small risk of encephalopathy after pertussis vaccine. Another large study of 368 000 children found no excess risk. Similarly, suggestions that MMR (mumps, measles, rubella) vaccine increases the risks of autism and epilepsy are now thought to be unfounded.

A recent study has shown that many cases of so-called post-vaccination encephalopathy carry the causal mutation of Dravet syndrome (usually an SCN1A mutation) and so the vaccination simply precipitates the encephalopathy which was in all likelihood going to develop anyway.

Thus, conventional medical advice is now that vaccination is safe, and although a small number of children do develop encephalopathic reactions that result in later epilepsy, this number is considerably less

than the risk of encephalopathy after the naturally occurring viral illnesses that vaccination prevents. The vaccines that have been thought to be associated with post-vaccination encephalomyelitis are small-pox, measles, DTP, Japanese B encephalitis and rabies.

### Cerebral tumour

About 6% of all newly diagnosed cases of epilepsy are caused by cerebral tumours, with the incidence of tumour higher in adults than in children. Seizures occur in about 50% of all brain tumours. Tumours of the frontal and temporal regions are more likely to cause epilepsy than other cortical tumours and epilepsy is rare in subcortical or cerebellar tumours.

Gliomas are most common brain tumour causing epilepsy, and low grade gliomas are more epileptogenic than high grade tumours. Overall, slow-growing or benign tumours account for about 10% of all adult-onset epilepsies. There can be a history of epilepsy for many years. In chronic refractory tumoural epilepsy, oligodendrogliomas account for 10–30%, dysembryoplastic neuroepithelial tumours (DNETs) for 10–30%, astrocytomas for 10–30%, gangliogliomas for about 10–20% and hamartomas for 10–20%. The epilepsy in all, except the DNETs, arises in the surrounding tissue and not the substance of the tumour and this can have implications for surgical therapy. Epileptogenesis can be caused by impaired vascularisation of the surrounding cortex, changes in the excitatory and inhibitory synapses or other morphological changes.

Ganglioglioma are mixed developmental tumours that are composed of neoplastic glial and neuronal cell types and comprise around 10% of the neoplasms removed at temporal lobectomy. Seizures are the primary presenting symptom in 80–90%. The dysembryoplastic neuroepithelial tumour (DNET or DNT) is a pathological entity only recently differentiated from other forms of 'benign gliomas' and accounts for 10–30% of resected tumours in the temporal lobe. They are benign tumours with only a slight propensity for growth, and epilepsy is usually the only clinical symptom. As these are developmental in origin, they have intrinsic epileptogenesis (in contrast to other cerebral tumours) and are important to identify as partial resection will often control the seizures. Hamartomas are benign tumours which account for 15–20% of tumours removed at temporal lobectomy. These are more common in children.

The hypothalamic hamartoma is usually a benign tumour, confined to the tuber cinereum, which characteristically presents with gelastic seizures, learning disability, behavioural disturbance and later with precocious puberty. The lesions are subtle and can be very easily missed on even high-quality MRI scanning. Gelastic seizures are characteristic of hypothalamic hamartoma but do occur in other midline lesions and also occasionally in TLE. The attacks take the form of sudden laughter associated with other variable motor features (clonic movements, head and eye deviation). The laughter is 'mirthless', in other words not associated with any emotional feelings of joy or happiness, and occurs in situations that do not provoke humour.

Meningiomas are also common causes of adult epilepsy, and epilepsy is the presenting symptom of the tumour in 20–50% of cases. Meningiomas are more likely to cause epilepsy when located over the convexity, parasagittal/falx and sphenoid ridge, or if there is peri-tumoural oedema. There is no relationship between the presence of epilepsy and histological type.

### Cerebrovascular disease

Stroke is the most commonly identified cause of epilepsy presenting over the age of 50 years, and occult stroke also explains the occurrence of other cases of apparently cryptogenic late onset epilepsy.

A history of stroke has been found to be associated with an increased lifetime occurrence of epilepsy (OR 3.3; 95% CI 1.3–8.5).

About 5–10% of patients with cerebral haemorrhage develop late epilepsy. The incidence of early epilepsy (seizures in the first week) is higher, up to 30% in some series and about one-third of those with early seizures continue to have a liability to epilepsy. Epilepsy is more common after large haemorrhages and haemorrhages that involve the cerebral cortex and almost always develops within 2 years of the haemorrhage. After cerebral infarction, epilepsy occurs in about 6% of patients within 12 months and 11% within 5 years of the stroke. Epilepsy is more common in cerebral infarcts located in the anterior hemisphere, and involving cortex. Epilepsy can also complicate occult cerebrovascular disease. Late onset epilepsy can be the first manifestation of cerebrovascular disease and, in the absence of other causes, newly developing seizures after the age of 40 years should prompt an urgent screen for vascular risk factors.

Epilepsy develops in 6–15% of survivors of subarachnoid haemorrhage caused by ruptured intracranial aneurysm, with a higher incidence in those with haematoma and cerebral infarction, disability on discharge, and those who have required an external ventricular drain or shunt or surgical treatment.

### Arteriovenous malformation

An arteriovenous malformation (AVM) is a congenital malformation comprising a network of arterial and venous channels communicating directly with each other. Between 17% and 36% of supratentorial AVMs present with seizures, with or without associated neurological deficits, and 40–50% with haemorrhage. Smaller AVMs (<3 cm diameter) are more likely to present with haemorrhage than large ones. Conversely, large and/or superficial malformations are more epileptogenic, as are AVMs in the temporal lobe. About 40% of patients with large AVMs have epilepsy, and epilepsy is the presenting symptom in about 20%. The annual risk of bleeding of an AVM is in the region of 2–4% per year, irrespective of whether the malformation presented with haemorrhage, and the average mortality about 1% per year. Venous malformations are congenital anomalies of normal venous drainage and these have a very low risk of haemorrhage or epilepsy.

### Cavernous haemangioma (cavernoma)

Cavernous haemangiomas account for 5–13% of vascular malformations of the CNS. At least 15–20% of patients remain symptom-free throughout their lives. Patients present with seizures (40–70%), focal neurological deficits (35–50%), non-specific headaches (10–30%) and cerebral hemorrhage. The seizures are typically partial in nature and often brief, infrequent and minor in form. Family histories can be found in about 10–30% of cavernous haemangiomas, and three different genes (or loci) have been identified. The most common gene with causative mutations is *KRIT1*. This gene contains 16 coding exons and is located on chromosome 7q21.2. Loss of function mutations result in the formation of cavernoma. The other identified genes are *MGC4607* and *PDCD10*, and there are some families without evidence of mutations in any of these three genes and in whom the genetic defect remains obscure.

### Other vascular lesions

Cortical venous infarcts are particularly epileptogenic, at least in the acute phase, and may underlie a significant proportion of apparently spontaneous epileptic seizures complicating other medical conditions and pregnancy for instance. Seizures occur in several connective tissue disorders and in patients with cerebral vasculitis.

The most commonly encountered is systemic lupus erythematosus. Seizures also occur with cerebrovascular lesions secondary to rheumatic heart disease, endocarditis, mitral valve prolapse, cardiac tumours and cardiac arrhythmia, or after carotid endarterectomy. Epilepsy is also common in eclampsia, hypertensive encephalopathy and malignant hypertension and in the anoxic encephalopathy that follows cardiac arrest or cardiopulmonary surgery. Unruptured aneurysms can cause epilepsy, especially if large and if embedded in the temporal lobe.

### Dementia and degenerative disorders

Epilepsy is a common feature of degenerative neurological disease that involves the grey matter, but is seldom a leading symptom in pure leukodystrophy.

The most common neurodegenerative disorders are the dementias in late life. Six per cent of persons over the age of 65 years have dementia, and the rate increases exponentially as a function of age. Alzheimer's disease is the most common cause of dementia, and patients with Alzheimer's disease are six times more likely to develop epilepsy than age-matched controls. Partial and secondarily generalised seizures occur, and are usually relatively easily treated with conventional antiepileptic therapy. Myoclonus is another common finding in patients with Alzheimer's disease, occurring in about 10% of autopsy-verified cases and is a late manifestation. Five per cent of patients with Huntington's disease have epilepsy, usually in the later stages. Epilepsy is more common in the juvenile type, and occasionally takes the form of a progressive myoclonic epilepsy. Epilepsy, and indeed status epilepticus, can be the presenting feature of Creutzfeldt–Jakob disease (CJD). Generalised tonic–clonic or partial seizures occur in 10% of established cases, and myoclonus in 80%, and can be induced by startle or other stimuli.

### Post-traumatic epilepsy

Head trauma is an important cause of epilepsy. It is customary to draw a distinction between open head injury, where the dura is breached, and closed head injury, where there is no dural breach. Post-traumatic seizures are traditionally subdivided into immediate, early and late categories. Immediate seizures are defined as those that occur within the first 24 hours after injury, early seizures are those that occur within the first week and late seizures occur after 1 week.

Closed head injuries are most common in civilian practice, usually from road traffic accidents, falls or recreational injuries, and in different series have accounted for 2–12% of all cases of epilepsy. Traumatic brain injury in the United States has been estimated to have an incidence of 825 cases per 100 000 per year, with about 100–200 per 100 000 per year admitted to hospital. Early seizures after closed head injury occur in about 2–6% of those admitted to hospital, with a higher frequency in children than in adults. Early seizures have not been found generally to be an independent predictive risk factor of late seizures. Of patients requiring hospitalisation for closed head trauma, 2–5% will subsequently develop epilepsy (late post-traumatic seizures). Mild head injury – defined as head injury without skull fracture and with less than 30 minutes of post-traumatic amnesia – is, in most studies, not associated with any markedly increased risk of epilepsy. Moderate head injury – defined as a head injury complicated by skull fracture or post-traumatic amnesia for more than 30 minutes – is followed by epilepsy in about 1–4% of cases. Severe head injury – defined as a head injury with post-traumatic amnesia of more than 24 hours,

intracranial haematoma or cerebral contusion – is followed by epilepsy, in most studies, in about 10–15% of patients. The excess risk of epilepsy is highest during the first year, with the time of onset of epilepsy peaking at 4–8 months post-injury, and diminishes during the ensuing years.

Post-traumatic epilepsy is much more frequent after open head injury. This is particularly so in penetrating wartime injuries, with 30–50% of patients developing subsequent epilepsy. Overall, the risk of late epilepsy, if early epilepsy is present, is about 25% compared to 3% in patients who did not have early seizures. The risk of epilepsy after open head injury is greatest if the extent of cerebral damage is large and involves the frontal or temporal regions.

Calculations of the risk of epilepsy in various circumstances following injury have been made. The presence of a dural breach (e.g. with a depressed fracture), an intracranial haematoma and long post-traumatic amnesia ( $\geq 24$  hours) have been found consistently to increase significantly the risk of subsequent epilepsy. In one series, the risk of seizures by 2 years was 27% in the presence of depressed skull fracture, 24% with subdural haematoma (and 44% if this was severe enough to need surgical evacuation), 23% with intracranial haematoma and 12% with long post-traumatic amnesia.

Antiepileptic drug therapy reduces the risk of early seizures. However, there is no evidence that prophylactic antiepileptic drug treatment after head trauma reduces the long-term risk of epilepsy. It is common practice to give antiepileptic drugs for a few weeks after a severe head injury, but then to discontinue the medication if no seizures have occurred.

### Epilepsy after neurosurgery

The risk of late postoperative seizures is greater in patients with younger age, early postoperative seizures and severe neurological deficit. The incidence of seizures varies according to the nature of the underlying disease process, its site and extent. A large retrospective study found an overall incidence of 17% for postoperative seizures in 877 consecutive patients undergoing supratentorial neurosurgery for non-traumatic conditions. The patients had no prior history of epilepsy and the minimum follow-up was 5 years. The incidence of seizures ranged from 4% in patients undergoing stereotactic procedures and ventricular drainage to 92% for patients being surgically treated for cerebral abscess. The risk of craniotomy for glioma was 19%, for intracranial haemorrhage 21% and for meningioma removal 22%. All these risks were greatly enhanced if seizures occurred pre-operatively. Among patients developing post-operative seizures, 37% did so within the first postoperative week, 77% within the first year and 92% within the first 2 years. If early seizures occurred (i.e. those occurring in the first week), 41% of patients developed late recurrent seizures.

Studies after unruptured aneurysm show an overall risk of about 14%. The risk of a middle cerebral aneurysm resulting in epilepsy is 19%, and anterior communicating aneurysms and posterior communicating aneurysms carry a risk of about 10%. If the aneurysm has bled, causing an intracranial haematoma, the incidence of epilepsy is higher.

An overall risk of epilepsy following shunt procedures is about 10%, although this depends on the site of the shunt insertion.

It is not clear whether the prophylactic use of anticonvulsants after neurosurgical procedures is worthwhile. Currently, it is usual to prescribe prophylactic anticonvulsant drugs for several months after major supratentorial neurosurgery and then gradually to withdraw the medication unless seizures have occurred.

### Bacterial or viral meningitis and encephalitis

CNS infections are a major risk factor for epilepsy. Seizures can be the presenting or the only symptom, or one component of a more diffuse cerebral disorder.

Encephalitis and meningitis result in a sevenfold increase in the rate of chronic epilepsy compared with that in the general population. The increased risk is highest during the first 5 years after infection, but remains elevated for up to 15 years. The risk is much higher after encephalitis (RR 16.2), especially herpes simplex virus 1 (HSV-1) infection, than bacterial meningitis (RR 4.2) or aseptic meningitis (RR 2.3). The incidence of severe HSV-1 encephalitis is about 1 per million persons per year, and seizures are a frequent symptom in the acute phase of severe HSV encephalitis. Most survivors are left with neurological sequelae including severe epilepsy. Epilepsy is also a leading symptom of tuberculoma. In patients presenting simply with epilepsy, it is now usual to treat with antitubercular and antiepileptic drugs (with a short course of adjunctive steroids), and to defer surgery. When medical therapy is initiated without diagnostic confirmation from a biopsy, the patient should be carefully monitored, and if the mass does not decrease in size after 8 weeks of therapy, biopsy should be reconsidered.

Pyogenic brain abscess is an uncommon but serious cause of epilepsy. The estimated annual incidence of brain abscess in the United States is 1/10 000 hospital admissions, and abscess surgery accounts for 0.7% of all neurosurgery operations. Brain abscess can develop in association with a contiguous suppurating process (usually otitis media, sinus disease or mastoiditis, 50%), from haematogenous spread from a distant focus (25%), as a complication of intracranial surgery (15%) and trauma (10%). Commonly isolated organisms are streptococci, including aerobic, anaerobic and microaerophilic types. *Streptococcus pneumoniae* is a rarer cause of brain abscesses, which are often the sequel to occult cerebrospinal fluid (CSF) rhinorrhoea and also to pneumococcal pneumonia in elderly patients. Enteric bacteria and *Bacteroides* are isolated in 20–40% of cases and often in mixed culture. Anaerobic organisms have become increasingly important organisms and in many instances more than a single bacterial species is recovered. Gram-negative bacilli rarely occur alone. Staphylococcal abscesses account for 10–15% of cases and are usually caused by penetrating head injury or bacteraemia secondary to endocarditis. Clostridial infections are most often post-traumatic. Rarely, *Actinomyces* or *Nocardia* are the causative agents in a brain abscess.

### Parasitic diseases

Neuro-cysticercosis is the most common parasitic disease of the CNS. Epilepsy is the most common clinical manifestation and usual presenting symptom and neuro-cysticercosis a major cause of epilepsy in endemic areas in parts of Latin America, Asia and West Africa. A solitary cerebral parenchymal lesion is a common form of presentation, but lesions are often multiple. Over time, the cysts shrink progressively and then calcify or disappear completely. Seizures develop when a cyst is degenerating or around a chronic calcified lesion. Where there is a single cyst it is usual to control seizures with antiepileptic drugs and not to use anticysticercal drugs. If anticysticercal drugs are to be used, steroids need to be given in co-medication to prevent sudden rise in intracranial pressure and exacerbation of symptoms.

In endemic regions, a common clinical scenario is the occurrence of a seizure with a single enhancing lesion on CT. The differential diagnosis includes neuro-cysticercosis, tuberculosis, gliomas and other tumours, toxoplasmosis and other infective

lesions. Over 90% of the lesions in India are caused by neurocysticercosis, and currently the usual management strategy is to screen the patient for other signs of tuberculosis but if none are present not to give antitubercular therapy. CT is repeated in 12 weeks and if the lesion has not regressed, or has increased, a review of diagnosis including surgical biopsy is the preferred approach. Antiepileptic drugs are given.

Malaria causes a 9–11-fold (95% CI 2–18) increase in the risk of chronic epilepsy – a risk that is at least double the risk of epilepsy after complex febrile seizures.

### Inflammatory and immunological disorders

The importance of inflammatory or immunological mechanisms in the precipitation and causation of epilepsy is increasingly being recognised. Inflammatory or immunological reactions can occur in infections or in vascular disease, and also in a range of primarily immunological conditions, in which epilepsy is a prominent feature.

**Immune-mediated diseases** The most common immunological disease associated with epilepsy is systemic lupus erythematosus (SLE). Seizures are the most frequent neuropsychiatric manifestation, both at disease onset and during the course of the disease, with a frequency ranging from 40% to 85%. In antiphospholipid syndrome, seizures occur in about 9% cases. Seizures also occur less commonly in Kawasaki disease, Henoch–Schönlein purpura, Wegener granulomatosis, in other causes of vasculitis and in scleroderma. Seizures are common in the rare condition of linear scleroderma (Parry–Romberg syndrome). In SLE, the seizures are related to disease activity and can be the only CNS manifestation. Both generalised and focal seizures occur and can be caused either by inflammatory or ischaemic pathologies.

Limbic encephalitis is an increasingly recognised subacute encephalopathic inflammatory disorder of the CNS, sometimes associated with benign or malignant neoplasms, and sometime idiopathic. The first identified condition (in 1960), was Hashimoto encephalitis, but in the last two decades increasing numbers of paraneoplastic and non-paraneoplastic antibodies associated with this condition have been described. Epilepsy occurs in almost all cases of limbic encephalitis regardless of cause. It can vary in form from very slight partial seizures to complex partial seizures or severe generalised seizures. Diagnosis is by MRI, blood and CSF examination and EEG. The range of identifiable antibodies in the serum and CSF includes intracellular antibodies: Hu/ANNA-1, Ma-2, CRMP-5, amphiphysin, glutamic acid decarboxylase (GAD), and extracellular antibodies: voltage gated potassium channel (VGKC) antibodies, *N*-methyl-D-aspartate receptor (NMDAR) antibodies, glycine receptor antibodies, adenylate kinase 5 antibodies, and BR serine/threonine kinase 2 antibodies. Sometimes, epilepsy occurs without encephalopathy associated with VGKC or VGCC, GLu-R3, anti-GAD or anti-GM1 antibodies and in these cases knowing whether the antibodies are pathogenic or not can be difficult.

Hashimoto encephalopathy (now often referred to as STREAT – steroid responsive encephalopathy associated with autoimmune thyroiditis) is one of the most common forms, and is associated with high serum levels of anti-thyroid peroxidase (anti-TPO) antibodies (formerly known as microsomal antibodies). These antibodies are probably not pathogenic but are a marker of some unknown cerebral-binding antibody. As its name suggests, most but not all cases are successfully treated with steroids.

Epilepsy also occurs in inflammatory bowel diseases, including ulcerative colitis, Crohn's disease and Whipple's disease. Ten per cent of people with coeliac disease develop neurological complications including epilepsy, which is often associated with occipital calcification on CT.

**Rasmussen encephalitis** This is an unusual condition in which chronic inflammation develops slowly and progressively in the cortex of one cerebral hemisphere. It usually begins in childhood although rare adult onset cases are described. The inflammatory process may evolve for up to 10 years or more and the symptoms and signs are usually initially slowly progressive and then eventually stabilise. The cause of the inflammation is quite unclear, but it is presumed to be an autoimmune response, and its remarkable uni-hemispheric distribution is also completely unexplained. Patients with the condition present with focal and secondarily generalised seizures which can be severe and periods of *epilepsia partialis continua* (EPC) are common. Associated with the seizures is progressive loss of motor and cognitive skills and speech (if in the dominant hemisphere, sometimes progressing to aphasia). Hemiparesis and hemianopia are common. Diagnosis is suspected on MRI scanning which shows marked unilateral and progressive unihemispheric focal atrophy. Treatment is difficult. Antiepileptic drugs are usually ineffective in controlling seizures. Various attempts to suppress or modulate the immune system, in particular with corticosteroids and/or intravenous immunoglobulin (IVIg) have proved effective in only a minority of cases. Surgery to control seizures can be carried out. Large resections are needed and hemispherectomy and hemispherotomy can be strikingly effective at controlling seizures and improving behaviour and cognition.

### Differential diagnosis of epilepsy

Epileptic seizures feature in the differential diagnosis of many transient neurological symptoms. Here, the principal differential diagnoses of the common presentations are described (Table 7.10). There are differences in the common presentations and differential diagnoses in adults, infants and children and we largely confine this description to adult patients.

**Table 7.10** The clinical presentations of epilepsy in relation to differential diagnosis.

Loss of awareness
Generalised convulsive movements
Focal convulsive movements
Facial muscle and eye movements
Drop attacks
Transient focal sensory symptoms
Transient visual symptoms
Transient vestibular symptoms
Psychic experiences
Aggressive outbursts
Episodic phenomena in sleep
Prolonged confusional or fugue states

The key to making a correct diagnosis is a detailed history from the individual patient and from a reliable witness who has seen the episodes in question. In individuals attending clinics with 'first seizures', not more than 25% of patients are usually considered to have had an epileptic seizure. The most common diagnostic error is to diagnose a syncopal episode as an epileptic seizure. Undue reliance is often placed on investigations, particularly the EEG and MRI. Inappropriate weight is often given to EEG findings that are 'compatible with epilepsy'.

It is a sound aphorism that the diagnosis of epilepsy is made primarily on the history, and the role of the EEG is to assist in the subsequent classification of the type of epileptic seizures and the epilepsy syndrome. The role of MRI is not to diagnose epilepsy, but to identify any underlying structural cerebral abnormality in those with diagnosed epilepsy.

There is considerable scope for the misdiagnosis or inaccurate diagnosis of epilepsy and epilepsy syndrome, which can have serious consequences. In tertiary referral practice it has been estimated that in about 20% of those with a diagnosis of refractory epilepsy the diagnosis is incorrect.

When taking the history it is a good tactic to first allow the individual and witnesses to give their own freehand account of the points that they consider most important and to then go through the salient points in a systematic manner. It is not uncommon that a dramatic event causes the individual to seek advice and for minor events that may have occurred for some time to have been overlooked. Such minor events may produce important diagnostic clues and so need to be specifically enquired for. For example, episodes of an epigastric rising sensation, déjà vu and premonition suggest temporal lobe focal seizures; brief blank staring spells and flurries of upper limb jerks in the first hour after waking (i.e. myoclonic jerks) suggest a generalised epilepsy. In contrast, a greying of vision or rushing sound in ears suggest syncope.

In those who have had repeated episodes, a video recording of an episode is frequently extremely helpful, conveying more information than can be relayed by even the most careful witness, and has the benefit of being objective. Video recorders, particularly on mobile telephones, have become commonly available. Where diagnosis is uncertain, these video recordings are invaluable.

The clinical examination is usually less rewarding than the history, but is still important. In addition to determining if there are any focal neurological deficits, the individual's mood and mental state need to be assessed. The skin should be examined for evidence of a neurocutaneous syndrome, systemic signs identified and blood pressure checked. If an individual presents with episodes of loss of awareness or falling, a cardiac examination and measurement of lying and standing blood pressure is indicated.

The following clinical presentations can occur.

### Loss of awareness and collapse

Whatever the cause, the patient may have amnesia for both the event and its exact circumstances. The main causes are syncope, seizures, psychogenic non-epileptic attacks (dissociative attacks) and cardiac arrhythmias. Transient cerebral ischaemia caused by vascular abnormalities is less common. Microsleeps (very short daytime naps) may occur with any cause of severe sleep deprivation or disruption. Other causes of diagnostic confusion are much less common and include hypoglycaemia or other intermittent metabolic disorders, structural anomalies of the skull base affecting the brainstem, or lesions affecting the circulation of the CSF.

### Epilepsy

Several types of epileptic seizure can present with loss of awareness as the only reported feature. These include absences, complex partial, tonic or atonic seizures. Typical absences are sometimes associated with eyelid blinking or twitching, and sometimes small myoclonic facial or limb jerks, or brief facial automatisms such as lip smacking or chewing. Atonic seizures usually give rise to drop attacks but may appear to cause blank spells if the patient is sitting or lying down and so cannot fall. Complex partial seizures may cause loss of awareness with few if any other features. Detailed enquiry must always be made for any associated psychic or motor phenomena that may raise the possibility of a seizure disorder.

### Syncope

Syncope is the most common cause of episodes of loss of awareness. A simple faint (*syn*: reflex syncope, vasovagal syncope) usually has identifiable precipitants – for instance from standing for prolonged periods, particularly if associated with peripheral vasodilatation (e.g. hot stuffy weather, crowds, drug or alcohol use), dehydration, frightening, emotional or unpleasant scenes, painful stimuli (blood taking). There is usually a prodromal period which can last seconds or minutes and consist of such symptoms as sweating, feeling of faintness, greying out of vision (due to retinal ischaemia, pathognomonic of syncope) and a rushing sound in the ears. The mechanism of syncope is a sudden fall in blood pressure with rapid resolution (providing an erect posture is not maintained, and there is rapid recovery without confusion).

There are other causes of syncope. Some are caused by valsalva-type restriction of cardiac return (e.g. cough syncope or the syncope from playing wind instruments); impaired baroreceptors resulting from atheroma of the carotid (carotid sinus syncope); postural syncope (e.g. in peripheral neuropathy, suddenly getting up from a decubitus position); autonomic disturbances (e.g. micturition syncope); cardiac syncope (see later). As these are not caused by vasovagal reflex changes, the typical aura of vasovagal syncope may not be present.

### Cardiac syncope

Cardiac syncope is caused through cerebral ischaemia because of a sudden reduction of cardiac output. There are sometimes prodromal features similar to simple syncope (due to falling cerebral perfusion). Other prodromal features that should suggest a cardiac cause include a history of palpitations, chest pain or shortness of breath. Attacks resulting from transient complete heart block or asystole are abrupt and short with rapid loss of consciousness. Lack of cardiac output may also be caused by short episodes of ventricular tachycardia or fibrillation. Prolongation of the QT interval may lead to such events and the familial genetic syndromes of prolonged QT interval must not be missed. Patients with mitral valve prolapse and aortic stenosis may present with episodic loss of awareness caused by fluctuating cardiac output or associated arrhythmias. Those with aortic stenosis and hypertrophic cardiomyopathy are especially prone to present with episodes of sudden collapse with loss of awareness during exercise. A cardiologist's opinion should be sought if there is the possibility of cardiac dysfunction causing episodes of loss of awareness, falls or convulsions (see later). A 12-lead electrocardiogram (ECG) should be carefully inspected, particularly for evidence of prolongation of the QT interval and consideration given to prolonged ECG monitoring with an implanted ECG loop recorder.

**Table 7.11** Differentiation of epileptic seizures and dissociative seizures.

	Epileptic seizure	Dissociative seizures
Precipitating cause	Rare	Common, emotional and stress-related
When alone or asleep	Common	May be reported
Onset	Usually short	May be short or over several minutes
Aura	Various, usually stereotyped	Fear, panic, altered mental state
Speech	Cry, grunt at onset; muttering, words in automatisms	Semi-voluntary, often unintelligible
Movement	Atonic, tonic; if clonic, synchronous small amplitude jerks	Asynchronous flailing of limbs; pelvic thrusting; opisthotonos
Injury	Tongue biting, fall; directed violence rare	May bite tongue, cheeks, lip, hands, throw self to ground. Directed violence not uncommon
Consciousness	Complete loss in generalised tonic-clonic; may be incomplete in complex partial	Variable, often inconsistent with seizure type
Response to stimulation	None in generalised tonic-clonic; may respond in complex partial and post-ictally	Often reacts and this may terminate episode
Incontinence	Common	Sometimes
Duration	Few minutes	Few minutes, may be prolonged

### Dissociative seizures

Dissociative seizures, sometimes known as non-epileptic attack disorder (NEAD) or pseudoseizures typically gives rise to episodes of two broad types: attacks involving motor phenomena, and attacks of lying motionless with apparent loss of awareness. The duration of the attack is a key diagnostic feature. The motionless attacks are often prolonged, continuing for several minutes or sometimes hours. Such behaviour is very rare indeed in epileptic seizures and there will nearly always be other positive phenomena in epileptic attacks that last for more than a few minutes. In addition, attacks are often precipitated by external events or stress. Patients with dissociative seizures often have a history of abnormal illness behaviour or childhood abuse, or some distinct psychological precipitant. Dissociative seizures are much more common in females than males, and usually commence in adolescence or early adulthood (Table 7.11).

**Microsleeps** Any cause of sleep deprivation can lead to brief daytime naps, sometimes lasting for only a few seconds. Impaired quality of sleep may also be a factor. The most important is obstructive sleep apnoea, although microsleeps also occur in other sleep disorders. Microsleeps are a common problem when driving, particularly on featureless straight roads and are the cause of many road traffic accidents. There are usually clear warning signs such as the driver feeling a need to close their eyes, yawn, turn the radio volume up or open the windows. These events are of legal significance as a driver who continues to drive despite such warning signs and who causes an accident is likely to be prosecuted for dangerous driving. Narcolepsy can present with short periods of suddenly falling asleep during the day. Systematic enquiry should be made for other symptoms of the narcolepsy cataplexy syndrome, such as loss of

body tone precipitated by emotion or laughter, sleep paralysis and hypnogogic hallucinations.

### Panic attacks

Panic attacks usually start with feelings of fear and anxiety, associated with autonomic changes and hyperventilation. This leads to dizziness or light-headedness, orofacial and/or peripheral paraesthesia (which may be asymmetric), carpopedal spasm, twitching of the peripheries, blurred vision or nausea. Occasionally, the preludes may be forgotten, and attacks present with loss of awareness. Often, but not always, there is a clear situational precipitant. Panic attacks are almost always longer than seizures. However, none of these features are consistent, and differentiation from epilepsy can be difficult.

### Hypoglycaemia

Hypoglycaemic attacks causing loss of consciousness are rare except in patients with diabetes mellitus treated with insulin or less commonly oral hypoglycaemics. Very occasional cases may be seen caused by insulin secreting tumours. There is usually a history of events occurring if meals are delayed or missed and marked prodromal symptoms of anxiety, sweating and unease which improve with taking glucose.

### Other neurological disorders

If a head injury causes loss of consciousness, there is amnesia. In accidental head injury, particularly road traffic accidents, it may be difficult to distinguish amnesia caused by the injury from cases in which there was a loss of consciousness that caused the accident. Isolated episodes of loss of awareness may also be caused by abuse of psychotropic drugs or other substances.

### Generalised convulsive movements

The differentiation from epilepsy is usually simple, but some conditions with generalised movements mimicking convulsions cause diagnostic confusion.

#### Epilepsy

A generalised convulsion is generally the most readily diagnosed epileptic seizure (described earlier). The diagnosis is usually clear from the history and a witnessed account. The prodromal symptoms, pattern of convulsions, lateral tongue biting, bloody frothing, apnoea, cyanosis, post-ictal confusion and headache, and injury (for instance, posterior dislocation of the shoulder) are characteristic of tonic–clonic seizures.

#### Syncope with myoclonic jerking movements

People who faint often have myoclonic twitches of the extremities. This may be associated with limb posturing and stiffening, and is caused by the transient cerebral ischaemia associated with syncope (possibly mediated at subcortical level). With prolonged cerebral hypoperfusion, as can occur if the syncopal person is maintained in an upright posture, the jerking can be severe and occasionally a true convulsion is precipitated (an ‘anoxic seizure’). Incontinence of urine may occur, particularly if the bladder is full and tongue biting may occur.

#### Primary cardiac or respiratory abnormalities presenting with secondary anoxic seizures

Episodes of complete heart block or transient asystole can have syncopal features followed by collapse to the ground and anoxic seizures. More commonly, there is an abrupt collapse with no warning and the person is observed to be pale and witnesses commonly remark that ‘they thought the person was dead’. The attacks last for less than 1 minute, but may be followed by a prolonged period of confusion, particularly in elderly patients. There should be a low threshold for obtaining a cardiological opinion in such cases and consideration given to insertion of an implanted ECG loop recorder to identify cardiac arrhythmias.

#### Involuntary movement disorders and other neurological conditions

The best known is paroxysmal kinesigenic choreoathetosis. Attacks are usually precipitated by sudden specific movements and last a few seconds to minutes. Paroxysmal dystonia can present with attacks that last for minutes to hours. Patients with involuntary movement disorders such as idiopathic torsion dystonia may show severe acute exacerbations that may mimic convulsive movements. There is no alteration in consciousness in any of these conditions.

Patients with mental retardation often have stereotyped or repetitive movements, which may include head banging or body rocking, and more subtle movements which may be difficult to differentiate from complex partial seizures.

#### Hyperekplexia

Hyperekplectic attacks are characterised by excessive startle, and the attack can take the form of stiffening and collapse with a sudden jerk of all four limbs. Attacks are provoked by sudden unexpected stimuli, most commonly auditory. Hyperekplexia needs to be distinguished from seizures induced by startle, which commonly arise from the central portions of the frontal lobe. Hyperekplexia usually has a genetic basis and a number of genes have been identified (including *GLRA1*, *GRLB*, *SLC6A5*, *GPHN* and *ARHGEF9*).

#### Dissociative seizure

Dissociative seizures involving prominent motor phenomena are more common than those with arrest of activity. The movements are varied but often involve semi-purposeful thrashing of all four limbs, waxing and waning over many minutes, showing distractibility or interaction with the environment, and sometimes prominent pelvic movements and back arching. To an experienced eye, the jerking is quite different from the coordinated jerking of tonic–clonic seizures, with its typical evolution and timing, but can be more difficult to differentiate from complex partial seizures of frontal lobe origin, which can take the form of bizarre motor features. The key feature of the latter is that the episodes are usually stereotyped, short, occur during both wake and sleep (dissociative seizures do not occur in sleep) and the associated features and context usually render differential diagnosis easy.

#### Focal convulsive movements

The differentiation from epilepsy of other conditions in which focal movements occur is more difficult than in those conditions in which generalised movements occur. It can be difficult especially if brief focal attacks occur, but the stereotyped nature of the attack and its context usually assist in differentiating focal epilepsies from the other conditions.

#### Focal motor seizures

Focal motor seizures involve jerking and posturing of one extremity, which can ‘march’. There is often associated paraesthesia. Following the attack, there may be localised transient weakness for seconds or minutes, sometimes longer. Seizures arising in many different brain regions may cause dystonic posturing. The seizures can be very frequent and are stereotyped.

Epilepsia partialis continua is a rare form of epilepsy that often causes diagnostic confusion. In this condition focal motor activity, such as jerking of the hand or part of the face, can persist for hours or days, continue into sleep, sometimes for years. The movements often become slow and pendulous, with some associated dystonic posturing.

#### Tics

Tics usually present with stereotyped movements in childhood or adolescence, sometimes restricted to one particular action (e.g. eye blinking) but can be multiple in nature. Tics may be confused with myoclonic jerks. However, unlike myoclonic jerks, they can be suppressed voluntarily, although to do so leads to a rise in psychological tension and anxiety which is then relieved by the patient allowing the tics to occur. This is a very useful diagnostic point. Repetitive tics and stereotypies are particularly common in those with intellectual disability.

#### Transient cerebral ischaemia

Those with transient ischaemic attacks (TIAs) usually present with negative phenomena (i.e. loss of use of a limb, hemiplegia or other deficits), although positive phenomena such as paraesthesiae may occur. TIAs may last for a few minutes, but may persist for up to 24 hours. TIAs are not usually stereotyped or repeated with the frequency of epileptic seizures, and there are usually associated features to suggest vascular disease. There is usually no loss of consciousness.

#### Tonic spasms of multiple sclerosis

These spasms usually occur in the setting of known multiple sclerosis, but can be the presenting feature, although other evidence of multiple sclerosis will usually be found on examination and

investigation. The spasms may last for several seconds and sometimes longer than 1 minute. They can be very difficult to differentiate from focal motor seizures.

### Paroxysmal movement disorders

Patients with paroxysmal kinesio-genic choreoathetosis may present with focal motor attacks that are very similar to epileptic seizures, but only occur on the initiation of movement and so usually do not pose diagnostic difficulty. Tremor can occur in a variety of movement disorders and is usually sufficiently persistent and rhythmical to make the non-epileptic nature clear, but may be difficult to distinguish from certain forms of *epilepsia partialis continua*. Myoclonus of subcortical origin may be suspected from the distribution of involved muscles (e.g. spinal myoclonus may be restricted to specific segments, either unilateral or bilateral). Patients with peripheral nerve entrapment (or other lesions) usually present with weakness but very rarely can present with episodic jerks or twitches.

### Transient facial muscle and eye movements

Abnormal facial movements occur in many neurological conditions including partial seizures, tics, dystonias or other paroxysmal movement disorders, drug-induced dyskinesias and hemifacial spasm, and psychological disorders.

### Partial seizures

Benign childhood epilepsy with centro-temporal spikes usually presents with seizures in childhood affecting the face, often with unilateral grimacing, hemibody sensory and motor phenomena, or secondarily generalised seizures occurring in sleep. Focal motor seizures may cause twitching of one side of the face which may be restricted to specific areas.

Complex partial seizures can cause automatisms with lip smacking, chewing, swallowing, sniffing or grimacing, with amnesia and impaired awareness. If these features are caused by seizure activity the attacks are usually relatively infrequent. Dystonia or other movement disorder episodes are likely to be more persistent or occur many times per day.

### Movement disorders

Hemifacial spasm typically presents in the elderly or middle aged with clusters of attacks of intermittent twitching that initially involve the eye but subsequently can spread to the rest of that side of the face. The twitching of the eyelid can result in forced closure of the eye. Less commonly, the spasms start lower in the face and spread to the eyelid. Facial weakness may develop and continue between attacks.

Bruxism can occur either during the day or in sleep, especially in children with learning disability. Episodes are usually more prolonged than with the automatisms of complex partial seizures, and there are no associated features to suggest an epileptic basis. As with dystonia and other movement disorders affecting the face, there may be evidence of involvement elsewhere, and attacks are usually more frequent than is seen with isolated seizures.

### Other neurological disorders

Defects of eye movement control are common in patients with a wide range of neurological disorders. There are usually associated features that indicate a non-epileptic basis. Bizarre eye movements also occur in blindness and may be mistaken for epileptic activity. Careful examination is required to ascertain the precise features of the eye movement disorder, and in particular any precipitating factors or features of cerebellar or brainstem disease.

### Drop attacks

Any cause of loss of awareness may proceed to a sudden collapse or drop attack. Epilepsy, syncope and other cardiovascular disorders are common causes of drop attacks.

### Epilepsy

Sudden drop attacks are common in patients with learning disability and secondary generalised epilepsies. The falls may be tonic or atonic in nature and frequently cause severe facial injuries if the individual falls forwards. In individuals without learning disability, epileptic drop attacks are rare. However, tonic-clonic seizures that are only partially treated can be modified to take the form of drop attacks.

### Cardiovascular causes

If cerebral hypoperfusion is sufficient to cause sudden collapse there is usually loss of awareness (see earlier), but a drop attack may be the dominant presenting symptom. This may occur particularly in posterior circulation hypoperfusion, and other associated symptoms usually make the diagnosis clear.

### Movement disorders

Most movement disorders that cause drop attacks have other more prominent features that make the diagnosis clear (e.g. Parkinson's disease). Patients with paroxysmal kinesio-genic choreoathetosis may present with drop attacks if there is lower limb involvement.

### Brainstem, spinal or lower limb abnormalities

There are usually fixed neurological signs that give a clue towards the diagnosis. Tumours of the third ventricle, such as colloid cysts, may present with sudden episodes of collapse. Spinal cord vascular abnormalities may present with abrupt episodes of lower limb weakness leading to falls, without impairment of awareness.

### Cataplexy

Cataplexy usually occurs in association with narcolepsy, although it may be the presenting clinical feature. There is no loss of consciousness with attacks. Attacks may be precipitated by emotion, especially laughter. Often there is only loss of tone in the neck muscles, with slumping of the head, rather than complete falls.

### Metabolic disorders

Periodic paralysis caused by sudden changes in plasma potassium is rare. The condition may be familial or associated with other endocrine disorders or drugs. Usually there is a gradual onset, and the attacks last for hours.

### Idiopathic drop attacks

These attacks are most common in middle-aged females. They take the form of a sudden fall without loss of consciousness. Characteristically, the patients remember falling and hitting the ground. Recovery is instantaneous, but injury may occur. The cause is quite unclear, but it may be a spinal reflex.

### Vertebrobasilar ischaemia

This condition is over-diagnosed and probably accounts for very few drop attacks. Typically, the attacks occur in the elderly, with evidence of vascular disease and cervical spondylosis. The attacks may be precipitated by head turning or neck extension resulting in distortion of the vertebral arteries and are of sudden onset, with features of brainstem ischaemia such as diplopia, vertigo and bilateral facial and limb sensory and motor deficits.

### Transient focal sensory symptoms

Epileptic seizures involving the primary sensory cortex are less common than motor seizures, and the symptoms take the form of spreading paraesthesia. Seizures involving the supplementary sensory areas or medial frontal cortex can cause sensory symptoms. There are usually other epileptic features because of involvement of adjacent or related brain structures. Transient sensory phenomena may also be seen in peripheral nerve compression or other abnormalities of the ascending sensory pathways, hyperventilation or panic attacks and in TIAs.

Lesions of sensory pathways cause persistent symptoms, but diagnostic confusion may arise early on in the natural history, when complaints are intermittent, or if they are posture related. Hyperventilation may be associated with unilateral and localised areas of paraesthesia (e.g. one arm). Intermittent sensory illusions may be experienced in relation to amputated or anaesthetic limbs. Migrainous episodes may also cause localised areas of paraesthesia, but usually have the distinction of a gradual evolution of sensory phenomena, both positive and negative, and associated features of migraine.

### Transient vestibular symptoms

Acute attacks of vertigo may occasionally be caused by a seizure in the parietal or temporal lobes. In these cases there are generally associated features that point to cerebral involvement, such as a focal somato-sensory symptoms, déjà vu or disordered perception. The attacks are very short-lived. Peripheral vestibular disease is a much more common cause and gives rise to paroxysmal rotational vertigo, which is longer lasting, and a perception of linear motion and there are often also other symptoms of auditory and vestibular disease such as deafness, tinnitus, pressure in the ear and relation to head position. Migraine also is a cause of transient vestibular symptoms and occasionally resembles epileptic seizures.

### Transient visual symptoms

Migraine is a common cause of episodic visual phenomena, and the differentiation from epilepsy can occasionally be difficult. In migraine, the evolution of the visual symptomatology is usually gradual, continuing over several minutes (up to 20 minutes). Fortification spectra are diagnostic of migraine and do not occur in epilepsy. In migraine there may be associated photophobia, nausea and headache but a migrainous visual aura without headache is not uncommon. Epileptic phenomena are usually much shorter, evolving over seconds, and the visual hallucinations are more commonly of coloured blobs rather than jagged lines. In both migraine and epilepsy, the phenomena may move across the visual field, but in epilepsy usually stay unilateral. On occasions, a migraine attack may precipitate an epileptic seizure (this phenomenon is known as migralepsy).

### Transient psychic experiences

Intermittent psychic phenomena can on occasions be very difficult to differentiate from epilepsy, especially if short. Again, their context and their stereotyped nature usually allow the diagnosis to be made.

### Epilepsy

Partial seizures of temporal lobe origin are commonly associated with fear, déjà vu, memory flashbacks, visual, olfactory or auditory hallucinations. Other features include altered perception of the environment with a distancing from reality or change in size or shape of objects; altered language function; emotions such as sadness, elation and sexual arousal.

Psychic experiences can have some relation to past experiences. They are usually recalled as brief scenes, sometimes in a sequence. They are usually unclear, for example a patient may describe an illusion of someone standing in front of them who they know, but they cannot name or describe them in detail. The déjà vu experiences in an epileptic seizure are very frequently associated with a dreamy sensation and are very intense – and both features help differentiate from non-epileptic déjà vu. A rising epigastric sensation can occur alone or in association with such experiences. Elemental visual phenomena, such as flashing lights or coloured circles, are more often seen in occipital lobe epilepsy.

### Migraine

Migrainous psychic phenomena sometimes involve an initial heightening of awareness. The principal features are usually visual illusions which may be elemental or complex. They rarely have the same intense emotional components of temporal lobe illusions or hallucinations. The time course is usually more prolonged than with partial seizures, with an evolution over several minutes and there are associated features of a pounding headache, photophobia and nausea or vomiting. There may be identifiable precipitants, and there is often a relevant family history.

### Panic attacks

These are usually associated with feelings of fear and anxiety. Hyperventilation may lead to dizziness and light-headedness. There are often unpleasant abdominal sensations similar to the epigastric aura of partial seizures. In epileptic seizures though the rising sensation extends above the region of the throat and neck – and this is rare in a panic attack, where the sensation is usually confined to the epigastrium and chest. The evolution, associated increases in heart rate and respiration, longer time course and history of precipitating factors usually make the diagnosis clear, but distinction from temporal lobe seizures may be difficult.

### Drug-induced flashbacks

These share many of the qualities of psychic temporal lobe seizures. Flashbacks are individualised hallucinations usually related to the circumstances of the drug abuse, often with emotional content of fear or anxiety. A careful history should be taken for substance abuse, especially LSD, psilocybin, peyote and mescaline.

### Hallucinations or illusions caused by loss of a primary sense

Hallucinations and illusions of an absent limb are well-recognised in amputees. Similarly, people who lose sight either in the whole or part field may experience visual hallucinations or illusions in the blind field. Such phenomena can be elemental or complex and include evolving scenes. Similar experiences can occur with deafness.

Such experiences resulting from the loss of a primary sense present particular diagnostic difficulty when they occur in the setting of a structural lesion, which could also result in epilepsy. Occipital infarction, for example, can cause visual loss and also gives rise to epileptic seizures. Often the hallucinations caused by sensory loss are usually more prolonged, lasting for minutes or hours, but on occasions can be brief.

### Psychotic hallucinations and delusions

Hallucinations and delusions are the hallmark of psychotic illnesses. The following features would suggest a psychiatric rather than epileptic basis: complex nature with an evolving or argued theme, auditory nature involving instructions or third person

language, paranoid content or associated thought disorder. Psychotic episodes are usually more long-lasting than isolated epileptic seizures, although intermittent psychosis may be difficult to differentiate. Persistent mood changes may be a helpful guide, but even short temporal lobe seizures can be followed by mood changes lasting for hours or days. Furthermore, flurries of epileptic attacks may themselves cause an organic psychosis lasting for several days. Ruminations and pseudo-hallucinations, in which the patient retains some insight, can occur in affective disorders.

### Dissociative seizures

Dissociative seizures can be associated with reports of hallucinations and illusions. Initially, the symptoms may seem plausible, but should be suspected if they are florid and multiple in type (e.g. auditory, olfactory and visual at different times) with evolving stories or patterns of expression and are associated with emotional outburst.

### Aggressive outbursts

These are rarely epileptic in nature if they occur in isolation. They are especially common in adults and children with a learning disability. In this setting there is organic brain disease that could lower the overall seizure threshold.

A not infrequent forensic issue is the occurrence of violent, or other, crimes in patients with epilepsy, in which it is a defence claim that the crime was committed in a state of automatism. Certain features are strong evidence against an epileptic basis to the attack:

- Absence of a prior history of epilepsy with automatisms
- Premeditation and evidence of planning or preparation
- Directed violence
- Evidence of complicated and organised activity during the episode
- Recall of events during the episode
- Witness accounts not indicative of a disturbance of consciousness
- Subsequent attempts at escape or concealment of evidence
- Prolonged aggression, and
- Motive.

Other features such as previous offending behaviours or personality disorder are also helpful in differentiating the very rare epileptic violence from the more common criminal behaviour.

### Episodic phenomena in sleep

Attacks occurring during sleep present some diagnostic difficulties because they are often poorly witnessed, and the patient has little, if any, recall of the event or the preceding circumstances.

### Normal physiological movements

Whole body jerks commonly occur in normal subjects on falling asleep. Fragmentary physiological myoclonus usually involves the peripheries or the face, and occurs during stages 1 and 2 and REM sleep. Periodic movements of sleep may be an age-related phenomenon, being seen in less than 1% of young adults, but occurring with increasing frequency during middle and old age such that they are present in perhaps half of the elderly population. Typically, these movements occur at regular intervals of 10–60 seconds and in clusters over many minutes.

### Frontal lobe epilepsy

Frontal lobe seizures can display specific sleep-related characteristics causing diagnostic confusion. Such attacks are often frequent, brief, bizarre and often only occur during sleep. Attacks may include apnoea, dystonic, myoclonic or choreiform movements which can be unilateral or bilateral, and some retention of awareness. The

attacks are scattered throughout the night, and usually arise from non-REM sleep. Frequency is highly variable, but some patients have more than 20 attacks in a night. An important clue to the diagnosis is the occurrence of additional secondarily generalised seizures and seizures also occurring in wakefulness. Other features of diagnostic importance are their stereotyped nature, their brief duration, association with spasm or tonic stiffening. The interictal EEG may or may not be abnormal and the MRI can show frontal lesions. The syndrome of ADNLE is a genetically determined form of frontal lobe epilepsy.

### Other epilepsies

Seizures arising in other brain regions can present with nocturnal attacks. The patient may be aroused by an aura, although often this is not recalled when attacks arise from sleep. Complex automatisms, in which the patient gets out of bed and wanders around, can cause confusion with parasomnias. With nocturnal seizures of any type the partner is frequently awoken by particular components, such as vocalisation, but does not witness the onset. Generalised tonic-clonic seizures not uncommonly occur on or shortly after awakening.

### Pathological fragmentary myoclonus

Excessive fragmentary myoclonus persisting into sleep stages 3 and 4 may be seen with any cause of disrupted nocturnal sleep.

### Restless leg syndrome

The restless leg syndrome (*syn*: Willis–Ekbom disease) is characterised by an urge to move the legs, especially in the evening when lying or sitting. It can be associated with unpleasant paraesthesiae. All patients with restless legs have periodic movements of sleep. These may be severe and can also occur during wakefulness. In addition, there may be a variety of brief daytime dyskinesias.

### Non-REM parasomnia

Non-REM parasomnias usually present in childhood or adolescence, and are often familial. The attacks take the form of night terrors or sleep walking. They arise from slow wave sleep, typically at least 30 minutes, but not more than 4 hours, after going to sleep and the timing is often consistent. Attacks can be spaced out by months or years and rarely occur more than once per week, and usually no more than one attack occurs in a single night. They are more likely after stressful events, or when sleeping in a strange bed.

Night terrors involve intense autonomic features (sweating, flushing, palpitations) and a look of fear. Patients may recall a frightening scene or experience, but do not usually recount a vivid dream prior to the attacks. Certainly children do not recall events. They can be difficult to arouse, and confused for several minutes. Vocalisations are common.

Sleep walking may involve getting out of bed and performing complex tasks. Sometimes it is possible to lead the patient back to bed without awakening. They may respond if spoken to, but their speech is usually slow or monosyllabic. Brief abortive episodes are more common, involving sitting up in bed with fidgeting and shuffling (mimicking a complex partial seizure).

Non-REM parasomnias may cause self-injury but rarely directed aggression. They are associated with enuresis.

### REM parasomnia

REM parasomnia usually occurs in middle age or the elderly, and shows a marked male predominance. It more often occurs in the later portion of sleep. During REM sleep, patients may have an

increase in the frequency or severity of fragmentary myoclonus, thrash about, call out, display directed violence or appear to enact vivid dreams. Attacks may last from seconds to minutes. If awoken, patients can recall part of these dreams. Although REM sleep behaviour disorders can occur in healthy elderly subjects, they are also seen in association with drugs (e.g. tricyclics) or alcohol, or CNS diseases such as multi-system atrophy. REM sleep disorders can be the presenting symptom of these conditions or occur during the course of the CNS disorders.

### Sleep apnoea

Patients with sleep apnoea usually present with daytime hypersomnolence. However, the apnoeic episodes can cause episodic grunting, flailing about or other restless activity that can appear to mimic nocturnal epilepsy. Occasionally, the resultant hypoxia precipitates secondary seizures.

### Other movements in sleep

Nocturnal body rocking occurs in patients with learning disability, or following head injury. In patients with many different forms of daytime dyskinesias, similar movements may occasionally occur during overnight sleep, usually in the setting of brief arousals.

### Prolonged confusional or fugue states

Epileptic seizures usually last for seconds or minutes. After generalised tonic-clonic seizures (or, less often, complex partial seizures) there may be confusion lasting for many minutes, but rarely more than an hour. Such episodes only present diagnostic difficulty if the initial seizure is unwitnessed. Nevertheless, epileptic states can last for longer periods of time, as can other types of cerebral disorder and the differential diagnosis of prolonged epileptic confusional states (non-convulsive status) should include acute encephalopathy, non-convulsive status epilepticus, transient global amnesia, intermittent psychosis and dissociative seizures.

### Acute encephalopathy

Virtually any severe metabolic disturbance can cause an acute encephalopathy (e.g. diabetic ketoacidosis; hypoglycaemia; respiratory, renal or hepatic failure; drug ingestion; hyperpyrexia; sepsis). Transient metabolic disturbances are most often seen in treated diabetes mellitus due to insulin-induced hypoglycaemia. Occasionally, metabolic disorders, such as porphyria and urea cycle enzyme defects, present with exacerbations with symptoms lasting for hours or days and give the appearance of an episodic condition. Acute neurological conditions also need to be considered, particularly encephalitis, meningitis, other intracranial infection, head injury, cerebral infarction or haemorrhage. Drug abuse can cause isolated episodes or recurrent bouts, related to intoxications.

### Non-convulsive status epilepticus

Patients with complex partial seizures, typical or atypical absences sometimes present with prolonged confusional states caused by complex partial epilepticus or absence status. Such attacks can be the first manifestation of the seizure disorder, or occur in the setting of known epilepsy.

### Intermittent psychosis

Although usually more sustained, patients with psychiatric disorders sometimes present with episodes of delusions, hallucinations or apparent confusion, lasting for hours or days.

### Transient global amnesia

These episodes typically commence acutely, and last for minutes or hours and involve both retrograde and anterograde amnesia. Patients are able to perform complex activities, but afterwards have no recall of them. There is a lack of other neurological features to the attacks, and consciousness appears to be preserved. During an attack, patients do not appear overtly confused. The attacks involve bilateral medial temporal dysfunction, which in some patients can be on the basis of ischaemia or have an epileptic basis.

### Hysterical fugue

A fugue state may arise without an organic physical cause, as a conversion symptom. These episodes may be brief or very prolonged, lasting for days or even weeks. If seen during the episode, inconsistencies are often found on examination of the mental state. There is usually a history of serious psychiatric disturbance or alcohol or drug abuse. In some cases, the question of malingering arises, most commonly in a situation in which the person's state prevents questioning by law officers and when the subject professes no memory of events. The diagnosis is more difficult to identify if the patient is only seen subsequently. The matching of witness accounts and the apparent sequence of events is essential, but it may remain difficult to come to a firm conclusion.

## Investigation of epilepsy

The investigation of epilepsy is aimed, broadly speaking, to address two questions: (a) is the diagnosis epilepsy, and if so, what type of epilepsy (seizure type, epilepsy syndrome)?; and (b) what is the cause of epilepsy?

The first question is determined largely by the clinical history (and hence the absolute necessity of a witnessed account and/or a video clip of a seizure). EEG is also a helpful adjunct, although as emphasised later, many patients with epilepsy will have normal findings on routine EEG. ECG and routine blood tests also exclude other conditions which can mimic epilepsy. The second question is addressed most commonly by MRI scanning (and other neuroimaging) and biochemical, haematological and immunological tests. The indications for each test depends on the clinical circumstance.

In addition to these questions, investigation can be directed at finding a surgically treatable epilepsy (see Presurgical assessment). The usefulness of investigations into directing medical therapy is disappointingly limited. It is confined largely to identifying those seizure types and syndromes for which specific therapy is available (a minority of cases). There are no genetic tests currently in clinical practice that can assist in 'personalising' treatment, and claims in this area have often been overstated.

### Routine tests to carry out in all cases

On presentation, all cases of epilepsy should have a full blood count, biochemical screening of hepatic and renal function and blood sugar, and screening immunological tests. Other investigations depend on age and context. An ECG and EEG should be carried out in all cases, and MRI in the great majority (see later).

### Biochemical, haematological and immunological tests

Other tests depend on the clinical context and Tables 7.12, 7.13, 7.14 and 7.15 list biochemical tests that can be made from serum and/or urine, CSF investigations and serum immunological tests. Some of these are highly specialised and are indicated only in the identification of rare disorders and are not routinely performed. Various haematological conditions include epilepsy amongst the

**Table 7.12** Biochemical tests in the investigation of epilepsy (blood and/or urine).

Test	Indication
Acylcarnitines	Fatty acid peroxidation defects, organic acidurias
Amino acids	Glycine, serine, theonine, glutamine, phenylalanine, proline, various aminoacidurias
Ammonia	Urea cycle disorders (arginino-succinic acidaemia, carbamoyl phosphate synthetase deficiency, citrullinaemia, ornithine transcarbamylase deficiency), organic acidaemias
Alpha-aminoadipic semialdehyde ( $\alpha$ -AASA)	Pyridoxine-dependent seizures (PDE, MoCoF and SUDX deficiencies)
Biotinidase activity	Biotinidase deficiency
B12, methylmalonic acid and homocysteine	B12 deficiency states, disorders of folate metabolism, and other non-specific clinical settings
Calcium and magnesium	Renal tubular disorders, PDE, neonatal seizures with hypomagnesaemia or hypocalcaemia, primary disorders of calcium and magnesium balance and endocrine function (e.g. hypoparathyroidism, pseudohypoparathyroidism)
Copper and caeruloplasmin	Menkes syndrome, Wilson's disease
CoQ10	Disorders of CoQ10 biosynthesis, mitochondrial diseases
Creatine and guanidinoacetate	Creatine synthesis disorders (GAMT and AGAT deficiencies)
Creatine kinase	Dystroglycanopathies
Drug/toxic screen (incl. alcohol)	Drug intoxication, poisoning
Electrolytes	Various disorders involving renal function
Folate and RBC folate	Folate deficiency
Glucose	Diabetes, disorders of fat oxidation, glycogen storage disorders, disorders of gluconeogenesis
Glycosaminoglycans	Mucopolysaccharidoses
Homovanillic acid/vanillylmandelic acid ratio	Menkes disease
Lactate	Mitochondrial diseases, PDHc deficiency, biotinidase deficiency, lipoic acid synthetase deficiency, fructose 1,6 diphosphatase deficiency
Liver function tests	Hepatic disorders of various causes, mitochondrial disorders
Oligosaccharides	Oligosaccharidoses (e.g. sialidosis)
Organic acids	In various organic acidaemias and acidurias such as methylmalonic acidaemia, glutaric acidaemia type 1), Krebs' cycle defects, fatty acid oxidation disorders
Orotic acid, uracil	Some urea cycle defects (e.g. ornithine transcarbamylase deficiency)
Porphyryns	Porphyrias
Pterins	Disorders of biogenic amine metabolism (tetrahydrobiopterin deficiency disorders)
Purine and pyrimidine metabolites	Hypoxanthine, succinyladenosine
Sulfite and sulfocysteine	SUDX deficiency, MoCoF deficiency
Uric acid	Lysch-Nyhan syndrome, MoCoF deficiency
Very long chain fatty acids	Peroxisomal disorders (including Zellweger syndrome)
White cell enzyme activity	Lysosomal storage disease, mucopolysaccharidosis, mucopolipidosis, gangliosidosis, leukodystrophies, neuronal ceroid lipofuscinosis, glycoprotein storage disorders

The application of these tests depends on the clinical situation (see text).

**Table 7.13** Haematological tests in the investigation of epilepsy.

Full blood count and differential	Primary haematological and other conditions
Blood culture	CNS/systemic infection
Blood film	Acanthocytosis Macrocytosis/megaloblastic RBCs – B12 and folate deficiency Sickle cells Blast cells
Vacuolated lymphocytes	Lysosomal storage disorders
Clotting profile	Bleeding tendency

The application of these tests depends on the clinical situation (see text).

**Table 7.14** CSF examination in the investigation of epilepsy.

General CSF examination (cell count, sugar, protein)	Infection, inflammation
Cytology	Primary or secondary CNS malignancies
Oligoclonal bands (unmatched in serum)	CNS inflammation, autoimmunity, infection, parainfectious process
14-3-3, S-100	Classic Creutzfeldt–Jakob disease
CSF: serum glucose $\leq 0.5$	GLUT1 deficiency
Lactate	Mitochondrial diseases
Serine and glycine	Disorders of serine biosynthesis
Alpha-amino adipic semialdehyde ( $\alpha$ -AASA)	Pyridoxine deficient seizures
5-methyl-tetrahydrofolate (5-MTHF)	Cerebral folate deficiency (idiopathic or secondary) after exclusion of systemic folate deficiency
Pyridoxal 5'-phosphate (PLP)	Pyridox(am)ine phosphate oxidase (PNPO) deficiency

The application of these tests depends on the clinical situation (see text).

symptoms but this is seldom the presenting symptom. Specific immunological tests are indicated where limbic encephalitis is suspected or in acute onset of status epilepticus in the absence of any obvious cause. Lumbar puncture is not routinely indicated in patients with epilepsy, and is warranted only when the clinical condition and/or other investigations raise the possibility of an

**Table 7.15** Immunological tests in the investigation of epilepsy.

Antibody	Condition
Anti-Hu	Limbic encephalitis associated with SCLC
Anti-Ma2	Limbic encephalitis associated with testicular cancer
Anti-CRMP-5/CV2	Limbic encephalitis associated with SCLC, thymoma
Anti-amphiphysin	Idiopathic or paraneoplastic limbic encephalitis associated with breast cancer and SCLC
Anti-GAD	Limbic encephalitis without neoplasia
Anti-adenylate kinase-5	Limbic encephalitis without neoplasia
Anti-voltage-gated potassium channel (VGKC)	Limbic encephalitis
Anti-NMDA receptor	Paraneoplastic (teratoma) or non-paraneoplastic limbic encephalitis
Anti-AMPA (GluR1/GluR2) receptor	Paraneoplastic limbic encephalitis associated with neoplasia of thymus, breast SCLC
Anti-AMPA (GluR3)	Rasmussen's encephalitis
Anti-GABA <sub>B</sub> receptor	Limbic encephalitis, 50% paraneoplastic to SCLC
Antiglycine receptor	Limbic encephalitis
Antigliadin, antireticulin, anti-endomyesial	Coeliac disease
ANA, anti-dsDNA, anti-Sm	Cerebral lupus
Anticardiolipin, lupus anticoagulant	Antiphospholipid syndrome
Antithyroid peroxidase	Hashimoto's encephalopathy (STREAT)
Oligoclonal bands in CSF (unmatched in serum)	Autoimmunity, infection, parainfectious process

The application of these tests depends on the clinical situation (see text).  
AMPA,  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; CSF, cerebrospinal fluid; NMDA, *N*-methyl-D-aspartate; SCLC, small cell lung cancer; STREAT, steroid-responsive encephalopathy with autoimmune thyroiditis; VGKC, voltage gated potassium channel.

infectious, inflammatory or autoimmune condition. GLUT-1 deficiency, which is important not to overlook, is also highly suggested by a low CSF glucose in the absence of any other cause.

There are, in addition to these investigations, a variety of histological tests that can be carried out on biopsy material – and these often provide the definitive diagnosis. These include biopsy of liver to detect Wilson's disease, mitochondrial disease and glycogen storage diseases; bone marrow for Niemann–Pick type C; hair for Menkes disease; muscle for mitochondrial disease; skin for Lafora body; neurofibromatosis and other systemic disorders and fibroblast assays for a variety of enzymes. Brain biopsy also can be carried out to diagnose a variety of inflammatory, infectious, structural, metabolic (including mitochondrial) or degenerative disorders.

### Electroencephalography

Electroencephalography (EEG) was introduced into clinical practice in the early 1940s, and has since developed into an array of digitally based techniques, integrated with video and other investigative modalities. However, like all investigations, it has limitations which must be recognised, and its applications should be targeted to specific clinical questions. Consideration here will be confined to its applications to epilepsy, and its use in other conditions (e.g. in confusional state, altered state of consciousness, sleep disorders, coma, CJD, subacute sclerosing panencephalitis [SSPE]) is to be found in the relevant sections of this book.

A standard EEG recording takes about 60–90 minutes to complete and about half of this time is necessary to place and remove the recording electrodes. Electrodes are applied using the international 10–20 system. Additional electrodes may be placed depending on the specific question of the study (e.g. anterior temporal and/or superior sphenoidal electrodes to allow better identification or characterisation of epileptiform abnormalities arising from this area, or surface electromyographic (EMG) electrodes to allow correlation of jerks with EEG activity).

The EEG signal is generated by the sum of all inhibitory and excitatory post-synaptic potentials and provides a view of the electrical activity generated in cerebral cortex. It is attenuated, filtered and potentially contaminated by structures between the cortex and the recording electrode: CSF, dura, bone, muscle, blood vessels, and skin. The EEG signal is further influenced by the patient's age, level of consciousness, underlying structural pathology, metabolic alterations and medication effects. It also varies according to brain region. EEG has a high temporal resolution (on the order of milliseconds); however, its spatial resolution is poor. The electric signal of interest needs to be amplified by a factor of 100 000 or more. This leaves the EEG signal vulnerable to both physiological (such as ECG, eye blinks, chewing, tongue movements) and non-physiological (such as electrode artefacts, electrical interference) artefacts. During routine EEG, recording conditions can be optimised and the technical quality of the study can be improved, as the physiologist can identify and eliminate artefacts online. Long-term ambulatory recordings are much more prone to artefacts that cannot be corrected.

Hyperventilation and photic stimulation increase the yield for abnormal EEG findings and should therefore be routinely included in the investigation of patients with suspected seizure or epilepsy, following standardised protocols. Although these procedures are generally safe, certain contraindications (e.g. significant pulmonary and cardiovascular disease, pregnancy) have to be considered. Both hyperventilation and photic stimulation can rarely trigger seizures. For this reason, the patient should provide consent.

Abnormal EEG findings (those that one would not expect in a healthy reference population) can be broadly categorised as non-specific, specific (usually for epilepsy, or rarely for certain neurodegenerative disorders, e.g. CJD or SSPE), or patterns of unclear significance (further discussed later).

### EEG in the diagnosis of epilepsy

EEG is the primary investigation in epilepsy. However, it should not be forgotten that the diagnosis of epilepsy is essentially clinical, and EEG has a high false negative rate and a low but important false positive rate. EEGs are liable to misinterpretation when there is insufficient knowledge of the range of normal and non-specific EEG phenomena – this has repeatedly been identified as a common reason for false diagnosis of epilepsy.

The sensitivity of a standard EEG in detecting interictal epileptiform features (discussed later) in patients with epilepsy is of the order of 30–40%. It increases if a substantial amount of sleep is included in the recording. If the initial EEG recording in a patient with a suspected seizure disorder is 'negative' (i.e. does not show any epileptiform discharges), further recordings should aim to record sleep.

The combination of wake and sleep records gives a yield of abnormalities in about 80% in patients with clinically confirmed epilepsy. Sleep EEG can be achieved by recording natural sleep, or by using hypnotics (e.g. chloral hydrate) to induce sleep. Whether sleep deprivation has additional value for induction of epileptiform activity is unclear, but there is some evidence that it specifically activates spikes in IGE. Evaluation of different EEG protocols in young people (<35 years) with possible epilepsy found that sleep-deprived EEG provided significantly better yield than routine EEG or drug-induced sleep EEG, and it may be the most cost-effective protocol for investigation of new onset epilepsy. The incremental yield of subsequent EEGs with sleep reaches a ceiling effect after the third recording, and it is estimated that up to 10% of patients with epilepsy never show epileptiform features on interictal EEG recordings. For these reasons, a 'negative' or normal EEG cannot 'rule out' epilepsy.

The sensitivity of an individual standard EEG is low; its diagnostic value relies on a high specificity. A misinterpreted EEG demonstrating epileptiform discharges where none exist is a common problem. It is potentially damaging with social and employment consequences, impaired quality of life and effects from unnecessary antiepileptic drug exposure. For this reason, most neurophysiologists agree that it is essential to be clear as to whether a particular sharpened waveform represents an epileptiform activity or not. The EEG reader must be thoroughly familiar with all pitfalls of misinterpreting spiky waveforms, which can occur as normal variants or background fluctuations. Sharpened features should only be reported as epileptiform if they are unequivocally so, using clear criteria regarding morphology and topography, and it is imperative that the report clearly communicates the neurophysiologist's assessment.

With conservative interpretation, only a very small percentage of otherwise normal subjects show epileptiform abnormalities in their EEG. The incidence of epileptiform discharges is very low, around 0.5–1% in adults with no known history of epilepsy and about 2–4% in children. In one study incidence was estimated at 4 in 1000 in a population of healthy men, and this includes spikes during photic stimulation only. There is variable follow-up duration reported and one person indeed developed epilepsy during that period. It can be concluded that unequivocal unprovoked interictal epileptiform

discharges in adults are highly associated with epilepsy, bearing in mind that epilepsy is a clinical diagnosis. Epileptiform phenomena may also be seen in up to 30% of patients who have neurological disorders or cerebral pathologies (e.g. tumour, head injury, cranial surgery), without a history of witnessed seizures. Thus, an abnormal EEG showing epileptiform activity does not in itself indicate that the subject must have a seizure disorder.

The National Institute for Health and Care Excellence (NICE) guidelines for diagnosis and management of the epilepsies recommend that routine EEG should be performed only if the clinical history of an event suggests that it was an epileptic seizure, and that EEG should not be used if the presentation suggests syncope or non-epileptic attack. In children, EEG is generally recommended after a second seizure, as the diagnostic yield from routine EEG after a single seizure is considered too low to influence management.

### Epileptiform phenomena

Transient (isolated) EEG features classified as epileptiform are spikes, sharp waves, and spike or polyspike and wave complexes. They reflect the fundamental electrical abnormality in epilepsy, namely the hyperexcitability of a cortical area. It has been estimated that 6–10 cm<sup>2</sup> of cortex needs to be activated synchronously for an epileptiform discharge to be visible on scalp EEG, and more recent studies found even larger cortical areas of 10–20 cm<sup>2</sup> that have to be activated on intracranial EEG. Although the terms ‘spike, sharp wave, and spike wave complex’ have been defined by morphology and duration, their distinction has relatively little clinical implications, and neurophysiologists often use them interchangeably. They can all occur as single discharges, or in runs or trains.

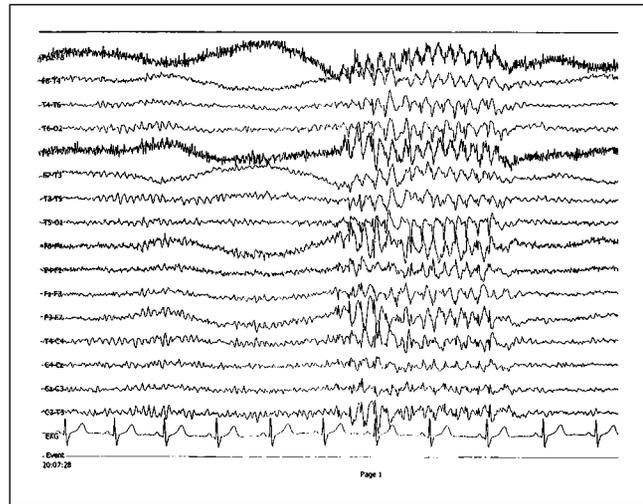

Some epileptiform phenomena – 3 per second spike-wave complexes, hypsarrhythmia and generalised photoparoxysmal responses – are strongly correlated with clinical epilepsy. Others, such as focal sharp waves in centro-temporal regions, are moderately correlated with clinically evident seizures. The probability therefore that an interictal epileptiform discharge indicates epilepsy relates to the location of the discharge and the age of the person.

The EEG of normal subjects can show a range of spiky, sharpened or rhythmic features that resemble epileptiform activity, particularly in sleep. These ‘patterns of unclear significance’ include benign epileptiform transients of sleep, wicket spikes, 14 and 6 Hz positive bursts, occipital 6 Hz spike and wave bursts, rhythmic mid-temporal theta of drowsiness, midline theta, frontal arousal rhythm and subclinical rhythmic epileptiform discharge in adults (SREDA). These variants mostly have no link with epilepsy, but are a potential source of confusion and EEG misinterpretation.

Location of electrodes and site of epileptic focus, age of patient, the presence of medication, diurnal timing of the EEG and the frequency, severity and type of epilepsy all influence the chance of detecting epileptiform discharges. The timing of EEG in relation to last seizure event may be relevant as one study has found that an interictal EEG within 24 hours of a seizure revealed an abnormality in 51% compared with 34% who had later EEG.

### EEG in the classification of epileptic seizures and syndromes

Clinical criteria alone are not necessarily sufficient for characterisation of a seizure or epilepsy type, or infallible. Both epileptiform activity and interictal background cortical rhythms provide information that can complement the history and aid diagnosis. EEG findings contribute to diagnostic refinement at different levels: by establishing whether the seizure disorder is focal or generalised, idiopathic or symptomatic, or part of an epilepsy syndrome. This information can help with prognosis and selection of an anticonvulsant.

**Figure 7.1** Typical spike-wave discharge in a patient with absence epilepsy.

Although division of seizure types into partial (focal) and generalised is a cornerstone of clinical practice, it is important to appreciate there can be EEG (and clinical) overlap between the two. Rapid spread and generalisation of epileptiform activity arising from a frontal lobe focus can mimic idiopathic generalised epilepsy; focal spikes and regional accentuation of generalised spike-wave discharges are well-recognised in IGE syndromes.

**Idiopathic generalised epilepsy** The typical interictal EEG findings in IGE are generalised spike or polyspike and slow wave complexes (spike-wave complexes) at 3–5 Hz (Figure 7.1), with normal background cortical rhythms. A subset of patients show photosensitivity (defined as a generalised photoparoxysmal response on photic stimulation). In childhood absence epilepsy, there is characteristic bilateral synchronous 3-Hz spike wave, usually lasting 5–10 seconds. Careful analysis of the individual spike wave complexes often reveals that they are slightly faster at the onset of a burst (3.5–4 Hz). During the main portion, they usually slow down to 3–3.5 Hz, and may slow down even further to approximately 2.5 Hz towards the end. Although generally seen in a widespread and symmetric distribution, there may be asynchronies between the two hemispheres of 5–20 ms. In childhood absence epilepsy, runs of 3 Hz spike-wave complexes are often enhanced or provoked by hyperventilation. Background cortical rhythms are normal, but some children show runs of occipital rhythmic delta slowing (up to 40% of cases), which may persist after remission of absences. Photosensitivity is uncommon (less than 10%), and possibly indicative of poorer prognosis. Patients with juvenile absence epilepsy usually show polyspike discharge or spike-wave frequency above 3 Hz. In juvenile myoclonic epilepsy, the interictal EEG characteristics are brief bursts of polyspike (sometimes single spike) and wave discharges up to 6 Hz. Variable asymmetry and slight asynchrony of the discharge is common between the two hemispheres, and interictal focal abnormalities occur in up to 40%. Not all patients with IGE show typical electrographic findings in the first EEG. Childhood or juvenile absence epilepsy is most likely to show diagnostic EEG abnormalities at initial investigation, whereas other syndromes may need serial recordings (including sleep deprivation) to elucidate the diagnosis. This should not delay appropriate treatment.

Ictal EEG patterns in IGE may occur as a prolongation of the interictal epileptiform features (e.g. in typical absence epilepsy). In fact, the longer a run of spike-wave complexes lasts, the more likely it is associated with a transient disturbance in cognition or working memory, and ultimately behavioural arrest. Myoclonic jerks may produce EMG artefacts in the recording, but they can be easier detected if surface EMG electrodes are placed over the extremities. In generalised tonic-clonic seizures, fast rhythmic spikes are commonly seen at the onset, before the ictal EEG becomes obscured by muscle artefacts. In the clonic phase, this activity becomes discontinuous, and is ultimately replaced by rhythmic slow waves with alternating spikes or polyspikes. In the immediate post-ictal phase, the EEG is often diffusely suppressed for several seconds. A period of diffuse irregular slow follows that is gradually replaced by the patient's baseline activity.

In seizures of focal onset, ictal EEG manifestations can be quite variable. In contrast to IGE, the morphology of the ictal pattern is often different from the associated interictal features. A common manifestation is a rhythmic activity that evolves in amplitude, frequency and distribution. This may be preceded by a more widespread or even diffuse attenuation of EEG activity. Diffuse attenuation may be the only ictal EEG manifestation, for example in the epileptic spasms that are characteristic of West syndrome. Repetitive epileptiform discharges can also constitute an ictal pattern, or they may be followed by an evolving rhythmic pattern. Low amplitude circumscribed fast activity is often the earliest ictal manifestation on intracranial EEG, which may be undetectable using scalp recordings. As in generalised tonic-clonic seizures, the ictal scalp EEG may become obscured by EMG and movement artefact (e.g. chewing automatisms). In the post-ictal phase, slowing is commonly seen, often most prominent over the area of seizure origin. Interictal epileptiform abnormalities may become more abundant following a seizure.

Ictal EEG patterns may occur without any behavioral or cognitive alteration (subclinical seizure). Conversely, focal seizures may occur without any detectable scalp EEG change. This is often the case for epileptic auras. However, even more severe focal seizures may occasionally lack a correlate on scalp EEG.

**Benign childhood epilepsy syndromes** The EEG is the definitive diagnostic test in benign childhood epilepsy with centro-temporal spikes. The defining EEG feature is the occurrence of high-amplitude focal sharp wave discharges in central and temporal regions, either bilateral or unilateral, and potentiated by sleep. A few children show focal discharges in other brain regions or generalised spike-wave activity. Background cerebral rhythms are normal. The EEG is often very abnormal even in the presence of infrequent (or indeed any) seizures. In the occipital variant, named after Panayiotopoulos, the majority of patients show shifting or multifocal spikes or spike and wave complexes with posterior emphasis; however, spikes may be seen over any brain region. The clinician should be alerted to a diagnosis of a benign childhood epilepsy syndrome in a child with infrequent, mostly nocturnal seizures or paroxysmal autonomic symptoms whose routine EEG shows frequent multi-focal discharges.

**Lennox-Gastaut syndrome** The classic EEG finding in this condition with severe intractable multiple seizure types and learning disability are slow spike-wave complexes that range from 1 to 2.5 Hz. These occur in a generalised or lateralised distribution and become enhanced in non-REM sleep. They may disappear in adolescence

and adulthood. Runs of rapid spikes in non-REM sleep are another common finding. The background EEG is often disorganised and excessively slow, reflecting a significant baseline dysfunction of the brain.

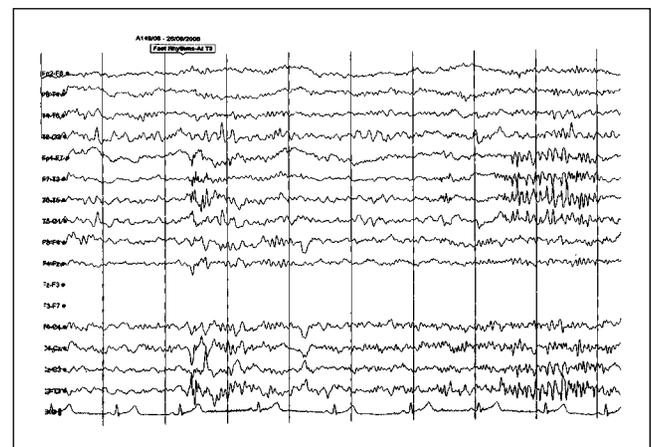

**Electrical status epilepticus in sleep** This rare childhood condition is characterised by the presence of continuous spike and wave discharges in non-REM sleep, combined with rare, if any, EEG abnormalities in the awake state and REM sleep. Most children have seizures, but the hallmark finding is regression of cognition and behaviour. It occurs in a number of childhood epilepsies, including the Landau-Kleffner syndrome of acquired aphasia and epilepsy.

**Progressive myoclonic epilepsies** These epilepsies show generalised spike and wave discharge, photosensitivity, 'giant' sensory-evoked potentials (SEPs), facilitation of motor-evoked potentials (MEPs) by afferent stimulation and abnormalities of background cerebral activity, typically an excess of slow activity. The background abnormalities are usually progressive, particularly in syndromes with dementia or significant cognitive decline such as Lafora body disease. Some specific features occur in some cases: vertex sharp waves in sialidosis, occipital spikes in Lafora body disease and giant visual-evoked potentials (VEPs) in lipofuscinosis.

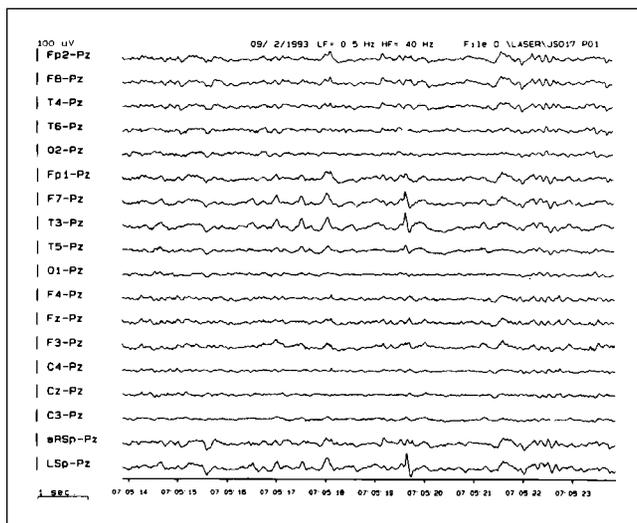

**Partial epilepsy** Broadly speaking, localised EEG changes are more common in TLE than in extratemporal epilepsies (Figure 7.2 and Figure 7.3), and spike, polyspike and/or high-frequency discharges are more likely to occur in foci that are located superficially in neocortex. However, even prolonged interictal EEG can be normal or non-localising in partial epilepsies if the epileptogenic region:

- 1 Is extensive
- 2 Is remote from the location of the scalp electrodes (e.g. mesial frontal lobar areas), or
- 3 Involves too small a neuronal aggregate for synchronised activity to be registered on the scalp.

In partial epilepsies, the most important ictal EEG changes for seizure localisation are those that occur within the first 30 seconds after the seizure onset. Later changes are of limited value for localisation or lateralisation of the epileptogenic region, because the discharge will by then have propagated to other brain areas.

**Figure 7.2** High-frequency interictal discharge in a patient with neocortical or lateral temporal lobe epilepsy.

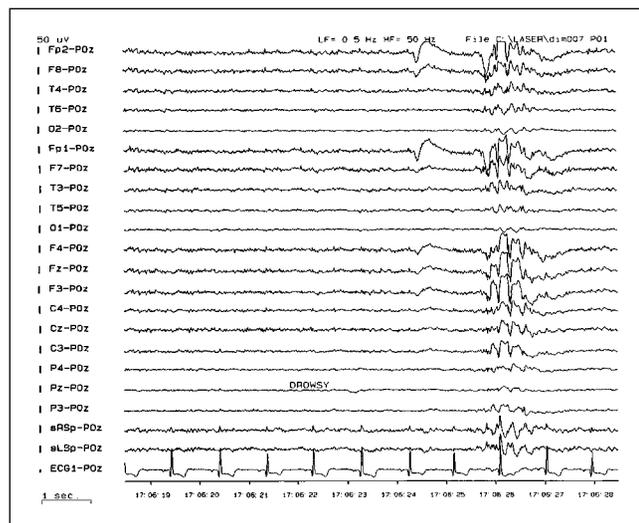

**Figure 7.3** Interictal EEG: left mesial temporal lobe epilepsy, referential recording. Focal spikes at electrodes sited near the left anterior temporal lobe (F7 and Sp1) and mid temporal lobe (T3).

**Temporal lobe epilepsy** Mesial TLE associated with unilateral temporal lobe pathology, usually hippocampal sclerosis, shows anterior and mid temporal interictal spikes, and a characteristic rhythmic ictal discharge accompanying seizures in more than 80% of cases. The appearance of a localised scalp EEG pattern may follow the onset of clinical symptoms by 30 s or more. Independent bitemporal interictal spikes are common, but predominate over the pathological temporal lobe in 60% of cases.

In lateral TLEs, interictal spikes tend to be located over the mid and posterior temporal lobar regions; the ictal EEG discharge is typically higher frequency than in mesial TLE, and lateralised in about 50% of cases. In practice, the EEG changes are not specific enough to differentiate lateral and mesial TLE in a reliable fashion and, furthermore, temporal changes can occur in frontal and other extratemporal epilepsies.

**Frontal lobe and other extratemporal epilepsies** Focal interictal EEG abnormalities are the exception, and there are no specific patterns associated with the subtypes of frontal lobe epilepsy. Many patients show widespread or even generalised abnormalities (Figure 7.4), because of rapid spread to other lobar regions and secondary generalisation. The same is true for ictal changes, the most common pattern in frontal lobe epilepsy being either high amplitude slow or a diffuse fast discharge followed by generalised attenuation and/or bilateral slow activity. In lateral frontal lobe epilepsy, repetitive spiking characterises the ictal EEG in about 40% of cases; evolving rhythmic patterns are about as common. The ictal EEG allows localisation or lateralisation in about 70%. In mesial frontal lobe epilepsy, the most common patterns are low amplitude fast activity, and diffuse attenuation of the EEG. In contrast to lateral frontal lobe epilepsy, the localising value is poor, of the order of 25%.

Patients with parietal lobe epilepsy (PLE) tend to have multifocal epileptiform discharges. The most common ictal EEG patterns are paroxysmal fast and repetitive epileptiform activity. As in mesial FLE, the patterns are often nonlocalisable, or may mislocalise. In occipital lobe epilepsy (OLE), rhythmic patterns of variable frequency are seen in about 60%, and paroxysmal fast or repetitive spiking in most other cases. False localisation is relatively common in patients with OLE.

**Figure 7.4** Widespread bilateral spike-wave discharge in a man with frontal lobe complex partial seizures (hypermotor semiology).

### EEG and prediction of seizure recurrence

If the initial EEG shows definite epileptiform discharge, there is a greater risk of seizure recurrence in individuals presenting with the first unprovoked seizure, particularly if idiopathic in type. EEG has distinguished between high and low risk groups in a number of studies: a systematic review showed risk of recurrence at 2 years was 27% if the EEG was normal, but 58% if epileptiform activity was present. Following epilepsy surgery, epileptiform activity on the interictal EEG has been shown to predict seizure recurrence.

### EEG and withdrawal of antiepileptic medication

The type of epilepsy syndrome is the most important variable in predicting likelihood of seizure recurrence for patients in remission who are considering withdrawal of medication. EEG can provide supplementary information: presence of spike-wave discharge in patients with IGE and evidence of a generalised photosensitive (photoparoxysmal) response are associated with high risk of recurrence. The prognostic significance of other patterns and abnormalities in other types of epilepsy is less clear.

### EEG and antiepileptic drugs

Acute administration of barbiturates and benzodiazepines suppresses interictal discharges, but the effect declines when these drugs are given as chronic therapy. Sodium valproate suppresses generalised spike-wave complexes, and photoparoxysmal responses, and EEG can be used to monitor therapeutic efficacy in patients with childhood absence epilepsy. Lamotrigine may have a similar effect, and ethosuximide also suppresses generalised discharges. Other antiepileptic drugs have variable or inconsistent effects on either focal or generalised epileptiform activity, and EEG is therefore of little or no use in monitoring response to drug treatment. 'Treating the EEG' is generally undesirable.

Antiepileptic drugs can affect background cortical rhythms, but significant slowing does not occur unless there is drug toxicity.

### Long-term EEG monitoring

Long-term monitoring (LTM) allows extended EEG recording, which can be undertaken as an ambulatory procedure using a portable recorder, or via hard wired recorders with time-linked video in a hospital setting. Usually, the aim is to document 'attacks' rather than the interictal state. LTM has been shown in several studies to change diagnosis and affect management in >50% of difficult to treat cases. Its principal applications are shown in Table 7.16.

Ambulatory EEG monitoring is most suited to clinical problems that do not require concurrent synchronised video to document clinical features, or for monitoring in a specific environment. It is more susceptible to artefacts than EEG recordings in a laboratory. Ambulatory recording does not have the advantage of inpatient video EEG telemetry units where specialised staff are usually experienced in the identification of subtle clinical events and the diagnostic assessment and care of patients during seizures. Systematic interview and focused examination during and after seizures contributes valuable information about areas of cortex

**Table 7.16** The principal clinical applications of long-term electroencephalogram (EEG) monitoring.

Differential diagnosis of paroxysmal neurological attacks
Distinction between nocturnal epilepsy and parasomnias
Diagnosis of psychogenic non-epileptic seizures
Characterisation of seizure type and the electro-clinical correlates of epileptic seizures
Quantification of epileptiform discharge and seizure frequency
Evaluation in epilepsy surgery candidates
Identification of sleep-related epileptiform discharge/electrical status in children
Electro-clinical characterisation of neonatal seizures
Monitoring of status epilepticus (convulsive, non-convulsive, electrographic)

activated during seizures or rendered dysfunctional by the seizure activity. High technical quality of the recording can be easier achieved than with ambulatory EEG, and simultaneous video recordings allow correlation of patient behaviour with EEG phenomena. These units are the safest environment for reduction in medication dose to provoke seizures. Their downside is that they are resource intensive.

The optimal length of study for LTM depends on the clinical problem, and frequency of attacks; if it is less than once per week in patients who do not take anticonvulsants, LTM is not likely to be beneficial.

### Neurophysiology for assessing patients for epilepsy surgery

Interictal and ictal EEG are pivotal investigations in presurgical evaluation, but are generally more important in resective surgical procedures than in functional procedures such as callosotomy and vagal nerve stimulation.

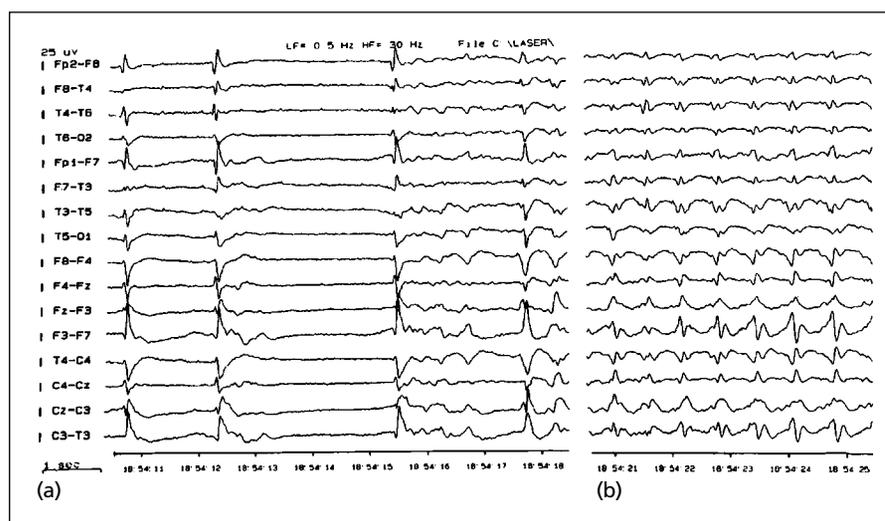

### EEG and tonic-clonic status epilepticus

EEG is essential for diagnosis and management of status epilepticus in convulsive (Figure 7.5) and non-convulsive forms. As a minimum standard, EEG should be performed within 12–24 hours for admissions with uncontrolled seizures or confusional states. EEG monitoring should be available during treatment of refractory status. There are generally no specific EEG markers of the different electro-clinical types of status: all show variations of waxing and waning rhythmic patterns, with or without frank epileptiform discharges.

EEG is used in convulsive status epilepticus to:

- Confirm status and exclude pseudostatus
- Differentiate causes of altered mental status – continuing seizures, drug-induced coma or encephalopathy, and
- In the refractory stage to monitor and guide treatment, as clinical manifestations of ongoing seizure activity may then be subtle or absent, even though seizure activity may continue in the brain.

EEG is used as guide to the dosing of anaesthetic treatment in refractory status, with dosing often modulated to obtain burst suppression on the EEG (Figure 7.5), although seizure suppression is deemed sufficient in patients unable to tolerate higher dose

**Figure 7.5** Segments from EEG monitoring in convulsive status: (a) burst suppression and some breakthrough discharge; (b) electrographic status.

anaesthesia. EEG may also contribute information of prognostic value, and for instance continuing electrographic status after the convulsive phase is associated with worse outcome in convulsive status epilepticus.

### Non-convulsive status epilepticus

This term describes a range of conditions, with variable clinical features and causes. EEG is necessary for diagnosis of non-convulsive status epilepticus (NCSE), especially when the clinical manifestations are subtle. The EEG expression of non-convulsive status depends on cause, and includes any of continuous spike-wave discharge (generalised in absence status epilepticus), discrete localised electrographic seizures, diffuse slow activity with or without spikes, and periodic and/or repetitive epileptiform discharge. Electrographic confirmation of NCSE is often difficult in focal status, as the EEG may, show only subtle changes. In epileptic syndromes, such as Lennox–Gastaut syndrome, when there is overlap of ictal and interictal EEG patterns; and in patients with acute cerebral damage (e.g. caused by infection or trauma), interpretation of EEG is complicated by the fact that the changes of NCSE may be subtle and also because EEG abnormalities can result directly from the primary pathology. EEG can be recorded during acute administration of intravenous benzodiazepine or other antiepileptic therapy, and the rapid resolution of the abnormal EEG patterns, when associated with clinical improvement, can be taken as supportive evidence of a diagnosis of NCSE.

### EEG in the intensive care setting

EEG has three main roles in the ICU patient. First, it can be used to distinguish coma from diminished responsiveness resulting from other causes (psychiatric, sedation, neuromuscular, locked-in syndrome); secondly, to detect non-convulsive or clinically subtle seizures (most cases of status in the ICU are non-convulsive or difficult to identify on clinical grounds alone); thirdly, to identify an encephalopathy. EEG is the cornerstone examination for non-convulsive seizures in the critically ill patient in intensive care, but it is difficult to interpret and subject to many errors that can lead to a wrong diagnosis and unnecessary or inadequate treatment. Differentiation between NCSE and a non-specific encephalopathy can be difficult, but the clinical context is critical.

It may be able to add information for the prognostication of patients with severe diffuse brain injury, such as following cardiac arrest. Generalised suppression of the background, absence of EEG reactivity or generalised epileptiform patterns indicate a poorer prognosis. However, there is evidence that a single EEG is not a useful test to predict outcome and has only limited diagnostic accuracy. EEG is also used as an adjunctive test in the determination of electrocerebral inactivity ('brain death').

### EEG and cognitive deterioration

Acute confusional states or acute and/or subacute cognitive decline in epilepsy may be caused by frequent subtle or clinically unrecognised seizures; a marked increase in epileptiform discharges; a metabolic or toxic encephalopathy; or non-convulsive status epilepticus. EEG can be very helpful in determining the cause in acute confusional states, but is less likely to be useful in chronic cognitive decline other than to confirm the presence of an organic brain syndrome.

### Imaging in epilepsy

#### X-ray computed tomography

MRI is generally the imaging modality of first choice for epilepsy. However, X-ray computed tomography (CT) is useful in acute situations where MRI is not appropriate and where rapid brain

imaging is required. CT is also superior to MRI in the detection of focal cortical calcification and in changes to the skull vault or other bony structures. CT is also helpful when there are contraindications to MRI, such as a cardiac pacemaker or cochlear implants.

CT is not as sensitive or specific as MRI for identifying most of the common epileptogenic abnormalities, such as indolent gliomas, cavernomas, malformations of cortical development (MCD) and lesions in the medial temporal lobe.

#### Magnetic resonance imaging

Most patients who develop epilepsy or whose chronic epilepsy has not been fully assessed should be investigated with MRI, to detect the underlying cause of the epilepsy (it should be remembered that the role of MRI is not to make a diagnosis of epilepsy per se). The ILAE commission has suggested the following clinical indications for MRI in the investigation of patients with epilepsy, although these will depend on availability and clinical circumstances:

- Focal onset of seizures
- Onset of generalised or unclassified seizures in the first year of life, or in adulthood
- Focal deficit on neurological or neuropsychological examination
- Difficulty in obtaining seizure control with first line antiepileptic drugs, and
- Loss of seizure control or change in the seizure pattern.

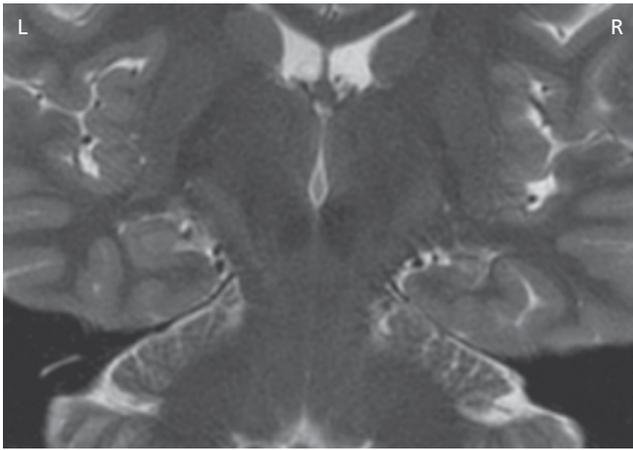

In patients with newly diagnosed epilepsy, MRI identifies a causal epileptogenic lesion in 12–14%. In chronic epilepsy, current MRI detects relevant lesions in 50–70%, rising to 75–80% in those with refractory focal epilepsy.

MRI is not required in patients with a definite electroclinical diagnosis of idiopathic generalised epilepsy who go into early remission.

All patients with intractable epilepsy considered for surgery should undergo high resolution structural MRI as the success of surgery is directly related to the ability to pinpoint the site of seizure onset and underlying structural abnormalities. A structural abnormality does not necessarily indicate the site of seizure origin, and clinical EEG and other data need to be correlated with imaging. Postoperative MRI is useful to identify the extent of a cortical resection or the presence of residual pathology, particularly if seizures continue after surgery.

**Hippocampal sclerosis** The hippocampus is best visualised by acquiring thin slices (1–3 mm) orthogonal to its long axis. The primary MRI features of hippocampal sclerosis are hippocampal atrophy, demonstrated with coronal T1-weighted images, and increased signal intensity within the hippocampus on T2-weighted and FLAIR images (Figure 7.6). Additionally, decreased T1-weighted signal intensity and disruption of the internal structure of the hippocampus may be present. Other MRI abnormalities associated with hippocampal damage include atrophy of temporal lobe white matter and cortex, dilatation of the temporal horn and a blurring of the grey–white border in the temporal neocortex. Atrophy of the amygdala and entorhinal cortex variably accompany hippocampal damage but may also occur in patients with TLE and normal hippocampi. FLAIR images provide an increased contrast between grey and white matter, and facilitate differentiation of the amygdala from the hippocampus.

Visual assessment can reliably detect hippocampal volume asymmetry of more than 20%; however, lesser degrees of asymmetry require quantitative volumetric analysis. The use of contiguous thin slices increases the reliability of measurements and permits localisation of atrophy along the length of the hippocampus. Automated

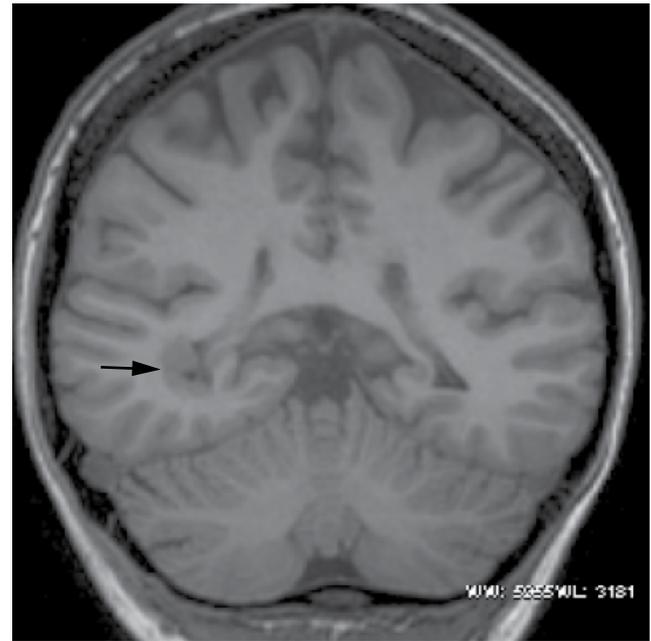

**Figure 7.6** Left hippocampal sclerosis. Coronal T2-weighted image showing atrophy and increased T2 signal in the left hippocampus. The right hippocampus is normal.

methods for measuring hippocampal volume are now becoming available, with the advantages of speed and avoidance of human error. However, hippocampal volumes should have a correction applied that takes into account intracranial volume, so that symmetrical bilateral atrophy can be identified. Patients with unilateral hippocampal volume loss, no other imaging abnormality and concordant clinical and EEG data have the optimal outcome after temporal lobe resective surgery. Measurement of T2 relaxation time is another objective way to assess hippocampal damage. The advantage of this technique is that hippocampal T2 (HT2) times are absolute values, which can be compared against control data. Increased HT2 reflects gliosis and neuronal loss. HT2 prolongation also correlates with the hippocampal volume loss. Both volumetry and T2 relaxometry techniques can be used to identify subtle amygdala pathology.

**Malformations of cortical development** There are many forms of malformations. The MRI features of focal cortical dysplasia are focal cortical thickening, simplified gyration, blurring of the cortical–white matter junction and T2 prolongation in the underlying white matter. A thin slice FLAIR acquisition gives the most sensitivity. Type 2B focal cortical dysplasia is the most obvious on MRI, with dysmyelination of white matter extending towards the lateral ventricle. Type 1 and 2A are more subtle and often not evident on MRI. Automated voxel-based image analysis can increase the pick-up rate, but with a risk of false positive findings. Complete surgical removal of focal cortical dysplasia is accompanied by a 30–50% remission rate, but the epileptogenic zone may be more extensive than the abnormality visible on MRI. Polymicrogyria with an excessive number of small and prominent convolutions is a frequently identified dysplasia. Several syndromes of region-specific symmetric polymicrogyria have been reported, and some have been linked to specific genetic loci. Schizencephaly is often found in MRI in conjunction with polymicrogyria. Peri-ventricular heterotopia may be unilateral or bilateral and has a characteristic MRI appearance (Figure 7.7).

**Primary brain tumour** Patients with low-grade primary brain tumours frequently have intractable focal seizures as a presenting symptom. Underlying histopathologies include dysembryoplastic neuro-epithelial tumours (DNT), ganglioglioma, gangliocytoma,

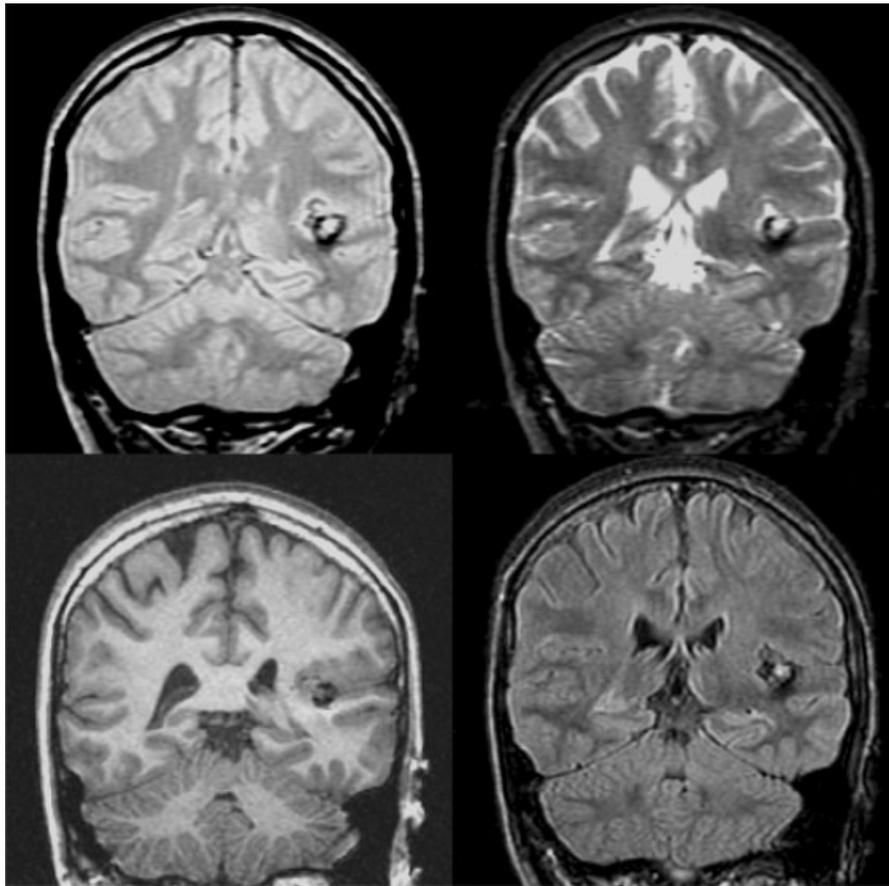

**Figure 7.7** Subependymal heterotopia on the right (arrow) in coronal IR<sub>prep</sub> T1-weighted image. Nodules of grey matter density are shown in the wall of the lateral ventricle.

and pilocytic and fibrillary astrocytoma. Most lesions have low signal on T1- and high signal on T2-weighted images, and are not usually associated with vasogenic oedema. Complete resection of the neoplasm and overlying cortex results in successful control of seizures in most cases. DNTs are benign developmental tumours with features of a focal circumscribed cortical mass which may indent the overlying skull. Cyst formation and contrast enhancement may occur. Some DNTs calcify and may be more readily demonstrated with X-ray CT. Confident differentiation from low grade astrocytomas and gangliogliomas is not possible by MRI.

**Vascular malformation** Cavernous haemangiomas (cavernomas) are relatively common lesions which are important to identify as they are often surgically resectable. Most cavernous haemangiomas are not visible on CT but come to light on MRI scanning. The lesions are circumscribed and have the characteristic appearance on MRI (Figure 7.8). The central part contains areas of high signal on T1- and T2-weighted images, reflecting oxidised haemoglobin, with darker areas on T1-weighted images as a result of the presence of deoxyhaemoglobin. The ring of surrounding haemosiderin appears dark on a T2-weighted image. Up to 50% of cavernous malformations are multiple, and can show autosomal dominant inheritance.

AVMs with high blood flow have a different and distinctive appearance with a nidus, feeding arteries and draining veins and the vascular supply can be further characterised by MR angiography or contrast angiography.

**Trauma, stroke and infection** Focal or diffuse cortical damage can develop as a consequence of trauma, infarction or infection of the CNS. Cerebrovascular disease associated with epilepsy is particularly common in older age groups. Worldwide, neurocysticercosis and tuberculomas are the most common causes of intractable focal epilepsy. These lesions have typical appearances on MRI which evolve with time and which, unless calcified, may resolve.

**Figure 7.8** Cavernoma on the left (coronal 3.0 T MRI). Proton density (top L), T2-weighted (top R), IR<sub>prep</sub> T1-weighted (low L), FLAIR (low R). The acquisitions demonstrate heterogeneous hyperintense signal caused by blood products in different stages of evolution, surrounded by a rim of low signal intensity from haemosiderin.

### Functional magnetic resonance imaging

Functional MRI (fMRI) can visualise regional brain activity. The areas are detected by measuring changes in blood oxygenation level-dependent (BOLD) contrast that occur during cognitive, sensory and other tasks, and allow the mapping of networks involved in the performance of these tasks. The clinical applications of fMRI are very limited. The most important are in the localisation and lateralisation of cognitive functions of epilepsy patients being evaluated for surgery in order to minimise the risk of causing a fixed deficit. However, the studies require patient cooperation, both in performing tasks and limiting motion, and findings may not be sufficiently sensitive or specific to reliably guide surgical planning, and it is important to choose activation procedures that are appropriate tests of function in the area of brain to be resected and to recognise the limitations. However, localisation of the primary motor and strip, and lateralisation of language are now routinely performed for clinical purposes. Important caveats are that areas that do not activate cannot be assumed to be functionally inert and not all areas that activate are crucial for function.

### Tractography

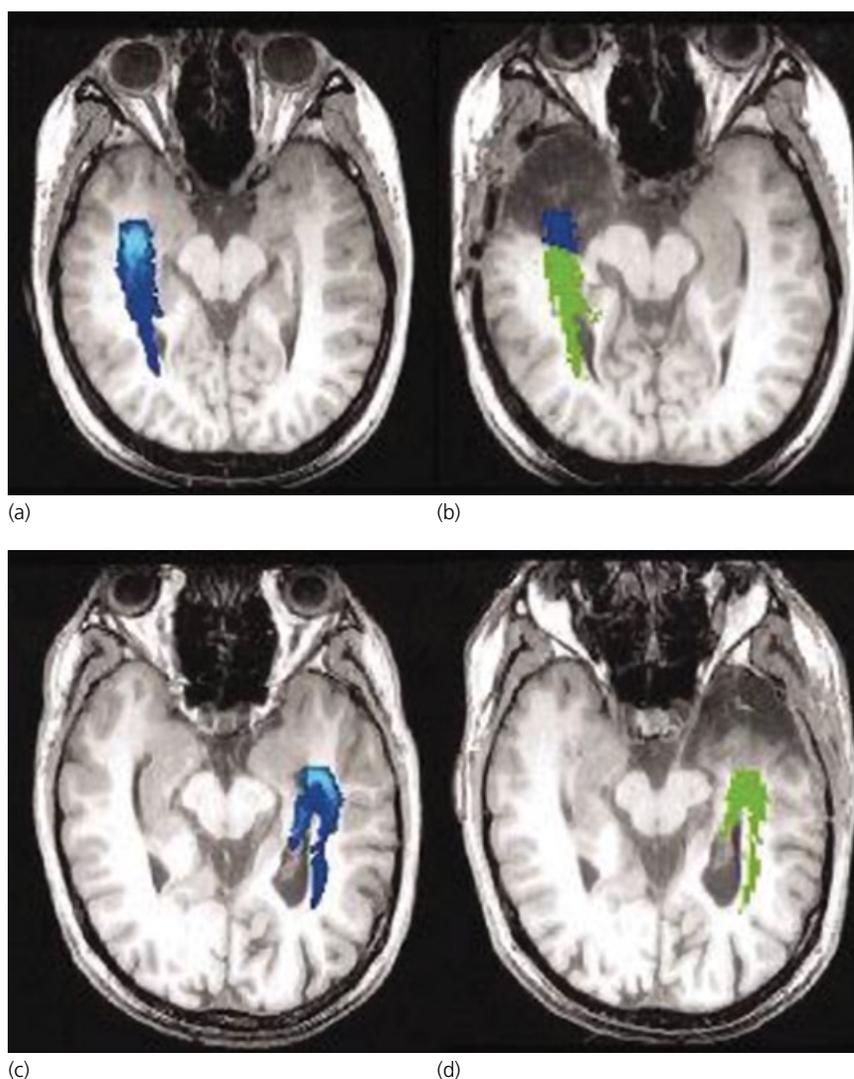

The course of major white matter tracks in the brain can be inferred using tractographic analysis of the directions of diffusion of water in the brain. The principle underpinning this

imaging technique is that water preferentially diffuses along axons and myelin sheaths (i.e. is directional not random) and this property allows the orientation of tracts to be visualised. Data are acquired using diffusion imaging and current spatial resolution, within a clinically reasonable imaging time, is approximately  $2\text{mm}^3$  – many orders of magnitude greater than the size of individual axons. There are a range of software packages for tractography: these can be deterministic and are quick to perform but not so reliable and are prone to error when tracts are curved, or probabilistic, which are more time consuming and computationally intensive.

In clinical epilepsy practice, the main role of tractography is to visualise the optic radiation and corticospinal tracts when planning surgical resection close to these critical structures. This is particularly relevant to anterior temporal lobe resections which are associated with a 5–20% incidence of clinically evident visual field defects which may prevent driving. Demonstration of the optic radiation, which extends anteriorly to a variable extent, allows prediction of the risk and modification of surgical approach to mitigate this (Figure 7.9).

### Single-photon emission computed tomography

Single-photon emission computed tomography (SPECT) allows measurements of regional cerebral blood flow changes in the areas affected by epileptic activity. The radioligands currently principally

**Figure 7.9** Preoperative structural T1-weighted image and optic radiation (a) and postoperative structural T1-weighted image with propagated preoperative tractography (b) show that part of the optic radiation was resected (blue) in patient, who developed a severe visual field deficit (VFD). Corresponding preoperative (c) and postoperative images (d) are shown in a patient who did not develop a VFD. Source: Winston et al. 2012. Reproduced with permission of John Wiley & Sons.

used in SPECT studies are  $^{99m}\text{Tc}$ -hexamethyl-propylenamine oxime ( $^{99m}\text{Tc}$ -HMPAO) and technetium- $^{99m}\text{Tc}$ -cysteinate dimer (ECD, bicisate). Currently available stabilised forms of  $^{99m}\text{Tc}$ -HMPAO and ECD are stable *in vitro* for several hours, whereas unstabilised  $^{99m}\text{Tc}$ -HMPAO needs to be produced immediately before intravenous injection. Seventy-five per cent of  $^{99m}\text{Tc}$ -HMPAO is extracted across the blood–brain barrier, reaching peak concentrations within 1 minute after injection. The images can then be acquired up to 6 hours after tracer injection. Both ictal and post-ictal SPECT studies should be performed during simultaneous video-EEG monitoring to determine the relationship between seizure onset and tracer injection. Interictal SPECT images serve as a reference baseline study for the interpretation of ictal images.

Ictal  $^{99m}\text{Tc}$ -HMPAO SPECT is highly sensitive and specific in localising seizure onset in intractable TLE. Correct localisation of complex partial seizures may be achieved in over 90% of TLE patients. The use of subtraction ictal SPECT co-registered to MRI (SISCOM) improves the rate of localisation. A characteristic

pattern in temporal lobe seizures is an initial hyperperfusion of the temporal lobe, followed by medial temporal hyperperfusion and lateral temporal hypoperfusion. Post-ictal and interictal SPECT injections are easier to perform than ictal injections, but the images are more difficult to interpret and have lower sensitivity and specificity and are not clinically as useful as a stand-alone test.

Extratemporal seizures are often brief and it is therefore difficult to obtain an ictal recording. Accurate localisation of an extratemporal seizure focus may be possible in 90% of the cases using the SISCOM technique. Ictal SPECT demonstrates ipsilateral frontal hyperperfusion in frontal lobe epilepsy. Activations may also be detected in the ipsilateral basal ganglia and contralateral cerebellum. The method provides additional information in patients with unrevealing EEG and MRI results, and can also be used to study the blood flow changes underlying specific clinical features observed in extratemporal seizures. Post-ictal and interictal SPECT is of very limited localising value in extratemporal epilepsy.

Ictal SPECT provides a complementary method for localising seizure foci in patients with intractable focal epilepsy evaluated for surgical treatment. The investigation may be particularly valuable in patients with normal MRI and presumed extratemporal seizures in order to generate a hypothesis that may then be tested with intracranial EEG recordings.

### Positron emission tomography

Positron emission tomography (PET) maps cerebral glucose metabolism using  $^{18}\text{F}$ -deoxyglucose ( $^{18}\text{FDG}$ ). Interictally, PET shows areas of reduced glucose metabolism that usually include the seizure focus but are more extensive. Regional hypometabolism is best analysed with co-registration of PET scans to MRI. Voxel-based statistical parametric mapping (SPM) and surface reconstruction of PET data are useful in clinical evaluation of the data. The spatial resolution of quantitative  $^{18}\text{FDG}$ -PET is superior to SPECT. Ictal  $^{18}\text{FDG}$ -PET scans are difficult to obtain because cerebral uptake of  $^{18}\text{FDG}$  occurs over 40 minutes after injection.

$^{18}\text{FDG}$ -PET detects interictal glucose hypometabolism ipsilateral to the seizure focus in 60–90% of patients with TLE. Unilateral, or asymmetric bilateral diffuse regional hypometabolism usually extends medially and laterally in the temporal lobe.  $^{18}\text{FDG}$ -PET has some additional sensitivity over optimal volumetric MRI but does not provide clinically useful information if hippocampal atrophy is present.  $^{18}\text{FDG}$ -PET is more useful for lateralising than precisely localising the epileptic focus. Unilateral focal temporal hypometabolism in  $^{18}\text{FDG}$ -PET predicts a good outcome of surgery for TLE. Absence of unilateral hypometabolism, however, does not preclude a favourable outcome. Symmetric bilateral temporal hypometabolism is associated with higher incidence of postoperative seizures as are areas of severe extratemporal cortical, or thalamic hypometabolism.

$^{18}\text{FDG}$ -PET has lower sensitivity for lateralisation of epileptic foci in extratemporal epilepsies than in TLE. The areas of decreased glucose metabolism are also less frequently well-localised. Sixty per cent of the patients with frontal lobe epilepsy show regional hypometabolism in  $^{18}\text{FDG}$ -PET, and a relevant underlying structural pathology is found on MRI in 90% of them. The area of hypometabolism may be either diffuse or widespread, or restricted to the co-localising MRI lesion. In a recent Queen Square series, PET scans were normal in 37% patients, showed unifocal hypometabolism in 51% and bilateral hypometabolism in 12%. The TLE group had a higher proportion of abnormal PET scans which were abnormal in 72% with TLE and 52% with frontal lobe epilepsy. PET data gave false lateralisation and/or localisation in 5%. An  $^{18}\text{FDG}$ -PET scan was useful in 53% patients; leading directly to surgery in 6% cases, helping to plan intracranial EEG in 35% and excluding 12% from further evaluation. It was more useful in TLE (66%) than frontal lobe epilepsy (38%). In summary, the place of interictal  $^{18}\text{FDG}$ -PET is in determining the lateralisation and approximate localisation of the epileptic focus, especially in the presurgical assessment of patients with normal MRI and when there is not good concordance between MRI, EEG and other data, in order to generate a hypothesis to be tested with intracranial EEG recordings.

**Magnetoencephalography** Magnetoencephalography (MEG) is a non-invasive neurophysiological technique that measures the magnetic fields generated by neuronal activity. These magnetic fields originate from dipolar intracellular currents associated with dendritic inhibitory and excitatory post-synaptic potentials within sulcal pyramidal neurones orientated tangentially with the cortical surface. MEG is insensitive to radially orientated neurones located

on the gyral crown, which comprise approximately one-third of cortical neurones, and which dominate the EEG, and it is because of this that MEG can potentially complement or enhance information provided by EEG. MEG has high temporal resolution, in the milliseconds range, which is comparable to EEG, and favourable to functional MRI which has a temporal resolution of several seconds.

The recorded magnetic field pattern is analysed to determine the localisation of either spontaneous (e.g. epileptic) or evoked (e.g. somatosensory) neuronal activity. The resulting map of magnetic dipoles is typically superimposed on a co-registered MRI scan to facilitate accurate neuro-anatomical localisation.

The utility of MEG has improved recently with the widespread availability of whole head magnetometers comprising up to 275 sensors which produce greater accuracy of dipole localisation and spatiotemporal propagation within an acceptable time period through more extensive spatial coverage.

Although MEG has been used to map somatosensory, motor, auditory and visual specific cortex, the main application of MEG in epilepsy is the characterisation of epileptic foci through the source localisation of interictal epileptiform activity, although, infrequently, ictal abnormalities are recorded by chance. The sensitivity of MEG for the identification of interictal epileptiform discharges, typically spikes, is approximately 50–70%, with 89% localisation accuracy.

MEG is more useful in patients with extratemporal lobe epilepsy because of the improved signal to noise ratio from neocortical generators rather than deep sources. It has been shown that the localisation of interictal MEG dipoles correlate with ictal-onset zones as defined by intracranial EEG and complete resection of these areas predicts good postoperative seizure outcome. At the present time, the information derived from MEG is complementary to data acquired from other investigations including MRI, PET and scalp and invasive EEG recordings but, in future, it is possible that it will be used to guide surgical resection or more commonly, inform placement of intracranial electrodes in patients with complex refractory focal epilepsy.

MEG is also ideally suited non-invasively to explore the occurrence and clinical validity of interictal high frequency oscillations, such as ripples and fast ripples, and this may provide improved localisation accuracy of epileptic foci in a greater proportion of patients, including those without frequent spikes.

## Medical treatment

### Principles of treatment of newly diagnosed patients

The decision to initiate drug therapy has important implications for a person with newly diagnosed epilepsy. In addition to its biological effects, therapy confers illness status, confirms the state of 'being epileptic', can affect self-esteem, social relationships, education and employment. The decision to treat depends essentially on a balance between the benefits and the drawbacks of therapy, and should be tailored to requirements of the individual patient. The benefits of therapy include the lower risk of recurrence of seizures, and thus of potential injury and even death, and the psychological and social benefits of more security from seizures. The drawbacks of therapy include the potential drug side effects, the psychological and social effects, the cost and inconvenience. Chronic, long-term or subtle side effects are not easily detected, and weigh heavily on the decision to treat. An example is the potential adverse effect on learning in children, and partly because of this pediatricians initiate therapy less early than adult neurologists. The following factors influence the decision.

## Diagnosis

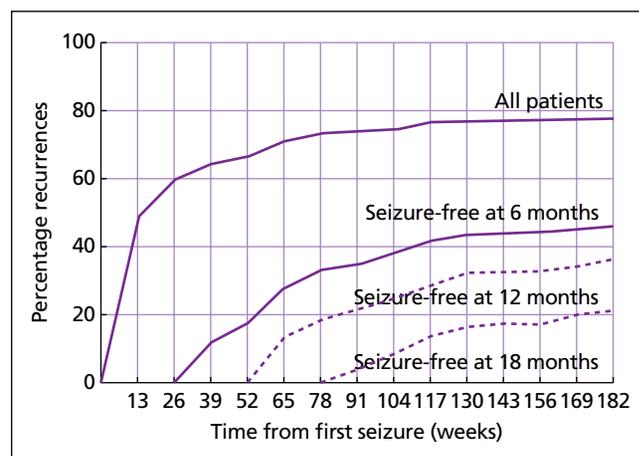

It is essential to establish a firm diagnosis of epilepsy before therapy is started. This is not always easy, particularly in the early stages of epilepsy. There is almost no place at all for a 'trial of treatment' to clarify the diagnosis; it seldom does. A good first-hand witnessed account is essential, as diagnostic tests are often non-confirmatory. In practice, the misdiagnosis rate is quite high. For example, about 20% of all patients with apparent epilepsy referred to a tertiary level epilepsy service turn out to have non-epileptic attack disorder.

## Risk of recurrence of seizure

The estimation of risk of seizure recurrence is obviously a key factor in deciding whether to initiate therapy. It is now generally accepted that about 50–80% of all patients who have a first unprovoked non-febrile seizure will have further attacks. The risk of recurrence is high initially and then falls over time. In a national UK study, the risk of a recurrence after the first seizure was 44% in the initial 6 months, 32% in the next 6 months and 17% in the second year. It follows therefore that the greater the elapsed time since the first attack, the less likely is subsequent recurrence (Figure 7.10) and in many cases, by the time of presentation, seizures will have already recurred. In a hospital-based study from the United Kingdom, the median number of tonic-clonic seizures occurring before the diagnosis was made was 4 (range 1–36) and the median number of partial seizures was 6 (range 1–180).

If more than one spontaneous seizure has occurred, the risk of further attacks in the future without treatment is, in most clinical circumstances, over 80%, and generally speaking the more seizures that have occurred prior to therapy, the greater the risk of further attacks. The risk of recurrence is influenced by a number of factors:

- **Aetiology** The risk is greater in those with structural cerebral disease, and least in acute symptomatic seizures provoked by metabolic or drug and/or toxin exposure. The risk of recurrence of 'idiopathic' or 'cryptogenic' seizures is approximately 50%. The risk is lowest after acute symptomatic (provoked) seizures providing the provoking factor is removed.

**Figure 7.10** Actuarial percentage risk of recurrence after a first seizure (from the National General Practice Study of Epilepsy [NGPSE]). The lines show the risk of recurrence in all patients ( $n = 564$ ) at the time of the first seizure, and then the subsequent risks for patients still seizure free at 6, 12 and 18 months after the first seizure. Source: Hart et al. 1990. Reproduced with permission of Elsevier.

- **EEG** Evidence in this area is contradictory. While there is consensus that the risk of recurrence is high if the first EEG shows spike and wave discharges, the predictive value of a normal EEG or an EEG with other types of abnormality after a single seizure – and if there is any predictive value – is slight.
- **Age** The risk of recurrence is somewhat greater in those under the age of 16 or over the age of 60 years, probably because of the confounding effect of aetiology.
- **Seizure type and syndrome** Partial seizures are more likely to recur than generalised seizures, again because of the confounding effect of aetiology. Children with most of the benign epilepsy syndromes (e.g. BECTS) have a few seizures only. In the other more severe childhood epilepsy syndromes, recurrent seizures are almost inevitable.

## Type, timing and frequency of seizure

Some types of epileptic seizure will have a minimal impact on the quality of life (e.g. simple partial seizures, absence or sleep attacks). The benefits of treating such seizures, even if happening frequently, can be outweighed by the disadvantages. If the baseline seizure frequency is very low, the disadvantages of treatment can be unacceptably high. It would be unusual to treat a person having less than one seizure a year, especially if this was confined to sleep, or a minor or partial seizure.

## A protocol for initial treatment

A protocol for the initial treatment in newly diagnosed patients is as follows (the principles are summarised in Table 7.17).

- 1 Establish diagnosis. There is little place for a 'trial of treatment'. Investigation will usually involve EEG and neuroimaging, and other investigations as necessary. Neuroimaging should be with MRI scanning in all patients with partial-onset epilepsy or epilepsy developing after the age of 15 without good explanation. The MRI must be of high quality, with T1-, T2-weighted and FLAIR sequences. Volumetric scanning is useful as this allows reformatting and quantitation.
- 2 Identify and counsel about precipitating factors – if these can be avoided, this occasionally obviates the need for drug therapy.
- 3 Decide upon the need for antiepileptic drug therapy. If therapy is needed, baseline biochemical and haematological parameters should be measured.
- 4 Advise about the goals, likely outcome, risks and logistics of therapy. Patients should be given clear instructions to seek immediate medical attention if signs of hypersensitivity or idiosyncratic drug reactions develop.
- 5 Start with monotherapy with the chosen first choice drug, initially at low doses, and titrating up slowly to a low maintenance dose. Emergency drug loading is seldom necessary except where status epilepticus threatens.
- 6 If seizures continue, titrate the dose upwards to higher maintenance dose levels (guided, where appropriate, by serum level monitoring). In about 60–70% of patients, these simple steps for initial therapy will result in complete seizure control.
- 7 In remaining patients, alternative monotherapy should be tried with another appropriate first choice antiepileptic drug. The second drug should be introduced incrementally at suitable dose intervals, and titrated to a low maintenance dose, and then the first drug can be withdrawn in slow decremental steps. If seizures continue, the dose of the newly introduced drug should be increased incrementally to maximal doses.

**Table 7.17** Principles of antiepileptic drug treatment in patients with newly diagnosed epilepsy.

Aim for complete control without adverse effects
Diagnosis of epileptic seizures should be unequivocal
Seizure type, syndrome and aetiology should be established
Baseline haematological and biochemical investigations should be performed prior to drug initiation
Use one drug at a time (monotherapy), at least initially
Initial titration should be to low maintenance doses
Further upward titration will depend on response and side effects
If first drug fails, alternative monotherapies should be tried
Upward and downward titration should be in slow, stepped doses
Polytherapy should be used only if monotherapy with at least three first choice drugs has failed to control seizures
Patients should be fully counselled about goals, role, risk, outcome and logistics of drug treatment

Source: adapted from Shorvon 2013. With permission of Oxford University Press.

**Table 7.18** Assessment and treatment plan in patients with chronic epilepsy.

<b>Assessment</b>
Review diagnosis and aetiology (history, EEG, imaging)
Classify seizures and syndrome
Review adherence to prescription
Review drug history:
Which drugs were useful in the past?
Which drugs were not useful in the past?
Which drugs have not been used in the past?
(also dosage, length of therapy, reasons for discontinuation)
Review precipitants and non-pharmacological factors
<b>Treatment plan</b>
Document proposed sequence of drug 'trials'
Decide what background medication to continue
Decide upon the sequence of drug additions and withdrawals
Decide the duration of drug 'trials'
Decide when to do serum level monitoring
Consider surgical therapy
Consider non-pharmacological measures (e.g. lifestyle, alternative therapy)
Recognise the limitations of therapy
Provide information on above to patients

Source: adapted from Shorvon 2013. With permission of Oxford University Press.

- 8 If the steps in (7) fail, a third alternative monotherapy should be tried in the same manner. If seizures continue, or recur after initial therapy with 1–3 drugs tried in monotherapy as above.
- The diagnosis should be reassessed in patients with continuing attacks. It is not uncommon in this situation to find that the

attacks do not have an epileptic basis. Investigation should be considered to exclude the possibility of a progressive lesion. The possibility of poor compliance should be explored.

- Alternative monotherapies or polytherapy should be considered.
- The patient should be referred for specialist epilepsy advice.

### Treatment protocol for patients with chronic epilepsy

When first seeing a patient with chronic uncontrolled epilepsy, a two-stage procedure should be adopted. First, an assessment of diagnosis and previous treatment history should be made. As a second step, a treatment plan should be devised (Table 7.18).

### Assessment

The steps in the assessment are summarised in Table 7.18. The review of previous treatment history is an absolutely essential step, often omitted. The response to a drug is generally speaking relatively consistent over time. Find out which drugs have been previously tried, what was the response (effectiveness, side effects), what was the maximum dose and why the drug was withdrawn.

### Treatment plan

A treatment plan (schedule) should be formed on the basis of this assessment. The plan should take the form of a stepwise series of treatment trials, each to be tried in turn (if the previous trial fails to meet the targeted level of seizure control). The treatment plan is ideally devised to trial each available antiepileptic in turn, in a reasonable dosage, singly or as two-drug therapy (or, more rarely, three-drug combinations). This will involve deciding which drugs to introduce, which drugs to withdraw and which drugs to retain. Decisions will also be needed about the duration of each treatment trial. There is often nihilistic inertia in much of the treatment of chronic epilepsy which should be resisted, and an active and logical approach to therapy can prove very successful.

**Choice of drug to introduce or retain** Generally, these should be drugs that are appropriate for the seizure type and that have either not been previously used in optimal doses or that have been used and did prove helpful. Rational choices depend on a well-documented history of previous drug therapy. Other factors are also important – and therapy where possible should be tailored to individual requirements; such factors include co-morbidities, co-medication, obesity, gender, lifestyle, age and presence of renal or hepatic disease.

**Choice of drug to withdraw** These should be drugs that have been given an adequate trial at optimal doses and that were either ineffective or caused unacceptable side effects. There is obviously little point in continuing a drug that has had little effect, yet it is remarkable how often this is done.

**Duration of treatment trial** This will depend on the baseline seizure rate. The trial should be long enough to have differentiated the effect of therapy from that of chance fluctuations in seizures.

**Trial of therapy** It is usual to aim for therapy with either one or two suitable antiepileptic drugs. If drugs are being withdrawn, it is wise to maintain one drug as an 'anchor' to cover the withdrawal period.

**Drug withdrawal** Drug withdrawal needs care. The withdrawal, or sudden reduction in dose, of antiepileptics can result in a severe worsening of seizures or in status epilepticus – even if the withdrawn drug was apparently not contributing much to seizure control. Only

one drug should be withdrawn at a time. If the withdrawal period is likely to be difficult, the dangers can be reduced by covering the withdrawal with a benzodiazepine drug (usually 10 mg/day clobazam), given during the phase of active withdrawal.

**Drug addition** New drugs added to a regimen should also be introduced slowly, at least in the routine clinical situation. This results in better tolerability, as too fast an introduction of these drugs will almost invariably result in side effects. It is usual to aim initially for a low maintenance dose, but in severe epilepsy higher doses are often required.

### Limits of therapy

Drug therapy will fail in about 10–20% of patients developing epilepsy. In this situation, the epilepsy can be categorised as ‘intractable’

and the goal of therapy changes to defining the best compromise between adequate seizure control and drug-induced side effects. Individual patients will take very different views about where to strike this balance. Intractability is inevitably an arbitrary decision. There are over 10 first line antiepileptic drugs, and far more combinations (with 10 first line antiepileptic drugs there are 45 different two-drug and 36 different three-drug combinations). All combinations cannot therefore be tried.

### Choice of drugs and details of antiepileptic drugs

The choice of drugs for use in newly diagnosed and chronic epilepsy is to some extent based on seizure type and syndrome (Tables 7.19 and 7.20). Details of the antiepileptic drugs in current usage are shown in Tables 7.21, 7.22, 7.23, 7.24, 7.25 and 7.26.

**Table 7.19** Drug options by seizure type (authors’ own practice, modified from NICE).

Seizure type	First line drugs	Second line drugs	Other drugs that may be considered	Drugs to be avoided (may worsen seizures)
Generalised tonic–clonic	Carbamazepine Lamotrigine Levetiracetam Oxcarbazepine Sodium valproate Topiramate	Clobazam Clonazepam Perampanel	Acetazolamide Felbamate Phenobarbital Phenytoin	Tiagabine Vigabatrin
Absence	Ethosuximide Lamotrigine Sodium valproate	Clobazam Clonazepam Topiramate	Phenobarbital	Carbamazepine Gabapentin Oxcarbazepine Pregabalin Tiagabine Vigabatrin
Myoclonic	Levetiracetam Sodium valproate Topiramate	Clobazam Clonazepam Lamotrigine Piracetam Zonisamide		Carbamazepine Gabapentin Oxcarbazepine Pregabalin Tiagabine Vigabatrin
Tonic	Lamotrigine Sodium valproate	Clobazam Clonazepam Levetiracetam Topiramate	Acetazolamide Phenobarbital Phenytoin	Carbamazepine Oxcarbazepine
Atonic	Lamotrigine Sodium valproate	Clobazam Clonazepam Levetiracetam Rufinamide Topiramate	Acetazolamide Phenobarbital	Carbamazepine Oxcarbazepine Phenytoin
Focal with/without secondary generalisation	Carbamazepine Lamotrigine Levetiracetam Oxcarbazepine Sodium valproate Topiramate	Clobazam Gabapentin Perampanel Pregabalin Zonisamide	Acetazolamide Clonazepam Felbamate Phenobarbital Phenytoin Tiagabine	

Antiepileptic drug listed in alphabetical order.

Source: adapted from Shorvon 2013. With permission of Oxford University Press.

**Table 7.20** Drug options by epilepsy syndrome seen in adult practice (author's practice).

Epilepsy syndrome	First line drugs	Second line drugs	Other drugs	Drugs to be avoided (may worsen seizures)
Juvenile absence epilepsy	Ethosuximide Lamotrigine Sodium valproate	Topiramate	Clonazepam Clobazam	Carbamazepine Oxcarbazepine Phenytoin Tiagabine Vigabatrin
Juvenile myoclonic epilepsy	Lamotrigine Levetiracetam Sodium valproate Topiramate	Clobazam Clonazepam Piracetam	Acetazolamide	Carbamazepine Gabapentin Oxcarbazepine Phenytoin Pregabalin Tiagabine Vigabatrin
Generalised tonic–clonic seizures only	Carbamazepine Lamotrigine Levetiracetam Sodium valproate Topiramate	Clobazam Clonazepam Oxcarbazepine Perampanel Zonisamide	Acetazolamide Phenobarbital Phenytoin	Tiagabine Vigabatrin
Focal epilepsies: cryptogenic, symptomatic	Carbamazepine Lamotrigine Levetiracetam Oxcarbazepine Sodium valproate Topiramate	Clobazam Clonazepam Gabapentin Perampanel Phenytoin Pregabalin Zonisamide	Acetazolamide Clonazepam Felbamate Gabapentin Phenobarbital Primidone Vigabatrin	
Benign epilepsy with centrotemporal spikes	Carbamazepine Lamotrigine Oxcarbazepine Sodium valproate	Topiramate Zonisamide		
Benign epilepsy with occipital paroxysms	Carbamazepine Lamotrigine Oxcarbazepine Sodium valproate	Levetiracetam Topiramate		
Lennox–Gastaut syndrome	Carbamazepine Lamotrigine Oxcarbazepine Sodium valproate Topiramate	Clobazam Clonazepam Felbamate Levetiracetam Rufinamide Zonisamide	Phenytoin Phenobarbital Vigabatrin	
West syndrome	ACTH or corticosteroid Vigabatrin	Lamotrigine Sodium valproate Topiramate Zonisamide	Felbamate	

Antiepileptic drug listed in alphabetical order.

### Monotherapy versus combination therapy

Single-drug therapy will provide optimal seizure control in about 70% of all patients with epilepsy, and should be chosen whenever possible. The advantages of monotherapy are:

- Better tolerability and fewer side effects
- Simpler and less intrusive regimens
- Better compliance, and
- No potential for pharmacokinetic or pharmacodynamic interactions with other antiepileptic drugs.

**Table 7.21** The range of antiepileptic drugs in current use.

Drug	Year of introduction	Main mode(s) of action	Main indication
Acetazolamide	1952	Carbonic anhydrase inhibition	Second line therapy for partial onset and generalised seizures
Carbamazepine	1963	Inhibition of voltage gated sodium channel	First line drug for partial and tonic–clonic seizures
Clobazam	1986	GABA receptor agonist	Second line therapy for partial onset and generalised seizures
Clonazepam	1975	GABA receptor agonist	Second line therapy for partial onset and generalised seizures
Eslicarbazepine acetate	2009	Inhibition of voltage gated sodium channel	Second line therapy for partial onset and generalised seizures
Ethosuximide	1953	Inhibition of T-type calcium channel	Generalised absences only
Felbamate	1993	Inhibition of NMDA glutamate receptor	Second line therapy for partial onset seizures (but because of side effects now rarely used)
Gabapentin	1993	Action on the alpha2-delta subunit of the voltage gated calcium channel	Second line therapy for partial onset seizures
Lacosamide	2008	Inhibition of voltage gated sodium channel (blocks slow inactivation)	Second line therapy for partial onset seizures
Lamotrigine	1991	Inhibition of voltage gated sodium channel	First line drug for partial, absence and tonic–clonic seizures
Levetiracetam	1999	Binding to the synaptic vesicle SV2A protein	First line drug for partial, absence and tonic–clonic seizures
Oxcarbazepine	1990	Inhibition of voltage gated sodium channel	First line drug for partial onset seizures
Perampanel	2012	Selective, non-competitive antagonist of AMPA glutamate receptor on post-synaptic neurones	Second line drug for partial onset seizures
Phenobarbital	1912	GABA receptor agonist	Drug for partial, absence and tonic–clonic seizures, currently used as second line drug
Phenytoin	1938	Inhibition of voltage gated sodium channel	Drug for partial, and tonic–clonic seizures, currently used as second line drug
Piracetam	1967	Binding to the synaptic vesicle SV2A protein	Second line therapy for myoclonic seizures
Pregabalin	2004	Action on the alpha2-delta subunit of the voltage gated calcium channel	Second line therapy for partial onset seizures
Primidone	1952	GABA receptor agonist	As for phenobarbital
Retigabine	2011	Opens neuronal potassium channels KCNQ2 and KCNQ3	Second line therapy for partial onset seizures (but because of side effects now rarely used)
Rufinamide	2007	Inhibition of voltage gated sodium channel	Drop attacks in Lennox–Gastaut syndrome
Stiripentol	2007	GABAergic, enhances action of other drugs possibly via interactions	Second line therapy in SMEI when taken with valproate and clobazam
Tiagabine	1996	Inhibition of post-synaptic GABA reuptake	Second line therapy for partial onset seizures (but because of side effects now rarely used)

*(continued)*

Table 7.21 (continued)

Drug	Year of introduction	Main mode(s) of action	Main indication
Topiramate	1995	Glutamate reduction; GABAergic; sodium channel modulation; calcium channel modification; carbonic anhydrase inhibitor	First line drug for partial, absence and tonic-clonic seizures
Valproate	1968	Not known	First line therapy for all generalised seizures and also useful in partial onset seizures
Vigabatrin	1989	Inhibition of GABA transaminase	Second line therapy for partial onset seizures (but because of side effects now rarely used)
Zonisamide	1990	Sodium channel modulation; calcium channel modification; carbonic anhydrase inhibitor; glutamate receptor action; GABAergic	Second line therapy for partial and tonic-clonic seizures

Not considered here are diazepam (introduced in 1965) and lorazepam (introduced in 1975) as these are mainly used in emergency (acute) rather than long-term chronic therapy.

Table 7.22 The range of antiepileptic drugs in current use: dosing in adults.

	Initial dose (mg/day)	Drug initiation: usual dose increment (mg/day) stepped up every 2 weeks	Usual daily maintenance dose (mg/day)	Usual maximum dose (mg/day)	Dosing intervals (per day)	Drug reduction: usual dose decrement (mg/day) stepped down every 4 weeks	Maintenance doses can be different when given as co-medication
Acetazolamide	250	250	500–1000	750	1–2	250	No
Carbamazepine*	100	100–200	400–1800	2400	2	200	Yes
Clobazam	10	10	10–30	30	1–2	10	No
Clonazepam	0.25	0.25–0.5	1–4	6	1–2	0.5	No
Eslicarbazepine	400	400	800–1200	1200	1	400	Yes
Ethosuximide	250	250	500–1500	1500	2–3	250	Yes
Felbamate	1200	1200	1200–3600	3600	2–3	600	Yes
Gabapentin	300–400	300–400	1800–3600	3600	2–3	300–400	
Lacosamide	50	50	200–400	600	2	50	Yes
Lamotrigine	12.5–25	25–100	100–400	600	2	100	Yes
Levetiracetam	125–250	250–500	750–4000	4000	2	250–500	No
Oxcarbazepine	300	300	900–2400	3000	2	300	Yes
Perampanel	2	2	8–12		1	2	Yes
Phenobarbital	30	15–30	30–180	180	1	15–30	Yes
Phenytoin	200	25–100	200–400	500	1–2	50	Yes

Table 7.22 (continued)

	Initial dose (mg/day)	Drug initiation: usual dose increment (mg/day) stepped up every 2 weeks	Usual daily maintenance dose (mg/day)	Usual maximum dose (mg/day)	Dosing intervals (per day)	Drug reduction: usual dose decrement (mg/day) stepped down every 4 weeks	Maintenance doses can be different when given as co-medication
Piracetam	4800	2400	12 000–32 000	32 000	2–3	1200–2400	No
Pregabalin	50	50	100–600	600	2	50	No
Primidone	62.5–125	125–250	500–1500	1500	1–2	125–250	Yes
Retigabine	300	300	900–1200	1200	3	300	No
Rufinamide	400	400	2400–3200	32000	2	400	Yes
Stiripentol	50	100	4000		2–3	100	Yes
Tiagabine	4–5	4–15	30–45	50–60	2–3	4–5	Yes
Topiramate	25–50	25–50	75–400	600	2	50	Yes
Valproate	200–500	200–500	400–2000	3000	2–3	200–500	Yes
Vigabatrin	500	500	1000–2000	4000	2	500	No
Zonisamide	50	50	200–600	600	1–2	50	Yes

Values in this table are based on the authors' own practice, and may vary from those published elsewhere.

\*Values are for the slow release formulation, which is the formulation of choice, particularly at high doses.

(continued)

**Table 7.23** (continued)

	Oral bioavailability (%)	Time to peak level (hours)	Half-life <sup>†</sup> (hours)	Protein binding (%)
Perampanel	<100	2	105	95
Phenobarbital	80–100	0.5–4	75–120 <sup>5</sup>	45–60
Phenytoin	95	4–12	7–42 <sup>2,5</sup>	85–95
Piracetam	>90	1	5–6	0
Pregabalin	90	1	5–7	None
Primidone	<100	3	5–18 <sup>5</sup> (75–120 <sup>1</sup> )	25
Retigabine	60	0.5–2	6–10	80
Rufinamide	<85	4–6	8–12	30
Stiripentol	<100	1.5	4–14	99
Tiagabine	<96	1–2 <sup>3</sup>	5–9 <sup>5</sup>	96
Topiramate	<100	2–4	19–25 <sup>5</sup>	13–17
Valproate	<100	0.5–2 <sup>4</sup>	12–17 <sup>5</sup>	70–95
Vigabatrin	<100	0.5–2	4–7	None
Zonisamide	<100	2–4.5	49–69 <sup>5</sup>	40–50

<sup>1</sup> Value for active metabolite.

<sup>2</sup> Phenytoin has non-linear kinetics, and so half-life can increase at higher doses.

<sup>3</sup> Absorption of tiagabine is markedly slowed by food, and it is recommended that the drug is taken at the end of meals.

<sup>4</sup> The time to peak concentration varies according to formulation (0.5–2 hours for normal formulation, 3–8 hours for enteric coated).

<sup>5</sup> Half-life varies with co-medication.

<sup>6</sup> Absorption of gabapentin is by a saturable active transport system, and rate will depend on capacity of the system.

<sup>†</sup> Half-life in healthy adult.

**Table 7.24** The range of antiepileptic drugs in current use: metabolic properties.

Drug	Major metabolic pathways	Hepatic enzymes	Inhibition or induction of CYP enzymes	Drug interactions	Active metabolite
Acetazolamide	None	No	No	No	No
Carbamazepine	Epoxidation and hydroxylation, and then conjugation	CYP3A4, CYP2C8, CYP1A2 and then UGT (15%)	Induces CYP2B6, CYP2C, CYP3A, CYP1A2	Common	Carbamazepine epoxide
Clobazam	Desmethylation and hydroxylation and then conjugation	Yes	Slight effects only	Minor only	<i>N</i> -desmethyloclobazam
Clonazepam	Reduction, hydroxylation and acetylation	Yes	Slight effects only	Minor only	No
Eslicarbazepine acetate	Hydrolysis and conjugation	Yes	Inhibits CYP2C9	Common	Eslicarbazepine

Table 7.24 (continued)

Drug	Major metabolic pathways	Hepatic enzymes	Inhibition or induction of CYP enzymes	Drug interactions	Active metabolite
Ethosuximide	Hepatic oxidation then conjugation	CYP3A4, CYP2E1	No	Common	No
Felbamate	hydroxylation and conjunction	CYP3A4 CYP2E1, UGT (10%)	Induces CYP3A4, inhibits CYP2C19	Common	No
Gabapentin	None	No	No	No	No
Lacosamide	O-desmethylation	CYP2C19	Inhibits CYP2C19	Some drug interactions	No
Lamotrigine	Only phase 2 glucuronidation	UGT14A (>80%)	No	Common	No
Levetiracetam	Hydrolysis in many body tissues	No	No	Minor only	No
Oxcarbazepine	Reduction to MHD, then conjugation	Aldo-ketoreductase enzymes (not via CYP enzymes), UGT (60%)	Inhibits CYP2C19, induces CYP3A	Some	MHD
Perampanel	Oxidation and glucuronidation	CYP3A	Induces CYP3A	Common	No
Phenobarbital	Oxidation, glucosidation and hydroxylation, then conjugation	CYP2C9, CYP2C19, CYP2E1	induces CYP2B6, CYP2C, CYP3A	Common	No
Phenytoin	Oxidation, hydroxylation, and glucosidation	CYP2C9, CYP2C19, CYP2C18 (possible), UDPGT1A	Induces CYP2B6, CYP2C, CYP3A	Common	No
Piracetam	None	No	No	No	No
Pregabalin	None	No	No	No	No
Primidone	Metabolism to phenobarbital, and then biotransformation as for phenobarbital	CYP2C9, CYP2C19, CYP2E1	Induces CYP2B6, CYP2C, CYP3A (derived phenobarbital)	Common	Phenobarbital
Retigabine	Acetylation and glucuronidation		Nil	No	No
Rufinamide	Hydrolysis	Carboxylesterase enzymes, (not via CYP enzymes)	Induces CYP 3A4	Common	No
Tiagabine	Oxidation then conjugation	CYP3A4	No	Common	No
Topiramate	No* (in polytherapy: hydroxylation or hydrolysis and then conjugation)	CYP enzymes	Inducer of CYP3A4	Some drug interactions	No
Valproate	Oxidation, epoxydation, reduction and then conjunction	CYP2C9, CYP2C19, CYP2B6, UGT (40%)	Inhibits CYP2C9 (and a very weak inhibitor of CYP2C19, CYP3A4)	Common	No
Vigabatrin	None	No	No	No	No
Zonisamide	Reduction, N-acetylation and conjunction	CYP3A4	No	Common	No

CYP, cytochrome.

\* In monotherapy. In polytherapy, some hepatic metabolism.

**Table 7.25** The range of antiepileptic drugs in current use: side effects.

Drug	Common side effects	Risk of hypersensitivity
Acetazolamide	Acidosis, drowsiness, anorexia, irritability, nausea and vomiting, loss of appetite, weight loss, enuresis, headache, thirst, dizziness, hyperventilation, flushing, loss of libido, renal stones. Severe hypersensitivity affecting skin and blood	Yes – marked risk
Carbamazepine	Drowsiness, fatigue, dizziness, ataxia, diplopia, blurring of vision, sedation, headache, insomnia, gastrointestinal disturbance, tremor, weight gain, impotence, effects on behaviour and mood, hepatic disturbance, rash and other skin reactions, bone marrow dyscrasia, leukopenia, hyponatraemia, water retention, endocrine effects, effects on cardiac conduction, effects on immunoglobulins	Yes
Clobazam	Drowsiness, sedation, asthenia, ataxia, weakness and hypotonia, diplopia, mood and behavioural change, dependency, withdrawal symptoms	Slight
Clonazepam	Drowsiness, sedation, asthenia, ataxia, weakness and hypotonia, diplopia, mood and behavioural change, drooling and hypersalivation, dependency, withdrawal symptoms	Slight
Eslicarbazepine acetate	Headache, dizziness, somnolence, nausea, diplopia, vomiting, blurred vision, vertigo, fatigue, constipation and diarrhoea	None to date
Ethosuximide	Gastrointestinal symptoms, drowsiness, ataxia, diplopia, headache, dizziness, hiccups, sedation, behavioural disturbances, acute psychotic reactions, extrapyramidal symptoms, blood dyscrasia, rash, lupus-like syndrome, severe hypersensitivity	Yes – marked risk
Felbamate	Severe hepatic disturbance and aplastic anaemia, insomnia, headache, weight loss, gastrointestinal symptoms, vomiting, constipation, rhinitis, urinary tract infection, fatigue, dizziness, lethargy, behavioural change, ataxia, visual disturbance, mood change, psychotic reaction, acne, neurological symptoms	Yes – marked risk
Gabapentin	Drowsiness, dizziness, ataxia, headache, tremor fatigue, weight gain, exacerbation of non-convulsive generalised seizures, pancreatitis, depression, psychosis, headache, myalgia and urinary incontinence; hepatitis, jaundice, movement disorders, thrombocytopenia and acute renal failure	Slight
Lacosamide	Dizziness, headache, nausea, diplopia. Also, depression, confusional state, insomnia, ataxia, memory impairment, irritability, somnolence, tremor, nystagmus, blurred vision, vertigo, tinnitus, vomiting, constipation, dry mouth, pruritus, asthenia, fatigue	None to date
Lamotrigine	Rash (sometimes severe), blood dyscrasia, headache, ataxia, asthenia, diplopia, nausea, vomiting, dizziness, somnolence, insomnia, depression, psychosis, tremor	Yes – marked risk
Levetiracetam	Somnolence, asthenia, infection, dizziness, headache, irritability, aggression, behavioural and mood changes. The irritability and behavioural change can be severe. Rarer side effects include confusion, psychosis, leukopenia, thrombocytopenia and alopecia	Slight
Oxcarbazepine	Somnolence, headache, dizziness, diplopia, ataxia, confusional state, apathy, agitation, tremor, memory disturbance, rash, hyponatraemia, weight gain, alopecia, nausea, vomiting, gastrointestinal disturbance, hypothyroidism, blurred vision, vertigo, pancreatitis	Yes – but very uncommon
Perampanel	Dizziness, somnolence, ataxia, dysarthria, irritability, aggression, anger, anxiety, confusional state, change in appetite, diplopia, blurred vision, vertigo, nausea, fatigue, weight gain	
Phenobarbital	Sedation, ataxia, dizziness, insomnia, hyperkinesia (children), dysarthria, mood changes (especially depression), behaviour change, aggressiveness, cognitive dysfunction, impotence, reduced libido, folate deficiency and megaloblastic anaemia, vitamin K and vitamin D deficiency, osteomalacia, Dupuytren's contracture, frozen shoulder, shoulder-hand syndrome, connective tissue abnormalities, rash. Risk of dependency. Potential for abuse	Slight

Table 7.25 (continued)

Drug	Common side effects	Risk of hypersensitivity
Phenytoin	Ataxia, dizziness, lethargy, sedation, headaches, dyskinesia, acute encephalopathy (phenytoin intoxication), hypersensitivity, rash, fever, blood dyscrasia, gingival hyperplasia, folate deficiency, megaloblastic anaemia, vitamin K deficiency, thyroid dysfunction, decreased immunoglobulins, mood changes, depression, coarsened facies, hirsutism, peripheral neuropathy, osteomalacia, hypocalcaemia, hormonal dysfunction, loss of libido, connective tissue alterations, pseudolymphoma, hepatitis, vasculitis, myopathy, coagulation defects, bone marrow hypoplasia	Yes
Piracetam	Dizziness, insomnia, nausea, gastrointestinal discomfort, hyperkinesia, weight gain, tremulousness, agitation, drowsiness, rash	No
Pregabalin	Weight gain, dizziness, drowsiness, irritability, speech disorder, paraesthesia, confusion, fatigue, visual disturbance, increased salivation, taste disturbance, oedema, depression, insomnia, mood swings, asthenia, muscle cramp, rash, pancreatitis, arrhythmia, rhinitis, menstrual disturbances, breast discharge, breast hypertrophy, neutropenia, rhabdomyolysis and renal failure	No
Primidone	As for phenobarbital. Also dizziness and nausea on initiation of therapy	Slight
Retigabine	Dizziness, somnolence, pigmentary changes (blue discoloration) around eyes, nails, lips and skin and also in retina, fatigue, asthenia, malaise, oedema, dysuria, urinary hesitation, urinary retention, dry mouth, constipation, memory disturbance, vertigo, paraesthesia, tremor, dysarthria, dysphasia, myoclonus, anxiety, psychosis, disorientation, appetite and weight change	
Rufinamide	Headache, dizziness, somnolence, fatigue, nausea, vomiting, diplopia, blurred vision, ataxia, anxiety, insomnia, tremor, oligomenorrhoea, rash, diarrhoea, dyspepsia, constipation, anorexia, weight loss, rhinitis, ear infection, sinusitis	None to date
Stiripentol	Loss of appetite, weight loss, nausea, vomiting, insomnia, drowsiness, ataxia, hypotonia, dystonia, aggressiveness, irritability, agitation, hyperexcitability, hyperkinesia. Side effects are probably mainly due to the increase in plasma concentrations of other anticonvulsants. Nausea and vomiting and weight loss are particularly noted when used in combination with sodium valproate	No
Tiagabine	Dizziness, tiredness, nervousness, tremor, ataxia, concentration difficulties, depressed mood, emotional lability, confusion, hostility, aggression, word-finding difficulties, psychosis, diarrhoea, abdominal pain, nausea, flu-like symptoms, muscular twitching. It also has a strong propensity to induce non-convulsive status epilepticus in patients with generalised epilepsy	No
Topiramate	Parasthesia, somnolence, dizziness, depression, nausea, diarrhoea, fatigue, weight loss, bradyphrenia, insomnia, expressive language disorder, anxiety, confusional state, disorientation, aggression, mood altered, agitation, mood swings, depressed mood, anger, abnormal behaviour, disturbance in attention, memory impairment, amnesia, cognitive disorder, mental impairment, psychomotor impairment, ataxia, tremor, lethargy, hypoesthesia, dysgeusia, vertigo, tinnitus, gastrointestinal effects, alopecia, pruritus, arthralgia, myalgia, muscle twitching, anhydrosis. Significant rare effects include renal calculi and pancreatitis	No
Valproate	Weight gain, nausea, vomiting, hepatic dysfunction, Tremor, extrapyramidal disorder, somnolence, memory impairment, headache, nystagmus, encephalopathy, lethargy, ataxia, confusional state, agitation, aggression, hyperactivity, hyponatraemia, hyperammonaemia, transient alopecia, curling of hair, angioedema, rash, dysmenorrhoea, polycystic ovaries, haemorrhage, bruising, anaemia, thrombocytopenia, pancytopenia, leukopenia, deafness, oedema, enuresis, reversible Falconi syndrome, osteopenia, osteoporosis, abnormal coagulation, pleural effusion, vasculitis, myelodysplastic syndrome. Hypersensitivity can rarely occur taking the form of toxic epidermal necrolysis, Stevens–Johnson syndrome, erythema multiforme, drug rash with eosinophilia and systemic symptoms (DRESS) syndrome	Yes

(continued)

Table 7.25 (continued)

Drug	Common side effects	Risk of hypersensitivity
Vigabatrin	Irreversible visual field defects, weight gain, somnolence, agitation, aggression, nervousness, depression, paranoid reaction, hypomania, mania, psychotic disorder, irritability, excitation (children), speech disorder, headache, dizziness, paraesthesia, disturbance in attention and memory tremor, dystonia, dyskinesia, hypertonia, blurred vision, nausea, abdominal pain, fatigue, oedema	No
Zonisamide	Weight loss, paraesthesia, renal stones, cholelithiasis, anhidrosis, heat stroke, aggression, suicidal ideation, cholecystitis, renal failure, rhabdomyolysis, myasthenic syndrome, malignant neuroleptic syndrome, metabolic acidosis, renal tubular aciduria, hypokalaemia. Very rarely hypersensitivity reactions which can cause: erythema multiforme, Stevens–Johnson syndrome, toxic epidermal necrolysis, pancreatitis, pneumonitis, agranulocytosis, aplastic anaemia, leukopenia, lymphadenopathy, pancytopenia, thrombocytopenia	Yes

Table 7.26 The range of antiepileptic drugs in current use: dosing in children.

Drug	Children – average initial dose	Children – average maintenance dose
Acetazolamide	10 mg/kg/day	250–750 mg/day
Carbamazepine	<1 year, 50 mg/day 1–5 years: 100 mg/day 5–10 years: 200 mg/day 10–15 years: 100 mg/day	<1 year: 100–200 mg/day 1–5 years: 200–400 mg/day 5–10 years: 400–600 mg/day 10–15 years: 600–1000 mg/day
Clobazam	0.25mg/kg/day	0.25–1.5mg/kg/day
Clonazepam	<1 year: 0.25 mg/day 1–5 years: 0.25 mg/day 5–12 years: 0.25 mg/day	<1 year: 1 mg/day 1–5 years: 1–2 mg/day 5–12 years: 1–3 mg/day
Eslicarbazepine acetate	–	–
Ethosuximide	10–15 mg/kg/day	20–40 mg/kg/day
Felbamate	15 mg/kg/day	45–80 mg/kg/day
Gabapentin	10–15 mg/kg/day/kg	3–4 years: 40 mg/kg/day 5–12 years: 25–35 mg/kg/day >12 years: as for adults
Lacosamide	–	–
Lamotrigine	2–12 years: 0.3 mg/kg/day (monotherapy) 0.15 mg/kg/day (with valproate co-medication) 0.6 mg/kg/day (with co-medication with enzyme-inducing drugs)	2–12 years: 1–10 mg/kg/day (monotherapy) 1–5 mg/kg/day (with valproate co-medication) 5–15 mg/kg/day (with co-medication with enzyme-inducing drugs)
Levetiracetam	10–20 mg/kg/day	20–60 mg/kg/day
Oxcarbazepine	4–5 mg/kg/day	20–45 mg/kg/day
Perampanel	–	–
Phenobarbital	Neonates: 1–2 mg/day 1 month–12 years: 1–1.5 mg/kg/day, >12 years: 15 mg/day	Neonates: 3–4 mg/day 1 month–12 years: 3–8 mg/kg/day >12 years: 30–180 mg/day

Table 7.26 (continued)

Drug	Children – average initial dose	Children – average maintenance dose
Phenytoin	1 month–12 years: 1.5–2.5 mg/kg/day >12 years: 50 mg/day	1 month–12 years: 2.5–7.5 mg/kg/day >12 years: 75–150 mg/day
Piracetam	–	–
Pregabalin	–	–
Primidone	1–2 mg/kg/day	10–20 mg/kg/day
Rufinamide	<30 kg: 200 mg	<30 kg not receiving valproate: 1000 mg/day <30 kg receiving valproate medication, 600 mg/day
Stiripentol	50 mg/kg/day	100 mg/kg/day (max 4000 mg)
Tiagabine	– nil –	–
Topiramate	0.5–1 mg/kg/day	5–9 mg/kg/day
Valproate	Neonates: 20 mg/kg 1 month–12 years: 0–15 mg/kg	Neonates: 20 mg/kg 1 month–12 years: 25–30 mg/kg (up to 60 mg/kg in infantile spasms)
Vigabatrin	10–15 kg: 125 mg/day 15–30 kg: 250 mg/day >30 kg: 500 mg/day	10–15 kg: 40 mg/kg/day or 500–1000 mg/day 15–30 kg: 1000–1500 mg/day >30 kg: 1500–3000 mg/day
Zonisamide	2–4 mg/kg/day	4–8 mg/kg/day

Combination therapy is needed in about 20% of all those developing epilepsy, and in a much higher proportion of those with epilepsy that has remained uncontrolled in spite of initial monotherapy (chronic active epilepsy). The prognosis for seizure control in these patients, even on combination therapy, is less good. Nevertheless, skilful combination therapy can make a substantial difference by optimising control of the epilepsy (including situations where it is not possible to obtain full control) and minimising the side effects of treatment. The choice of drugs in combination has not been satisfactorily studied. It has been proposed, but without any substantial supporting evidence, that mixing drugs with differing modes of action has a synergistic effect. Patients need to be advised carefully about the implications of polytherapy in terms of drug interactions, teratogenesis and potential pharmacodynamic effects.

#### Role of antiepileptic drug level measurements

The measurement of drug levels of some antiepileptic drugs is helpful for a number of reasons. In chronic refractory patients these include assessing optimal doses, assessing toxicity and side effects, assessing interactions with other drugs and compliance. The levels of phenytoin should be regularly measured because of the non-linear kinetics of this drug.

#### Patient information

All treatment is a balance between benefits (seizure control) and risk (e.g. side effects) and it is important to tell patients of the risks

of therapy so that an informed decision can be made. Written information is generally better than simple verbal instruction. Consent to therapy must be informed and patients should be given enough time to discuss and explore the various treatment options.

#### Treatment of patients with epilepsy in remission

Epilepsy can be said to be in remission when seizures have not occurred over long time periods (conventionally 2 or 5 years). Some 70–80% of patients will be in remission at some point after the initiation of therapy. Many cases of untreated epilepsy also remit and in the long term at least 50% of patients are in remission and off medication.

The clinical management of ongoing therapy in patients in remission is usually straightforward. Drug doses should be minimised, and it is usually possible to avoid major adverse effects. In most cases, little medical input is required with appropriate care provided at primary care level and annual visits to the specialist. The seizure type, epilepsy syndrome, aetiology, investigations and previous treatment should be recorded. Routine haematological or biochemical checks are recommended on an annual basis in an asymptomatic individual. Enquiry should be made of long-term side effects (e.g. bone disease in post-menopausal women) and counselling about issues such as pregnancy made where appropriate. At some point, the calm of this ideal situation is likely to be disturbed by the question of discontinuation of therapy.

**Table 7.27** Some factors that increase the risk of seizure recurrence after withdrawal of therapy in patients with epilepsy in remission.

Short duration of seizure freedom prior to drug withdrawal
Age above 16 years
History of myoclonic seizures or secondarily generalised seizures
History of multiple seizure types
Certain epilepsy syndromes (e.g. juvenile myoclonic epilepsy, childhood encephalopathies)
Symptomatic epilepsy
Prolonged period of active epilepsy before achieving seizure control
History of seizures after treatment was initiated
Seizure control requiring multiple drug therapy
EEG showing generalised spike-wave discharges
Presence of learning disability or associated neurological handicaps

### Discontinuation of drug therapy

It is often difficult to decide when (if ever) to discontinue drug treatment. The decision should be made by a specialist who is able to provide an estimate of the risk of reactivation of the epilepsy. This risk is influenced by the factors listed in Table 7.27; but it must be stressed that withdrawal is never entirely risk free. The decision whether to withdraw therapy will depend on the level of risk the patient is prepared to accept.

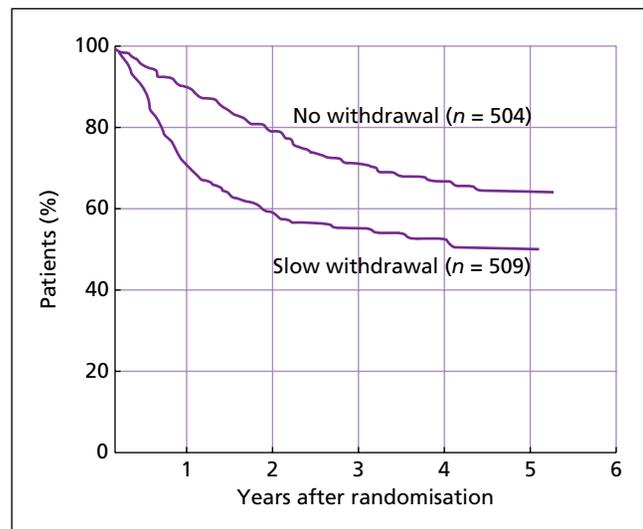

**Probability of remaining seizure free after drug withdrawal** The best information comes from the Medical Research Council (MRC) antiepileptic drug withdrawal study, which included 1013 patients who had been seizure free for 2 years or more (Figure 7.11). Within 2 years of starting drug withdrawal 59% remained seizure free (compared with 79% of those who opted to stay on therapy). Other studies have had essentially similar findings.

**Seizure-free period** The longer the patient is seizure free, the less is the chance of relapse. The overall risk of relapse after drug withdrawal, for instance, after a 5-year seizure-free period is under 10%.

**Duration of active epilepsy** This is probably an under-studied factor. One has a strong impression that the shorter the history of active seizures (i.e. the duration of time from the onset of epilepsy to the onset of remission), the less is the risk of relapse.

**Type and severity of epilepsy** The type of epilepsy and its aetiology are important influences on prognosis. The presence of symptomatic epilepsy, secondarily generalised or myoclonic seizures, neurological deficit or learning disability greatly lessen the chance of remission, and also increase the chances of recurrence should remission occur. The higher the number of seizures prior to remission, the greater the number of drugs being taken to control the seizures and the presence of two or more seizure types (a surrogate for severity of epilepsy) all increase the risk of relapse.

**EEG** The persistence of spike-wave complexes in those with IGE is the most useful prognostic EEG feature, indicating a higher chance

**Figure 7.11** Medical Research Council (MRC) drug withdrawal study. Actuarial percentage of patients seizure free amongst those randomised to continuing or to slow withdrawal of antiepileptic drugs. A study of 1013 patients who were seizure free for 2 years or more. Two years after randomisation, 78% of those who continued treatment and 59% of those who withdrew antiepileptic drugs were seizure free. Source: Chadwick et al. 1996. Reproduced with permission of John Wiley & Sons.

of relapse. This is especially the case in childhood and juvenile absence epilepsy. Other EEG abnormalities have no great prognostic utility, and the presence of focal spikes or changes to EEG background in adults are of little help in estimating the chances of remission or relapse after drug withdrawal.

**Age** There is no clear overall relationship between age and the risk of relapse, although there are age-specific syndromes that have specific prognostic patterns. There is a low chance of relapse in the benign epilepsies of childhood or in generalised absence epilepsy. These data simply emphasise the obvious point that the overriding determinant of prognosis is the type and aetiology of epilepsy.

### How to withdraw therapy – the importance of slow reduction

When a decision to withdraw therapy is made, the drugs should be discontinued slowly one at a time. Fifty per cent of patients who are going to experience seizure recurrence on withdrawal do so during the reduction phase, and 25% in the first 6 months after withdrawal; this should be explained carefully to the patient. Although not mandated in law, driving restrictions should be recommended during the withdrawal period and the subsequent 6 months.

Recommended rates of withdrawal in routine practice are given in Table 7.22, although in many instances there is no need to proceed so rapidly. In general terms, the slower the withdrawal, the less likely are seizures to recur. If seizures do recur, the drug should be immediately restarted at the dosage that controlled the attacks. About 10% of patients will not regain full remission even if the drug is replaced at the dosage that previously resulted in long remission. Why this should be the case is unclear, but in some patients at least, it seems that recurrence alters subsequent seizure risk.

## Management of epilepsy in learning disability

### Definition

Learning disability is a descriptive concept, not a disease or illness. Learning disability is defined as a composite of:

- Deficiency in learning with an IQ of less than 70 (i.e. 2 standard deviations below the mean)
- Difficulties with daily living skills, and
- An onset within the developmental period (less than 18 years of age).

It does not infer a particular aetiology. Social functioning is an integral part of the diagnosis. It is different from mental illness; a person with learning disability can also develop mental illness. As a concept, it is also different from learning difficulties, which generally refers to specific learning problems (e.g. dyslexia), rather than a global impairment or intellect and function, although some ambiguity does exist in the use of the terms.

### Prevalence of epilepsy in people with learning disability

People with learning disabilities are 30 times more likely to experience seizures than the general population. In most cases, both the cognitive difficulties and the seizures represent overt symptoms of the underlying pathology. The risk of epilepsy increases with more significant intellectual disabilities and additional motor and sensory impairments. Prevalence of epilepsy in people with severe learning disabilities and additional impairments ranges from 50% to 75%. The mortality ratio of people with learning disabilities and epilepsy is also higher than that of people with learning disabilities alone.

### Assessment

There are a number of specific issues that complicate the evaluation of epilepsy in people with learning disabilities. Furthermore, assessment is compounded by recollection and communication difficulties, coexistence of mental illness and by related problems that may mimic epileptic seizures.

*Communication difficulties – ‘management by proxy’* People with learning disabilities and epilepsy tend to have consistently poorer adaptive and social skills and more speech difficulties than people with intellectual disabilities alone. In this population, it is common to make a diagnosis and decisions about treatment based on carers’ reports: a witness report from a carer or family member is common, a report from the individual is less so. Thus, history and management will commonly progress through another – ‘management by proxy’. The degree of this will increase as the individual’s communicative skills decrease. This is problematic, as people with learning disability often rely on paid care staff. Even though the content of concerns was found to be similar between families, care staff and clinicians, care staff showed the lowest degree of concern with poorest inter-rater reliability of all three groups, reflecting the level of emotional involvement with the client.

*Psychiatric co-morbidity – ‘diagnostic overshadowing’* People with learning disability and epilepsy are twice as likely to experience mental health problems, particularly affective disorders, than their peers without epilepsy. ‘Diagnostic overshadowing’ is common with a person’s presenting symptoms put down to their learning disability, rather than seeking another, potentially treatable cause. Is the observed strange behaviour caused by epilepsy, mental illness (i.e. depression, psychosis related or unrelated to epilepsy), physical

ailment (i.e. pain, deterioration in vision), an attempt at communication, a response to a stressful situation (i.e. change in carers, bereavement) or a side effect of a drug? People with learning disabilities can experience difficulties recognising or communicating their internal experiences and therefore it is particularly important for this group that those around them survey all factors potentially implicated in behavioural change (e.g. antiepileptic drug intoxication).

With an increase in prevalence of nearly all forms of psychiatric disorders, people with learning disability and additional epilepsy are further socially disadvantaged. Other risks include potentially life-threatening accidents and head injuries, which also can result in further brain damage and dependency on others. They often have less effective and cruder coping mechanisms, which can lead to difficulties in the diagnostic and treatment process:

- Non-epileptic attack disorders are more common in people with learning disability who have limited communication skills to express emotional conflicts.
- Self-induced seizures can be stress-avoidance mechanisms with pleasurable auras experienced in photosensitive patients, or providing a sense of control over the unpredictable epilepsies.
- Increased aggression is often reported, when seizures are reduced, either because of complex electrophysiological interactions (‘forced normalisation’) or less seizure-related sedation and, thus, greater awareness mixed with limited communication skills and ways to express frustration.

*Behaviour or seizure?* Seizures are paroxysmal episodes of abnormal behaviour. A generalised tonic-clonic convulsion is well defined and does not mimic many other conditions. Other seizure types, however, are less confidently diagnosed and are more dependent on the quality of the verbal description from the individual and witnesses. Patterns of behaviour seen in complex partial seizures, particularly when there are associated ictal or post-ictal automatisms, can be difficult to differentiate from psychiatric disturbances or from non-epileptic attack disorders. Differentiating these in people with learning disability is further complicated by communication issues and the high prevalence of repetitive episodes of manneristic or stereotyped behaviours and motor disorders in this population.

It is not entirely clear how epilepsy is related to challenging behaviour. The results of studies have been at times contradictory, with some finding a relationship and others not. This is perhaps not surprising considering the wide variety of aetiologies and syndromes encompassed under the general umbrella of epilepsy and the fact that it is usually associated with additional impairments. There is a complex relationship between poor impulse control and epilepsy, in particular arising from the frontal lobe in people with learning disability. These people have been found to be more at risk of displaying challenging behaviour or episodic rage and aggression, which appears to be involuntary, can have some features shared with frontal lobe seizures, and most likely is brought about by frontal lobe dysfunction.

### Diagnostic difficulties

People with learning disabilities often have difficulties complying with medical procedures. Good planning and communication between the person and staff, carers and/or relatives is important to increase the chance of tolerating an EEG and/or MRI or any other tests. Even though people with learning disability often have

diffuse brain abnormalities, and thus are poor candidates for resective curative surgery, both MRI and EEG can provide important diagnostic clarification and prognostic information. People with learning disabilities are often under-investigated and epilepsy often undiagnosed because of therapeutic nihilism by some doctors as well as management-by-proxy disproportionately carried out by carers who are often poorly paid people with little understanding of the complexities of people with learning disabilities or carers from different social backgrounds and little appreciation of health issues.

### Treatment

As for all those with epilepsy, antiepileptic medication constitutes the first line of treatment. However, seizures remain poorly controlled in approximately 68% of clients with learning disabilities, despite the fact that around 40% regularly take more than one antiepileptic drug.

There is little evidence-based prescribing in people with learning disability and epilepsy who are usually excluded from most regulatory antiepileptic drug trials. The majority of data come from add-on open non-randomised studies, usually of the novel antiepileptic drugs. Examples are studies using an open non-controlled methodology in populations with learning disability and refractory epilepsy which have shown a 50% reduction in seizures in 33% of patients at 3 months follow-up on vigabatrin, with a reduction in this response by one-third at 5-year follow-up and a 50% improvement in seizure control on lamotrigine in 74% of children, with an associated improvement in quality of life based on subjective clinical judgement. There are a few randomised controlled trials, mainly focusing on the difficult to define epileptic syndrome of Lennox–Gastaut, which is strongly associated with learning disability. Both lamotrigine and topiramate led to significant reduction in atonic (drop) attacks and improvement in global health or reduction in seizure severity as assessed by parents. In West's syndrome, an impressive efficacy for vigabatrin was shown in both open and a limited placebo-controlled trials.

For the majority of people, we therefore apply knowledge on interventions gained in the general population to this special population, but the validity of this approach in this population remains unproven. Seizure reduction, although still the prime aim of epilepsy treatment, should not be the only parameter by which the success of interventions can be assessed. Broader quality of life issues should be considered. This is particularly important in this already disadvantaged group, for whom freedom from seizures can be very elusive. The UK government's 2001 White Paper emphasises the need to involve the person with learning disabilities and to devise individually planned care. It seems vital therefore that we consider the individual's own concerns about their epilepsy if we are to develop more effective, broader treatments enabling people with learning disability and epilepsy, to achieve their aspirations in life unimpeded by their epilepsy.

### Management in the elderly

After stroke and dementia, epilepsy is the third most common serious chronic neurological disorder in the elderly with the highest prevalence (1.5%) and incidence (136/100 000). Almost 25% of all new cases of epilepsy occur in those over 65 years of age. These figures are furthermore an underestimate because of the difficulties in the clinical diagnosis of epilepsy in the elderly.

### Causes of epilepsy

Stroke is the leading cause of new onset epilepsy after the age of 65 years and accounts for 50–75% of cases where a cause is found. Seizures are more likely to be associated with larger haemorrhagic areas of infarction, with cortical rather than subcortical involvement and to recur if dementia or other neurological disorders are also present. Neurodegenerative disorders, such as Alzheimer's disease, increase the risk of developing epilepsy by tenfold. The third most common cause of seizures in later life are tumours: gliomas, meningiomas, and metastases. Elderly patients do not always show neurological signs, and are less likely than younger patients to present with seizures.

### Diagnosis and investigations

NICE has made no specific recommendations for older people. Epilepsy in the elderly, as in other age groups, is a clinical diagnosis and relies upon accurate clinical history and eye witness accounts, which often are not available as many elderly people live alone. The accurate diagnosis is further complicated by co-morbidities and polypharmacy.

The main differential diagnoses of an epileptic seizure at any age are syncope which can be reflex, cardiogenic or orthostatic. A 12-lead ECG is essential in patients presenting with falls or transient loss of consciousness, in order to diagnose, risk stratify and refer urgently those with (often not previously recognised) features of ischaemic heart disease.

Interictal EEG should be interpreted with caution, as it is much less diagnostically helpful in the elderly than in younger people, with up to 40% of elderly people showing non-specific EEG abnormalities, but rarely typical epileptiform activity.

Similarly, non-specific age-related changes on MRI, such as diffuse atrophy and peri-ventricular hyperintensities from hypertension, are common and increase with age.

### Medical treatment

There is a very small evidence base concerning the management of newly diagnosed epilepsy in the elderly. The First Seizure Trial Group highlighted old age as a significant predictor of recurrence. Therefore, prescribing an antiepileptic drug to an elderly patient should be considered after one unprovoked seizure, especially if there is a structural lesion on neuroimaging which increases the risk of recurrence, or a high risk of injury from a further seizure.

In general, all commonly used antiepileptic drugs appear similarly effective for seizure control in the elderly, and thus drug choice depends more on tolerability than individual antiepileptic drug efficacy. Antiepileptic drug side effects, such as cognitive disturbance, dizziness and somnolence can contribute to falls and injuries, even if not caused by seizures. Adverse drug events are common in elderly people, particularly sedation from drugs such as barbiturates, phenytoin and topiramate. The co-morbidities of mild cognitive impairment and dementia have implications for carers, especially regarding medication concordance and adherence.

Antiepileptic drugs sometimes also aggravate pre-existing disorders in the elderly, such as dementia, cardiac arrhythmias, polyneuropathy and osteoporosis. Antiepileptic drugs increase already increased risk of fracture in the elderly and in patients taking enzyme-inducing antiepileptic drugs should be prescribed prophylactic vitamin D and calcium.

Pharmacokinetics of antiepileptic drugs differ in old age because of altered volume of distribution, lower protein binding, impaired hepatic metabolism, less enzyme inducibility and slower renal elimination. Drug metabolism depends on the physical status of the patient, co-morbidities and effects of other medications. As renal function declines with age, care is needed when using renally excreted drugs; lower doses should generally be prescribed. Antiepileptic drugs without active metabolites and limited drug interactions are generally preferred.

Certain drugs commonly prescribed to elderly people, such as tramadol, also reduce seizure threshold. Older people seem to be more susceptible to the epileptogenic effects of antipsychotics, antidepressants (particularly tricyclics), antibiotics, theophylline, levodopa, thiazide diuretics and even the herbal remedy, ginkgo biloba, which is the most commonly prescribed herbal remedy in nursing home populations. The vulnerability of elderly patients and the increased likelihood of multiple prescribed medications make them susceptible to drug interactions:

- Potent hepatic enzyme inducers, such as phenobarbital, phenytoin, carbamazepine and primidone, can decrease plasma concentration of warfarin, many psychotropic (amitriptyline, haloperidol, chlorpromazine and clozapine), immunosuppressive, antimicrobial, antineoplastic and cardiovascular/antiarrhythmic drugs (digoxin,  $\beta$ -adrenoreceptor blocking agents, calcium antagonists, verapamil and amiodarone)
- Concomitant prescription of particular drugs (erythromycin, isoniazid, verapamil, diltiazem) inhibit hepatic metabolic pathways and so increase concentrations of antiepileptic drugs.

Elderly patients with medically intractable epilepsy and an underlying structural cerebral lesion should occasionally be considered for surgical treatment. The presurgical work-up is similar to that in younger patients; however, there are limited data on the long-term outcomes of resective epilepsy surgery in elderly patients. The risk of complications is considered higher than with younger patients.

## Antiepileptic drug treatment

Currently available antiepileptic drugs are presented in alphabetical order. Data are presented in Tables 7.21, 7.22, 7.23, 7.24, 7.25 and 7.26 which summarise the clinical, pharmacological and pharmacokinetic properties for each drug.

### Acetazolamide

Acetazolamide, a carbonic anhydrase inhibitor, which is primarily used in the treatment of glaucoma and for other medical indications, can also be used in epilepsy. It is a broad-spectrum antiepileptic drug but it is used mainly in seizure disorders in the paediatric age group. In the adult population, it can be useful for intermittent use in catamenial epilepsy. One caveat is that many responders develop tolerance to its antiepileptic action if used continuously. Common side effects include paraesthesia of extremities, alterations of taste, nausea and vomiting, diarrhoea, arthralgia, loss of appetite, dizziness, fatigue, irritability, thirst and polyuria. Very rarely, rashes including Stevens–Johnson syndrome and toxic epidermal necrolysis may occur. As a carbonic anhydrase inhibitor, acetazolamide is associated with an increased risk of kidney stones. Patients should be advised to increase fluid intake to decrease this risk. Its main clinical relevant interaction is with carbamazepine as acetazolamide may increase its levels.

### Benzodiazepines

Benzodiazepines are useful in epilepsy as both a rescue medication for serial seizures or prolonged seizures as well as for long-term treatment. Clobazam, a 1,5 benzodiazepine, can be very useful as an add-on for patients with refractory seizures, either partial or generalised, and may produce long-lasting seizure freedom in up to 30% of patients. Clonazepam can also be used, particularly in myoclonic seizures, but tends to be less well-tolerated. Diazepam, midazolam or lorazepam are not used much nowadays for chronic oral treatment but are useful in the emergency treatment of status epilepticus, serial or prolonged seizures.

The main disadvantages of benzodiazepines are tolerance and related problems of dependency, and a tendency for seizure exacerbation on withdrawal. Common side effects include drowsiness, sedation, ataxia, muscle weakness and hypotonia, mood and behavioural change, and in children drooling and hypersalivation. Hypersensitivity reactions do not usually occur with benzodiazepines. Benzodiazepines are relatively devoid of clinically significant interactions. Clobazam and clonazepam are the best suited for long-term treatment.

### Carbamazepine

Carbamazepine, an iminodibenzyl, is a first line drug for initial treatment of partial seizures and tonic-clonic seizures. Carbamazepine is a potent auto-inducer and must be started at a low dose to keep development of transient neurotoxicity at a minimum. The dosage can be increased every 1–2 weeks to a maintenance level that controls the seizures. Even when taking this cautious approach, some people may experience diplopia, nausea, dizziness or headache on initiation of therapy, although these effects are usually transient. Common side effects, apart from these, include drowsiness, ataxia, confusion and agitation (particularly in the elderly), hyponatraemia, neutropenia and idiosyncratic skin rashes. Very rare side effects include hepatitis, Stevens–Johnson syndrome, toxic epidermal necrolysis and cardiac conduction disturbances. Fluid retention may limit the use of carbamazepine in the elderly or those with cardiac failure. In addition, carbamazepine may aggravate bradycardia in patients with heart disease. Hyponatraemia seen with carbamazepine is rarely symptomatic but occasionally leads to confusion, peripheral oedema and an increase in the number of seizures. The associated neutropenia does not usually cause any clinical manifestations.

The use of controlled release preparations are preferable in all situations in routine practice, as they reduce toxicity associated with peak plasma concentrations of the drug.

Carbamazepine, as an enzyme inducer, reduces the levels and effectiveness of several drugs, such as oral contraceptives, steroids, haloperidol, antineoplastic drugs, antihypertensive drugs, tricyclic antidepressants, antipsychotic drugs, theophylline and warfarin. Conversely, other drugs inhibit its metabolism which can result in neurotoxicity: cimetidine, clarithromycin, dextropropoxyphene, diltiazem, erythromycin, imidazole antifungal drugs, isoniazid, tricyclic antidepressants, antipsychotic drugs, verapamil and viloxazine. Interactions of carbamazepine with other antiepileptic drugs are also common. Carbamazepine increases the clearance particularly of ethosuximide, sodium valproate, topiramate and lamotrigine. Inhibition or enzyme induction is seen with phenobarbital, phenytoin or primidone with usually small but unpredictable changes in the plasma concentrations of these drugs.

### Eslicarbazepine acetate

Eslicarbazepine acetate is licensed as an add-on medication for focal epilepsy. It is the pro-drug of eslicarbazepine which is the major active metabolite of oxcarbazepine. It therefore has a very similar efficacy and side effect profile to oxcarbazepine, although peak dose effects seen with oxcarbazepine are less with eslicarbazepine and so it is claimed to be better tolerated. It inhibits activity of voltage-gated sodium channels and this is likely to be its main mode of action. There are no head-to-head comparisons between this drug and oxcarbazepine or carbamazepine but in a randomised clinical trial response was seen in some people who had not responded to carbamazepine or oxcarbazepine.

### Ethosuximide

Ethosuximide, a succinimide, is a first line drug for the treatment of generalised absence seizures in children and young adults. It is not generally effective for other seizure types. The most important side effects are sedation, headaches, malaise, nausea, vomiting, abdominal pain and anorexia. Very rarely, it can cause psychotic episodes with paranoid ideation, aplastic anaemia, systemic lupus erythematosus and Stevens–Johnson syndrome. Ethosuximide-induced headache and abdominal pain can be severe in individual patients. Ethosuximide does not inhibit or induce the metabolism of other drugs but its clearance is reduced by valproate.

### Felbamate

Felbamate, a dicarbamate, is an effective drug in partial and in generalised seizures, and has been found to be particularly useful in refractory partial epilepsy. It was also the first antiepileptic drug to have shown efficacy as add-on treatment in refractory Lennox–Gastaut syndrome.

However, its use is currently restricted to very refractory cases only for safety reasons as there is a relatively high rate of hypersensitivity, causing aplastic anaemia or hepatotoxicity. These rare but often fatal reactions affect about 1 in 4000 people exposed. There are other common side effects including insomnia, fatigue, dizziness, lethargy, behavioural change, mood change and psychotic reaction. It interacts with many drugs and dosing is affected by these interactions.

### Gabapentin

Gabapentin, an amino acid, is a mild antiepileptic drug occasionally useful as add-on treatment of partial seizures. It is not effective for any other seizure type. Its major indication currently, however, is an analgesic for chronic neuropathic pain. Side effects of gabapentin include nausea, vomiting, peripheral oedema, dizziness, drowsiness, ataxia, tremor, asthenia, emotional lability, weight gain, dysarthria and diplopia. Rare but serious side effects include pancreatitis, depression, psychosis, thrombocytopenia and acute renal failure. Gabapentin can precipitate non-convulsive status epilepticus in some patients with generalised epilepsy. Gabapentin is devoid of drug interactions.

### Lacosamide

Lacosamide is licensed as an add-on for focal epilepsy in people over the age of 16 years. It is a sodium channel blocking drug, but it differs from other sodium channel blocking agents in that its effect is mainly on the slow inactivation of the sodium channel.

The most common side effects of lacosamide are dizziness, headaches, nausea and diplopia. It seems better tolerated if no other sodium channel blockers are used concomitantly. No idiosyncratic side effects

have yet been associated with this drug. However, it should be used with caution in people with a history of cardiac conduction problems as it is known to increase the PR interval in some people.

No clinically significant drug–drug interactions are known but there are suggestions of pharmacodynamic interaction with traditional sodium channel blockers such as carbamazepine and oxcarbazepine.

### Lamotrigine

Lamotrigine, a triazine, is a first line drug for partial and generalised seizures. It is a broad-spectrum drug but may occasionally exacerbate myoclonic seizures particularly as part of Dravet syndrome. The initiation of lamotrigine therapy should be at a very low dosage with a slow upward titration to decrease the risk of the development of skin rash, which is one of the most common and important side effects. The rash may be severe and lead to Stevens–Johnson syndrome in some rare cases, particularly if the medication is not stopped promptly. Other side effects include nausea, fatigue, dizziness, insomnia, tremor, agitation, confusion, hallucinations and blood disorders (including leukopenia, thrombocytopenia and pancytopenia).

Lamotrigine has the potential for various drug interactions. The elimination of lamotrigine is accelerated by enzyme-inducing antiepileptic drugs, such as carbamazepine, phenytoin and phenobarbital, and inhibited by valproate. Therefore, if lamotrigine is used as an add-on then dose and titration schedule needs to be adjusted according to the concomitant medication.

In women, lamotrigine levels may be reduced, occasionally dramatically, with the use of the combined contraceptive pill or during pregnancy and dosage adjustments may be necessary to avoid breakthrough seizures.

### Levetiracetam

Levetiracetam, a pyridoline, is a broad-spectrum first line medication for partial and generalised seizures which is well tolerated overall. The most frequent side effects encountered in clinical practice are lethargy, irritability, drowsiness, dizziness, headache, emotional lability, insomnia and anxiety. The irritability and behavioural change can be severe and the drug should be used with caution in patients with pre-existing anxiety.

Levetiracetam should be started at a low dose and titrated upwards every 2 weeks to the initial maintenance dose because of the risk of behavioural change.

No clinically relevant interaction with other drugs has yet been described; however, it is likely that it has pharmacodynamic interactions with other antiepileptic drugs.

### Oxcarbazepine

Oxcarbazepine is a structural variant of carbamazepine with a similar efficacy as an add-on drug for refractory partial seizures and as a first line agent in previously untreated patients with tonic–clonic and partial seizures. It also shares many side effects with carbamazepine but overall oxcarbazepine is claimed to be slightly better tolerated. Common side effects include nausea, dizziness, headache, drowsiness, agitation, lethargy, ataxia, impaired concentration, depression, tremor, hyponatraemia, acne, alopecia, skin rash and diplopia. Rare side effects include hepatitis, pancreatitis, arrhythmias, hypersensitivity reactions, thrombocytopenia, systemic lupus erythematosus and Stevens–Johnson syndrome. Hyponatraemia is more marked than with carbamazepine and occasionally leads to confusion and increase

of seizures. Cross-sensitivity with carbamazepine in skin rashes is seen about one-third of patients.

Oxcarbazepine has less potential for pharmacokinetic interactions than carbamazepine but nevertheless interactions occur (e.g. with oral contraceptives), and co-medication with oxcarbazepine can significantly lower lamotrigine levels. Oxcarbazepine can lower the levels of ciclosporin.

### Perampanel

Perampanel is licensed for the adjunctive treatment of refractory partial epilepsy. It acts by antagonising AMPA receptor function and is the first licensed antiepileptic drug with this mode of action. The most common treatment emerging events so far seen are dizziness, drowsiness, ataxia, lethargy, irritability, weight gain and blurred vision. It has no clinically significant pharmacokinetic effects on other drugs, although its levels can be affected by co-medication with strong inducers of hepatic P450 enzymes, and dose adjustments may be necessary.

Perampanel has an extremely prolonged half-life and can be given in a once a day regimen. It has a marked peak-dose effect (causing dizziness) and so is taken usually just before retiring at night to sleep.

### Phenobarbital

Phenobarbital, the oldest barbiturate in the pharmacopoeia, is an effective broad-spectrum antiepileptic against most seizure types, intravenously or with long-term oral use. It is hardly used nowadays in developed countries as a long-term oral drug, although it is still widely used in emergency situations intravenously. In patients controlled at low daily doses, phenobarbital is a cost-effective and well-tolerated medication which is used especially in resource-poor countries. The main disadvantage of phenobarbital is its potential to affect cognition, although at low doses this effect is minimal. Side effects include drowsiness, depression, lethargy, cognitive slowing, Dupuytren's contracture, ataxia and allergic skin reactions. In the elderly, hyperactivity, restlessness and confusion may be seen, while hyperkinesia is a problem in children. Megaloblastic anaemia is a chronic side effect and the use of concomitant folic acid supplementation is recommended.

Phenobarbital interacts with a number of drugs, antiepileptic or otherwise, and this must be taken into account. It has pharmacokinetic interactions with steroids, antibiotics, oral contraceptives, tricyclic antidepressants, antipsychotic drugs, antineoplastic and other drugs. It decreases the levels of carbamazepine, lamotrigine, phenytoin, valproate, zonisamide and ethosuximide.

### Phenytoin

Phenytoin, a hydantoin, is an effective oral treatment of partial seizures and tonic-clonic seizures and is also useful intravenously in status epilepticus. However, because of its great potential to cause chronic side effects and pharmacokinetic interactions, it is now not used as first line therapy in many countries. The most common side effects include cosmetic changes as gingival hyperplasia, acne, hirsutism, facial coarsening and neuropsychiatric disturbance, particularly depression, fatigue and cognitive slowing. Other side effects include nausea, tremor, paraesthesias, dizziness, headache, anorexia and skin rash. Rarely, it may cause hepatotoxicity, peripheral neuropathy, Dupuytren's contracture, lymphadenopathy, osteomalacia, megaloblastic anaemia, leukopenia, thrombocytopenia, lupus erythematosus and Stevens-Johnson syndrome. As is the case with phenobarbital, it can cause megaloblastic changes and the use of concomitant folic acid supplementation with phenytoin is recommended in some patients.

It has non-linear pharmacokinetics and this can result in large increases in plasma concentrations even with small dose increments; conversely, levels may fall abruptly even with modest dose reduction. Routine monitoring of plasma levels of phenytoin therefore is recommended (in fact phenytoin is the only antiepileptic drug for which blood level monitoring is essential).

Phenytoin is a potent enzyme inducer, and as such can be expected to lower levels of other drugs such as carbamazepine, phenobarbital, and other antiepileptic drugs, anticoagulants, amiodorone, antihypertensive drugs (including losartan), chloramphenicol, digoxin, statins, steroids, ciclosporin, sulphonamides, imidazole antifungal drugs, tricyclic antidepressants, antipsychotic drugs, antineoplastic drugs and the oral contraceptives. Conversely, the metabolism of phenytoin can be inhibited by enzyme inducers such as allopurinol, chloramphenicol, cimetidine, isoniazid, metronidazole, phenothiazine and sulphonamides.

### Piracetam

Piracetam is a -racetam drug, as is levetiracetam, but binds less strongly to the SP1V binding site and has no strong action against partial or tonic-clonic seizures. It was licensed first as a memory enhancer but has been found to have a remarkable effect against myoclonic seizures in some (but not all) patients, and is especially useful in progressive myoclonic epilepsy. It has few side effects and no interactions and is excreted unchanged. It has to be taken in very large doses.

### Pregabalin

Pregabalin, a gabapentin analogue, is a second line antiepileptic for partial seizures. It has no indication in any other seizure type. In addition to epilepsy, pregabalin also has use in generalised anxiety disorder and neuropathic pain. Weight gain is a prominent side effect, as are drowsiness and fatigue. Like gabapentin, it seems devoid of any clinically significant interactions.

### Primidone

Primidone is a barbiturate that is largely metabolised to phenobarbital, and its effects are very similar to those of phenobarbital. It is currently rarely used for the treatment of epilepsy.

### Retigabine

Retigabine is licensed as add-on therapy in partial epilepsy. It is the first drug licensed that acts as a modulator of potassium channels. The most common emerging treatment side effects are CNS-related and drowsiness, dizziness, slurred speech, ataxia, tremor and diplopia. It also causes difficulty with micturition in some patients, because of the presence of potassium channels in the bladder wall. An unexpected side effect, noticed soon after licensing, is a blue discoloration of the skin, particularly around the eyes and the nails, and pigmentary changes in the retina. The mechanism of this is unknown but this side effect has severely limited the utility of this drug which is now not widely prescribed.

### Rufinamide

Rufinamide is a triazole derivative, unrelated to any other currently used antiepileptic drugs, and it was licensed, under the orphan drug scheme, for adjunctive use in the Lennox-Gastaut spectrum where it has modest effects on drop attacks. It is relatively well tolerated, although has a range of side effects characteristic of sodium channel blocking drugs.

### Stiripentol

Stiripentol is licensed, under the orphan drug scheme, for use in Dravet's syndrome in conjunction with sodium valproate and clobazam. It is an aromatic alcohol and is unrelated to any other antiepileptic drug. Its mode of action is unknown and some of its action may well be a result of its potent blocking effects on the metabolism of other antiepileptic drugs. Its positive effects are relatively modest.

### Tiagabine

Tiagabine, a GABAergic drug, has a mild to moderate efficacy in the control of partial seizures. It has no indication in other seizure types and indeed is known to exacerbate generalised seizures. The most common adverse events are CNS-related and consist of sedation, tremor, headache, mental slowing, emotional lability, speech impairment, tiredness, depression and dizziness. Rarely, confusion, psychosis and leukopenia may occur. Increases in seizure frequency. Episodes of non-convulsive status also occur, particularly when used in idiopathic generalised epilepsy.

Drugs that induce CYP3A4/5 enzymes can increase the clearance of tiagabine significantly and higher doses are often required if they are used concomitantly. It needs to be taken three times a day, with meals, because of its short half-life. Because of the side effect profile, and peak dose effects, which especially occur if the drug is taken on an empty stomach, tiagabine is now rarely prescribed.

### Topiramate

Topiramate, a sulfamate-substituted monosaccharide, with multiple modes of action, is an antiepileptic drug that is extremely effective against partial and secondarily generalised seizures. However, it has a difficult side effect profile at high doses, with a high incidence of neurological side effects. These can be avoided by using low doses or titrating the dose upwards very slowly. These adverse effects include headache, sedation, impaired memory and concentration, speech disturbance, asthenia, anxiety, depression, sleep disorders, visual disturbances and confusion. Weight loss and paraesthesia are very common. Very rarely, topiramate may cause acute myopia with secondary angle-closure glaucoma. Topiramate is an inhibitor of carbonic anhydrase and as such is associated with an increased risk of renal stones; patients should be advised to increase fluid intake during treatment to decrease this risk.

Enzyme inducers tend to accelerate the clearance of topiramate and higher doses may be required if they are used concomitantly. Topiramate though does not affect the clearance of other antiepileptic drugs to any significant effect.

### Valproate

Valproate, a pentanoic acid, is the most effective drug in the treatment of idiopathic generalised epilepsy and is very effective in this syndrome in controlling absences, myoclonus and generalised tonic-clonic seizures. It is also effective against partial seizures. Common side effects include weight gain, tremor, behavioural disturbances, menstrual disturbances, ankle swelling and loss or curling of hair. Cognitive impairment is sometimes seen and encephalopathy has been occasionally reported, possibly because of hyperammonaemia, which is a common result of valproate therapy. Rare cases of hypersensitivity have occurred including cases of fatal hepatotoxicity, especially in infants during polytherapy. Valproate is effective in controlling anxiety and agitation is used in psychiatric practice for this purpose. The use of valproate during

pregnancy is associated with an increased risk of teratogenicity and later learning disability even in the absence of malformation, and valproate should therefore be used cautiously if at all in pregnancy.

Valproate has a complex interaction profile. It mildly inhibits the metabolism of other antiepileptic drugs which is rarely of clinical relevance except when prescribed with lamotrigine, the plasma levels of which are greatly elevated on co-medication with valproate. Interactions with phenytoin and carbamazepine can also be significant. Carbapenem antibiotics cause a profound lowering of valproate levels and this combination should be avoided. Valproate concentrations are also lowered by some antineoplastic drugs. Valproate concentrations can be greatly elevated with co-medication with antidepressant drugs.

Valproate serum level monitoring is not recommended as there is no relationship between clinical effects and the plasma concentration.

### Vigabatrin

Vigabatrin, a GABA analogue that binds to and irreversibly inhibits GABA transaminase, the principle metabolising enzyme of GABA, and this results in a marked increase in synaptic GABA. Its use is currently limited by the finding (some 8 years after it was licensed) of irreversible visual field defects in over half of patients on long-term therapy. These are usually asymptomatic in the early stages but can progress and lead to severe visual impairment. It also can cause severe behavioural change and psychiatric disturbance, including agitation and psychosis. Because of these side effects, prescription of the drug is now limited to situations where all other therapy has failed. It also has a niche indication as first line treatment of West syndrome as an alternative to ACTH or steroids.

### Zonisamide

Zonisamide is a sulphonamide, which has antiepileptic action against a wide variety of epileptic seizure types including partial seizures and for myoclonic and tonic-clonic seizures. The common side effects of zonisamide include nausea, drowsiness, dizziness, irritability, depression, ataxia, speech disorder, impaired memory and attention, anorexia and weight loss. Less common effects include psychosis and hypokalaemia. There is also a small risk of severe hypersensitivity. Zonisamide is a carbonic anhydrase inhibitor, and is associated with an increased risk of kidney stones; patients should be advised to increase fluid intake during treatment to decrease this risk.

Zonisamide does not cause any significant change in the clearance of other antiepileptic drugs or other drugs such as the oral contraceptive. Drugs which induce CYP3A4, *N*-acetyl-transferases or glucuronidation enzymes may accelerate the clearance of zonisamide and higher doses of zonisamide are sometimes required if used concomitantly with inducing drugs. The drug interactions of zonisamide are complex and the safety of co-medication should be carefully assessed.

## Emergency drug treatment

### Prolonged convulsions or serial seizures

If a tonic-clonic seizure continues for 5–10 minutes, benzodiazepine therapy, either intravenously (IV), or via the buccal or rectal route, should be given. Undiluted IV diazepam is given at a rate not exceeding 2–5 mg/min, using the Diazemuls® formulation. The adult bolus intravenous or rectal dose is 10–20 mg, and in children

the equivalent bolus dose is 0.2–0.3 mg/kg. Intravenous lorazepam is an alternative with some advantages over IV diazepam (longer time of action, less risk of cardiovascular collapse) The dose is 4 mg in adults or 0.1 mg/kg in children.

In out of hospital settings, buccal midazolam 10 mg has become the drug of choice, as an alternative to rectal diazepam and is preferred by patients and carers for ease of use and preservation of dignity.

If clusters of seizures occur, acute therapy after the first seizure can be given to prevent subsequent attacks. Oral clobazam (10–20 mg) is a common choice, and will take effect within 1–2 hours and last for 12–24 hours.

### Status epilepticus

Seizures are mostly self-terminating, usually within a couple of minutes; however, on occasions they endure, leading to status epilepticus. Conventionally, status epilepticus is defined as seizure activity that continues for at least 30 minutes, but practically seizures that continue beyond 5 minutes or which repeat without full recovery in between are categorised as a premonitory (pre-status epilepticus) phase, which often progresses to status epilepticus. There have been various estimates of the incidence of status epilepticus, ranging 10–60 per 100 000 person years depending upon the characteristics of the population studied (the incidence is higher in poorer populations).

More than half of the cases of status epilepticus occur in people without a prior history of epilepsy. Usually the cause of the status epilepticus is obvious from the history and imaging. The common causes of *de novo* status epilepticus, in other words in patients without a history of epilepsy, are acute cerebral anoxia (causing myoclonic status epilepticus in coma), alcohol abuse, cerebral tumour, cerebral infection (especially encephalitis), stroke, head injury, fever (febrile status epilepticus in children), drugs or toxins or metabolic disorders. If there is a history of epilepsy, status epilepticus is often caused by reduction or withdrawal of antiepileptic drugs or intercurrent illness. If the cause is not immediately obvious, the status can be a result of uncommon conditions such as mitochondrial disease, inflammatory or immunological disease, unusual infectious causes, drugs or toxins, or genetic disorders. In some cases no cause is found and in many such cases unidentified autoimmune mechanisms are presumed to be present.

About 10–20% of people developing status epilepticus will die in the acute phase, mostly because of the underlying cause. The mortality rate is higher in (20–50%) in those resistant to first line therapy. Neuronal damage, cognitive deficits, focal neurological deficits and epilepsy can also result from convulsive status epilepticus, especially if prolonged and inadequately treated.

### Treatment of non-convulsive status epilepticus

In non-convulsive status epilepticus, the approach to treatment depends on the subtype. In typical absence status epilepticus, which responds very well to oral or intravenous benzodiazepines, intensive emergency therapy is rarely needed. The treatment of complex partial status epilepticus is more challenging, and the outcome depends upon aetiology and degree of consciousness. If consciousness is relatively retained, complex partial status has a good prognosis and responds well to oral or intravenous benzodiazepines (in the elderly intravenous valproate or levetiracetam may be better tolerated). In contrast, patients in coma with non-convulsive status epilepticus have a very poor prognosis and aggressive treatment in this group is probably justified, although clinical trials are lacking.

### Treatment of convulsive status epilepticus

If tonic–clonic status epilepticus is allowed to persist for more than about 2 hours, there is a substantial risk of seizure-induced cerebral damage. The risk rises the longer the seizures continue. For this reason, the drug treatment of tonic–clonic status epilepticus is best divided into stages:

- Early status epilepticus is defined as the first 30 minutes of seizure activity.
- Established status epilepticus is reached if early stage (benzodiazepine) treatment fails.
- Refractory status epilepticus is reached if seizures continue for more than 1–2 hours after initiating therapy, despite early or established stage therapy.
- Super-refractory status epilepticus is reached when refractory status epilepticus has continued despite 24 hours of anaesthesia.

In addition, the development of status may be preceded by a *premonitory stage* characterised by a crescendo of seizure activity. Treatment with benzodiazepines at this stage is often very effective and can prevent the progression into status epilepticus. The treatment of choice has become buccal midazolam, but benzodiazepines can also be used by other routes, including rectal diazepam and buccal or intramuscular midazolam.

### Stage of early status epilepticus

Once status epilepticus has developed, intravenous therapy is required. However, intramuscular midazolam should be considered in situations where intravenous access is delayed or difficult. Intravenous benzodiazepines (preferably lorazepam because of its more favourable pharmacokinetic profile with a longer redistribution half-life) are the initial treatment of choice. Also at this stage, systemic factors need to be considered. Blood should be tested for electrolytes, glucose, full blood count, calcium and magnesium. Intravenous fluids should be administered and glucose and/or thiamine should be given if hypoglycaemia is suspected. Status epilepticus results in respiratory depression and oxygen should be administered.

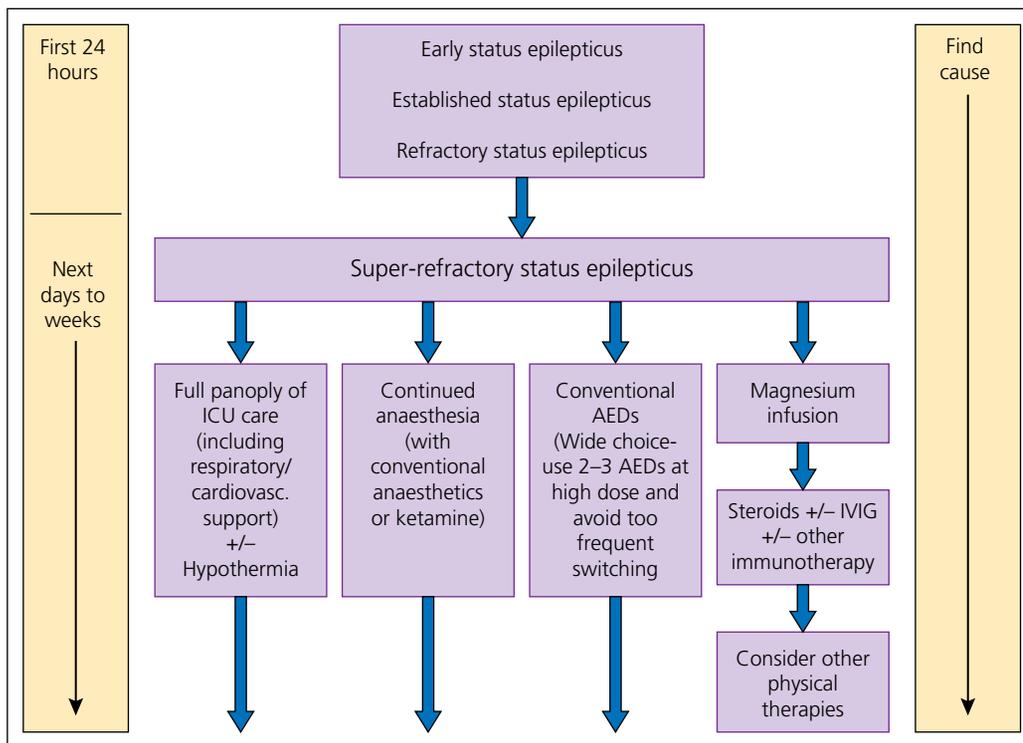

### Stage of established status epilepticus

If intravenous benzodiazepines are not completely effective then loading with another intravenous agent is usually required. Traditionally this has been phenytoin (or fosphenytoin) but valproate or levetiracetam are increasingly being used as alternatives especially as both lack the cardiovascular complications that can accompany a phenytoin infusion.

### Stage of refractory status epilepticus

If convulsive status epilepticus continues and has not responded to benzodiazepine and then second-stage therapy, the status epilepticus will be entering a phase of physiological compromise, with the danger of neuronal damage and increasing drug resistance. At this stage the patient should be transferred to an intensive care unit and given an anaesthetic (propofol, thiopentone/pentobarbital or midazolam) to reduce electrographic activity which is the source of cerebral damage. Antiepileptic drug therapy should be continued.

In addition to the treatment of status epilepticus itself, it is also necessary to treat the cause. Refractory status epilepticus has a very different spectrum of causes from drug-responsive status epilepticus; in particular, encephalitis is more frequent and a prior history of epilepsy is less frequent. Antiviral therapies, especially aciclovir, are now well established in the treatment of suspected encephalitis. However, the use of corticosteroids is more controversial. Steroids

**Figure 7.12** The treatment of super-refractory status epilepticus. In parallel to the treatment of seizures outlined, emergency therapy should also be directed where possible at the underlying cause of the status epilepticus. AEDs, antiepileptic drugs; ICU, intensive care unit; IVIG, intravenous immunoglobulin. Data from Shorvon and Ferlisi 2011.

have been recommended in cases of acute viral encephalitis where there is evidence of progressive cerebral oedema. Autoimmune encephalitis (in particular resulting from NMDA receptor antibodies) has increasingly been recognised as a cause of refractory status epilepticus, and may respond to immunosuppressive therapy including high dose methylprednisolone, intravenous immunoglobulin and plasma exchange.

### Stage of super-refractory status epilepticus

Super-refractory status epilepticus has been defined as status epilepticus that continues for more than 24 hours after the onset of anaesthetic therapy. General anaesthesia remains the backbone of therapy in refractory super-refractory status epilepticus. The three anaesthetic drugs commonly used are propofol, midazolam and thiopentone. Ketamine is reserved as a second line drug because of the very limited clinical evidence base and the potential neurotoxic effects. It is usual initially to reverse anaesthesia every 24–48 hours initially and if seizures continue then to re-establish it (cycling). Antiepileptic drugs should always be given, so that when the anaesthetic agent is withdrawn there is adequate antiepileptic cover. The choice of drug is rather arbitrary, but one or two drugs in high doses should be given, frequent switches should be avoided, and where possible drugs with low interaction potential and predictable kinetics, low allergenic potential and without renal or hepatic toxicity should be given. Hypothermia, magnesium infusion, pyridoxine infusion (in children), immunological therapy with steroids and or IVIg or plasma exchange should be considered. If the seizures continue, other therapies have been tried including the induction of

a ketogenic diet, and the use of electroconvulsive therapy or emergency neurosurgery (Figure 7.12).

A systematic protocol-driven approach is important in this emergency situation. The choice of drug regimen is somewhat arbitrary. A protocol favoured is shown in Table 7.28 and details of the drugs used are given in Tables 7.29 and 7.30.

### Epilepsy surgery

Epilepsy surgery is carried out with three objectives: to stop seizures, to ameliorate the seizures or to remove a progressive lesion or one that carries other risks such as haemorrhage. The term applies to an approach to the assessment and the surgery, which differs from surgery carried out for other reasons.

Here we concentrate on the assessment, surgery and outcome of those who have surgery primarily for their epilepsy. These are patients whose epilepsy proves resistant to antiepileptic drugs. Given the conservative estimates that approximately 20% of patients are resistant to treatment with antiepileptic drugs, and 50/100 000 people per year develop epilepsy. Then every year approximately 1/10 000 people develop refractory epilepsy (i.e. 6000 every year in the United Kingdom). In the United Kingdom, approximately 1000 of these patients (3% of the incident cohort) are suitable for presurgical assessment of whom approximately half (500) patients per year are suitable for surgery.

All patients who are being considered for surgery need a detailed presurgical evaluation, this is necessary not only to assess the likelihood of surgical success, but also to establish the suitability

**Table 7.28** Protocol for the treatment of status epilepticus in adults.**Stage of early status (0–30 min)**

Lorazepam 4 mg IV bolus (can be repeated once)

↓ (if seizures continue after 30 min)

**Stage of established status (30–60/90 min)**

Phenobarbital IV infusion 10 mg/kg at 100 mg/min

or

Phenytoin IV infusion 15 mg/kg at 50 mg/min

or

Fosphenytoin IV infusion 15 mg PE/kg at 100 mg PE/min

or

Valproate IV infusion 25 mg/kg at 3–6 mg/kg/min

↓ (if seizures continue after 30–90 min)

**Stage of refractory status (>60/90 min – general anaesthesia)**

Propofol: IV bolus 2 mg/kg, repeated if necessary, and then followed by a continuous infusion of 5–10 mg/kg/hour initially, reducing to a dose sufficient to maintain a burst suppression pattern on the EEG (usually 1–3 mg/kg/hour)

or

Thiopental: IV bolus 100–250 mg given over 20 seconds with further 50 mg boluses every 2–3 min until seizures are controlled, followed by a continuous IV infusion at a dose sufficient to maintain a burst suppression pattern on the EEG (usually 3–5 mg/kg/hour)

or

Midazolam: IV bolus 0.1–0.3 mg/kg at a rate not exceeding 4 mg/min initially, followed by a continuous IV infusion at a dose sufficient to maintain a burst suppression pattern on the EEG (usually 0.05–0.4 mg/kg/hour)

When seizures have been controlled for 12 hours, the drug dosage should be slowly reduced over a further 12 hours. If seizures recur, the general anaesthetic agent should be given again for another 12 hours, and then withdrawal attempted again. This cycle may need to be repeated until seizure control is achieved

**Table 7.29** Drugs used in the pre-anaesthetic management of convulsive status epilepticus.

	Route of administration	Adult dose	Paediatric dose
Diazepam	IV bolus (not exceeding 2–5 mg/min)	10–20 mg	0.25–0.5 mg/kg
	rectal administration	10–30 mg	0.5–0.75 mg/kg*
Midazolam	IM or buccal	5–10 mg*	0.15–0.3 mg/kg*
	IV bolus	0.1–0.3 mg/kg at 4 mg/min*	
	IV infusion	0.05–0.4 mg/kg/h	
Clonazepam	IV bolus (not exceeding 2 mg/min)	1–2 mg at 2 mg/min*	250–500 mg
Fosphenytoin	IV bolus (not exceeding 100 mg PE/min)	15–20 mg PE/kg	
Lorazepam	IV bolus	0.07 mg/kg (usually 4 mg)*	0.1 mg/kg
Phenytoin	IV bolus/infusion (not exceeding 50 mg/min)	15–20 mg/kg	20 mg/kg at 25 mg/min
Phenobarbital	IV bolus (not exceeding 100 mg/min)	10–20 mg/kg	15–20 mg/kg
Valproate	IV bolus	15–30 mg/kg	20–40 mg/kg

\* May be repeated.

PE, phenytoin equivalents.

**Table 7.30** Anaesthetic drugs used in status epilepticus.

Midazolam	0.1–0.3 mg/kg at 4 mg/min bolus followed by infusion of 0.05–0.4 mg/kg/hour
Thiopentone	100–250 mg bolus over 20 seconds then further 50-mg boluses every 2–3 min until seizures are controlled. Then an infusion of 3–5 mg/kg/hour to maintain burst suppression
Pentobarbital	10–20 mg/kg bolus at 25 mg/min followed by an infusion of 0.5–1 mg/kg/hour increasing to 1–3 mg/kg/hour to maintain burst suppression
Propofol	2 mg/kg bolus followed by an infusion of 5–10 mg/kg/hour to maintain burst suppression

of the patient, to determine the type of operation (including further invasive investigations) and to assess the potential risks.

### Who is suitable for presurgical assessment?

The main criterion for selecting patients for presurgical assessment is drug resistance. Thus, there has to have been an adequate trial of medical therapy, but what is adequate? This question has generated a certain amount of debate. Although some studies have suggested that failure to respond (rather than withdrawal because of side effects) to an initial treatment results in an 11% chance of becoming seizure free with subsequent treatments, this is overly pessimistic and long term remission rates on therapy are much greater. Furthermore, patients who are turned down for surgery or refuse surgery have been shown to have a 15–25% chance of becoming seizure free over subsequent years. This is partly because patients seen at time of presurgical assessment are at the nadir of their disease, but also because new antiepileptic drugs have had an impact; adding new antiepileptic drugs in a sequential fashion to the drug regimen of refractory patients can render one-quarter of these patients seizure free.

A generally accepted minimum is that a person should have tried at least 2–3 first line antiepileptic drug treatments at appropriate dosage over a period of 2 years (although some consider this much too soon to contemplate surgical referral). Whether to continue with trials of antiepileptic drugs or to refer directly for surgery depends upon the chance of surgical success and the severity of the epilepsy.

Epilepsy severity is difficult to characterise and to evaluate; it has to be considered on an individual basis and assessed in the light of the likely success and adverse effects of surgery. It is also important to consider the morbidity and mortality attached to even infrequent seizures. SUDEP has a particularly high incidence in patients evaluated for but refused surgery – over 1% per year. Nevertheless, it has to be established that reducing the frequency or stopping the seizures will result in a significant improvement of quality of life. In people with multiple problems (e.g. epilepsy and severe psychiatric disease or severe learning difficulties), the epilepsy may only contribute a small amount to the person's disability. Indeed, during the presurgical period it is paramount to ascertain the expectations that carers, family and the patient have of surgery. Only too often, people feel that epilepsy surgery will resolve all problems, and so are disappointed if seizure freedom has had little impact on their lives. Counselling is therefore necessary so that all involved can have realistic expectations.

Another consideration is the risk of operation. The risks of surgery may be unacceptable, even in cases where the chance of seizure freedom is high. Risks depend not only upon the type of operation (e.g. removal of eloquent cortex or memory problem following dominant temporal lobe resection), but also on the health of the individual (e.g. surgery in patients with other

medical conditions). The immediate risks of operation have to be considered in relation to longer term benefits and this is often a difficult equation (e.g. the mortality of the operation may be offset by the reduction in the chance of SUDEP, or the loss of memory following an operation may be offset by the risks to memory of continued seizures).

### Presurgical assessment

The goals of the presurgical assessment are to identify the epileptogenic zone (defined as the minimum area of cortex that has to be removed in order to render a patient seizure free), and assessment of the risks associated with its removal. It is a multidisciplinary process, involving the neurologist, neurophysiologist, neuropsychologist, neurosurgeon, psychiatrist and radiologist.

There are two main strategies for the surgical treatment of seizures. The first involves curative resective surgery, in which the aim of the surgery is the removal of the epileptogenic zone. This can be restricted to a focal lesion or may involve lobar or multi-lobar resection (e.g. hemispherectomy). The second approach is palliative, aimed at decreasing the frequency or severity of seizures but not removing the epileptogenic zone.

The assessment of the epileptogenic zone relies upon the convergence of findings from a range of presurgical investigations including clinical history, seizure semiology, scalp EEG, neuroimaging and neuropsychometry. Discordance between these may lead to a lesser chance of surgical success and also points to the need for further investigation such as invasive EEG recordings. The relative weight that is lent to each of these investigations varies depending on the type of operation and the pathogenesis of the epilepsy and in many instances is either controversial or undetermined. Although it is good clinical practice to consider each piece of information independently (i.e. unbiased by results of other investigations), in practice it is not uncommon to reassess a certain finding in the context of all available data.

### Clinical history

The clinical history contains a number of details that are critical in preoperative assessment. The age of the patient is relevant as surgery has a greater neuropsychological impact on older patients. Further, there is some evidence to suggest that the longer someone has had mesial TLE, the less chance that there will be of long-term seizure freedom following resection. Handedness gives an indication of hemisphere dominance. Antecedent history is of relevance, for example a history of febrile seizures is a good prognostic factor for surgery in those with hippocampal sclerosis, but a poor prognostic factor in those undergoing frontal lobe resection. The semiology of the seizures is critical (see below). In temporal lobe resections, a history of secondary generalised seizures is predictive of poorer outcome. It is also important to have details of social support and psychiatric concerns.

### Psychiatric history

A psychiatric assessment is necessary prior to surgery. First, there are relative contraindications to surgery including active depression or psychosis that will need treating. It is also important to ascertain whether the person is able to give fully informed consent. The additional presence of dissociative seizures is a relative contraindication, as they can often worsen after resective surgery. The risks of post-resective depression and/or psychosis also need to be estimated. Patients may require additional psychiatric support both peri- and postoperatively. About one-quarter of patients have transient mood disturbances in the first year following surgery and approximately 10% may require treatment for depression. A proportion also develop frank psychosis. There are also other personality changes and organic mental disorder which follow resective surgery, particularly on the temporal or frontal cortex.

### Neuroimaging

High-quality MRI has become a cornerstone of preoperative assessment. The presence of an identifiable well-defined lesion has a considerable impact on the surgical approach and the prognosis for surgery. If it can be shown that a lesion is the substrate for the epilepsy, then complete resection of that lesion stands a high chance of rendering the patient seizure free, while failure to resect or incomplete resection carry a poorer prognosis. The presence of an identifiable lesion on MRI also increases the chance of surgical success compared to 'MRI-negative' patients. At a minimum, the MRI investigation should involve T2-weighted sequences, proton density sequences, FLAIR sequences and T1-weighted volume acquisition (partition size less than 1.5 mm). Finer cuts and also other sequences may also be helpful, for example gradient echo or susceptibility-weighted imaging to look for blood products in association with cavernomas or arteriovenous malformations.

The role of FDG-PET, other PET ligands and ictal SPECT remains less certain, but they are useful in MRI-negative patients, on occasions when there is discordance between other investigations and in patients in whom there are extensive or multiple pathologies (e.g. tuberous sclerosis).

Ictal SPECT may be helpful when seizure semiology, interictal and ictal EEG and other imaging modalities are uninformative and can add to help guide intracranial evaluation, or confirm the ictal onset zone in patients with discordant imaging and neurophysiology findings (in order to avoid intracranial evaluation), and in patients with extensive or multiple pathologies (e.g. tuberous sclerosis). It is very resource intensive, and thus practical only in patients with a high frequency (daily or near daily) of suitable seizures.

Functional MRI can be used to identify eloquent cortex and to lateralise language. In this latter capacity, it has largely replaced the Wada test. It is likely that as a non-invasive investigation, fMRI will be increasingly used as a method for correlating structure with function such as in the assessment of memory, but currently it is not reliable enough for these purposes.

### Electroencephalography and other neurophysiological investigations

The interictal EEG is useful and can be of prognostic relevance (e.g. atypical epileptiform abnormalities in patients with hippocampal sclerosis predicts poorer outcome). Interictal epileptiform abnormalities can usually be localised with higher precision than ictal patterns. Adding selected interspaced electrodes to the standard

10–20 system may improve the localising yield and allow sublobar classification of interictal and ictal EEG changes.

However, ictal video-EEG telemetry to record seizures is the pivotal investigations in presurgical evaluation, although there are occasional cases with clear-cut pathology, typical history and interictal EEG findings in whom recording habitual seizures during video EEG telemetry may not be essential. The hope is that this is concordant with neuroimaging, as discordance reduces the chance of a good outcome and can necessitate invasive EEG recordings.

Drug reduction and other activation procedures such as sleep deprivation are often employed to facilitate the occurrence of seizures in video-telemetry settings. This may be helpful even in some patients with frequent daily seizures (e.g. if habitual seizures have no localising behavioral or EEG features). Drug reduction carries a small risk of secondary generalisation, seizure clusters and status epilepticus, and may therefore be contraindicated in some patients. In any case, patients need to consent, and benzodiazepines have to be available for rapid intravenous or mucosal application to abort seizure clusters or prolonged convulsions. Experienced nursing staff are needed to ensure patient safety during a seizure.

The assessment of the patient in the ictal and post-ictal period can provide valuable localising information about the patient's cognitive state, for example level of awareness, impairment of language function out of proportion to impairment of consciousness (ictal/post-ictal aphasia), visual field deficits, areas of inattention or extinction and subtle post-ictal paresis. Detailed analysis of the behavioural manifestations during an attack may yield further localising or lateralising information.

In addition, some patients may be able to provide a detailed description of their subjective experience at the beginning of their seizures (aura), even though they may be amnesic for this after the attack. Specific somatosensory and visual auras at the beginning of a seizure typically have a higher localising value than the scalp EEG pattern.

Seizure history, ictal behaviour and EEG thus provide complementary information that help to localise the seizure onset zone. How many seizures need to be recorded varies depending on aetiology and results of neuroimaging. If there are doubts about laterality or localisation then more seizures will need to be recorded. It is also important to ensure that the attacks recorded during long-term monitoring are representative of the patient's habitual attacks.

Protocols for electrode placement and drug reduction vary from unit to unit. In all patients being investigated for TLE, additional EEG electrodes covering the sphenoidal area are used (the authors use surface zygomatic electrodes and have found no significant advantage in using needle sphenoidal electrodes). In cases without an identifiable lesion, high density EEG with source localisation can be helpful.

Although most epilepsy surgery candidates can be adequately investigated by scalp interictal and ictal EEG, intracranial EEG monitoring over 1–2 weeks may be required in selected cases. Typical indications are dual or possible multiple potential epileptogenic pathologies, bilateral hippocampal sclerosis, focal lesions in eloquent cortex and individuals with negative neuroimaging in whom other investigations have suggested a likely location of the epileptogenic region. Invasive EEG uses a range of electrode types (depth, strip, grid) inserted neurosurgically. Electrode choice and placement is determined by where the epileptogenic region is sited: subdural grids are best for coverage of a relatively large cortical surface area, and they allow extensive cortical mapping of eloquent

areas. They do require a craniotomy and carry a 3–5% risk of infection. Depth electrodes are more suited to deep foci, and can be used to sample from both hemispheres. They carry a risk of approximately 0.2% of hemorrhage per electrode. In any case, only a limited area of cortex can be sampled (usually there are 6–15 contacts in each electrode). Subdural grids do not breach the pial boundary, have a lesser chance of causing haemorrhage and can cover a much larger area. The disadvantage of subdural grid electrodes is that they require a craniotomy and carry a higher risk of infection (approximately 3–5%); over one-quarter of patients develop an aseptic meningitis – usually restricting recordings to 10 days or less. The placement of the electrodes is dependent on the hypothesis that is to be tested. Intracranial stimulation either during awake craniotomy or with chronic subdural electrodes may also be necessary to delineate eloquent cortex and so determine the safe margins of resection. Newer methods of analysing the intracranial EEG such as single pulse stimulation techniques and the identification of high frequency bursting activity are beginning to be used to localise the epileptogenic zone. The yield of an intracranial EEG investigation thus largely depends on an appropriately formulated implantation hypothesis. Intracranial electrocortical stimulation either during awake craniotomy or with chronic subdural electrodes may also be necessary to delineate eloquent cortex and to determine the safe margins of resection.

Acute electrocorticography at the time of resection is used in some units to define the extent of resection, but we usually use extra-operative recordings.

There is an increasing role of MEG in defining the epileptogenic zone in people without an identifiable lesion, and in addition MEG can be used to identify eloquent cortex such as speech areas. Measuring changes in the magnetic field has the advantage of detecting currents that run perpendicular to the brain surface (such currents are often undetectable by scalp EEG). MEG can also detect spikes that originate deeper in the cortex. Recordings are usually limited to 1 hour. Currently, it is useful only in patients with relatively frequent interictal epileptiform discharges, and is used mainly in patients who are considered for intracranial EEG, in order to refine the implantation plan.

### Neuropsychology

Neuropsychological assessment has a role in localisation; discordant neuropsychological deficits implicating cortex distinct from the putative epileptogenic cortex indicate more widespread cortical pathology. Psychometric testing can also be used to estimate the psychological sequelae of epilepsy surgery, most commonly in the context of memory deterioration following temporal lobe resection.

Injection of sodium amytal into each hemisphere (the ‘amytal test’) is used to ‘anesthetise’ each hemisphere in turn. This test was originally devised to lateralise language in uncertain cases, but this function is now increasingly determined by fMRI. The amytal test is also extensively used to determine the possible neuropsychological sequelae of temporal lobe resection, and fMRI cannot substitute for this. However, because of variations of blood flow, access of the drug to relevant structures (e.g. the mesial temporal structures) and cross flow the amytal test can be misleading. More selective amytal tests can be performed by super-selective injections of amytal into specific cerebral vessels; however, these are more technically challenging and provide a greater risk for the patient. In some units, an intracarotid sodium amytal test is used in every patient undergoing temporal lobe resection. Other units restrict the use of this test to

patients in whom there is discordance between neuropsychometric testing and neuroimaging. The authors now rarely use the amytal test and depend upon the information gleaned from standard neuropsychometric testing and neuroimaging. The amytal test has an approximately 0.5% risk of causing cerebral infarction because of the risk of arterial catheterisation.

### Counselling

All patients should be counselled prior to surgery. They should be given details of risks and benefits; the authors find it advantageous not only to record these discussions in the notes, but also to send a letter to the patient with all these details. An estimate of the odds of success along with associated risks including catastrophic risks (stroke/death), neuropsychological risks, neuropsychiatric risks and more specific risks (e.g. visual defect) is given to the patient. The counsellor will also describe in more detail the practicalities (e.g. the length of time off work). They will also ascertain the degree of postoperative social support.

### Surgery

Surgery for epilepsy can be divided into resective curative surgery and palliative surgery, although some forms of palliative surgery can occasionally render patients seizure free, and on some occasions resective surgery is performed to palliate rather than to cure the epilepsy.

#### Curative resective surgery

Although resective surgery has been the mainstay of curative surgical techniques, other approaches such as stereotactic radiosurgery using a gamma knife have grown in popularity. The gamma knife is ideal for lesions that are difficult to resect (e.g. hypothalamic hamartomas) or for patients who are unlikely to be able to tolerate resective surgery. Whether the technique has a place in other situations remains to be determined. The main disadvantages are a lack of long-term follow-up, the risk of delayed radionecrosis and a significant delay from the radiosurgery to obtaining maximum benefit (as long as 1 year).

**Lesionectomy** Patients with discrete lesions have a good outcome from resective surgery, provided that the lesion can be completely removed and that there is no concomitant pathology. Thus, patients with dysembryoplastic neuro-epithelial tumours or discrete vascular lesions have a 50–80% chance of seizure freedom following removal of the lesion. In situations where the lesion is less well defined or is associated with more widespread abnormalities, the chance of seizure freedom drops markedly. Thus, cortical dysplasia visualised on MRI may only be the ‘tip of the iceberg’ and resection margins invariably have to be delineated using intracranial recordings. Nevertheless, resections of focal cortical dysplasia have a 10–50% chance of rendering a patient seizure free. Temporal lobe lesions are frequently associated with hippocampal sclerosis, and experience dictates that removal of both the lesion and the hippocampus is usually necessary for a successful outcome. The complications of surgery depend upon the location of the lesion, and in particular its proximity to eloquent cortex.

**Surgery in temporal lobe epilepsy** Temporal lobe resection is the most common operation for seizure control. The most common pathology is hippocampal sclerosis although temporal lobe resection is also used to treat other lesions in the temporal lobes. There have been a variety of surgical approaches to temporal lobe resection, with variations aimed to minimise the temporal neocortex resection, while maintaining the hippocampal resection. The usual

operations are either anterior temporal lobectomy or selective amygdalo-hippocampectomy. The relative advantages and disadvantages of each of these approaches are relatively minor. These operations result in approximately 50% of patients becoming seizure free in the long term (this figure may be higher in those with hippocampal sclerosis and concordant investigations) and 20% showing significant improvement. However, the chances of remaining seizure free diminish over time (probably by 3% per year for the first 5 years). The overall mortality of temporal lobectomy is less than 0.5%. A transient hemiparesis can occur in up to 5%, but the risk of permanent hemiparesis is less than 1%. The chance of significant memory decline depends upon baseline memory test, age and side of operation (dominant versus non-dominant). Significant visual field defects occur in 10%, and 5% of patients in the United Kingdom may be unable to drive because of these. Postoperative depression is not uncommon. Postoperative psychosis is less common and usually occurs in patients whose seizures are continuing. Other organic mental disorders can result, in a seemingly largely unpredictable fashion. There is also a risk of a late decline in cognitive function some years later due, it is postulated, to reduction in cerebral reserve.

**Extratemporal surgery** Extratemporal surgery is performed less frequently and mainly consists of frontal lobe surgery. The presence of a lesion is the most important predictor of surgical success. Overall, approximately 30–50% become seizure free, depending on nature and extent of the pathological basis of the epilepsy, but a normal MRI reduces these odds. The risks of operation are related to the site of resection.

**Hemispherectomy** This is particularly effective in controlling seizures, with approximately 80% becoming seizure free. This operation is only suitable for people with a profound hemiparesis, and care needs to be taken if it is the dominant hemisphere. Early theories concerning language development suggested that resection of the dominant hemisphere should not occur after the age of 6 years, but recent experience suggests a cut-off of 9 years and indeed language recovery has been noted at even later ages. The operation is usually carried out in people with extensive abnormalities of one hemisphere or with a pathology affecting one hemisphere (e.g. Rasmussen's encephalitis). Mortality is approximately 1–2%. In the past, long-term outcome was poor because of problems resulting from hydrocephalus that is attributed to superficial haemosiderosis. These risks have diminished with modern refinements of the operation – most centres now carry out the safer functional hemispherectomy. In this operation, the temporal lobe is removed, a corpus callosotomy is performed and the frontal and occipital lobes are disconnected rather than resected.

#### **Palliative procedures**

These operations aim to reduce the frequency or severity of seizures but rarely render people seizure free.

**Corpus callosotomy** Callosotomy is considered in patients with frequent tonic or atonic seizures (and more controversially tonic-clonic seizures) and when resective surgery is not possible. The chances of long-term seizure freedom with this operation are slim, approximately 5%. The morbidity from this operation can be considerable. When language representation occurs in both hemispheres language problems can occur and disconnection

syndromes with apraxia and 'alien' hand are the cause of considerable disability. These are more common in patients who undergo the operation after the age of 12 years. The operation is often performed as a two-stage procedure with first section of the anterior two-thirds and then, if seizure control is inadequate, a further procedure to section the posterior one-third can be considered. Because of the morbidity and disappointing long-term results, many centres have discontinued this operation and use vagal nerve stimulation in its place.

**Multiple subpial transection** This procedure is considered when eloquent areas of cortex form part of the epileptogenic zone. The procedure is based on the concept that functional cortical activity occurs in a radial plane, whereas seizures spread in a tangential plane. Thus, by making radial sections it should be possible to prevent seizure spread without interfering with physiological function. The cortex is exposed and acute corticography is used to determine the extent of the irritative zone. Radial cuts are made at intervals of less than 5 mm and the procedure is deemed successful once interictal discharges are abolished or minimised. Some groups report that 60–70% of patients experience a 95% reduction or more in seizure frequency, but in other centres the success rate is much lower. Some 20–30% of patients sustain focal deficits as the result of surgery and there is also a significant long-term relapse rate. The operation therefore is now usually performed only as an adjunct to and in combination with a cortical lesion resection with subpial transections made around the edge of the resection margin, or for the treatment of patients with Landau-Kleffner syndrome.

**Neuro-stimulation** The use of stimulation of various structures has a long and chequered history, but has recently been placed on a more scientific basis, with better trials and a better understanding of mechanisms of action.

Vagal nerve stimulation (VNS) for epilepsy has now been licensed throughout the world. This involves the placement of a stimulator under the skin with a wire to the left vagus nerve which is then intermittently stimulated. The stimulation parameters vary but are usually in the range: amplitude 0.25–3.5 mA; pulse width 250–500  $\mu$ s; frequency 20–30 Hz; duty cycle 30 seconds on, 5 minutes off. In addition, patients or caregivers can activate a stimulation cycle with a magnet in an attempt to abort a seizure in its early stages. Long-term results are generally disappointing and <50% of patients can expect a 50% or greater reduction in seizures. The technique is considered worthwhile in patients with tonic or atonic seizures, and VNS is increasingly being used in preference to corpus callosotomy. Dyspnoea, throat pain and hoarse voice are the main adverse events. It has to be noted that some patients are unable to tolerate the stimulation even at very low intensity. Furthermore, VNS currently precludes MRI at field strengths >1.5 T.

More recently, trigeminal nerve stimulation (TNS) has been introduced. This has the advantage that it is carried out with external electrodes and stimulator just at night, removing the need for an operation and not posing problems for MRI examination. How effective this procedure will prove to be is currently uncertain.

Stimulation of other targets such as the thalamus, subthalamic nuclei and the hippocampus are still in the early stages of development, but these methods are beginning to show promise not only as palliation, but also as potential cures. A recent trial of bilateral

stimulation of the anterior thalamic nucleus (SANTE) and responsive cortical stimulation of one or two predetermined seizure foci (NEUROPACE) reported results similar to those of VNS, with approximately 50% of patients reporting a >50% reduction in seizure frequency at 2 years, and around 10% of patients reporting periods of seizure freedom of 3 months or more. Although these results are encouraging, the authors feel that they do not justify the routine use of deep brain or cortical stimulation yet.

### Follow-up and prognosis

All patients undergoing epilepsy surgery need close follow-up in order to detect postoperative problems (e.g. depression, psychosis, organic mental disorders, seizure recurrence) to inform surgical practice and to counsel patients. The authors routinely repeat neuropsychological tests and MRI at 3–6 months following surgery, and then may repeat the neuropsychology again at a year.

If a patient becomes seizure free, then drug withdrawal will need to be considered. In the authors' series less than 30% of those who are seizure free following surgery choose to withdraw antiepileptic drugs completely. In those who do wish to reduce or withdraw medication, some recommend withdrawal at 1 year postoperatively and slowly taper over the subsequent year (drug withdrawal thereby usually occurs by 2 years post-operation). Others withdraw drugs more slowly, and the authors' practice is not to withdraw drugs in the first 5 years. The occurrence of early seizures, the inability to remove all the pathology, normal preoperative MRI, longer duration of epilepsy and older age all predict a less successful withdrawal from drugs.

## Driving regulations in the UK

In the United Kingdom, it is the role of the Driving and Vehicle Licensing Agency (DVLA) to issue driving licences. Epilepsy is a condition in which special rules for licensing apply, and the patient must notify the DVLA of the occurrence of epilepsy or an isolated seizure. In other countries different rules apply. The DVLA applies the following rules.

### Group 1 licensing

Driving rules for a group 1 licence (a normal driving licence for car and motorcycles) are as follows:

- 1 The occurrence of a single epileptic attack will result in the removal of a driving licence for 6 months from the date of the seizure. If there are clinical factors or investigation results that suggest an unacceptably high risk of a further seizure (i.e. 20% or greater per annum), driving will be prohibited for 12 months from the date of the seizure.
- 2 For some types of awake seizures, driving is permitted after 1 year after the first attack, even if seizures are continuing. This is only the case if consciousness is preserved in all seizures, the seizures do not affect the ability to react and control a vehicle normally during the seizure, and providing that no other seizure types have occurred.
- 3 If epilepsy has developed with sleep attacks, licensing will be prohibited for a period of 1 year from the date of the attack. However, if a pattern of sleep-only attacks has been established for 3 years or more, without any awake attacks occurring during this period, licensing is allowed even if sleep attacks have occurred in the preceding year.

A provoked or acute symptomatic seizure may be dealt with on an individual basis by the DVLA if there is no previous seizure history. The decision to prohibit driving in this situation will be influenced by such aspects as:

- 1 Whether the provoking stimulus carries any risk of recurrence, and
- 2 Whether the stimulus had been successfully or appropriately treated or was unlikely to occur at the wheel.

Thus, for example, the following seizures are usually considered provoked: eclamptic seizures; reflex anoxic seizures; an immediate seizure at the time of a head injury; a seizure in first week following a head injury, which is not associated with any damage on CT scanning, nor with post-traumatic amnesia of longer than 30 minutes; a seizure at the time of a stroke/TIA or within the ensuing 24 hours; or a seizure occurring during intracranial surgery or in the ensuing 24 hours. Seizures associated with alcohol or drug misuse, sleep deprivation or a structural abnormality are not considered as 'provoked' for licensing purposes.

Driving during periods of change of medication is discretionary, and depends on the advice given by the doctor on the risks of a seizure. Special care needs to be exercised where complete withdrawal of medication is being carried out.

### Group 2 licensing

Group 2 licences cover the driving of lorries, heavy goods vehicles and buses, and the rules are much stricter.

- 1 After a single seizure, driving is prohibited for a period of 5 years after the seizure, providing antiepileptic drugs have not been taken.
- 2 In patients with a diagnosis of epilepsy, a period of 10 years must pass without a seizure and without antiepileptic medication.

For taxis, many local authorities apply the regulations for Group 2 licences. However, each local authority has the ability to decide its own standards for driving.

### For both types of licence

A person must have no other medical reason which may affect his/her ability to drive. The person must comply with advised treatment and check-ups for epilepsy, and the driving of a vehicle by such a person should not be likely to cause danger to the public.

### Role of the doctor vis-à-vis the driving regulations

The following policy should be followed. The doctor must make it clear to a driving licence holder that they have a condition that may affect their safety as a driver, and therefore that the driver has a legal duty to inform the DVLA about the condition.

If the patient refuses to accept the diagnosis or the effect of the condition on their ability to drive, the doctor should advise the patient that a second opinion can be sought and appropriate arrangements should be made for this. It is important that the patient is advised not to drive until the second opinion has been obtained. If the patient continues to drive when not fit to do so, the doctor should make every reasonable effort to dissuade driving. If the patient continues to drive despite the above measures, the doctor should disclose relevant medical information immediately, in confidence, to the DVLA. Before giving information to the DVLA, the doctor should inform the patient of the decision to do so. Once the DVLA has been informed, the doctor should also write to the patient to say that a disclosure has been made.

## Other types of vehicle

The DVLA regulations cover vehicles that are driven on public highways, not vehicles that are used on private land, and thus the driving for instance of forklift trucks, tractors and quad bikes, or sit-on lawnmowers is permitted providing this is on private land. However, employers need to take into account health and safety regulations.

Electric wheelchairs and mobility scooters also are not considered to be 'vehicles', so a driving licence is not needed to use them, on public or private land.

## CHAPTER 8

# Dementia and Cognitive Impairment

Martin Rossor<sup>1</sup>, John Collinge<sup>1</sup>, Nick Fox<sup>1</sup>, Simon Mead<sup>1</sup>, Catherine Mummery<sup>2</sup>, Jonathan Rohrer<sup>1</sup>, Jonathan Schott<sup>1</sup> and Jason Warren<sup>1</sup>

<sup>1</sup>UCL Institute of Neurology

<sup>2</sup>National Hospital for Neurology & Neurosurgery

Dementia and cognitive impairment are very common and accompany many neurological as well as systemic diseases. The array of syndromes arising from damage to the neural circuitry underlying cognition can be as bewildering as the terminology. Cognitive impairment is a useful umbrella term that encompasses the severe dementia of late stage degenerative diseases such as Alzheimer's disease (AD), the mild cognitive slowing of a patient on a sedative drug and the florid confusional state or delirium in the severely systemically ill. A useful distinction, easier in theory than in practice, is the distinction between delirium and dementia. Delirium, also referred to as an acute confusional state, is characterised by fluctuation, prominent impairment of attention and/or arousal, and accompanied often by agitation and autonomic features. Delirium is commonly seen in systemic diseases and as a side effect of a variety of drugs and toxins (see delirium tremens, Chapter 19). Dementia, by contrast, refers to widespread cognitive impairment in the setting of normal arousal. This distinction can be difficult especially because confusional states can supervene in patients with many forms of dementia, and dementia with Lewy bodies (DLB) can present with fluctuating arousal and attentional deficits.

Definitions of dementia vary. The key features of the International Classification of Diseases (ICD) and the Diagnostic and Statistical Manual of Mental Disorders (DSM) definitions are that the disruption of cortical function should involve more than one cognitive domain which should include memory, more specifically episodic memory. The requirement for a memory impairment has largely been determined by the prototypic dementia AD which normally has a major amnesic component. However, other dementias such as frontotemporal dementia may only develop memory impairment late in the disease. The cognitive deficits should be sufficiently severe to cause significant social and occupational impairment. It is often assumed that dementia is progressive but a dementia can be progressive, static or reversible, depending on the aetiology. There is an increasing need to identify patients early before they fulfil the criteria of dementia, which has led to the introduction of terms such as mild cognitive impairment (MCI) to describe those patients with early disease who have not progressed to fulfil the criteria for dementia. If memory is impaired (amnesic MCI) most patients are in the early stages of AD. The recent DSM revision DSM5 now refers to minor and major neurocognitive disorders.

A useful distinction has been drawn between patients with prominent cognitive deficits arising from pathology in the cerebral cortex (cortical dementia) and those with prominent basal ganglia, thalamic or brainstem pathology (subcortical dementia). The latter patients are often very slow but accurate and exemplified by progressive supranuclear palsy (PSP). Cortical and subcortical pathologies often overlap, but the clinical distinction is useful.

It is important to realise that:

- Dementia is a syndrome caused by many different diseases, and
- Dementia may be reversible if the correct diagnosis of the cause is made and treated.

## Epidemiology: Delirium, dementia and cognitive impairment

Delirium is a problem of universal importance; it is encountered in all branches of medicine, and in both community and hospital practice. It has been estimated to occur in 5–15% of patients in general hospital wards, and a higher proportion in intensive care units. A plethora of systemic and intracranial disease processes may give rise to delirium (Table 8.1); the elderly and patients with any pre-existing cognitive impairment, and those with chronic systemic illness are especially vulnerable.

Dementia is an issue of enormous medical and socio-economic significance in societies with ageing populations. Prevalence rates in Europe, for people over the age of 65 years, are approximately 6% for all causes of dementia and approximately 4% for AD. Dementia in people under the age of 65 years (young onset dementia) is increasingly recognised as an important social problem, with UK prevalence rates estimated as 67–81/100 000 in people aged 45–65 years. Although data for individual diseases are limited by diagnostic accuracy, as a group degenerative diseases are numerically the most important causes of dementia in both older and younger adults in Western countries and probably worldwide. The young onset forms of these diseases are frequently familial. Some rarer degenerative dementias such as variant Creutzfeldt–Jakob disease (vCJD) occur typically in the young patient, while other disease processes, such as frontotemporal dementia (FTD) and alcohol-related dementia, are also common in younger age groups. In contrast, DLB, a common cause in patients over 65 years of age, accounts for only a small proportion of young onset cases. Vascular

**Table 8.1** Causes of delirium and dementia.

Category of disease	Delirium	Dementia
<b>Acquired/sporadic</b>		
Metabolic disturbance	Electrolyte disorders (especially hyponatraemia, hypercalcaemia), hypoglycaemia, respiratory failure/hypoxia (any cause), uraemia, liver failure, pancreatic encephalopathy, cardiac failure, dehydration, severe anaemia	Uraemia, dialysis dementia (now rare), liver failure, respiratory failure, cardiac failure, pancreatic encephalopathy, chronic/recurrent hypoglycaemia (e.g. insulinoma)
Intoxication/withdrawal syndromes	Alcohol, anticholinergics, antihistamines, anxiolytic-hypnotics, corticosteroids, anticonvulsants, cardiovascular drugs, opiates, levodopa, dopaminergic agonists, neuroleptic malignant syndrome, prescription of multiple drugs, illicit drugs, carbon monoxide, heavy metals, herbicides (organophosphates), industrial poisons	Alcohol, carbon monoxide, heroin (inhaled), heavy metals, organic solvents, organophosphates, lithium, methotrexate, alpha-interferon
Nutritional deficiency	Thiamine (Wernicke–Korsakoff syndrome), nicotinic acid	Thiamine, vitamin B <sub>12</sub> , nicotinic acid, multiple vitamin deficiencies
Endocrinopathies	Thyroid, adrenal, parathyroid, pituitary	Thyroid, adrenal, parathyroid, pituitary
Infections	Systemic Urinary tract infection, viral exanthemas, pneumonia, endocarditis, septicaemia (all causes)	
	CNS Encephalitis (especially herpes simplex), meningitis, brain abscess, HIV, cerebral malaria, neurocysticercosis, Mycoplasma, post-infectious syndromes	CNS HIV, neurosyphilis, tuberculosis, Whipple's disease, Lyme disease, cryptococcal/fungal meningitis, neurocysticercosis, JC virus (PML), measles (SSPE), encephalitis lethargica (may be post-infectious-autoimmune)
Inflammation and autoimmune	ADEM, cerebral vasculitis (primary CNS or systemic), voltage-gated potassium channel antibody/other channelopathies	Multiple sclerosis (primary progressive), cerebral vasculitis (primary CNS or systemic), neurosarcoidosis, Behçet's disease, voltage-gated potassium channel antibody/other channelopathies, anti-basal ganglia antibody syndrome, Hashimoto's encephalopathy, coeliac disease
Epilepsy	Epileptic status (non-convulsive), post-ictal states	Non-convulsive status, transient epileptic amnesia, Rasmussen's encephalitis
Neoplastic	Raised intracranial pressure (including acute hydrocephalus), carcinomatous or lymphomatous meningitis, paraneoplastic limbic encephalitis, post-radiotherapy (acute radionecrosis, thrombo-angiopathy)	Brain tumours (especially frontal/callosal/midbrain), CNS lymphoma, carcinomatous/lymphomatous meningitis, limbic encephalitis and other paraneoplastic syndromes, post-radiotherapy (accelerated cerebral atherosclerosis, radiation leukodystrophy)
Vascular	Subarachnoid haemorrhage, venous sinus thrombosis, arterial stroke (esp posterior circulation, non-dominant parietal), hyperviscosity syndromes, polycythaemia	Multiple cortical or subcortical strokes, lacunar state, strategic infarct (esp thalamus, medial frontal), hyperviscosity syndromes, polycythaemia, sickle cell disease, steal syndromes (e.g. AVM), Susac's syndrome

Table 8.1 (continued)

Category of disease	Delirium	Dementia
Head injury	Post-concussional syndrome, diffuse axonal injury, subdural haematoma, focal cerebral trauma	Subdural haematoma, repeated head injury/dementia pugilistica, late deterioration post-head injury
Other treatable causes	Pain, sleep deprivation, sensory deprivation and distortion (as in ITU), hypothermia, heat stress, postoperative recovery (multifactorial), migraine	Obstructive sleep apnoea, normal pressure hydrocephalus, obstructive hydrocephalus/aqueduct stenosis
Degenerative	Rapid cognitive fluctuation in Lewy body/Parkinson's disease dementia	Alzheimer's disease, Parkinson's disease/dementia with Lewy bodies, frontotemporal lobar degenerations, corticobasal degeneration, progressive supranuclear palsy, motor neurone disease dementia, neurofilament inclusion body disease, Creutzfeldt–Jakob/other prion diseases
<b>Genetic</b>		
Metabolic	Metabolic crises in porphyria, urea cycle disorders, others	Wilson's disease, acute intermittent porphyria, lysosomal and peroxisomal storage disorders, urea cycle disorders, leukodystrophies, others
Arteriopathies	Strokes and stroke-like episodes	CADASIL, cerebral amyloid angiopathies, British dementia, Fabry's disease, others
Degenerative	Rapid cognitive fluctuation in familial parkinsonism syndromes	Familial Alzheimer's disease, frontotemporal lobar degeneration (chromosome 17/chromosome 3/other), Huntington's disease, DRPLA, familial Parkinson's disease/Lewy body disease, mitochondrial encephalopathies, spinocerebellar ataxias, neuro-acanthocytosis, pantothenate kinase-associated neurodegeneration, neuro-ferritinopathy, neuro-serpinopathy, familial prion diseases, others

Ab, antibody; ADEM, acute demyelinating encephalomyelopathy; AVM, arteriovenous malformation; CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; DRPLA, dentato-rubro-pallido-luysian atrophy; HIV, human immunodeficiency virus; PML, progressive multifocal leukoencephalopathy; SSPE, subacute sclerosing panencephalitis.

disease is a common cause of dementia across all age groups. The epidemiology of dementia diseases in younger and older adults is presented graphically in Figure 8.1. It is important to recognise that data on the epidemiology of less common neurodegenerative diseases causing dementia, less well defined entities such as 'mild cognitive impairment', precursors or transitional states leading to established dementia, and dementia secondary to other neurological or systemic diseases remain very limited.

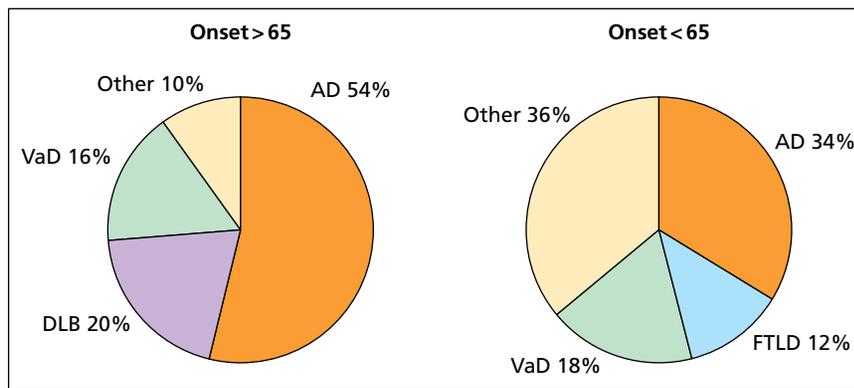

## Cognitive functions and their clinical syndromes

Cognition, like other aspects of human brain function, has a modular organisation, and different cognitive functions have distinct anatomical substrates. While a global impairment of cognitive function is often observed in delirium, specific cognitive profiles in acute brain disease are potentially of great localising and diagnostic value. This is exemplified by the different subtypes of dysphasia in

left hemisphere strokes, or the profound amnesia of Wernicke–Korsakoff syndrome. Our present understanding of the dementias has been transformed by the concept that different brain regions are affected in a characteristic and non-uniform manner as disease evolves (Table 8.2); the identification of an evolving rather than static pattern of cognitive deficits is often critical in establishing a clinical diagnosis of dementia.

### Attention

Considered very broadly, attention is the ability to gate and focus sensory information and to direct awareness. The control mechanisms for attention are mediated by a hierarchy of brain structures: awareness and alertness are maintained by the ascending reticular activating system in the brainstem which projects to the thalamus and cortex; a bilateral frontal and parietal cortical network enables selective attention to particular events and types of stimuli, and divided attention to multiple events and stimuli. This cortical control system modulates activity in sensory cortices as well as the

**Figure 8.1** Epidemiology of dementia in older adults (onset age >65 years) and younger adults (onset age <65 years). Composite prevalence data derived from European series are displayed. The prevalence of dementia with Lewy bodies (DLB) shows wide variation between series. motor areas involved in response preparation. The distributed brain networks that regulate attention are vulnerable to many different disease processes. Deficits of attention are a cardinal feature of delirium, and impaired or inefficient attention is a feature of many dementias. However, the most striking deficits of attention, and those with greatest localising value, occur with focal lesions such as stroke involving the non-dominant parietal lobe. The syndrome of hemi-neglect manifests as unawareness of contralateral (most frequently left) space. The patient may not perceive contralateral stimuli, or contralateral stimuli may be perceived when presented alone, but extinguished on presentation of simultaneous bilateral stimuli (sensory extinction). The neglect syndrome is not simply attributable to sensory deficits such as hemianopia or hemianaesthesia. Failure to direct attention to the affected field is illustrated by constructional or cancellation tasks in which stimulus features on the affected side are systematically omitted or overlooked, and there may be associated neglect of contralateral auditory stimuli that have a bilateral cortical sensory representation. Breakdown in body schema is suggested by lack of awareness of deficits involving the contralateral side of the body (anosognosia) or failure of the patient to own their contralateral limbs. The deficit may also extend to mental imagery (Figure 8.2).

## Memory

Impaired memory is a defining feature of acute disorders of cognition such as the discrete clinical syndrome of transient global amnesia, and a very common complaint in a variety of different dementias. In order to make an accurate diagnosis, it is important to determine the nature of the memory complaint. Memory is a multi-component process supported by anatomically and functionally distinct brain networks. There is a fundamental distinction between explicit memory, the contents of which can be consciously accessed, and implicit memory, the contents of which are accessed automatically and do not depend on conscious mediation (e.g. the sequence of procedural skills required when driving a car). Explicit memory has 'short-term' and 'long-term' components. In the neuropsychological sense, 'short-term' memory refers to the span for which information is retained for immediate repetition or reproduction, without rehearsal or other reinforcement (typically, less than a minute). Information that is retained for longer periods constitutes 'long-term' memory. Long-term memory can be further subclassified into memory for episodes or events from the

individual's past experience, i.e. remembering what has happened (episodic, event or autobiographical memory), and conceptual knowledge about the world, i.e. remembering what something is (semantic memory). The selective breakdown of semantic memory is a cardinal feature of the semantic dementia phenotype of FTD.

Episodic memory can itself be further divided into operationally distinct processes: the encoding and subsequent retrieval of new events (anterograde memory); retrieval of events prior to the onset of the illness (retrograde memory); and memory for different types of material (e.g. verbal material, faces and topography).

A characteristic amnesic syndrome with severe deficits of anterograde and retrograde memory in the setting of a clear sensorium and with preserved immediate (short-term) recall was originally described in the setting of thiamine deficiency in chronic alcoholism (Wernicke–Korsakoff syndrome, Chapter 19), and subsequently in patients undergoing bilateral temporal lobe resection for intractable epilepsy (notably the much-studied patient known as H.M.) and in other conditions such as herpes simplex encephalitis (Chapter 9). Such patients are profoundly disabled, as they are effectively marooned in the immediate present with no capacity to lay down new memories, although it may be possible to demonstrate preserved implicit memory and procedural learning. Amnesic syndromes of varying severity are common after traumatic brain injury.

Less profound and incomplete deficits of verbal, visual and topographical memory are common early in the course of AD, DLB, vascular dementia (VaD) and other diseases. Patients frequently describe an inability to recall the details of conversations and messages, and the names of acquaintances. Impaired verbal episodic memory is the most sensitive cognitive marker of early AD, although it is not specific. Impaired topographical memory commonly presents as a difficulty with route finding, and a tendency to become lost in unfamiliar locations.

The medial temporal lobes (hippocampal formation, parahippocampal gyrus and entorhinal cortex, Chapter 2) are critical for episodic memory. The diencephalic system, comprising the thalamus and its limbic connections including the fornix and mammillary bodies, and the basal forebrain also have important roles. Postmortem findings in Wernicke–Korsakoff syndrome typically include petechial haemorrhages with astrocytic degeneration in the mammillary bodies and medial dorsal thalamic nuclei. Functional imaging studies during transient global amnesia have demonstrated

localised transient hypo- or hyperperfusion consistent with dysfunction of these structures and their connections. The ascending cholinergic projection pathways, which exert important modulatory and attentional influences on the medial temporal lobe and neocortex (Figure 8.3), are disrupted in cholinergic deficient disease states such as AD and DLB. Posterior cortical areas including the posterior cingulate, retrosplenial and temporoparietal association cortex are densely connected via the diencephalic system with the medial temporal lobes and have also been implicated in AD. Memory impairment in the setting of frontal lobe disease is likely to be heterogeneous and multifactorial: memory processes that may be affected include the editing of encoded material, organised search of memory stores, attribution of the source of particular memories, and possibly emotional valence or significance.

Short-term memory comprises separate systems for the temporary storage of auditory verbal, visual and spatial information. Rather than being passively stored, information in short-term memory generally undergoes some form of cognitive manipulation, for example when dialing a new telephone number, making sense of an ambiguous spoken message or visualising an unfamiliar route. These are active processes that are directed by executive systems (see later). The interaction of executive systems with short-term memory stores constitutes 'working memory'. This interaction is illustrated in the distinction between forward digit span (passive storage of information) and backward digit span (active manipulation of online material). Working memory deficits are common in acute conditions with impaired attention and have been documented in many degenerative disorders, including AD, DLB, VaD and FTD. It is likely that verbal short-term memory is supported by a fronto-parietal network in the left cerebral hemisphere, and visuo-spatial short-term memory by a corresponding network in the right cerebral hemisphere. These short-term storage mechanisms can be regarded as 'slave' systems under the executive control of fronto-subcortical networks.

## Paramnesias

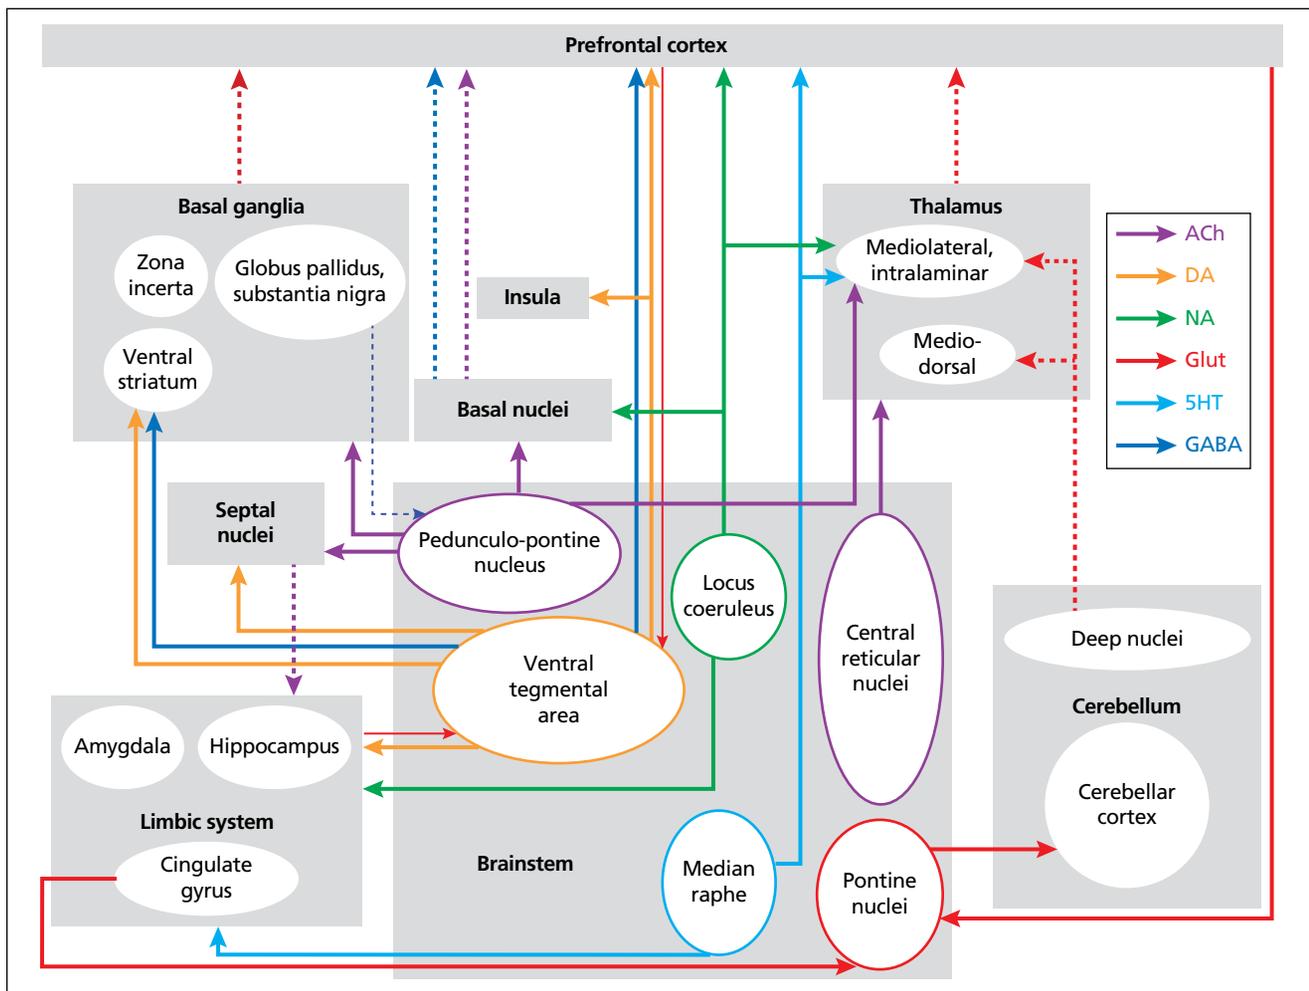

The paramnesias are characterised by false or distorted recall and may occur in acute or chronic settings. When prompted to fill a gap in the record of everyday experience the patient may describe events that never occurred, or may spontaneously supply detailed accounts of events that could not possibly have occurred (confabulation). Reduplicative paramnesias are characterised by the belief that particular places or persons have been transposed or duplicated: the patient may report that their house is an exact replica of the 'real' one (topographical paramnesia), or that their spouse has been replaced by an impostor with identical appearance (the Capgras delusion, Chapter 22). Confabulatory disturbances are most often observed in the setting of frontal lobe or fronto-limbic damage.

## Transient global amnesia

Transient global amnesia is a distinct and striking syndrome characterised by the sudden onset of severe anterograde amnesia generally lasting less than 24 hours. The patient often appears bewildered, repetitively asking the same questions. There is no disturbance of alertness and, in contrast to psychogenic fugue, personal identity is retained. Procedural and semantic memory are spared (e.g. the person may carry on driving or perform occupational tasks competently during the episode), other cognitive functions are intact and the neurological examination is normal. Complete recovery with amnesia for the period of the episode and a variable retrograde time-span is usual, although there may be persistent subtle memory deficits, and recurrence is rare. The condition generally occurs in later life. There are a number of associations, including physical exertion, exposure to cold, strong emotion, sexual activity and migraine; however, in the substantial majority, the aetiology remains unclear. Investigations are indicated to exclude mimics such as temporal lobe lesions, but are generally unrevealing. Recurrent attacks, especially on waking from sleep, suggest the syndrome of transient epileptic amnesia (Chapter 7), often accompanied by interictal memory impairment; this is an important differential diagnosis of dementia.

## Perception

Perceptual analysis of the environment is a complex multi-stage process. Visual processing is the most widely studied modality and in general the most clinically relevant. The processing of visual objects involves dissociable stages of early sensory analysis, formation of structural representations and the association of those representations with meaning. Objects have locations in space, and the perception of space requires specific neural mechanisms. The mechanisms that process visual objects and visual space can be damaged selectively, supporting a broad anatomical and physiological distinction between ventral 'what is an object' and dorsal 'where is an object' cortical processing streams (Chapter 2). Selective impairments of visual functions such as motion detection (akinetopsia) and colour perception (achromatopsia) have been described with posterior circulation strokes and other focal lesions involving the cortical visual pathways in the posterior cerebral hemispheres. These syndromes may be transient or appear during the recovery phase of a more extensive visual deficit. Syndromes of progressive visual dysfunction are associated with relatively focal tissue loss and metabolic derangements involving the posterior cerebral hemispheres, and are often classified together on anatomical grounds as the posterior cortical atrophies (PCA). The most frequent tissue pathology is AD; however, a variety of others are

**Figure 8.3** A schematic diagram of the major pathways linking the brainstem with other cortical and subcortical regions. The schema is based on evidence derived from both humans and non-human species. Pathways are colour-coded according to their major neurotransmitters. Direct efferent pathways from the brainstem are represented using heavy solid lines; other efferent pathways are represented using heavy dotted lines; afferent projections to the brainstem are represented using fine lines. It is likely that most of these pathways are functionally bi-directional. The pedunculo-pontine nucleus, locus coeruleus, median raphe and central reticular nuclei can be loosely grouped on anatomical grounds as the 'reticular formation'. 5-HT, 5-hydroxytryptamine; ACh, acetylcholine; DA, dopamine; GABA,  $\gamma$ -aminobutyric acid; Glut, glutamate; NA, noradrenaline. represented, including cortico-basal degeneration (CBD), DLB and prion disease.

Cortical blindness may result from bilateral occipital lobe damage and involvement of lateral occipito parietal areas may be associated with denial of blindness or visual anosognosia (Anton's syndrome). Partial forms of cortical blindness affecting visual acuity, stereopsis or the discrimination of elementary visual patterns (form, colour or motion) also occur in PCA. Clinically, such deficits may mimic peripheral visual loss: patients may complain of blurred vision, decreased acuity or desaturation of colours. Letters of similar shape may be confused. Difficulties may be particularly apparent under conditions of reduced contrast or changing illumination. Misperceptions of visual information may occur; patterns on fabric or wallpaper may seem to shift and change, objects in the environment or body parts (especially faces) may appear distorted (metamorphopsia), abnormally persistent or transposed (palinopsia) or multiply reduplicated (polyopia).

Identification of visual objects may be impaired despite intact early visual processing. The patient may fail to recognise common household items or familiar people. There may be difficulty in distinguishing coins, banknotes or playing cards, and on examination the patient may be unable to identify fragmented, distorted or overlapping pictures or letters, silhouettes or unusual views (Figure 8.4). Such patients have apperceptive visual agnosia: this means an inability to form structural representations of visual objects, the distinctive geometric and volumetric features that enable object identity to be abstracted despite changing contexts and viewpoints. The anatomical substrates of early visual processing and object representation are likely to involve a cortical pathway extending from early visual cortices into parieto-occipital association areas. This pathway is vulnerable to various disease processes, such as infarcts, hypoxic damage and focal degeneration in PCA. Processing of complex objects such as faces involves the ventral 'what' visual stream in the inferior temporal lobe, including the 'fusiform face area'.

**Figure 8.4** An example of a test of visual apperceptive function (fragmented letters) for use at the bedside. Patients with visual apperceptive agnosia have difficulty identifying the letters when presented in fragmented form but can read them easily when presented in unfragmented form and (unlike patients with reduced visual acuity) may find the letters easier to resolve at a distance. Damage involving this region may lead to impaired face perception (prosopagnosia).

Deficits in the perception of visual space are more common than selective disorders of visual object processing. These deficits interact with mechanisms for spatial attention, which are generally more severely affected in focal brain lesions such as stroke involving the parietal lobes. However, visuo-spatial deficits are often prominent in dementias affecting the posterior cerebral hemispheres such as AD and DLB. Visuo-spatial disorders can be broadly classified as visual disorientation, the impaired perception of space relative to self (egocentric space), and visuo-spatial agnosia, the impaired perception of spatial configurations that are not referenced to one's own position (exocentric space). Patients with visual disorientation may be unable to locate objects such as cutlery immediately after they are put down or when the item is in front of them, and typically misreach for items. Threading a needle, reading lines of text, writing, using an index or even keeping within traffic lanes when driving may become impossible. Accidents when walking or driving are common, because of loss of the ability to judge distances or motion. Ultimately, such individuals become functionally blind. On examination, these patients have components of Balint's syndrome: fragmented perception of the visual field (simultanagnosia), inability to perform visually guided movements (optic ataxia) and/or inability to direct the eyes to a point in space (ocular apraxia). Because of the retinotopic encoding of egocentric space, these deficits frequently resemble hemi- or quadrantanopic field defects.

Patients with visuo-spatial agnosia may be unable to orient clothing when dressing, a camera when taking a photograph or an envelope when posting a letter. Loss of the ability to tell the time from a clock is characteristic. Patients are commonly unable to navigate familiar routes, and become lost in the neighbourhood or even within their own house (topographical disorientation). Skills such as reading text or maps, writing and calculation, which depend on accurate perception of spatial patterns, are often degraded. On examination, copying and constructional tasks are poorly performed and there may be specific deficits of spatial discrimination or spatial search (such as counting dots in an array). Anatomically, visuo-spatial deficits are associated with damage to the superior and posterior parietal lobes, within the dorsal cortical 'where' visual processing stream.

Perceptual defects in cognitive disorders are not confined to the visual domain. Cortical deafness is a rare accompaniment of bilateral damage involving auditory cortex and ascending auditory pathways, and auditory agnosia for complex sounds such as music

and environmental noises may occur with diseases involving either temporal lobe. Loss or distortions of taste (dysgeusia) occurs with damage involving the gustatory pathways and cortex in the region of the insula. Olfactory identification deficits may occur early in the course of AD, Parkinson's disease and other degenerative dementias, and are likely to be at least partly central in origin. Disorders of cortical somatosensory function such as impaired perception of shape (astereognosis) and spatial configurations on the body surface (such as drawn numbers: agraphaesthesia) and impaired recognition of objects by touch (tactile agnosia) may occur with both acute damage involving the parietal lobes and in degenerative conditions such as CBD.

### Hallucinations

Hallucinations are perceptual experiences in the absence of an external sensory stimulus. They may occur in normal individuals under conditions of fatigue or sensory deprivation, or at the onset of sleep (hypnagogic hallucinations). In organic brain disease, hallucinations occur most commonly in the visual modality, and are a frequent feature of delirium. However, hallucinations in other disease states and in non-visual modalities are well recognised (e.g. olfactory hallucinations in temporal lobe epilepsy). Complex verbal (auditory) hallucinations are typical of psychiatric disorders such as schizophrenia but distinctly unusual in organic disease. Visual hallucinations can arise from a variety of insults at different stages of the retino-calcarine and cortical ventral visual pathways. Hallucinations may arise from two general mechanisms: abnormal release of sensory cortex because of loss of sensory inputs from the periphery or other regulatory controls, or abnormal excitation or disinhibition of sensory cortex by irritative processes such as seizures or migraine. Deafferentation of early visual cortex in the setting of peripheral visual loss may be associated with isolated well-formed visual hallucinations in the absence of cognitive decline (Charles Bonnet syndrome). An analogous auditory mechanism may produce musical hallucinations in acquired deafness. Damage involving the ventral midbrain may produce vivid 'dream-like' peduncular hallucinations of cartoon-like images or complex scenes, resulting from dysfunction of the reticular activating system. Structural or functional lesions involving early visual cortices may produce elementary visual hallucinations (exemplified by 'fortification spectra' or teichopsia in migraine) while more complex or multimodal hallucinations, sometimes involving distortions of self-perception, may occur in the setting of temporal lobe disease.

Visual hallucinations are modulated by dysfunction of neurotransmitter pathways. Hallucinations are particularly striking and complex in diseases such as DLB in which there is a cortical deficiency of acetylcholine. Descriptions of hallucinations are often remarkably stereotyped: the patient typically sees unfamiliar people or animals (especially cats or other small creatures), mobile or stationary, often multiple, but generally silent. Hallucinations frequently appear in the evening or in darkness. They may be glimpsed transiently at the edge of view, or emerge from an environmental feature such as a piece of furniture or a garden scene. Extracampine hallucinations are associated with the sense of a presence beyond the field of view. The 'phantom boarder' delusion (the sense that there is another person in the house when there is not) may be a related phenomenon.

### Knowledge

The brain mechanisms that mediate the storage and retrieval of knowledge constitute those of semantic memory. The most striking and selective deficits of knowledge are produced by focal lesions involving the ventral visual pathways in the inferior temporal lobes and by focal degeneration of the left temporal lobe in semantic dementia (SD). In SD, disintegration of word knowledge produces a progressive impairment of word-finding and word comprehension which is generally the presenting and most prominent feature of the syndrome. Naming deficits are characteristically early and prominent; a generic or superordinate term is often used in place of the more specific one (e.g. 'animal' in place of 'camel'). These patients do not grasp the meaning of words and typically have particular difficulty with definitions.

The selective inability to associate visual representations of objects with meaning constitutes an associative visual agnosia, which may occur as a relatively isolated deficit with temporo-occipital lesions or may develop in the course of SD. As is the case for verbal knowledge, semantic deficits can be relatively specific for the visual domain. Patients may be unable to identify everyday objects or describe their function despite accurate and detailed analysis of perceptual features. Patients with prosopagnosia lose the ability to recognise familiar faces, including acquaintances, famous people or even close family members. The recognition deficit may be selective for faces, dissociating from other types of person knowledge and from other categories of knowledge.

Neocortical regions in the anterolateral and inferior temporal lobes are likely to be critical for conceptual knowledge. Impaired word knowledge in SD is associated with atrophy involving the dominant (left) anterolateral temporal lobe. Person knowledge is likely to be asymmetrically distributed between the right and left anterior temporal lobes, the left anterior and inferolateral temporal lobe representing verbal information (such as personal names) and corresponding regions of the right temporal lobe representing familiar face information. Progressive prosopagnosia has been described much less frequently than SD. This is likely to be at least partly attributable to the clinical silence of the right temporal lobe relative to the eloquent left temporal lobe.

### Voluntary action

Diseases that disturb the cognitive control processes involved in programming and guiding voluntary action produce apraxia: a disturbance of voluntary movement that cannot be explained by elementary motor or sensory deficits. The classification of apraxia poses conceptual and practical difficulties; however, a basic distinction can be drawn between disorders that affect unfamiliar, novel or

meaningless actions (ideomotor apraxia), and disorders that affect previously learned actions (ideational apraxia). Apraxia generally occurs in association with more widespread deficits involving the dominant parietal or frontal lobes; however, cases of primary progressive apraxia have been described.

Apraxia for novel and meaningless actions is a prominent feature of dementias such as AD that involve the posterior hemispheres, and in this setting there is often additional evidence of impaired visuo-spatial perception. Novel tasks requiring mechanical problem-solving (such as assembling prefabricated furniture or models) and learning new motor skills pose particular difficulties. The patient has difficulties in imitating the examiner's meaningless hand positions. There may be particular difficulty when movements must be combined into a short sequence. Characteristically when attempting to imitate a gesture the patient will attempt to put their own hand into the space occupied by the examiner's (analogous to overlaying the drawing when attempting to copy a design): the 'closing-in' phenomenon.

Less commonly, apraxia leads to impaired production of actions previously learned. Manual occupations and hobbies may be abandoned, and the patient may be unable to use common household tools and utensils, or attempt to use them inappropriately (e.g. attempting to write with scissors). When instructed to perform a symbolic gesture (such as waving goodbye or saluting) or to pantomime the use of a tool (such as a screwdriver or hammer) an awkward or fragmentary approximation may be produced. Both the configuration of the fingers and the movements themselves are typically abnormal. Action production may be facilitated by holding the corresponding tool or other contextual cues. In addition, the patient may fail to recognise familiar gestures mimed by the examiner.

Apraxias affecting specific parts of the body are well recognised. Asymmetric limb apraxia is a cardinal presenting feature of CBD, where it is characteristically accompanied by asymmetric rigidity and other extrapyramidal or cortical sensory signs. Actions involving the affected limb comprise coarse, uncoordinated or mutilated constituent movements, sometimes termed limb-kinetic apraxia. Impairments affecting the voluntary control of orofacial movements often dissociate from disorders of limb praxis. Orofacial apraxia is frequently observed in association with impaired speech production. The patient may lose the ability to whistle and may complain of difficulty initiating chewing or swallowing. When instructed to cough, yawn or sigh the patient may produce an inadequate facsimile or simply repeat the instruction emphatically; however, these actions are typically normal when performed spontaneously and the examiner's orofacial gestures may be imitated competently.

So-called constructional apraxia, impaired ability to copy drawings of objects or designs, is observed both with focal lesions and degenerative diseases variously affecting visuo-spatial perception, spatial attention and executive processes. In the majority of cases it is likely to be multifactorial in origin rather than representing a specific disorder of voluntary action. Similar reservations apply to several other disorders, including dressing apraxia which is probably largely attributable to deficient visuo-spatial analysis, and apraxia of eyelid opening which in many cases has the features of a focal dystonia. The true status of gait apraxia, the selective impairment of walking (and often other axial motor programmes), remains somewhat controversial, as gait abnormalities may arise at various levels of the motor hierarchy. However, it is observed in association with focal lesions and degenerative processes affecting the frontal lobes and subcortical projections (as in hydrocephalus).

Patients with asymmetric limb apraxia may have difficulty in making cooperative movements using both hands because the more affected hand tends to mirror the other or otherwise interferes with the action: the alien limb phenomenon. The patient may complain that the affected arm is useless or seems not to belong to them, and the arm may tend to levitate or assume other odd postures (especially when attention is diverted or during walking). Forced grasping or reaching for objects in the immediate environment may occur, or there may be more organised purposeless actions such as repeatedly removing and replacing spectacles. Among the dementias, the most characteristic association is with CBD, although other pathologies have been described.

The neural control mechanisms for the control of voluntary action are distributed within a network of cortical and subcortical areas, and mixed forms of limb apraxia are common. Conceptual knowledge of gestures is likely to be mediated at least in part by the dominant temporal lobe, while the left parietal lobe is likely to have a key role in the integration of sensory information in the organisation of actions. An anterior system for the production of gestures may represent motor programmes for action in each hemisphere, and predominantly unilateral damage involving this system may lead to asymmetric limb-kinetic apraxia involving either side. Orofacial apraxia is associated with focal lesions or degenerative syndromes (such as progressive non-fluent aphasia) with asymmetric atrophy predominantly involving left inferior frontal and opercular regions.

### Speech and language

The complex operations of human speech can be broadly classified as sensory decoding, comprehension, repetition, retrieval and production. Each of these operations can be considered at the level both of single words and sentences. These different operations are affected in a variety of acute and chronic cognitive disorders. Speech and language impairments (the dysphasias) are most commonly the result of focal lesions affecting the cortex of the dominant (left) cerebral hemisphere, but the recent recognition of focal 'language-based' dementias has revolutionised contemporary thinking about the degenerative brain diseases. Classic concepts of the human language system such as that of Lichtheim posited a cortical centre for word concepts connected by transcortical pathways with a posterior centre for processing word sounds and an anterior centre for programming speech output. This model has undergone considerable refinement in recent decades, influenced by functional imaging studies in healthy individuals as well as clinical observations in both stroke and focal cortical degenerations. The basic bedside distinction between fluent ('Wernicke's', 'sensory', 'posterior') and non-fluent ('Broca's', 'motor', 'anterior') dysphasia remains useful; however, it is not absolute clinically, anatomically or pathologically. Because of its quite different anatomical and clinical significance, it is important to distinguish fluent dysphasia from confusion (e.g. in the context of delirium); this can usually be accomplished by a careful analysis of the patient's spontaneous speech, in particular the presence of speech errors (paraphasias).

Comprehension of speech depends fundamentally on the accurate decoding of the acoustic signal at the level of its constituent sounds. In the setting of acute disease such as stroke, impaired speech comprehension or Wernicke aphasia is generally associated with damage involving Wernicke's area in the dominant posterior superior temporal lobe. However, the true functional and anatomical status of this area remains contentious. Selective impairments of speech perception manifesting as word deafness have been

described rarely with acute bilateral or left-sided damage and degenerative disease affecting the posterior temporal lobe. Such patients have difficulty both in understanding and repeating spoken words despite normal comprehension of written material. Impaired comprehension of single words in the setting of intact acoustic analysis and repetition constitutes a transcortical sensory aphasia, originally described with posterior watershed infarcts. However, a similar syndrome is associated with breakdown in verbal knowledge systems in SD, suggesting an important role of the left anterior temporal lobe in normal language processing which is more difficult to reconcile with classic models of language organisation derived from the study of stroke and other acute lesions. Impaired sentence comprehension occurs in dementias such as progressive non-fluent aphasia (PNFA) in which there is disturbed processing of grammatical structure. Functional disconnection of posterior (input) from anterior (production) language areas produces a selective impairment of speech repetition or conduction aphasia, observed chiefly with focal damage involving the left parieto-temporal junction and the arcuate fasciculus.

Impaired word retrieval leads to word-finding pauses or circumlocutions in everyday conversation and a reduced ability to name (anomia). It is most often studied using confrontational naming tasks, in which nouns must be produced in response to pictures or other stimuli. Failure of retrieval in this situation is characteristic of anomia, which may be associated with a variety of focal lesions affecting the language system (e.g. during the recovery phase of stroke). Progressive anomia is a hallmark of SD; however, naming (and, more generally, word retrieval, often known loosely as nominal aphasia) deficits are also observed in AD and many other dementias. It is important to appreciate that confrontational naming depends on many distinct subprocesses, including intact perception and executive function, and intact connections between the cortical areas mediating these functions. This is illustrated by naming impairment resulting from visuo-perceptual deficits in PCA, and modality-specific impairments (e.g. optic and tactile anomia) with focal lesions interrupting transcortical and interhemispheric sensory pathways. Normal propositional speech involves not simply the retrieval of individual words, but the construction of a sentence that conveys an idea or message. Disruption of the process of message generation produces dynamic aphasia, with characteristics similar to transcortical motor aphasia: reduced spontaneous propositional speech despite the ability to produce speech relatively normally in specific contexts such as naming, repetition or reading. Dynamic aphasia has been documented with focal lesions and dementias that damage frontal or fronto-subcortical circuitry.

The spoken output of words and sentences in turn requires a number of distinct operations. The components of the verbal message must be combined according to morphological and syntactic rules. The breakdown of grammatical output (syntax) is a hallmark of Broca's aphasia, observed classically with focal lesions involving the inferior frontal gyrus of the dominant hemisphere. As is the case with Wernicke's area, however, the true functional role of Broca's area has not been fully clarified and should not be equated simply with language output. Broca's aphasia is characterised by effortful, dysfluent and agrammatic speech with a disjointed and telegraphic quality because of omission of verbs, prepositions and other function words. The production of single words involves both the selection and grouping of appropriate syllable codes (phonology) and the articulation of the corresponding motor programme. Progressive breakdown in either or both of these operations commonly occurs in PNFA, and in other disorders such as

CBD and motor neurone disease dementia. This syndrome includes relatively pure cases of cortical anarthria. Phonemic paraphasias (such as 'stirel' for 'squirrel') are often accompanied by articulatory errors. Prosody, the pattern of stress and timing that constitutes the melody of speech, is frequently abnormal. It is also important to distinguish dysfluency resulting from a primary disorder of speech production from interrupted output resulting from prolonged word-finding pauses ('logopenic' aphasia), which may occur in other conditions including AD. The spontaneous production of novel non-words (neologisms) and jargon may accompany fluent aphasia in acute disorders but rarely in degenerative disease.

Disorders that produce selective impairments of speech processing are associated with focal lesions or asymmetric atrophy predominantly involving the left peri-sylvian region. Deficits of speech perception are associated with damage involving the left posterior superior temporal gyrus, a region that includes early auditory areas. Impaired syntactic comprehension has been correlated with involvement of the left posterior temporo-parietal region. Impaired word retrieval occurs with interruption of a distributed asymmetric (predominantly left-sided) brain network including left lateral temporal cortex, left inferior and lateral frontal areas. Partially overlapping regions including the left inferior frontal gyrus, frontal operculum and anterior insula have been identified in group and single-case studies of speech production breakdown in stroke, PNFA and other disorders, implicating these dominant anterior regions in the motor programming of speech. The basal ganglia, thalamus and subcortical pathways in the dominant hemisphere participate in distributed cortico-subcortical networks mediating language and speech, and focal lesions involving these structures may closely resemble the corresponding cortical functional deficit.

### Literacy and numeracy

An individual's premorbid level of literacy and numeracy is heavily influenced by educational attainment and potentially by specific long-standing limitations such as developmental dyslexia or dyscalculia. Such factors must be taken into account when interpreting the effects of disease.

A basic distinction is often made between reading disorders that occur without writing impairment (alexia without agraphia) and those that are accompanied by writing impairment (alexia with agraphia), originally described with acute lesions such as stroke affecting the posterior cerebral hemispheres. Alexia without agraphia is classically produced by the conjunction of a right homonymous hemianopia and damage involving the posterior corpus callosum, precluding the transfer of information from the left hemi-field (right occipital lobe) to the verbal left hemisphere; alexia with agraphia results from more extensive lesions involving the posterior left hemisphere. An alternative classification of the dyslexias is based on the cognitive operations involved, whereby disturbed visual analysis of written words produces a peripheral dyslexia (often with preserved writing ability) and disturbed analysis of written words for sound or meaning produces a central dyslexia (often with associated deficits of written output). Impaired visual analysis of written words or peripheral dyslexia is often a prominent feature of PCA, in which associated visuo-perceptual and visuo-spatial impairments are common. These individuals typically read letter by letter. Central deficits of written word processing beyond the stage of visual analysis fall into two general categories, which may dissociate: these correspond to two parallel routes to reading, based on analysis for sound (the phonological encoding of print-to-sound correspondences) and analysis of

meaning (sight vocabulary). If reading by sound is damaged, there is a failure to use the general rules of phonological encoding (phonological dyslexia). These patients have particular difficulty reading meaningless words, grammatical function words (e.g. 'and', 'if', 'for') and morphological features such as tense or plurals. If reading by sight vocabulary is damaged (surface dyslexia), there is reliance on reading by sound. Irregular words are incorrectly regularised according to surface orthographic features (e.g. 'yacht' may be pronounced 'yached'), while regular words are read correctly. Impaired reading by sight vocabulary is a frequent and characteristic feature of SD.

Visually based (peripheral) dyslexia is associated with bilateral or predominantly left-sided occipito-temporo-parietal damage or specific involvement of the ventral visual pathway. In central dyslexia, impaired reading by sight vocabulary is associated chiefly with degeneration of the left anterior and inferior temporal lobe, in common with other components of the SD syndrome, while impaired reading by sound is associated with pathology in left peri-sylvian language regions.

Impairments of writing and spelling (the dysgraphias) can be broadly classified according to whether the core defect lies with spelling processes (central dysgraphias) or the motor programming and execution of writing (peripheral dysgraphias). As is the case for the dyslexias, mixed forms are common. Spelling can proceed via sound-based (phonological) and vocabulary-based routes, and central dysgraphias affecting each route have been described in patients with dementia. Impaired spelling by sound (phonological dysgraphia) is associated with particular difficulty writing grammatical function words and word endings. The breakdown of vocabulary-based spelling (surface dysgraphia) manifests as regularisation errors in rendering exception words (e.g. 'juice' may be spelled 'juse') while phonologically regular words are spelled correctly. Impaired spelling vocabulary is a characteristic feature of the SD syndrome, but also occurs commonly in AD and in other dementias. The various stages of letter shape selection, formation, placement and sequencing that underpin the motor output process of writing may be deranged in disease processes that disrupt visuo-spatial analysis or voluntary action. Dysgraphia is generally a feature of diseases involving the left parietal lobe; however, surface dysgraphia is associated with surface dyslexia and other features of SD in the setting of left temporal lobe atrophy.

Disorders of calculation can be classified according to whether the core defect lies with computation proper or with the procedures required to process written and spoken numbers. Patients typically complain of a loss of facility in handling change or household accounts, and may have relinquished these responsibilities to others. There may be specific difficulties in adding scores and calculating totals in games, in using measuring instruments, or in reading and writing numerals and number words (e.g. when issuing a cheque). Like dysgraphia, dyscalculia is often a prominent feature of diseases affecting the dominant parietal lobe. The association of dysgraphia and dyscalculia with finger agnosia and right-left disorientation is known as Gerstmann's syndrome (Chapter 4), although it is unlikely this particular constellation has special significance other than implicating the dominant angular gyrus.

### Executive function

The generation of complex behaviour demands that many cognitive operations are combined, coordinated, adapted to different contexts and directed to relevant goals. The regulatory and supervisory

brain mechanisms that achieve this together constitute the cognitive executive. These mechanisms reside chiefly in frontal lobe cortex and its subcortical connections, and indeed the recognition that frontal lobe damage may produce profound alterations in conduct and personality (as in the celebrated case of Phineas Gage) was one of the cornerstones of modern behavioural neurology. However, it is important to recognise that executive dysfunction and frontal lobe impairment are not equivalent concepts. The cognitive and anatomical organisation of the executive remains poorly understood: while it is possible to identify broad syndromes of executive dysfunction, in clinical practice these almost invariably overlap. Executive impairments are produced by a very wide range of acute and chronic diseases.

Perhaps the most striking frontal lobe syndrome is characterised by loss of capacity to gate or modulate the effects of cognitive inputs according to the overall context. Patients with impaired response modulation have particular difficulty in taking account of feedback or assessing the consequences of their own behaviour. Affected individuals almost invariably lack insight into their difficulties, but a change in the patient's personality is all too evident to others, and is accompanied by poor social judgement and inappropriate behaviour or insensitive remarks. Disinhibition and impulsivity may disrupt personal and occupational relationships. There is a reduced capacity for abstract thought, and patients typically display an inflexible and concrete approach to occupational and daily life tasks. Defective processing of social signals may contribute to impaired understanding of the mental states of self and others ('theory of mind'). Checking or counting routines, ritualised daily routes and schedules, clock-watching and hoarding are common. Analogies and similarities may not be recognised, and proverbs interpreted literally (e.g. 'People in glass houses shouldn't throw stones' meaning 'that the glass will break'). The ability to formulate a strategy for searching cognitive or sensory inputs is often compromised: this commonly manifests as reduced verbal fluency (the number of words generated in 1 minute according to a specified criterion, usually semantic category or initial letter).

An impaired ability to generate behavioural outputs leads to a loss of autonomy and increasing dependency on environmental cues and events to initiate behavioural subroutines. Apathy (abulia), inertia, passivity, perseveration, and motor and verbal stereotypies are common features of this syndrome. Left undisturbed, patients may contentedly spend all day watching television or absorbed in jigsaw puzzles or word games, and they may be disengaged from these activities only with difficulty. Loss of initiative commonly extends to household tasks and personal hygiene. There may be utilisation behaviour (e.g. the patient may don spectacles or peel a piece of fruit automatically when the item is placed before them), hyperorality (sometimes including mouthing of inedible items) or mimicry of others' speech (echolalia) or actions (echopraxia).

Slowness of thought (bradyphrenia) and difficulty in switching between behavioural subroutines or 'sets' spontaneously or according to context are hallmarks of fronto-subcortical damage. There may be perseverative errors on attempting to draw a sequence of alternating shapes or produce a sequence of alternating hand movements. Palilalia (repetition of the patient's own words or terminal phrases) also occurs.

Executive difficulties are exposed by tasks that demand planning, abstract thought, flexibility and consideration of alternative solutions. There is often little consistency between tests or even between

testing sessions in the individual patient. Characteristic features include implausible but over-precise estimates (distance from London to New York is '266 miles'), impaired performance on dual tasks (such as tracking a visual target while reciting a list of numbers), and difficulty grasping simple rules (sorting multi-dimensional items by size, shape or colour) or in devising a problem-solving strategy (such as the 'Tower of London' puzzle). More complex behaviours that underpin social cognition including the understanding of social signals (such as sarcasm) and other people's mental states can be assessed quantitatively using widely available tests such as the Awareness of Social Inference Test (TASIT) and the Reading the Mind in the Eyes test, though these are time-consuming to perform.

The anatomy and pathophysiology of executive dysfunction remains poorly understood, and there is little consensus regarding the neural correlates of core executive functions. A similar pattern of cognitive and behavioural impairments may be associated with variable findings on structural and metabolic brain imaging. Disinhibition, sociopathic behaviour and altered physiological drives broadly correlate with predominantly right-sided anterior temporal and inferior frontal lobe damage and hypometabolism, and abulia with dorsolateral frontal and anterior cingulate involvement. Disinhibition, impaired theory of mind and disturbed modulation of sensory inputs are associated particularly with orbitofrontal and ventromedial frontal damage.

## Emotion

Although they have traditionally been regarded as the domain of the psychiatrist, disturbances of emotion comprehension and expression are integral to many neurological disorders and are often closely allied with other behavioural and executive impairments, particularly those around social cognition and the understanding of others' mental states. Defective processing of emotions often has major social consequences. Poor understanding of the emotional states of people and animals, lack of empathy and reduced expressivity are often interpreted as coldness and lack of affection. Other patients display fatuous and puerile emotional responses. Paradoxically, there may be increased engagement with religious, philosophical or artistic pursuits. A dramatic illustration of the breakdown of normal emotion processing is the Klüver-Bucy syndrome, originally described in monkeys following bilateral temporal lobe ablation. The syndrome has been reported rarely in humans, but does occur in the context of acute destructive processes such as herpes simplex encephalitis, and is characterised by loss of normal emotional reactivity, abulia, altered sexual responses and hyperorality.

Disturbances of mood (in particular, depression and dysphoria) are commonly associated with stroke, temporal lobe epilepsy and head injury, and with AD and other degenerative disorders (Chapter 22). These affective changes are likely to be caused, at least in part, by damage involving limbic circuits (Chapter 2) and their neocortical projections. Specific deficits of emotion comprehension have been documented in both acute and chronic disorders with mesolimbic damage, and are a hallmark of certain degenerative diseases, notably FTD and Huntington's disease. A distributed predominantly right-sided frontotemporal network including the amygdala and orbitofrontal cortex is likely to be critical for normal emotion processing; this network is a plausible interface between primitive emotional states linked to biological drives and the neocortical cognitive machinery of complex goal-directed behaviours.

## Investigation of the patient with cognitive impairment

### Basic principles

The differential diagnosis of delirium and dementia is very extensive (Table 8.1), and a structured approach to the investigation of cognitive impairment is therefore essential. This approach should be tailored to the clinical problem at hand, guided by an accurate and complete history and examination (Tables 8.1 and 8.2). However, the first priority of investigation in every patient is to exclude a reversible condition. Most causes of delirium and a number of causes of dementia fall into this category, and delirium frequently supervenes on a background of more insidious cognitive decline in elderly patients and those with limited cognitive reserve. Accurate diagnosis, particularly in dementia, may have important implications for prognosis and possibly genetic counselling of other family members.

### Initial investigation

Initial investigations should be minimally invasive and directed toward the identification of reversible metabolic, infective, inflammatory and other systemic processes. A number of investigations are relevant in the initial approach to both acute and chronic impairment, especially where the precise time course is difficult to establish or more than one process is likely (Tables 8.3 and 8.4). A basic initial battery includes full blood count and differential, biochemistry including serum calcium, renal, liver and thyroid function tests, coagulation profile, serum B<sub>12</sub> and folate, inflammatory markers (erythrocyte sedimentation rate and C-reactive protein), an autoimmune screen (antinuclear factor), a chest radiograph, ECG and urinalysis. Clinical judgement is required in interpreting the significance of such screening results e.g. a low serum B<sub>12</sub> is common in the elderly, but it is rarely the sole cause of cognitive decline.

### Neuropsychometry

Neuropsychometry is an extension of the bedside cognitive examination and can be very valuable in characterising the cognitive profile in more detail (in particular, the identification of subclinical deficits that might not be volunteered in the history). It is most useful and relevant for the detection of change in cognitive function, either in assessing the effect of static insults, where ongoing deterioration is a diagnostic issue (typically, in the identification of dementia) or in assessing response to therapy. Many neuropsychometric tests provide quantitative and normative data that allow the individual's premorbid cognitive attainment to be estimated and their current cognitive performance to be measured in relation to a healthy age-matched population. Documentation of performance in particular cognitive domains allows the likely origin of the cognitive problem to be specified, because particular patterns of deficit have localising value (Table 8.2). A plethora of neuropsychological tests is available. These require a trained neuropsychologist to administer and interpret, ideally informed by a clinical summary that identifies the purpose of the referral and areas of chief concern. The timing of test administration should be considered carefully: it is rarely informative to perform neuropsychometry during a delirium or the acute phase of a stroke or head injury (because further alteration in cognitive state can be anticipated), or repeatedly within a short timeframe (because practice effects are likely to make interpretation difficult). The patient's age and level of education must always be taken into account and, as with any investigation, results

**Table 8.3** An approach to investigation of the patient with rapid onset cognitive impairment.

Associated features	Investigations
	<b>Screening investigations</b>
May have systemic symptoms and signs	Blood: full blood count, renal function, electrolytes, liver function, coagulation, glucose, thyroid function, ammonia, amylase, ESR/CRP, ANF urinalysis ECG, chest X-ray
	<b>Additional investigations</b>
Head injury, signs of raised ICP, focal cognitive deficit, neurological symptoms and signs, no systemic explanation, neurological assessment unreliable, headache, meningism, fever	Brain imaging: CT, MRI, MRI venography, angiography CSF examination, including cultures and viral PCR, septic screens, serology vasculitis screens, neoplasia screens
Recurrent attacks suspicion inherited disease	EEG, echocardiogram autoimmune, thrombotic screens, urinary catecholamines, serotonin metabolites, porphyrins, consider specialised metabolic screens
Drug use/possible toxic exposure	Rationalise medications Drug/toxicological screens
Poor nutrition	Nutritional screens
Pain sensory/sleep deprivation environmental factors	Identify source
Major affective disorder, psychosis not attributable to above; fugue state, factitious disorder	Psychiatric evaluation

ANF, antinuclear factor; CRP, C-reactive protein; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalography; ESR, erythrocyte sedimentation rate; ICP, intracranial pressure; MRI, magnetic resonance imaging; PCR, polymerase chain reaction.

should be interpreted in the context of the specific clinical scenario.

Brief mental state schedules such as the 30-point Mini Mental State Examination (MMSE; the Folstein test) are simple to administer at the bedside and give an overall snapshot of cognitive performance, but lack sensitivity for the detection of subtle or isolated cognitive deficits while depending heavily on particular domains, notably verbal processing. Such schedules may be of most value in charting change in cognitive function over time, although they remain crude indices. Frequently used standardised tests include the National Adult Reading Test (NART), which provides an index

**Table 8.4** An approach to investigation of the patient with dementia.

Associated features	Investigations
	<b>Screening investigations – all patients</b>
May have systemic symptoms and signs	Blood: full blood count, renal function, electrolytes, liver function, coagulation, glucose, thyroid function, ESR/CRP, ANF, syphilis serology, B <sub>12</sub> , folate, urinalysis ECG, chest X-ray, brain imaging: CT, MRI if available EEG
	<b>Additional investigations – selected patients</b>
Young onset, non-cognitive neurological features, family history	HIV serology, copper studies, slit lamp examination, consider specialised metabolic and genetic screens, muscle/axillary skin, marrow, liver biopsy
Rapid course, headache, meningism, fever other features atypical for common degenerations (including age <65, systemic features, neurological signs)	Vasculitis, auto-antibody screens (incl ANCA, APL, VGKC Ab, coeliac screens) antineuronal antibodies, other neoplasia screens (incl whole-body PET, CT) CSF examination (including cells, protein, glucose, oligoclonal bands, cytology, cultures; may include 14-3-3, S100, Whipple PCR, JC/other viral PCR, cryptococcal Ag, measles Ab, syphilis serology, TB and other special cultures) MRI FLAIR sequences, prion genotyping if suspect prion disease, tonsillar biopsy if suspect vCJD
Clinical seizures prominent fluctuation (not in context of DLB)	Prolonged EEG (if routine EEG not diagnostic) autoimmune, thrombotic screens echocardiogram, other vascular screens urinary porphyrins
Sleep disorder	Sleep study
Drug use/possible toxic exposure	Rationalise medications drug/toxicological screens
Poor nutrition, suspicion of deficiency	Nutritional screens
Major affective disorder, psychosis not attributable to above; fugue state, factitious disorder	Psychiatric evaluation
Suspicion of treatable (inflammatory) process when diagnosis not established by non-invasive means	Brain biopsy

Ab, antibody; Ag, antigen; ANCA, antineutrophil cytoplasmic antibody; ANF, antinuclear factor; APL, antiphospholipid antibody; DLB, dementia with Lewy bodies; FLAIR, fluid-attenuated inversion recovery; PCR, polymerase chain reaction; PET, positron emission tomography; vCJD, variant Creutzfeldt-Jakob disease; VGKC, voltage-gated potassium channel antibody.

of premorbid intellectual attainment, and the Wechsler Adult Intelligence Scale (WAIS; revised, WAIS-R), which provides a profile of a range of verbal and non-verbal abilities. A variety of quantitative memory tests are in use, including the Recognition Memory Test for words and faces, which provides measures of verbal and non-verbal material-specific memory. Automated tests such as the Cambridge Neuropsychological Test Automated Battery (CANTAB) are in widespread use, incorporating specific subtests (e.g. paired associative learning) with demonstrated sensitivity for detecting the early stages of AD. Many tests have been used to assess executive function, including the Wisconsin Card Sorting Test (which requires the classification of stimuli according to various implicit rules) and Raven's Progressive Matrices (a test of abstract pattern continuation that does not depend on verbal mediation); however, this is a notoriously difficult domain to quantify and results are heavily affected by deficits in other domains (e.g. visual

perception). Batteries to assess other functions such as visual object and space perception, praxis, naming and semantic knowledge are widely available.

### Brain imaging

Structural brain imaging is indicated in all patients with dementia, and in patients with delirium where no systemic cause is identified, or where focal cognitive or neurological signs, headache, evidence of raised intracranial pressure or head trauma are present. This may be particularly critical in situations where neurological status cannot be reliably assessed, for example in acute alcohol or drug intoxication, or where an acute process may have supervened on pre-existing cognitive impairment. Computed tomography (CT) is widely available, and is adequate for detection of hydrocephalus and focal intracranial lesions such as subdural haematoma, brain abscess and tumours. CT is specifically indicated for detection of

subarachnoid haemorrhage or intracranial calcification. However, magnetic resonance imaging (MRI) is distinctly superior for examination of the brainstem and posterior fossa structures, the basal ganglia and detail of cerebral white matter and the cortical mantle. In patients with dementia, T1 MRI sequences can be particularly valuable in detecting pathological atrophy: volumetric MRI employing thin slices can be used to delineate patterns of regional atrophy that may have diagnostic significance, while serial MRI has an increasing role in the assessment of progressive atrophy (both generalised and regional) for diagnosis and prognosis. T2-weighted sequences are used to assess white matter signal change and tissue oedema. Additional sequences may be useful for certain indications, for example fluid attenuated inversion recovery (FLAIR) sequences to assess basal ganglia and thalamic signal in suspected prion disease, and diffusion-weighted imaging (DWI) to detect acute ischaemic damage and prion disease with cortical diffusion signal change, reflecting spongiform histology.

Functional brain imaging techniques have a limited role in clinical practice. Metabolic imaging using single photon emission tomography (SPECT) or positron emission tomography (PET) may occasionally be useful in identifying regional functional changes in patients with frontal lobe syndromes and normal structural imaging; however, these techniques are not widely available and interpretation is difficult. The use of ligands to image amyloid is likely to become a useful adjunct in the investigation of AD.

### Electroencephalography

The EEG is generally of limited diagnostic usefulness in delirium, which is frequently accompanied by generalised slowing of cerebral rhythms indicating diffuse cortical dysfunction. As a tool for the detection of local pathology it has been largely supplanted by brain imaging techniques; however, it remains essential for the detection and localisation of seizure discharges (particularly in non-convulsive status epilepticus). In dementia, the EEG is often helpful in the differential diagnosis. Conditions such as AD with diffuse cortical dysfunction are frequently accompanied by degeneration or loss of the normal alpha rhythm, while in focal dementias such as FTD alpha rhythm is generally preserved at presentation. The EEG may also detect covert epileptiform changes in amnesic syndromes resulting from partial seizures, or periodic complexes in classic CJD, subacute sclerosing panencephalitis (SSPE) and other conditions with severe cortical derangement. Prolonged ambulatory or video-EEG may be indicated where there is strong suspicion of covert or unrecognised partial seizures.

### Cerebrospinal fluid examination

Examination of the cerebrospinal fluid (CSF) is indicated where CNS infection is suspected, provided no contraindications exist (Chapter 9). Lumbar puncture is also recommended for younger patients with dementia and in cases where there is an unusual presentation or rapid course, to exclude an inflammatory process. Suspicious features include a raised CSF cell count (pleocytosis), and/or unmatched oligoclonal bands (indicating local synthesis of immunoglobulin in the CNS). Polymerase chain reaction (PCR) can be used to amplify and detect viral and other infectious agent DNA. Cytological examination may reveal atypical or malignant cells. Elevated total CSF protein is a non-specific finding in isolation. Elevated protein 14-3-3 is associated with rapid neuronal destruction in classic CJD, while elevated S-100 is associated with gliosis. AD is associated with a reduction in CSF A $\beta$  1–42 and an

increase in tau, and diagnostically specific CSF protein biomarkers are increasingly entering routine clinical practice.

### Additional investigations

Additional investigations are dictated by clinical features in conjunction with the results of the initial battery (Tables 8.3 and 8.4). These may include vasculitic, infectious, autoimmune, neoplastic and toxicological investigations, and in younger patients, copper studies, white cell enzymes and genetic testing. HIV serology, although not routine, should always be considered, especially where risk factors exist. The more common familial dementias have autosomal dominant inheritance, and the diagnostic yield of genetic analysis is therefore likely to be higher in the younger patient with a positive family history (see Table 8.8); however, late onset cases of genetically mediated dementia do occur (e.g. in Huntington's disease) and the family history may be censored, incomplete or inaccurate.

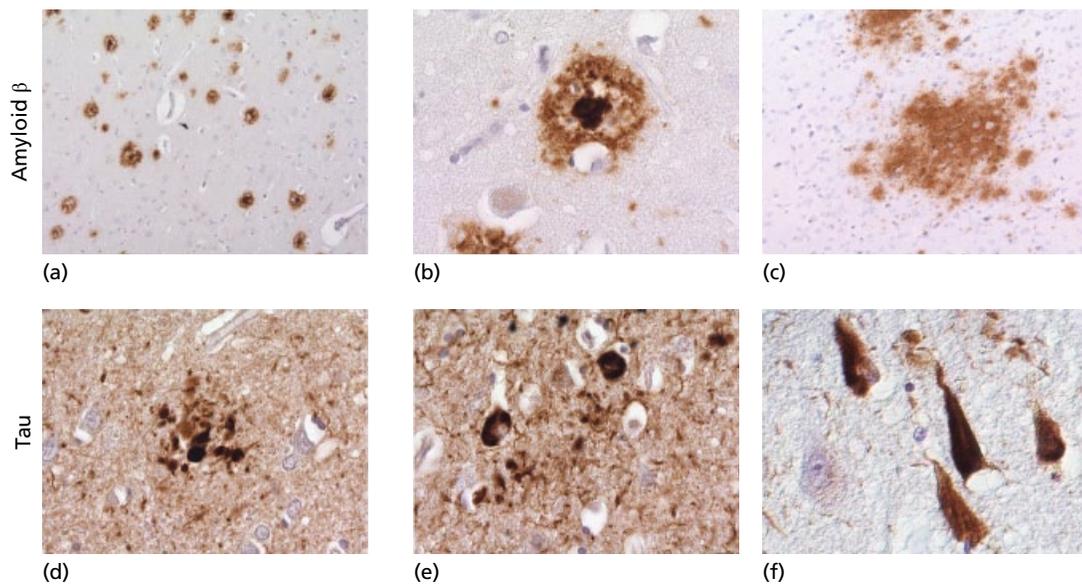

Tissue biopsy may be required to establish the diagnosis in a minority of patients with dementia, especially in younger individuals, as directed by clinical features (Tables 8.2 and 8.8). Skin biopsy (including apocrine sweat glands) may detect abnormal accumulations in Lafora, Kufs or other storage diseases and in CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy). Nerve biopsy may be diagnostic in rare dementias with peripheral nerve involvement. Muscle biopsy including histochemistry and respiratory enzyme analysis may confirm a mitochondrial disorder. Marrow biopsy may identify the 'sea-blue histiocyte syndrome' of Niemann–Pick disease type C and other storage diseases, and may also be indicated in the diagnosis of haematological and other malignancies in suspected paraneoplastic syndromes. Small bowel biopsy may be indicated to exclude Whipple's disease, and liver biopsy is occasionally indicated to exclude Wilson's disease. In exceptional cases, brain biopsy may be necessary where there is unresolved suspicion of a treatable (inflammatory or infectious) process where the diagnosis cannot be made by other means and potentially toxic treatment is contemplated. In some cases this is directed to a focal lesion; however, in most patients it is necessarily a 'blind' biopsy from the non-dominant frontal lobe. A full-thickness open biopsy including cortex, white matter and meninges should be performed by a neurosurgical team experienced in the technique. Disposable instruments should be used in cases where the risk of prion disease is considered clinically significant. Brain biopsy in patients with dementia carries an approximately 10% combined risk of significant morbidity or mortality, and should always be a carefully weighed decision.

## The dementias

### Alzheimer's disease

AD is the most common cause of cognitive decline with AD pathology, in part or in whole, underlying at least 50% of all cases of dementia. AD is the prototypical cortical dementia against which other dementias are compared in a differential diagnosis. An understanding of the clinical features and diagnostic approach to AD is central to being able to distinguish the different dementias.

The prevalence of dementia due to AD is strongly age-dependent – doubling every 5 years after the age of 60 years with around 1% of those aged 65–69 years affected rising to almost 20% in those aged 85 years or over. It is therefore important to have a low threshold of suspicion for cognitive decline in elderly patients who may not necessarily have cognitive problems as the presenting complaint;

**Figure 8.5** Alzheimer's disease: amyloid- $\beta$  (a, b, c) and tau deposits (d, e, f). Autopsy specimen with abundant amyloid plaques in the neocortex seen at low power magnification (a), which are predominantly mature (neuritic) plaques which are characterised by a dense core and a peripheral halo seen at high power magnification (b). Diffuse plaques or large protein deposits (c) are probably a precursor of core plaques and can also be found in the ageing brain without being necessarily associated with dementia ('pathological ageing'). Neurites crossing the plaque become dystrophic and contain hyperphosphorylated tau protein, as shown in (d). Tau immunohistochemistry also shows multiple intraneuronal inclusions, neurofibrillary tangles, which may assume various shapes: small globose perikaryal (e) band shaped, or flame shaped (f), all at high power magnification.

however, these (undeclared) impairments can complicate management of other neurological or medical conditions.

AD is also the most common cause of early onset dementia, arbitrarily defined as symptom onset before the age of 65 years. However, sporadic AD starting before the age of 50 years is very rare, and in these cases a genetic cause should, even in the absence of a family history, be suspected.

A definitive diagnosis of AD requires histopathological examination of brain tissue usually only confirmed at postmortem demonstrating excess accumulation of extracellular amyloid plaques and intracellular neurofibrillary tangles (Figure 8.5). In established AD, amyloid plaques are found widely distributed throughout the cortex with heaviest deposition in the cortical association areas. Amyloid may also be laid down in cerebral blood vessels leading to amyloid angiopathy. The key building block of the amyloid plaque is beta-amyloid ( $A\beta$ ), a 40–42 amino acid long peptide, formed following the cleavage of a much larger precursor polypeptide called amyloid precursor protein (APP) encoded by the *APP* gene on chromosome 21.

The relative proportions of parenchymal amyloid (plaques) and vascular amyloid (angiopathy) varies considerably between patients. In transgenic mouse models of AD, the relative proportions of these two forms of amyloid deposition seem to be related to the length of peptide generated by the pathogenic mutation, with a higher proportion of  $A\beta_{1-42}$  promoting parenchymal deposition whereas relatively greater amounts of  $A\beta_{1-40}$  leads to more vascular amyloid.

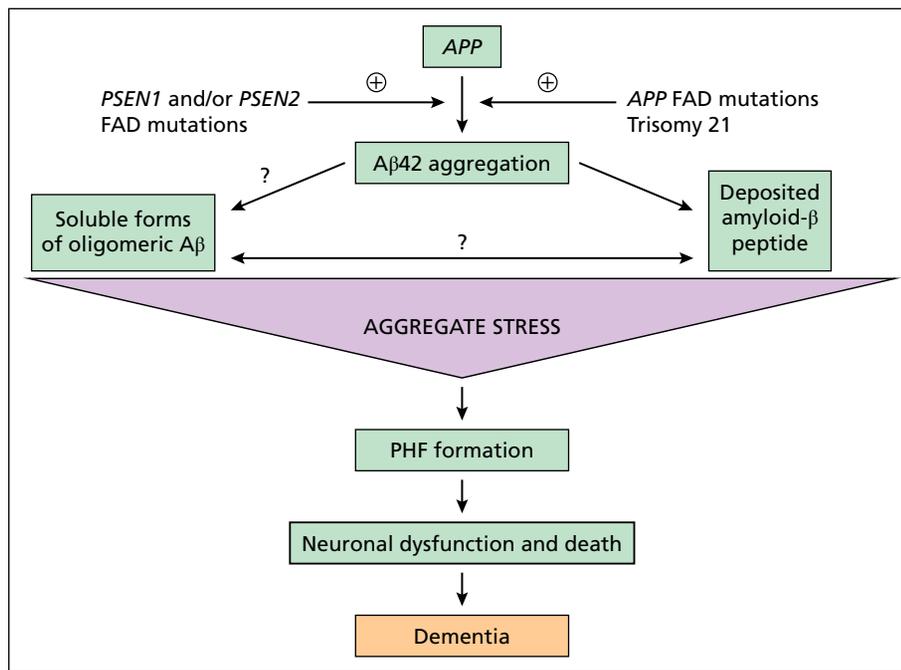

Neurofibrillary tangles result from the breakdown of the microtubule component of the neuronal cytoskeleton. Tau, a protein whose normal function is to promote and stabilise microtubule assembly, becomes hyperphosphorylated in AD and aggregates into an insoluble tangle of paired helical filaments (PHF) within the

neuron. Autopsy studies suggest that neurofibrillary tangles first appear in the entorhinal cortex before progressively involving the hippocampus and other limbic structures and then becoming widely distributed in neocortical association areas. Primary motor and sensory cortices are relatively spared.

The vast majority of AD is 'sporadic'; however, in a small number of cases there is a strong family history usually with an early age at onset. Mutations in three genes (*APP*, *PSEN1* and *PSEN2*) cause autosomal dominant AD with a high level of penetrance. Together these mutations account for only 1% of all cases of AD. They have contributed greatly to the understanding of AD and underpin the amyloid cascade hypothesis for AD pathogenesis and also led to transgenic models of disease (Figure 8.6).

*APP* mutations cause single peptide substitutions largely clustered around either end of the  $A\beta$  peptide – at sites of enzymatic cleavage from APP – and result in either greater amounts of  $A\beta$  or a greater proportion of longer  $A\beta$  peptide. This longer peptide has a greater propensity to aggregate into dimers, oligomers and then fibrils and ultimately amyloid plaques. Presenilin is a key component of the gamma secretase complex that cleaves the  $A\beta$  peptide, at its C terminus end, from APP – with pathogenic mutations also causing a higher proportion of longer and more amyloidogenic forms of  $A\beta$ .

Point mutations in the *APP* gene on chromosome 21 were the first genetic causes of AD to be discovered. These account for approximately 15% of autosomal dominant familial AD and produce symptom onset typically between 45 and 60 years of age. Trisomy 21 and *APP* gene duplications also cause early onset AD with a similar age at onset. Mutations in the presenilin-1 gene (*PS-1*) on chromosome 14 account for over 50% of all familial AD and overall have the youngest age at onset: typically between 35 and 50 years of age but some manifest as early as 30 years of age and may

**Figure 8.6** The amyloid cascade hypothesis posits that the deposition of the amyloid- $\beta$  peptide in the brain parenchyma is a crucial step that ultimately leads to Alzheimer's disease. Autosomal dominant mutations that cause early onset familial Alzheimer's disease (FAD) occur in three genes: presenilin 1 (*PSEN1*), *PSEN2* and amyloid precursor protein (*APP*). This hypothesis has been modified over the years as it has become clear that the correlation between dementia or other cognitive alterations and amyloid- $\beta$  accumulation in the brain in the form of amyloid plaques is not linear, either in humans or in mice. The concept of amyloid- $\beta$ -derived diffusible ligands or soluble toxic oligomers has been proposed to account for the neurotoxicity of the amyloid- $\beta$  peptide. These intermediary forms lie somewhere between free, soluble amyloid- $\beta$  monomers and insoluble amyloid fibrils, but the exact molecular composition of these oligomers remains elusive. Toxic, soluble amyloid- $\beta$  in different forms has been isolated from transfected Chinese hamster ovary cells transgenic mouse brains the human brain or it has been reconstituted *in vitro* under various experimental conditions. The amyloid cascade hypothesis now suggests that synaptotoxicity and neurotoxicity may be mediated by such soluble forms of multimeric amyloid- $\beta$  peptide species. The dynamic nature of these species and the poorly defined mechanism (or mechanisms) of toxicity make this topic particularly controversial in the field. Given this uncertainty, we prefer to use the term 'aggregate stress' to describe the potential mechanisms that may lead to amyloid- $\beta$  aggregation, the formation of paired helical filaments (PHFs) of tau aggregates and, ultimately, result in neuronal loss. A $\beta$ 42, the 42-amino acid form of amyloid- $\beta$ . Source: Karran *et al.* 2011. Reproduced with permission of Macmillan.

occasionally present after the age of 65 years. Mutations in presenilin-2 (*PSEN2*) on chromosome 1 are relatively rare as causes of AD; cases have a young, although variable age at onset.

The clinical features of familial AD are similar to each other and to sporadic AD although there are rare atypical presentations such as a spastic paraparesis in *PSEN1*. Therefore, in a patient presenting with cognitive decline suggestive of AD with a family history of early onset dementia, testing for mutations in all three genes is appropriate. Presymptomatic testing of 'at-risk' individuals from known pedigrees is also possible, with appropriate counselling. In a number of countries, pre-implantation genetic diagnosis is now available and relevant to mutations carriers or at-risk individuals thinking about starting a family.

Overall, a family history of AD in a first degree relative occurring at any age confers an approximately twofold increase in an individual's lifetime risk. This is largely because of the risk-modifying effect of the apolipoprotein E gene (*ApoE*). *ApoE* exists in three isoforms: e2, e3 and e4. The most common isoform is e3, with e4 being less common and e2 relatively rare. Inheriting a single e4 allele increases the risk of AD approximately two- to threefold and is associated with an earlier age at onset. This risk is dose dependent,

with e4 homozygosity being associated with a four- to eightfold relative risk, and a mean age at onset 5–10 years earlier than average. The e2 allele is relatively protective. However, the e4 allele is neither sufficient (in contrast to *APP* and *PSEN*) nor necessary to produce AD: approximately 20–30% of the general population carries one or more e4 alleles, and only 60–70% of all cases of AD have one or more e4 alleles. As a result, current consensus guidelines do not recommend testing for *ApoE* as part of the diagnostic work-up of a patient with possible AD. Recent genome-wide association studies have identified a number of genetic associations each with much lower relative risk than *ApoE*. With increasing longevity more and more people will have a family history of late onset AD; in most cases (e.g. a parent with onset in their seventies or eighties) it will be possible to reassure individuals that this confers very little additional risk and that genetic testing is not indicated.

#### Clinical features and assessment

The regional distribution and progression of the pathology of AD largely accords with the march of clinical symptoms, which start insidiously, and gradually and inexorably progress. Obtaining a reliable history is key to the diagnosis. Patients often lack insight and it

is essential to obtain a collateral history from a close informant. Partners or family members may not want to embarrass or contradict the patient and therefore, with the patient's consent, it is helpful to speak in part without the patient present in order to understand the extent of an individual's problems.

The most common complaint, often made by a carer, spouse or other family member rather than by the patient, is of problems with memory. Patients become repetitive in questioning, forgetting that they asked the same question recently, be it minutes, hours or days ago. Messages or errands are forgotten, there is progressive difficulty often with misplacing items (e.g. keys, glasses) and errors may be made in route finding. A particular early feature of the memory deficit is the inability to place memories correctly; thus, patients may remember that someone visited but be unsure of the context (when the visit happened or who else was there). While many of these symptoms may be reported during normal ageing or by patients later determined to be 'worried well', what distinguishes AD is the severity of the deficit and its inevitably progressive nature.

In neuropsychological terms, these early symptoms reflect impairment of episodic memory. Recall is usually worse than recognition memory and although patients commonly lack insight into the severity of their problems they are often aware that memory is a problem. This memory deficit is a harbinger of the progressive impairment of other higher cortical functions. However, an isolated memory deficit is not sufficient for a clinical diagnosis of AD. Historically diagnostic criteria for AD required dementia to be present before a diagnosis of AD could be made. Dementia by definition involves deficits in multiple cognitive domains of sufficient severity to impair activities of daily living. Recent advances in biomarkers have led to new criteria being proposed that allow a diagnosis of AD to be made prior to dementia if there is biomarker support. In particular, these criteria recognise that AD is very likely if memory deficits are accompanied by evidence of cerebral amyloid deposition, from CSF measurement showing low  $A\beta_{1-42}$  or from PET amyloid imaging; or a typical pattern of AD atrophy or hypometabolism (see Investigations). In the earliest stages, patients may have objective deficits of episodic memory without any other cognitive impairments and may have little problem continuing their activities of daily living. Amnesic MCI describes such individuals with objective impairment of memory (scoring 1.5 standard deviations below the age-related mean for healthy controls) but without dementia. Longitudinal studies have shown that patients fulfilling criteria for MCI develop AD at a rate of about 10–15% per year. However, MCI represents a heterogeneous group and includes individuals who score badly on tests of memory because of anxiety or depression and also individuals who have static deficits (e.g. resulting from vascular damage).

How best to identify those patients who will go on to develop AD is a major topic of research. Some factors in the history may provide clues: if the carer is more aware of the problems than the patient, the probability of the symptoms being caused by AD is more likely. Conversely, if it is the patient who is complaining more of their problems than the informant, an alternative non-neurodegenerative cause is more likely. Asking the patient and informant to provide detailed examples of memory problems is often helpful. It is clearly less significant if someone occasionally forgets a message or cannot remember where they have placed an item when they have been distracted, multi-tasking or simply not been giving it their full attention. However, it is of more concern if the carer reports salient information being forgotten (a conversation the day before) or more frequently repeating questions (e.g. the timing of hospital

appointments). It is also characteristic for problems to be apparently 'brought on' by a change in environment (e.g. hospitalisation) or illness – reflecting a reduced cognitive reserve that makes acute confusional states more likely.

There are a number of associated features that may accompany these early deficits. In particular, carers often report that the patient has become less confident, less spontaneous and more apathetic, and may seem depressed. Depression and AD commonly coexist and depressive symptomatology may mimic AD. It is sensible to have a low threshold for suspecting and treating depression, ideally avoiding antidepressants with anticholinergic activity. However, the presence, proportion and progression of cognitive deficits are the key to determining that depression is related to the onset of AD rather than an alternative explanation. A common complaint of relatives of patients with AD is that initial problems were attributed to depression, and the cognitive decline was overlooked because the informant's history was not properly considered.

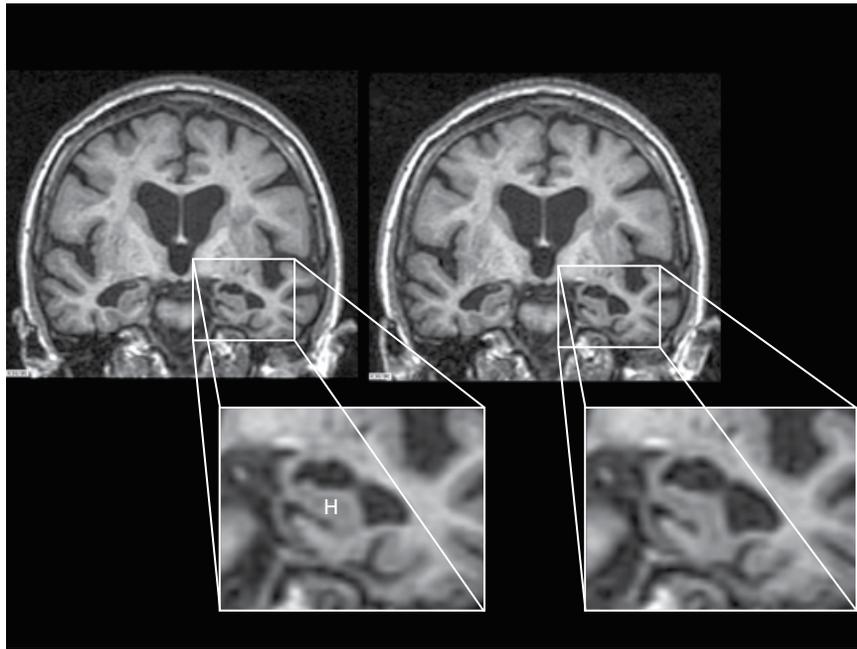

As the pathological process progresses beyond the medial temporal lobes, so too do the cognitive deficits. Patients with AD typically develop cortical deficits that are symmetrical, left and right hemisphere involved simultaneously, and generalised, posterior cognitive functions affected at least as much as frontal. The clinical assessment therefore should aim to assess the pattern of cognitive decline from the history, from bedside testing and, ideally, with formal neuropsychometry. In addition to memory and orientation problems there are often early subtle impairments of planning, decision-making and working out complex sequences, and learning new tasks (e.g. failures to master new equipment either at home or at work). The presence of posterior dysfunction (i.e. parietal and/or occipital problems – such as calculation, spelling, praxis or visual processing problems) should be sought, as this makes an alternative diagnosis of FTD less likely.

Unlike FTD or the frontal subcortical deficits of VaD, AD is not usually associated with marked behavioural and personality change in the early stages apart from a loss of confidence and some apathy. Thus, a useful contrast to FTD is that spouses of those with AD usually feel that the patient has essentially the same personality albeit less outgoing. While individuals with AD are less confident in a number of cognitive areas (especially memory), maintenance of a remarkably preserved social façade is a common feature whereas insight may be poor.

As the disease progresses, all these initially subtle cognitive deficits become more marked and generalised and behavioural problems become more common. More severe language problems develop, including naming difficulties. Carers often report that patients no longer read as much as they have before, often because of a combination of impaired memory for what they have read and difficulties following the plot. With time, problems with speech and naming become increasingly marked, eventually leading to significant impairment of communication.

There may also be a history of increasing difficulty in using tools or implements that had previously not been a problem. Problems with praxis, which may sometimes be picked up in the early stages as subtle difficulty in copying complex hand movements, become more obvious with time.

Visuo-spatial difficulties may manifest as a deterioration in an individual's ability to drive, more often reported by their passengers. Minor accidents may occur, as a consequence of misjudging distances or delayed decisions. This is compounded by a greater tendency to get lost in unfamiliar circumstances, and errors of

**Figure 8.7** Hippocampal atrophy. Two coronal T1-weighted MRI scans of a patient with probable AD: baseline on the left; follow-up 1 year later registered to baseline. The inset shows a magnified view of the left hippocampus (H) with progressive atrophy over the year.

judgement. Therefore, patients with a diagnosis of AD and their carers must be reminded of their legal obligation to inform licensing authorities (DVLA in the United Kingdom) and depending on severity may need to be advised to stop driving. In the later stages, agitation is relatively common and occasionally aggression often associated with frustration may be a major problem. Delusions are common and can be particularly distressing for patient and carer. The kernel of the delusions can often be understood in the context of failing memory and reasoning abilities (e.g. delusions of theft are common as an inpatient).

In the early stages, there are generally no focal neurological signs and apart from the praxis problems mentioned earlier, the examination may be normal. Myoclonus (often most noticeable in the fingers) may occur later in the disease, although patients with autosomal dominant AD tend to have early and prominent myoclonus, often a harbinger of seizures later on. In the late stages, there may be a generalised increase in tone in a *Gegenhalten* fashion.

Brainstem and motor function are typically preserved when many higher cognitive abilities have been significantly degraded. Patients ultimately become unable to self-care but may still be capable of wandering, often with marked sleep-wake cycle reversal. In the later stages, problems with continence develop. Relentless progression leads to increasing dependency and institutional care. Diminishing capacity means that it is important for the person with AD to plan for the end of their life at an early stage. Symptomatic treatments may give a period of some months of apparent stabilisation of symptoms (see Management) but there is no evidence that current treatments alter the underlying disease progression. Seizures, when present, are usually a late feature. Swallowing difficulties can also develop and contribute to pneumonia, one of the most common causes of death. Survival is age-related (lower with older patients) but is typically 4–8 years from

diagnosis of AD although may be up to 15 years in a minority; survival from first symptoms is 2–3 years longer because of delays in diagnosis.

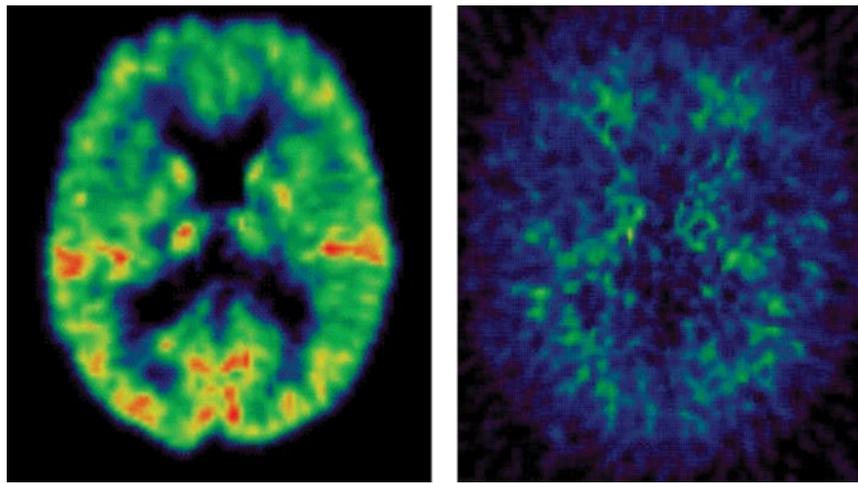

### Investigations

Apart from familial cases where demonstration of a pathogenic mutation in *APP*, *PSEN1* or *PSEN2* is diagnostic, there are no definitive laboratory tests for AD. It is therefore important to exclude, as detailed elsewhere in this chapter, alternative causes for cognitive decline.

A number of investigations have positive predictive value for AD. Neuropsychometry is important in establishing the extent and pattern of cognitive deficits, and in established cases typically demonstrating deficits in a broad range of cognitive domains, prominent problems with episodic memory and posterior dysfunction at least as significant as anterior without a marked left–right asymmetry.

Current (e.g. National Institute for Health and Care Excellence; NICE) guidelines suggest that all patients with dementia should undergo structural imaging (preferably MRI) as part of their diagnostic work-up. As with neuropsychometry, structural imaging, in addition to excluding a space-occupying lesion, can help in making a diagnosis of AD by identifying the pattern of atrophy. AD is associated with marked and disproportionate medial temporal lobe atrophy, which is most easily assessed by looking for evidence of bilateral hippocampal atrophy (Figure 8.7). AD is also associated with ventricular enlargement and generalised cortical atrophy symmetrically involving both parietal and frontal lobes. These findings are best seen with MRI using a coronal T1-weighted volumetric sequence.

Imaging, and in particular MRI (T2-weighted or FLAIR), can be used to assess the extent of cerebrovascular disease. Functional imaging, PET and SPECT, show symmetrical temporo-parietal hypometabolism and hypoperfusion. Nonetheless, the wide range

**Figure 8.8** The left image shows a positive amyloid (11C-PIB) scan with the cortical amyloid binding shown in red and yellow; this is typical of Alzheimer's disease (AD). On the right is a negative scan with only non-specific white matter binding. Both subjects had mild cognitive impairment and were of a similar age. The individual on the left progressed to AD dementia in the following year whereas the subject on the right has remained well with stable memory complaints.

of normality means structural or functional scans may be reported as normal in the early stages of AD. NICE guidelines recommend functional imaging (SPECT or PET) to be used to help differentiate AD, vascular dementia and frontotemporal dementia if the diagnosis is in doubt.

Amyloid imaging (with  $C^{11}$  or  $F^{18}$  PET ligands) has high sensitivity for the presence of cerebral amyloid. Asymptomatic amyloid deposition may precede dementia by up to a decade; 25% of healthy elderly individuals aged about 75 years have positive amyloid scans. Although currently mainly research tools they are likely to be used increasingly in clinical practice but may find most utility in younger patients; in older patients they may be most useful in ruling out AD if the scan is negative (Figure 8.8).

EEG may be important to exclude seizure activity as a relatively uncommon cause of memory impairment and, if this is suspected, prolonged recordings may be required. In AD the EEG typically shows generalised slowing and loss of alpha rhythm, although in mild cases may appear normal.

There is increasing interest in using CSF markers to differentiate AD from other neurodegenerative dementias. In AD the CSF is usually acellular with normal protein. CSF tau (total levels and specific phosphorylated forms) are increased in AD while CSF  $A\beta$  1-42 is reduced. The combination of these markers appears to differentiate AD from controls with sensitivity and specificity of approximately 90% but rather lower discriminatory ability to separate AD from other dementias such as FTD or DLB.

### Management

It is important that both patient and carer are considered in management. A holistic approach that covers social support, prognostic information and advice on legal, benefit and support issues is essential. Treatment of depression must not be missed. Specific symptomatic pharmacological treatments for AD are discussed later; these include the cholinesterase inhibitors and memantine, an NMDA antagonist.

AD continues to be the subject of intensive research. Drugs aimed at modifying the disease process are under development.  $A\beta$  immunotherapy has so far failed to show efficacy in Phase III

clinical trials. In mice such therapy has been shown to clear amyloid plaques from the brain and be neuroprotective if given before the onset of significant pathology. Other strategies include beta or gamma APP secretase inhibitors which aim to reduce  $A\beta$  production; or targeting tau or ApoE4.

**Cholinesterase inhibitors** The cholinesterase inhibitors (AChEIs) have been specifically developed as symptomatic treatment for AD. The rationale for their use is based on neurochemical findings in the cerebral cortex of patients with AD, in whom there is reduced activity of the enzyme choline acetyltransferase, with subsequent reduction in cortical levels of the neurotransmitter acetylcholine (ACh). By inhibiting the breakdown of ACh, AChEIs enhance the levels of ACh in cerebral cortex. There are currently three AChEIs licensed for the treatment of mild to moderate AD: donepezil (Aricept), galantamine (Reminyl) and rivastigmine (Exelon). Donepezil is a specific and reversible inhibitor of acetylcholinesterase (AChE); galantamine is a selective, competitive and reversible inhibitor of AChE, which additionally enhances the intrinsic action of ACh on nicotinic receptors; and rivastigmine inhibits both AChE and butyrylcholinesterase. They have similar symptomatic efficacy and there is no evidence of any disease slowing benefit. Once daily modified release formulations, oral solutions and patches are available.

The clinical efficacy of AChEIs has been measured using the Alzheimer's Disease Assessment Scale (ADAS-Cog), which assesses cognitive function, and the Clinician Based Impression of Change plus carer input (CIBIC-plus), which takes a more holistic view of the patient. A number of large randomised controlled trials have shown statistically significant, if clinically modest, symptomatic benefits of AChEIs on both ADAS-Cog effects and CIBIC over their 6-month duration, equivalent to a delay in symptomatic cognitive decline and temporary stabilisation of the patient's clinical and functional state. Further, in open label extensions of these trials effects have been reported to last up to 5 years, and Cochrane reviews report significant improvements on rating scales for activities of daily living and neuropsychiatric symptoms. Current NICE guidelines ([www.nice.org.uk](http://www.nice.org.uk)) for treatment with AChEIs (Table 8.5)

**Table 8.5** Summary of NICE Guidelines for treatment of Alzheimer's disease (November 2006).

NICE recommend donepezil, galantamine and rivastigmine as options for managing mild to moderate Alzheimer's disease (typically, but not exclusively MMSE >10/30) under the following conditions:

- Treatment should be initiated by specialists but may be continued by general practitioners using a shared care protocol
- The carer's views should be sought before and during treatment
- Patients should be reviewed regularly and treatment should be continued only when it is considered to be having a worthwhile effect on cognitive, global, functional or behavioural symptoms
- It is recommended that therapy should be initiated with a drug with the lowest acquisition cost (since there is insufficient evidence to differentiate between the AChE inhibitors in terms of cost effectiveness)
- Memantine is recommended as an option for managing Alzheimer's disease for people with: moderate Alzheimer's disease who are intolerant of or have a contraindication to AChE inhibitors; or severe Alzheimer's disease

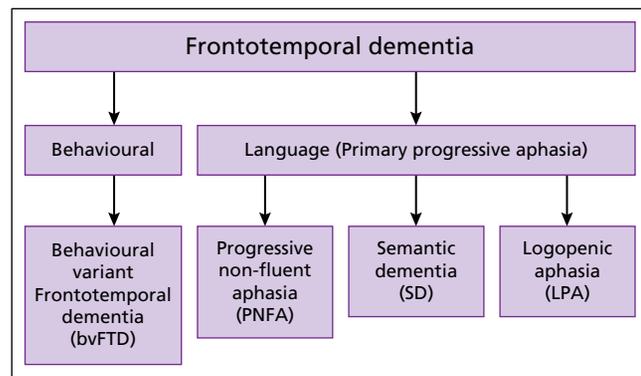

Source: <http://www.nice.org.uk/page.aspx?o=288826>. Reproduced with permission of NICE.

suggest that cholinesterase inhibitors should be used in mild to moderate AD and can be continued into the more severe stages of the disease as long as it is felt they are still providing benefit. Treatment should be stopped when benefit is no longer evident. This is often a subjective and difficult decision made by the clinician after discussion with the patient and carer, based on either a global impression or deterioration on a rating scale such as the MMSE. As AChEIs can provide other benefits, particularly on behavioural and neuropsychiatric symptoms, their effectiveness in all areas should be considered. If in doubt, the drug should be withdrawn for a few weeks and if there is rapid decline in behaviour and/or cognition, the drug should be restarted.

**Memantine** Memantine has an entirely different mode of action from the AChEIs, potentially preventing glutamate-mediated neurotoxicity. It is a voltage-dependent, moderate affinity, non-competitive *N*-methyl-D-aspartate (NMDA) receptor antagonist and blocks the effects of pathologically elevated tonic levels of glutamate by preventing calcium influx into the neurone. It has beneficial effects in slowing cognitive decline in mild to moderate AD, but also in vascular dementia and is generally well tolerated. It was previously licensed for use in moderately severe AD. It is currently used when AChEIs are thought to have lost efficacy, in AD patients intolerant of AChEIs or in whom these are contraindicated. There is some evidence that a combination of donepezil and memantine gives greater improvement in cognition, activities of daily living and neuropsychiatric symptoms than donepezil combined with placebo; however, combination therapy is not currently recommended by NICE. Side effects are uncommon; they include hallucinations, confusion, dizziness, headaches and tiredness.

### Frontotemporal dementia

Frontotemporal dementia (FTD) is an umbrella term used to describe a clinically and pathologically heterogeneous group of non-Alzheimer's neurodegenerative disorders, characterised by relatively focal frontal and temporal cerebral atrophy. The nosology

**Figure 8.9** Syndromic variants of frontotemporal dementia.

for this group of disorders is complex. Cases have been recognised since the nineteenth century, when Pick first described a case of dysphasia with focal temporal atrophy and historically his name was used to describe the entire group of disorders. Recognition of the different clinical syndromes led to a proliferation of descriptive names although for this chapter we use the descriptions as outlined in Figure 8.9.

FTD is less common than AD, with prevalence estimates of 4–15/100 000 under 65 years. In general, onset occurs between 50 and 70 years, with most patients surviving 6–12 years. However, onset can be much earlier (twenties) or much later (eighties) and is likely to be under-recognised.

In recent decades, the clinical and pathological complexity of these disorders has been better understood. There are three broad syndromic variants, each of which is associated with a distinct set of presenting symptoms. Over half of the patients present with behavioural change (behavioural variant FTD) and the remainder present with language decline often referred to as primary progressive aphasia (PPA). Traditionally, two subtypes of PPA have been described, those with impaired comprehension, naming and semantic impairment (semantic dementia), and those with impaired speech production (progressive non-fluent aphasia). However, more recently further subtypes have been described.

### Behavioural variant frontotemporal dementia

Patients with behavioural variant frontotemporal dementia (bvFTD) typically present with personality change and breakdown in behaviour, including apathy, disinhibition, loss of empathy and abnormal eating behaviour such as the development of a sweet tooth. Repetitive, obsessive or compulsive behaviours may also be seen. Early changes can be very subtle, and recognition of minor changes in social behaviour is important in detection of the problem, for example switching jobs, 'forgetting the rules' of social engagement or becoming more childlike. It is vital that the caregiver is interviewed as well as the patient, as frequently the patient lacks insight into the problem. Often, carers have recognised a change but have not realised why, for example in taste in clothes, in politeness with others or in developing obsessions about certain things.

As the disease progresses, disruptive behavioural symptoms usually worsen. Disinhibited patients often develop inappropriate antisocial behaviours, and may even be arrested for stealing or disorderly behaviour. Angry outbursts are common, and conversation can be punctuated by tactless remarks. When apathy is dominant, patients become progressively inert, robotic and emotionally detached. Such issues are distressing for the family, and greatly

increase the caregiver burden. Drug treatments or other mechanisms for dealing with these problems are unfortunately limited.

Often observation of the patient's behaviour during the consultation is more revealing than formal neuropsychology. They can show impulsivity, be easily distracted (e.g. by the computer screen saver in the office), they may be disinhibited towards the examiner, picking up things on their desk or show suggestive behaviour towards them. Neuropsychological testing early on can be remarkably normal. It may reveal executive dysfunction as the sole or most prominent finding, particularly within the first couple of years of disease onset. Specific deficits (and the neuropsychological instruments with which they may be detected) include a tendency to perseverate (verbal fluency), impaired planning (Wisconsin card sorting test), loss of inhibition (go-no-go task), sequencing (Luria's test), failure of recall with improvement on cueing (Wechsler Memory Scale), limited problem-solving (Raven's progressive matrices) and concreteness of thought (Cognitive Estimates test). In contrast to executive dysfunction, memory and posterior functions tend to be relatively spared. Social cognition (including theory of mind) is commonly impaired early in the disease process but is rarely tested in formal neuropsychometric batteries.

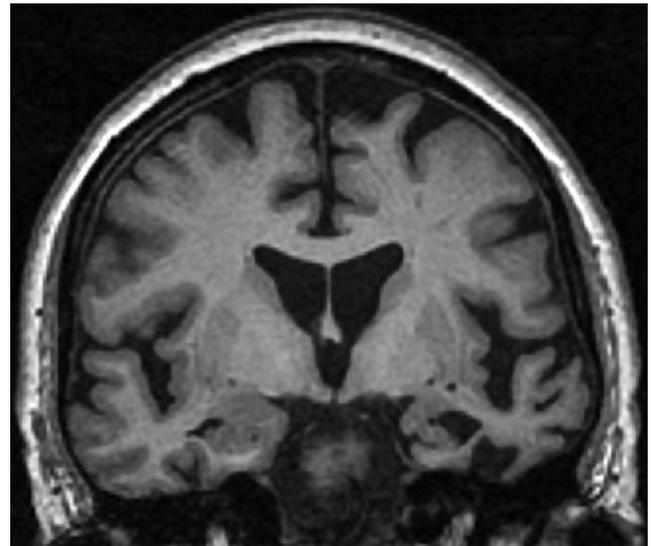

Imaging (MRI) may normal in the early stages, but usually reveals focal atrophy of the frontal and/or temporal lobes, often asymmetrical. Fluoro-deoxyglucose positron emission tomography imaging (FDG-PET) can be useful in patients where structural imaging is normal to reveal frontal hypometabolism.

A subgroup of patients with bvFTD present with behavioural symptoms consistent with the diagnostic criteria and yet do not seem to progress over many years. These patients are often men and commonly are in their fifties or sixties. They have been called FTD 'phenocopies' and have normal structural and functional imaging. The underlying cause is uncertain but may represent decompensation of a previous personality or autistic spectrum disorder.

### Semantic dementia

The onset of semantic dementia (SD) is insidious with a characteristic presentation of progressive deterioration in semantic memory. Patients may complain of 'memory' problems with words; the presenting feature is typically word-finding difficulty, especially problems with producing common nouns. During a typical consultation, if asked for example where they went on holiday, a patient might say 'what's a holiday?' – this loss of understanding of what a word means is pathognomonic of SD. Spontaneous speech is fluent and grammatically correct but empty of content, with word-finding difficulties, circumlocution, impaired confrontation naming and reduced verbal fluency, especially for conceptual categories (e.g. types of animal or vehicle). Typical responses when asked to name might be superordinate; for example, 'owl' becomes 'bird' or a description of the item is given that is autobiographical; for example, when asked to name a dog 'oh, you know, I see that every day next door; I like him'. Although verbal semantic impairment is usually predominant, with progression, semantic impairment of other modalities occurs, for example recognition of faces (prosopagnosia) or of visual objects (visual agnosia).

In contrast to the severe semantic deficit, phonology, prosody and grammar remain relatively intact. Other aspects of language become affected to a degree. Patients typically show surface dyslexia such that irregularly spelt words (such as 'sew' or 'pint') are read according to typical spelling-sound mappings (in this example, to rhyme with 'few' and 'mint'). Behavioural changes similar to those seen in bvFTD will develop as the disease progresses.

**Figure 8.10** Coronal section of T1-weighted brain MRI showing focal atrophy predominantly involving the antero-inferior left temporal lobe, a pattern typical of semantic dementia.

Other cognitive domains such as episodic memory, perceptual and visuo-spatial abilities are relatively preserved until late in the course of the disease.

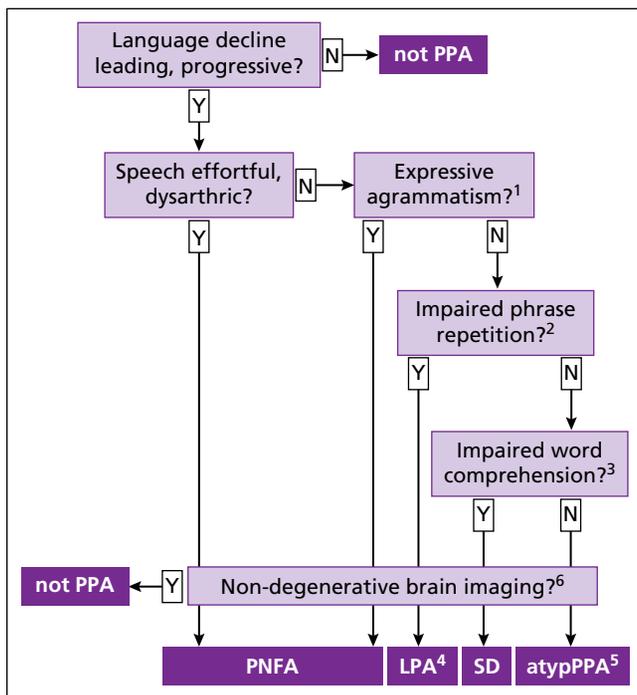

Imaging is particularly characteristic in SD. MRI of brain reveals severe asymmetrical antero-inferior temporal lobe atrophy, in particular affecting the fusiform gyrus (Figure 8.10). The temporal poles often appear as 'knife-blade'. Left temporal atrophy is dominant when the earliest symptom is one of verbal semantic loss, but when there is initial non-verbal semantic loss right temporal atrophy is present. In these right temporal cases, there may also be more evident behavioural change.

### Progressive non-fluent aphasia

Patients with progressive non-fluent aphasia (PNFA) have a non-fluent language disorder, a deficit that may remain circumscribed for many years. Patients produce hesitant, effortful speech (often called 'apraxia of speech') and/or agrammatism with the presence of phonemic errors. With agrammatism, phrases become telegraphic, sentences short and disjointed, and comprehension is often impaired at the sentence level. However, there is a strikingly preserved ability to understand individual words in the early phases of the disease. Writing is similarly affected in many cases. Insight is usually retained, often with extreme distress.

In addition to the language-specific features there may be an associated orofacial apraxia, which can be tested by asking the patient to cough or yawn. This can sometimes lead to difficulty swallowing. It is not until late in the course of the disease that overt behavioural features such as rigidity and loss of concern for others arise; however, there may be evidence of executive dysfunction on formal psychometric testing. MRI of the brain often shows dominant left peri-sylvian atrophy involving the inferior frontal and anterior insular cortex; however, findings vary widely.

**Other PPA syndromes** Logopenic aphasia (LPA, or the logopenic variant of PPA) is a recently described further clinical subtype of primary progressive aphasia and is worth differentiating as it is usually associated with underlying AD pathology. The presentation is

**Figure 8.11** Bedside clinical assessment of the progressive aphasia: a simple algorithm (informed by current consensus criteria for progressive aphasia) for syndromic diagnosis of patients presenting with progressive language decline. The clinical syndromic diagnosis should be supplemented by neuropsychological assessment, brain magnetic resonance imaging (MRI), and ancillary investigations including cerebrospinal fluid examination. atyp, atypical; LPA, logopenic aphasia; PNFA, progressive non-fluent aphasia; PPA, primary progressive aphasia; SD, semantic dementia.

- 1 Tense, telegraphic phrasing with errors of tense or function words.
- 2 Disproportionate to repetition of single (polysyllabic) words.
- 3 This can be probed by having the patient select a nominated item from an array or supply a definition. Associated semantic deficits should also be sought: in other language channels (surface dyslexia and dysgraphia); a tendency when reading aloud or writing to 'regularise' words according to superficial rules of phonemic correspondence rather than learnt vocabulary, such as sounding 'sew' as soo) and other semantic domains (such as by asking the patient to list visual attributes of an object or to indicate the purpose of a familiar household item from sight).
- 4 Third major subtype of progressive aphasia, in most cases a result of Alzheimer's pathology.
- 5 Atypical PPA variants represent a substantial minority of cases, including patients presenting with 'pure anomia' deficits primarily affecting language channels other than speech or relatively pure dysprosody.
- 6 Non-degenerative pathologies (such as brain tumours) should always be excluded on brain imaging.

Adapted from Warren *et al.* 2013 with permission of BMJ.

one of word-finding difficulties, anomia and poor working memory leading to difficulty repeating phrases rather than single words (Figure 8.11).

Recent studies have suggested that there may be other subtypes of PPA, with up to 20% of patients not fitting diagnostic criteria for SD, PNFA or LPA. In particular, there is some evidence that familial PPA syndromes are phenotypically distinct.

**Overlap with other syndromes** Neurological examination in FTD is usually normal, although there is overlap with other clinical syndromes including motor neurone disease and atypical parkinsonism, particularly PSP and cortico-basal syndrome. In FTD-MND, behavioural symptoms (or more rarely language problems) are present in conjunction with weakness and wasting in limb and/or bulbar muscles, although in the early stages the only sign of MND may be fasciculations. Around 10–15% of patients with FTD develop MND and, vice versa, 10–15% of patients with MND develop FTD (although up to 50% will develop cognitive impairment not meeting criteria for FTD).

### Investigations

These syndromes must be distinguished from non-degenerative processes such as primary psychiatric illness, tumours, vascular disease and from atypical forms of AD. Neuropsychological assessment can help define the phenotype and reinforce the clinical impression, especially detecting subclinical cognitive involvement and for documenting progression. Structural imaging with MRI can be helpful, commonly showing the characteristic imaging pattern of asymmetrical frontal and/or temporal lobe atrophy. Distinct patterns are seen in the PPA syndromes with asymmetrical (usually left predominant) anterior and inferior temporal lobe atrophy in SD, left inferior frontal, insula and peri-sylvian atrophy in PNFA, and left posterior temporal and inferior parietal atrophy in LPA. Increasingly, CSF A $\beta$ 1–42 and tau assays are used to diagnose underlying AD pathology in those cases where differentiation from FTD is difficult.

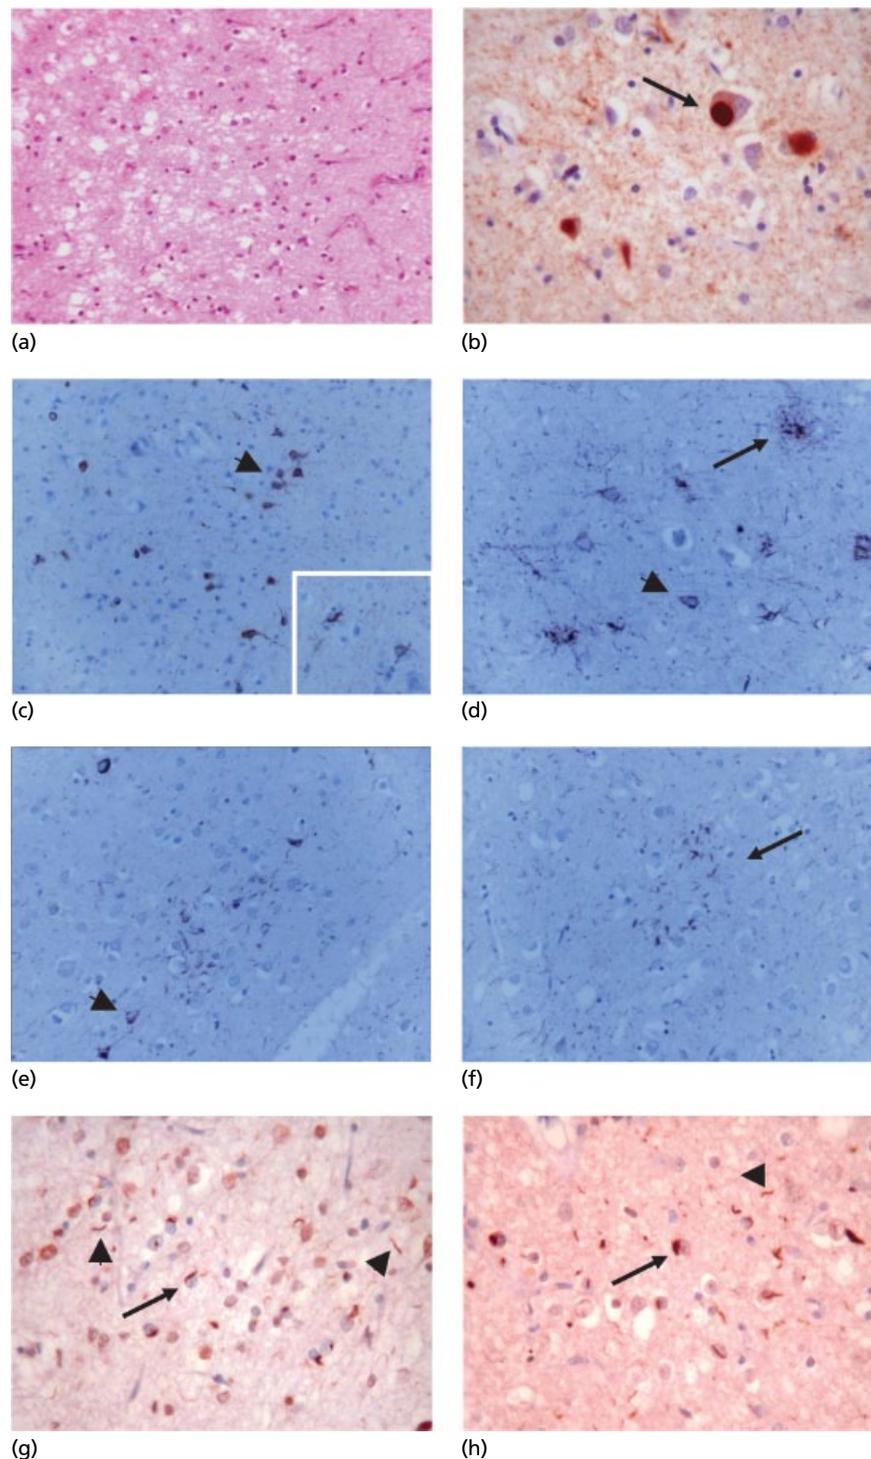

### Genetic pathological correlations

Recent advances in the genetic field have accelerated our understanding of molecular genetics, biochemistry and neuropathology of FTD. Some 35–50% of patients with FTD have a family history of dementia with an autosomal dominant inheritance pattern or an identified genetic mutation in around 20%. Most cases have mutations in the *MAPT* (microtubule associated protein tau), *GRN* (progranulin) or *C9orf72* genes. These three genes account for the majority of cases of genetic FTD but rarely mutations in other genes can also be causes, for example mutations in the valosin containing protein (*VCP*) gene cause FTD in association with inclusion body myositis and Paget's disease of bone.

The term frontotemporal lobar degeneration (FTLD) is a collective term sometimes used to denote the three major pathological forms that cause FTD, characterised by the abnormally aggregated proteins found in the neuronal inclusions:

- 1 **Tauopathies** In tau-positive FTLD (around 40–50% of cases), histology shows cellular inclusions containing phosphorylated protein tau. Subtypes of the tauopathies include Pick's disease, PSP, CBD and the pathology seen in patients with *MAPT* mutations (often called FTLD with parkinsonism linked to chromosome 17 or FTDP-17).
- 2 **TDP-43 proteinopathies** (around 40–50% of cases) Four subtypes of TDP-43 positive FTLD are described, named A to D. Patients with mutations in the *GRN* (type A), *C9orf72* (type A or B) and *VCP* (type D) genes fall into this group
- 3 **FUS proteinopathies** A minority of cases (5–10% of cases) have inclusions containing fused-in-sarcoma (FUS) protein.

For most cases there is poor clinico-pathological correlation (e.g. bvFTD can be associated with tau, TDP-43 or FUS inclusions). However, FTD-MND is reliably associated with TDP-43 pathology as is semantic dementia. Very young onset sporadic FTD (age of onset <40) is commonly associated with FUS pathology (Figure 8.12).

**Figure 8.12** (a) Neurophil spongiosis occurring in superficial cortical laminae is seen in FTLDs (haematoxylin and eosin preparation, frontal cortex). (b) Tau-positive Pick body is a characteristic feature of Pick's disease (AT8 immunohistochemistry, temporal cortex). (c) A combination of tau-positive neuronal (arrowhead) and glial pathology is found in frontotemporal lobar degeneration (FTLD) due to intronic mutations located close to the alternatively spliced exon 10 (this case: exon 10 +16 mutation). Insert showing tau-positive oligodendroglial coiled bodies (AT8 immunohistochemistry, temporal cortex). Tau-positive neurofibrillary tangles and pretangles (arrowhead) occur both in progressive supranuclear palsy and cortico-basal degeneration (d and e arrowhead). However, tufted astrocytes are the characteristic glial pathology in progressive supranuclear palsy (d arrow) and the so-called astrocytic plaques are found in cortico-basal degeneration (f arrow) (AT8 immunohistochemistry, frontal cortex). Neuronal intracytoplasmic inclusions (arrow) and neurites (arrowhead) are ubiquitin-positive (g) and are immunoreactive for TDP-43 (h) in FTLD-U (g: ubiquitin immunohistochemistry; (h) TDP-43 immunohistochemistry, temporal cortex). Courtesy of Professor Tamas Revesz, Queen Square Brain Bank, Department of Molecular Neuroscience, UCL Institute of Neurology.

## Prognosis

All syndromes slowly progress over time leading to dependency and institutional care. The most aggressive course is found in FTD-MND, with death within 3–5 years of onset. For the other syndromes many patients survive for well over a decade.

## Management

The carer burden for this group of patients is significant and distinct in quality both comparing syndromes such as bvFTD and PNFA and from the more typical issues in AD. Often carer burden in this group is particularly severe because of behavioural issues and lack of insight from patients. Respite and counselling are vital for the carer and family – they often feel they have lost their loved one and this can lead to significant distress. There are difficult decisions to be made to balance independence and safety. For example, improving wandering behaviour by changing the environment, alerting local community police or shopkeepers about forensic behaviour, removing bank cards to avoid indiscriminate spending. For the language variants, speech and language therapy can be very helpful in providing strategies to improve communication, such as use of tablet programs to 'speak for' the patient if significant word-finding difficulties. In addition, it may be necessary to assess swallow, especially where there is orofacial apraxia in PNFA. Management is primarily symptom control and supporting patients and their carer cope with the disease burden. This includes signposting to local services in the mental health and social services teams, and disease-specific support networks such as the FTD Support Group and the Association for Frontotemporal Degeneration.

There are currently no disease-modifying treatments for FTD. There is limited evidence that selective serotonin re-uptake inhibitors may modulate abnormal behaviours in some patients. New generation neuroleptics are reserved for when agitation cannot be controlled by other means and are used very cautiously at low dosage.

## Dementia with Lewy bodies and Parkinson's disease dementia

Dementia with Lewy bodies (DLB; also known as 'Lewy body dementia' or 'diffuse Lewy body disease') and dementia associated with Parkinson's disease (Parkinson's disease dementia; PDD) together constitute the second or third most common cause of dementia in later life in most series. These disorders appear to lie on a neuropathological and clinical continuum. Although estimates vary, in cross-sectional studies approximately 30% of patients with idiopathic Parkinson's disease have dementia; and in longitudinal studies individuals with idiopathic Parkinson's disease have a three- to sixfold higher risk of developing dementia than age-matched controls. Risk factors for development of PDD include older age, duration of disease and motor disability (especially symmetric, non-tremor dominant disease with postural instability and gait disturbance), diminished response to levodopa and levodopa-induced confusion, early visual hallucinations, olfactory dysfunction and mood and sleep disturbance.

Pathologically, both DLB and PDD are characterised by the formation of Lewy bodies (the hallmark of Parkinson's disease, Chapter 6): intracytoplasmic eosinophilic neuronal inclusions with a central core and pale halo, containing the protein  $\alpha$ -synuclein aggregated with abnormally phosphorylated neurofilaments and ubiquitin. Lewy bodies are found in the neocortex, limbic cortices and subcortical nuclei and there is associated neuronal loss. Pathological subtypes of DLB have been categorised as brainstem predominant, limbic (transitional) or diffuse neocortical based

on the predominant distribution of pathological changes. No neuropathological features that reliably separate DLB, PDD and Parkinson's disease without dementia have been identified, and the particular clinical phenotype is likely to depend on the pattern of spread of pathological changes in the brain. In individuals developing DLB in later life, pathological features of AD (senile plaques and neurofibrillary tangles) and vascular disease commonly coexist at postmortem.

The pathological determinants of cognitive dysfunction in association with DLB and PDD are complex. Although it is not a universal finding, a number of studies have found a correlation between the regional density of cortical Lewy bodies and cognitive dysfunction (in particular visual hallucinations), while conversely, dementia is uncommon in patients with *parkin* mutations that lack cortical Lewy body involvement. Lewy bodies have also been correlated with cortical Alzheimer's changes, and it has been suggested that the interaction of these factors predisposes to the development of dementia and modifies the clinical phenotype. However, the development of dementia in some patients with *SNCA* mutations that lack significant associated Alzheimer pathology suggests that this is not a critical factor in all cases. Disruption of ascending dopaminergic and cholinergic pathways gives rise to clinically significant deficiencies of these neurotransmitter systems that interact with intrinsic cortical pathology.

Unresolved issues of pathological classification notwithstanding, DLB and PDD remain clinically defined syndromes and together these diseases present characteristic clinical problems that justify their status as a distinct dementia category. According to the current revised DLB consortium guidelines, and Movement Disorders Society Task Force clinical criteria for PDD DLB should be diagnosed when dementia occurs before or coincides within 1 year of parkinsonism, and PDD when dementia develops in established Parkinson's disease (criteria for probable PDD and DLB are shown in Table 8.6). DLB is typically a sporadic disease of later life with an overall survival similar to AD; however, young adult, familial and rapidly progressive forms, although rare, are well described. As with AD, there is an increasing move to diagnose the cognitive impairments associated with PD earlier, leading to the concept of PD-mild cognitive impairment (Table 8.6).

Core features of DLB are progressive cognitive decline with fluctuating cognition, recurrent visual hallucinations and spontaneous parkinsonism. The cognitive profile is often dominated by executive, attentional and visuo-spatial disturbances. A history of some variation in cognitive function from day to day is common in many dementias; however, the fluctuations in DLB are more marked and often paroxysmal within a 24-hour period. They may manifest as drowsiness, decreased responsiveness or disorganisation of speech or behaviour. Fluctuations may be profound and prolonged, and frank delirium with protracted confusion and hallucinosis may supervene. Visual hallucinations should be enquired about specifically: in DLB, they are generally animate, vivid, stereotyped and silent, and often emerge from background visual features or patterns under low-light conditions. Although it is a core diagnostic feature of DLB, parkinsonism is not recorded in a significant proportion of autopsy-proven cases, implying that the absence of extrapyramidal features does not exclude the diagnosis. Other characteristic features of DLB are marked neuroleptic sensitivity and REM sleep behaviour disorder, the occurrence of complex and bizarre (often violent) sleep-related behaviour because of acting of dream content (the result of abnormal restoration of muscle tone resulting from synuclein pathology in the region of the pontine tegmentum). Additional supportive features include recurrent

**Table 8.6 (a)** Criteria for probable Parkinson's disease dementia (PDD).

- 1 Diagnosis of Parkinson's disease according to Queen Square Brain Bank criteria  
*and*
- 2 A dementia syndrome with insidious onset and slow progression, developing within the context of established Parkinson's disease and diagnosed by history, clinical and mental examination, defined as impairment in more than one cognitive domain; representing a decline from premorbid level. Deficits severe enough to impair daily life (social, occupational, or personal care), independent of the impairment ascribable to motor or autonomic symptoms  
*and*
- 3 Typical profile of cognitive deficits including impairment in at least two of the four core cognitive domains (impaired attention which may fluctuate, impaired executive functions, impairment in visuo-spatial functions, and impaired free recall memory which usually improves with cueing). The presence of at least one behavioural symptom (apathy, depressed or anxious mood, hallucinations, delusions, excessive daytime sleepiness) supports the diagnosis of probable PDD, lack of behavioural symptoms, however, does not exclude the diagnosis

**Exclusion criteria**

- Coexistence of any other abnormality which may by itself cause cognitive impairment, but judged not to be the cause of dementia (e.g. presence of relevant vascular disease in imaging)
- Time interval between the development of motor and cognitive symptoms not known
- Features suggesting other conditions or diseases as cause of mental impairment, which, when present, make it impossible to reliably diagnose PDD
- Cognitive and behavioural symptoms appearing solely in the context of other conditions such as acute confusion caused by systemic diseases or abnormalities; 'major depression' according to DSM-IV; features compatible with 'probable vascular dementia'

**Table 8.6 (b)** Criteria for probable dementia with Lewy bodies (DLB).

- 1 Dementia defined as progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Prominent or persistent memory impairment may not necessarily occur in the early stages but is usually evident with progression. Deficits on tests of attention, executive function and visuo-spatial ability may be especially prominent
- 2 Core features (two required for a diagnosis of probable DLB, one for possible DLB):
  - Fluctuating cognition with pronounced variations in attention and alertness
  - Recurrent visual hallucinations that are typically well formed and detailed
  - Spontaneous features of parkinsonism
- 3 Suggestive features (probably DLB can be diagnosed with  $\geq 1$  core +  $\geq 1$  suggestive feature)
  - REM sleep behaviour disorder
  - Severe neuroleptic sensitivity
  - Low dopamine transporter uptake in basal ganglia demonstrated by SPECT or PET imaging
- 4 Supportive features (commonly present but not proven to have diagnostic specificity): repeated falls and syncope; transient, unexplained loss of consciousness; severe autonomic dysfunction (e.g. orthostatic hypotension), urinary incontinence; hallucinations in other modalities; systematised delusions; depression; relative preservation of medial temporal lobe structures on CT/MRI scan; generalised low uptake on SPECT/PET perfusion scan with reduced occipital activity; abnormal (low uptake) MIBG myocardial scintigraphy; prominent slow wave activity on EEG with temporal lobe transient sharp waves
- 5 A diagnosis of DLB is less likely: in the presence of clinical or imaging evidence of cerebrovascular disease; in the presence of any other physical illness or brain disorder sufficient to account in part or in total for the clinical picture; if parkinsonism only appears for the first time at a stage of severe dementia
- 6 Temporal sequence of symptoms. DLB should be diagnosed when dementia occurs before or concurrently with parkinsonism (if it is present). In research studies in which distinction needs to be made between DLB and PDD, the existing 1-year rule between the onset of dementia and parkinsonism DLB continues to be recommended

Adapted from McKeith *et al.* 2005 with permission of AAN/LWW.

syncope and falls, significant autonomic dysfunction, hallucinations in non-visual modalities and early prominent delusions (including misidentification delusions such as the Capgras phenomenon and topographical and other reduplicative paramnesias), apathy and depression.

PDD has a very similar neuropsychological profile to DLB and shares many other clinical characteristics. Visual hallucinations are common in PDD even after medication effects are taken into account. In contrast to spontaneously occurring visual hallucinations, drug-induced hallucinations in treated Parkinson's disease are

**Table 8.6 (c)** Criteria for mild cognitive impairment–Parkinson's disease dementia (MCI-PDD).

- 1 Diagnosis of Parkinson's disease (PD) as based on the UK PD Brain Bank Criteria
- 2 Gradual decline, in the context of established PD, in cognitive ability reported by either the patient or informant, or observed by the clinician
- 3 Cognitive deficits on either formal neuropsychological testing or a scale of global cognitive abilities\*
- 4 Cognitive deficits are not sufficient to interfere significantly with functional independence, although subtle difficulties on complex functional tasks may be present

**Exclusion criteria**

- 1 Diagnosis of PD dementia based on MDS Task Force proposed criteria
- 2 Other primary explanations for cognitive impairment (e.g. delirium, stroke, major depression, metabolic abnormalities, adverse effects of medication or head trauma)
- 3 Other PD-associated co-morbid conditions (e.g. motor impairment or severe anxiety, depression, excessive daytime sleepiness, or psychosis) that, in the opinion of the clinician, significantly influence cognitive testing

\* Depending on the scales used and how comprehensive the neuropsychological battery, PD-MCI can be classified as level 1 (lesser diagnostic certainty) or level 2 (higher diagnostic certainty); and for classifications within level 2 as single or multiple domain PD-MCI.

Source: Litvan *et al.* 2011.

often perceived as frightening or threatening and accompanied by paranoid delusions. REM sleep behaviour disorder is also a feature of PDD. Parkinsonism in both PDD and DLB may closely mimic that of uncomplicated idiopathic Parkinson's disease, although predominant axial involvement with postural instability, absence of tremor and limited response to levodopa are more common.

Certain investigations in DLB and PDD can help to support the clinical impression, although no diagnostic or disease-specific biomarkers have been identified. On structural brain MRI, mesial temporal structures tend to be relatively better preserved than in AD. Metabolic brain imaging typically shows reduced striatal dopamine transporter uptake, and cortical perfusion and metabolism are globally reduced, often with a posterior emphasis. Degradation of alpha rhythm in the EEG occurs as a non-specific marker of cortical degeneration.

No specific or disease-modifying therapies are currently available for DLB or PDD. Cholinesterase inhibitors (AChEIs) modestly improve cognitive function, attention, alertness and behaviour in a substantial proportion of patients, and indeed may be more effective than in AD at a comparable disease stage. More particularly, these agents may help in the management of fluctuations, sleep disturbance, confusion and hallucinations. The side effect profile of the AChEIs in DLB and PDD is broadly similar to that in AD. The impact on extrapyramidal symptoms is variable: modest benefit is seen in some patients, but significant worsening of parkinsonism or dystonia does occasionally occur and patients should be monitored for this possibility. The evidence base in favour of particular AChEIs remains limited and the choice of agent should be tailored to the individual patient (e.g. the convenience of once-daily dosing with donepezil set against the shorter half-life and more flexible regimen of rivastigmine, which can also be given as a transdermal patch). Neuroleptic drugs should in general be avoided in DLB and PDD, in view of the potential to cause severe, prolonged and sometimes life-threatening extrapyramidal reactions. However, these drugs may sometimes be necessary for the management of agitation or hallucinations where behavioural strategies or cholinesterase inhibitors have failed. In this situation, a new generation agent such as quetiapine or aripiprazole should be introduced cautiously and titrated slowly to the smallest effective dose. Clozapine is probably the most effective neuroleptic and least likely to cause extrapyramidal side effects, but its use is lim-

ited by the requirement for close supervision and blood monitoring because of the risk of agranulocytosis.

Management of parkinsonism in both DLB and PDD follows principles similar to those in idiopathic Parkinson's disease, although dopamine agonists are generally avoided because of their higher incidence of psychiatric side effects. Levodopa may benefit motor symptoms less than in uncomplicated Parkinson's disease, and dopaminergic effects on cognition are variable. Special care is needed to avoid exacerbating hallucinations and psychotic symptoms; in practice, the balance between immobility and confusion is often very finely poised and difficult to strike.

**Dementia with other movement disorders**

Cognitive decline is a feature of a number of other extrapyramidal disorders (described in more detail in Chapter 6), and most commonly manifests as a subcortical dementia resulting from involvement of fronto-subcortical circuitry. Although diagnosis generally rests on non-cognitive features, the type and relative prominence of cognitive deficits may assist in the clinical differentiation of atypical parkinsonism and 'Parkinson's-plus' syndromes. Progressive supranuclear palsy (Steele–Richardson–Olszewski syndrome) is frequently accompanied by profound bradyphrenia and executive deficits, which may include perseverative responses, environmental dependency and utilisation behaviours. The 'applause sign', when a patient asked to clap three times as fast as possible after the examiner, makes additional handclaps or may initiate applause, is suggestive of PSP. In contrast to other 'Parkinson's-plus' disorders, cortico-basal degeneration can present as a purely motor, purely cognitive, or more commonly mixed disorder. As cortico-basal degeneration is strictly a pathological diagnosis, the term 'cortico-basal syndrome' is increasingly preferred to describe the clinical syndrome, which can comprise early prominent cortical deficits such as limb and orofacial apraxia, parietal signs and impaired speech production, which may be relatively focal or asymmetric, and which overlap with disorders in the FTD spectrum. The presence of alien limb phenomena of variable complexity is said to be characteristic, but can occur in other pathologies. Although severe cognitive decline is an exclusion criterion for multiple system atrophy, many patients do have mild executive deficits and cognitive slowing.

Cognitive impairment is a core feature of Huntington's disease. Attentional deficits and behavioural disturbances often dominate

early in the disease course, and patients frequently present via psychiatric services, especially where the family history is concealed or not recognised. Visuo-spatial deficits are also well documented. Deficits of emotion recognition may be present, even in presymptomatic carriers. Cognitive decline in Huntington's disease has been shown to correlate with caudate atrophy and frontal hypometabolism, consistent with a primary disruption of fronto-subcortical circuitry.

Cognitive dysfunction is common in the expanding group of inherited spinocerebellar ataxias (Chapter 17), and executive and verbal memory deficits, affective disturbances and personality change have all been described. The severity of cognitive decline varies with the underlying genetic abnormality and may be particularly evident in *SCA2* and *SCA17*. There is much interest in defining a cognitive and behavioural signature of cerebellar damage, but this is difficult because of the frequent co-occurrence of damage involving other neuronal systems.

## Prion disease

### Introduction and disease biology

The prion diseases, or transmissible spongiform encephalopathies, affect both humans and animals. The human prion diseases have been traditionally classified into CJD, Gerstmann-Sträussler-Scheinker (GSS) disease, fatal familial insomnia and kuru. Animal prion diseases include scrapie of sheep and goats, transmissible mink encephalopathy, chronic wasting disease of mule deer and elk, and bovine spongiform encephalopathy (BSE) which first appeared in the United Kingdom from the mid-1980s and rapidly evolved to a major epizootic estimated to have infected over 2 million UK cattle. The recognition of a novel human prion disease, vCJD, from the mid-1990s onwards and experimental confirmation that it was caused by the same prion strain as BSE raised major public health concerns. While the number of human cases to date has been relatively modest, key uncertainties, notably with respect to major genetic effects on incubation period, allied with the widespread population exposure, suggest the need for caution.

Prions are transmissible agents with unique composition and properties, being apparently devoid of significant nucleic acid. Prion diseases are associated with the accumulation in the brain of an abnormal, partially protease-resistant, isoform of a normal cell surface glycoprotein found in healthy people known as prion protein (PrP). The disease-related isoform, PrP<sup>Sc</sup>, is derived from its normal cellular precursor, PrP<sup>C</sup>, by a post-translational process that involves conformational change and aggregation. According to the 'protein-only' hypothesis, an abnormal PrP isoform is the principal, and possibly the sole, constituent of the transmissible agent or prion. PrP<sup>Sc</sup> is hypothesised to act as a conformational template, promoting the conversion of PrP<sup>C</sup> to further PrP<sup>Sc</sup> by an autocatalytic process. In addition to public health concerns, prions have assumed much wider relevance in understanding neurodegenerative and other diseases involving accumulation of misfolded host proteins (protein-folding diseases).

### Aetiological categories and classification of human prion disease

The human prion diseases are unique in having three distinct aetiologies (Table 8.7). They may occur sporadically, be acquired by dietary or iatrogenic exposure to prions, or inherited in an autosomal dominant fashion as a result of coding mutations in the prion protein gene (*PRNP*). Remarkably, Mendelian inherited forms of prion disease are also experimentally transmissible by inoculation of laboratory animals. The majority of recognised human prion disease

occurs as sporadic CJD. The aetiology of sporadic CJD is unclear but may arise from somatic mutation of *PRNP* or spontaneous conversion of PrP<sup>C</sup> to PrP<sup>Sc</sup> as a rare stochastic event. The alternative hypothesis, exposure to an environmental source of either human or animal prions, is not supported by epidemiological evidence.

Prion diseases show marked phenotypic variability. A major factor in explaining this diversity is the existence of distinct prion strains. Prion strains can be distinguished by differences in the biochemical properties of PrP<sup>Sc</sup>. Prion strain diversity appears to be encoded by differences in PrP<sup>Sc</sup> conformation and pattern of glycosylation. Four main types are seen amongst CJD cases, sporadic and iatrogenic CJD being of PrP<sup>Sc</sup> types 1–3, while all vCJD cases are associated with a distinctive PrP<sup>Sc</sup> known as type 4 (London classification). A similar type 4 PrP<sup>Sc</sup> is seen in BSE and in BSE when transmitted to several other species.

A common *PRNP* polymorphism at codon 129, where either methionine or valine can be encoded, is a key determinant of genetic susceptibility to acquired and sporadic prion diseases, the large majority of which occur in homozygous individuals. Heterozygosity is protective against developing sporadic and acquired prion disease and leads to increased age at onset in some forms of inherited prion disease. Codon 129 genotype also has a key role in determining clinicopathological phenotypes, in part via an effect on selection of particular prion strain types.

### Sporadic prion disease

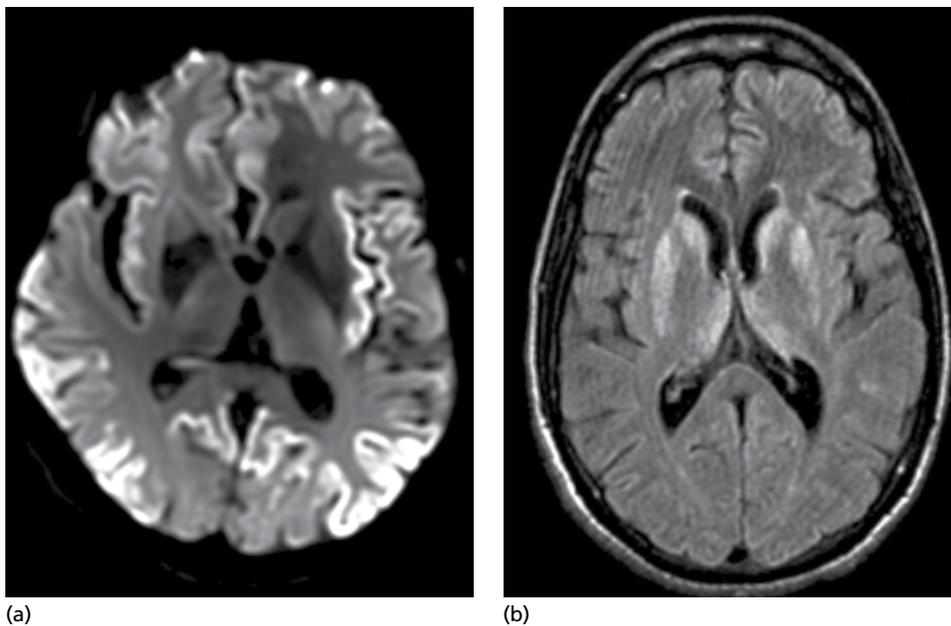

**Creutzfeldt-Jakob disease** The core clinical syndrome of classic sporadic CJD is of a rapidly progressive multifocal dementia usually with myoclonus. The onset is usually in the 45–75 year age group with peak onset between 60 and 65 years. The clinical progression is typically over weeks progressing to akinetic mutism and death often in 2–3 months; most die in under 6 months. Prodromal features include fatigue, insomnia, depression, weight loss, headaches, general malaise and ill-defined pain sensations. Frequent additional neurological features include extrapyramidal signs, cerebellar ataxia, pyramidal signs and cortical blindness. About 10% of patients present initially with cerebellar ataxia.

Routine haematological and biochemical investigations are normal. Routine CSF examination is normal but 14-3-3 protein is usually elevated. However, it is also positive in recent cerebral infarction or haemorrhage and in viral encephalitis, and may also be elevated in rapidly progressive AD which may be difficult to clinically distinguish from CJD. New CSF tests such as the real-time Quaking Induced Conversion (rtQUIC) assay may be more specific. CT or MRI is crucial to exclude other causes of subacute neurological illness but MRI has become increasingly useful in diagnosis of sporadic CJD, showing high signal in the striatum and/or cerebral cortex in FLAIR or DW images (Figure 8.13). Cerebral and cerebellar atrophy may be present in cases of longer duration. The EEG may show characteristic pseudoperiodic sharp wave activity. Brain biopsy may be considered in highly selected cases to exclude treatable alternative diagnoses using appropriate CJD infection control precautions.

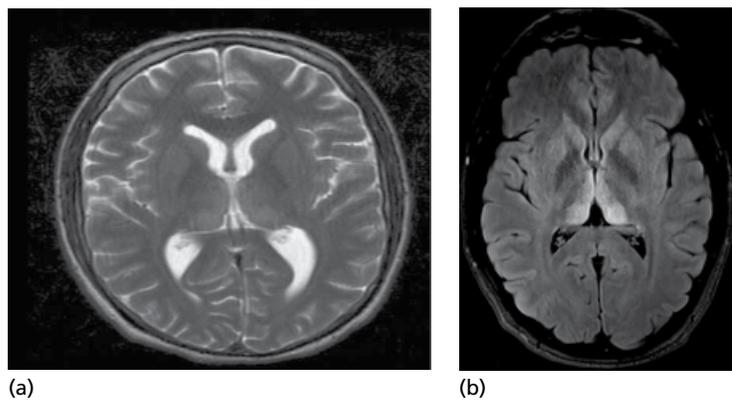

Neuropathological confirmation of CJD is by demonstration of spongiform change, neuronal loss and astrocytosis together with positive PrP immunohistochemistry. PrP amyloid plaques are usually not present in CJD. PrP<sup>Sc</sup> can be demonstrated by immunoblotting of brain homogenates and is diagnostic of prion disease. PrP<sup>Sc</sup> types 1–3 are demonstrated, distinct from type 4 which is exclusively seen in variant CJD. *PRNP* analysis is important to exclude pathogenic mutations even in the absence of a family history because several mutations are not fully penetrant. Most cases of classic CJD are homozygous with respect to the common 129

**Table 8.7** Classification of human prion disease.

Aetiology	Phenotype	Frequency
<p><b>Sporadic</b></p> <p>Unknown: random distribution worldwide; incidence of 1–2 per million per annum</p>	Sporadic CJD: subacute myoclonic form and range of atypical forms; multiple distinct prion strains associated with distinct clinico-pathological phenotypes which includes sporadic fatal insomnia	~85%
<p><b>Inherited</b></p> <p>Autosomal dominantly inherited conditions with high penetrance; all forms have germline PRNP coding mutations</p>	Extremely variable: readily mimics familial Alzheimer's disease and other neurodegenerative conditions; over 30 mutations identified; includes Gerstmann–Sträussler–Scheinker disease, familial CJD and fatal familial insomnia	~10–15%
<p><b>Acquired</b></p> <p>Iatrogenic infection with human prions via medical or surgical procedures: human cadaveric-derived pituitary hormones, tissue grafts and contaminated neurosurgical instruments</p>	Iatrogenic CJD: typical CJD when direct CNS exposure; ataxic onset when peripheral infection	<5% (most from USA, UK, France and Japan)
Exposure to human prions via endocannibalism	Kuru	Unique to small area Papua New Guinea; major epidemic in 1950s with gradual decline since cessation of cannibalism
Environmental exposure (presumed dietary) to BSE prion strain	Variant CJD	Total to date ~200. Mainly in UK but now reported from a number of countries
Iatrogenic infection via blood transfusion from healthy donor infected with vCJD prions	Secondary vCJD	UK only to date

**Figure 8.13** Sporadic Creutzfeldt–Jakob disease (CJD). MRI demonstrates typical increased signal intensity in the caudate and putamen bilaterally and widespread increased cortical signal intensity involving the occipital, frontal, temporal and insula cortex on (a) fluid attenuated inversion recovery (FLAIR) and (b) diffusion-weighted imaging (DWI) ( $b = 1000 \text{ s/mm}^2$ ) sequences. The cortical signal changes are more apparent on the DWI sequence.

**Figure 8.14** Variant CJD. MRI demonstrates symmetrical increased signal intensity in the pulvinar nuclei bilaterally ('pulvinar sign') and dorsomedial thalami on (a) T2 weighted and (b) FLAIR sequences.

polymorphism of PrP and MM is by far the most common genotype in classical subacute CJD.

Atypical forms of CJD are well recognised. Around 10% of cases of CJD have a much more prolonged clinical course of over 2 years. *PRNP* codon 129 genotype is often VV or MV, rather than the MM type usually seen in subacute myoclonic CJD. Around 10% of patients with CJD present with cerebellar ataxia rather than cognitive impairment, so-called ataxic CJD, although this presentation should lead to a consideration of acquired prion disease. Heidenhain's variant of CJD refers to cases in which cortical blindness predominates with severe involvement of the occipital lobes.

#### Acquired prion diseases

**Kuru** Kuru is now largely of historical interest. It reached epidemic proportions amongst a defined population living in the Eastern Highlands of Papua New Guinea and was the major cause of death amongst adult women and children in the affected region when first described by Western medicine in the 1950s. It was the practice in these communities to engage in consumption of dead relatives as a mark of respect and mourning. Males over the age of 6–8 years participated little in mortuary feasts, which is thought to explain the differential age and sex incidence. Its gradual disappearance since the cessation of cannibalism in the late 1950s has allowed estimation of the range of incubation periods possible in human prion infection which may exceed 50 years. The mean clinical duration of illness is 12 months with a range of 3 months to 3 years. The dominant clinical feature is progressive cerebellar ataxia. In contrast to CJD, dementia is much less marked.

**Iatrogenic Creutzfeldt–Jakob disease** Iatrogenic transmission of CJD has occurred by accidental inoculation with human prions as a result of medical procedures. Such iatrogenic routes include contaminated neurosurgical instruments, dura mater and corneal grafting, and human cadaveric pituitary-derived growth hormone or gonadotrophin. The diagnosis is usually based on a progressive cerebellar syndrome and behavioural disturbance or a classic CJD-like syndrome together with a history of iatrogenic exposure to human prions, and may occur in any age group. The incubation period in intracerebral cases is short (2–4 years for dura mater grafts) compared with peripheral cases (typically 15 years or more). EEG, CSF and MRI are generally less diagnostically helpful than in sporadic CJD. *PRNP* analysis is important to exclude pathogenic mutations. Diagnosis is confirmed by PrP immunocytochemistry or Western blot of brain tissue for PrP<sup>Sc</sup> types 1–3.

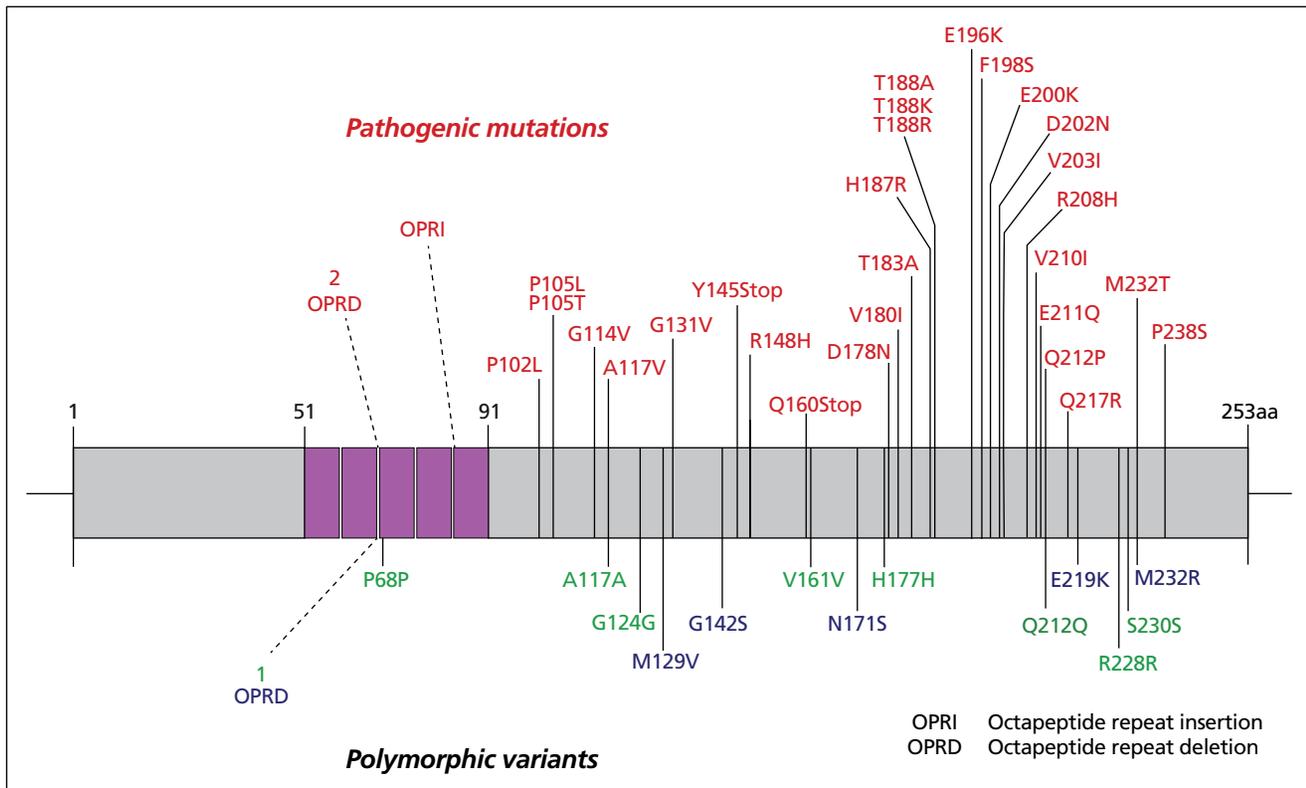

**Variant CJD** vCJD was first described in 1996. Its occurrence initially in teenagers and young adults and distinctive neuropathology differentiated it from sporadic CJD. A link with BSE was confirmed by molecular and biological strain typing of prions.

The early features of vCJD are non-specific, often with behavioural and psychiatric disturbances and in some cases with sensory disturbance. Initial referral has frequently been to a psychiatrist and the most prominent feature is depression but anxiety, social withdrawal and behavioural change are frequent. Delusions, which are complex and unsustained, are common. Other features include emotional lability, aggression, insomnia and auditory and visual hallucinations. A prominent early feature in some is dysaesthesiae or pain in the limbs or face which is persistent rather than intermittent and unrelated to anxiety levels. In most patients a progressive cerebellar syndrome develops with gait and limb ataxia. Cognitive impairment then occurs with inevitable progression to akinetic mutism. Myoclonus is seen in most patients, and chorea is often present which may be severe in some. Cortical blindness develops in a minority in the late stages of disease. Upgaze paresis has been noted in some patients. Age at onset ranges from 12 to 74 (mean 28) years and the clinical course to death is relatively prolonged (median 14 months).

The EEG is abnormal, most frequently showing generalised slow wave activity, but without the pseudoperiodic pattern seen in most sporadic CJD cases. MRI, particularly FLAIR sequence, demonstrates bilateral increased signal in the posterior thalamus (the pulvinar sign) in the large majority of cases (Figure 8.14). However, this sign appears as a late feature of the disease process and is not specific for vCJD.

Tonsillar biopsy is a sensitive and specific diagnostic procedure for vCJD. CSF 14-3-3 protein may be elevated or normal. *PRNP* analysis is essential to rule out pathogenic mutations, as the inherited prion diseases present in younger patients and may clinically mimic vCJD, and should be performed prior to tonsil biopsy. To date all clinically probable cases of vCJD have been of the *PRNP* codon 129 MM genotype; a single patient has been reported who possibly died from vCJD with a codon 129 MV genotype, but no autopsy was conducted.

The neuropathological appearances of vCJD are striking and relatively consistent, generally allowing differentiation from other forms of prion disease. While there is widespread spongiform change, gliosis and neuronal loss, most severe in the basal ganglia and thalamus, the most remarkable feature is abundant PrP amyloid plaques in cerebral and cerebellar cortex. These consist of kuru-like, 'florid' (surrounded by spongiform vacuoles) and multicentric plaque types. Western blot analysis (molecular strain typing) of brain tissue demonstrates PrP<sup>Sc</sup> type 4 which is pathognomonic of vCJD.

**Figure 8.15** Pathogenic mutations and polymorphic variants in the prion protein gene.

**Secondary (iatrogenic) vCJD** The prominent lymphoreticular involvement prompted speculative concerns that vCJD may be transmissible by blood transfusion. Since 2004, four transfusion-associated cases of vCJD prion infection have been recognised amongst a small cohort of 23 surviving patients identified as having received blood from a donor who subsequently developed vCJD. The three clinical cases had the *PRNP* codon 129 MM genotype, while one patient, who died of an unrelated condition, was found to have prion infection at autopsy. This patient had the *PRNP* codon 129 MV genotype associated with relative resistance to prion disease. In each case transfusion was with a single unit of implicated red cells. Clinical features and investigations are as for primary vCJD.

### Inherited prion diseases

These are adult onset autosomal dominantly inherited conditions associated with *PRNP* coding mutations (Figure 8.15). They were first classified as familial CJD and GSS. Classic GSS is a chronic cerebellar ataxia with pyramidal features, with dementia occurring later in a much more prolonged clinical course than that seen in CJD. The onset of GSS is usually in either the third or fourth decades and characterised histologically by the presence of multi-centric PrP-amyloid plaques. However, inherited prion disease kindreds show remarkable phenotypic variability, which can encompass both CJD-like and GSS-like cases as well as atypical cases which readily mimic other neurodegenerative conditions. Inherited prion diseases are a frequent cause of presenile dementia and a family history is not always apparent: *PRNP* should be analysed in all suspected cases of CJD, and certainly considered in all early onset dementia and in ataxias. Cases diagnosed by *PRNP* analysis have

been reported that are not only clinically atypical, but also lack the classic histological features.

The identification of a pathogenic *PRNP* mutation allows not only molecular diagnosis of an inherited prion disease but also its subclassification according to mutation. Over 30 pathogenic mutations are reported in the human PrP gene and consist of two groups:

- 1 Point mutations within the coding sequence resulting in amino acid substitutions in PrP or production of a stop codon resulting in expression of a truncated PrP, and
- 2 Insertions encoding additional integral copies of an octapeptide repeat present in a tandem array of five copies in the normal protein (octapeptide repeat insertion; OPRI).

The key clinical features in inherited prion disease are progressive dementia, cerebellar ataxia, pyramidal signs, chorea, myoclonus, extrapyramidal features, pseudobulbar signs, seizures and amyotrophic features, which are seen in variable combinations. The most frequent forms include PrP E200K, which may mimic subacute sporadic CJD (and, in contrast to other inherited prion diseases, often has a typical EEG), PrP P102L which may present as a progressive cerebellar ataxia or dementia, and insertional mutations which have a particularly variable clinical presentation, often with a long duration mimicking AD. Fatal familial insomnia, usually associated with the D178N mutation, is characterised clinically by untreatable insomnia, dysautonomia and motor signs, and neuropathologically by selective atrophy of the anterior-ventral and mediodorsal thalamic nuclei. One variant, PrP P105L, presents as a progressive spastic paraparesis. Parkinsonism may be prominent in A117V and peripheral neuropathy occurs in E200K. Age at onset varies from the early twenties (seen often with insert

mutations) to the seventies. The duration varies from less than a year to over 20 years.

Direct gene testing allows unequivocal diagnosis in patients with inherited forms of the disease and presymptomatic testing of unaffected but at-risk family members, as well as antenatal testing. Most of the mutations appear to be fully penetrant; however, experience with some is extremely limited. Exceptions include E200K and D178N (fatal familial insomnia) where there are examples of elderly unaffected gene carriers. Genetic counselling is essential prior to presymptomatic testing and follows a protocol similar to that established for Huntington's disease. It is vital to advise both those testing positive for mutations and those untested but at-risk that they should not be blood or organ donors and that they should inform surgeons, including dentists, of their risk status prior to significant procedures, as precautions may be necessary to minimise risk of iatrogenic transmission. Some truncation mutations are associated with PrP-systemic amyloidosis which presents with diarrhoea, autonomic failure and a mixed predominantly sensory neuropathy. Cognitive involvement is late in these pedigrees.

### Prevention and treatment

While prion diseases can be transmitted to experimental animals by inoculation, it is important to appreciate that they are not contagious in humans. Documented case-to-case spread has only occurred by cannibalism (kuru) or following accidental iatrogenic inoculation with prions. As already discussed, there is now evidence that vCJD prion infection is transmissible by blood transfusion. UK policy for some time has been to leukodeplete all whole blood and to source plasma for plasma products from outside the United Kingdom. A further possible route of transmission of vCJD is via contaminated surgical and medical instruments. Prions resist conventional sterilisation methods and neurosurgical instruments are known to be able to act as a vector for prion transmission: several cases of iatrogenic transmission of sporadic CJD prions via neurosurgical instruments are documented.

Certain occupational groups are at risk of exposure to human prions: neurosurgeons and other operating theatre staff, pathologists and morticians, histology technicians, as well as an increasing number of laboratory workers. Because of the prolonged incubation periods for prions following administration to sites other than the CNS, associated with clinically silent prion replication in the lymphoreticular tissue, treatments inhibiting prion replication in lymphoid organs may represent a viable strategy for rational secondary prophylaxis after accidental exposure. A short course of immunosuppression with high-dose oral corticosteroids in individuals with significant accidental exposure to human prions has been advocated.

All patients with or at-risk of developing prion disease should be counselled on infection control as described for gene carriers. New diagnoses should be notified to the local consultant in communicable disease control who can assess if public health measures are necessary, notably if a patient has had recent surgery or donated blood prior to diagnosis.

All recognised prion diseases are invariably fatal following a progressive course. A variety of drugs have been tried in individual or small numbers of patients but there is no clear evidence of efficacy of any agent.

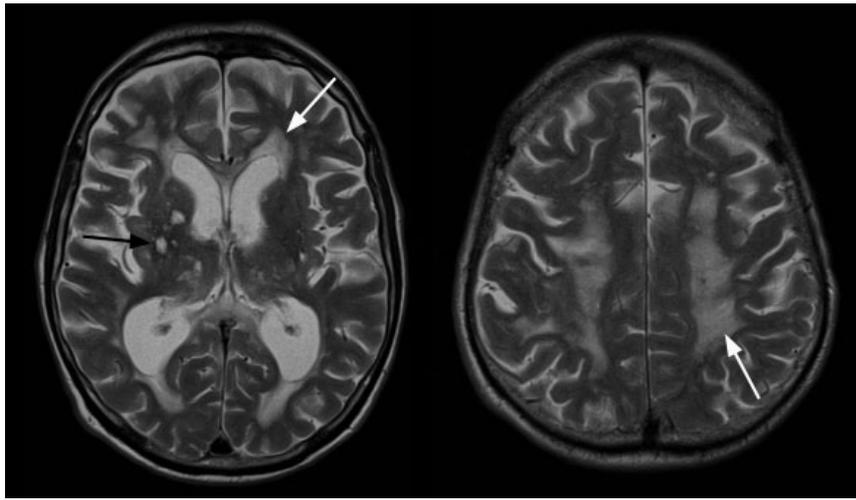

### Vascular dementia and vascular cognitive impairment

Cerebrovascular disease (Chapter 5) is a major cause of cognitive impairment and dementia both in its own right and in association with AD ('mixed dementia'). In the acute phase, stroke may be

associated with delirium and this in turn is associated with increased mortality and a worse functional outcome in survivors. Dementia has been estimated to occur in up to one-third of individuals within a year of stroke. Despite its frequency and importance, there is little consensus as to how 'vascular dementia' should be defined, whether in clinical or research settings. 'Vascular cognitive impairment' (VCI) may be a more appropriate catch-all term, because it reflects the broad range of clinical presentations including (in addition to clearly progressive cognitive decline) static or indolent cognitive syndromes and mild cognitive impairment on a vascular basis. In contrast to AD and other primary neurodegenerative disorders, VCI has been relatively little studied. The status of 'mixed' dementia is a particularly vexed issue. The frequent coexistence of vascular and Alzheimer changes presents serious practical challenges to the development and interpretation of treatment trials in both diseases, as well as complicating the interpretation of epidemiological studies suggesting common factors that may predispose to both AD and VCI.

Pathologically, there are no absolute criteria for a diagnosis of VCI. A spectrum of changes of variable severity occurs. Atheromatous involvement of large vessels may be found, although small vessel disease is typically prominent. Vascular changes are accompanied by lacunar and sometimes larger infarcts, typically in watershed regions between large arterial territories. Microscopically, there is lipohyalinosis of small arteries and arterioles, rarefaction and cavitation of white matter (leukoaraiosis) resulting from the conjunction of nerve fibre degeneration, gliosis and demyelination, and scattered cortical microinfarcts. Foci of old haemorrhage and amyloid angiopathy may also be observed. Pathophysiologically, lacunes are the result of completed infarction, whereas incomplete ischaemia resulting from partial vessel occlusion or hypotension can give rise to white matter lesions. There is evidence that autoregulatory perfusion reserve is decreased in zones of white matter damage, which is probably compounded by labile blood pressure control and raised plasma viscosity in vascular disease. The blood-brain barrier breaks down in these areas, and extravasated plasma proteins and other factors may contribute to neurotoxicity. Metabolic brain imaging and diffusion tensor MRI can demonstrate white matter abnormalities extending beyond the zone of damage on conventional structural brain imaging, underlining the dynamic nature of the vascular lesion and helping to explain why the relation between structural damage and cognitive impairment is not straightforward.

The clinical picture of VCI is diverse, and a given cognitive phenotype can result from a spectrum of pathogenetic mechanisms, including atherosclerosis, thromboembolism, thrombophilia, haemodynamic insufficiency, haemorrhage, and specific metabolic and genetic arteriopathies. Executive and attentional impairments, behavioural changes (disinhibition or abulia) and cognitive slowing with relative sparing of memory are clinical features common to many forms of vascular damage. This reflects the relative vulnerability of cognitive processes that depend on distributed neural networks and subcortical structures and pathways: an essential theme in our current understanding of VCI. Traditionally, emphasis was placed on the cognitive effects of acute stroke affecting a single large arterial territory or the stepwise accumulation of cognitive deficits accompanying recurrent cortical strokes: 'multi-infarct dementia'. However, it is increasingly recognised that VCI comprises a number of other clinico-anatomical syndromes, defined according to distinct patterns of clinical and brain imaging findings. Vascular changes are very common on brain imaging of

**Figure 8.16** Small vessel disease. T2-weighted axial MR images showing confluent abnormal signal around the ventricular margins and throughout the centrum semiovale (white arrow) and multiple lacunes in the basal ganglia (black arrow) typical of severe small vessel disease.

healthy elderly individuals, and determining that a particular cognitively impaired individual has VCI, rather than an alternative cause such as AD, may be difficult. Diagnostic instruments such as the Hachinski Ischaemia Score are available but are of limited value in clinical practice.

Discrete strategically located cortical infarcts that implicate the medial frontal lobe (anterior cerebral artery) or mesial temporal lobe (posterior cerebral artery) can have a disproportionate effect on executive function and memory respectively: such lesions may simulate the cognitive effects of more diffuse brain damage. Single strategic subcortical infarcts can lead to impairment of multiple cognitive functions by damaging functional circuitry linking the cortex with subcortical structures or by interrupting projection pathways to the cortex. Critical sites include the thalamus, basal ganglia, internal capsule, limbic circuit and upper brainstem. Because of the distributed cortical connections of these sites, infarcts here may give rise to a surprising diversity of clinical presentations: for example, thalamic lesions may present with varying combinations of diencephalic amnesia (in which the patient may become mentally 'marooned' in a remote place or time), semantic deficits, perceptual disorders, apraxia or other sensori-motor disturbances.

More commonly, VCI results from diffuse involvement of cerebral white matter and subcortical nuclei caused by small vessel disease. This is the clinical entity known as Binswanger's disease, a somewhat controversial term that has also been applied to the neuropathological substrate. These patients typically present with an indolent cognitive decline and lack a history of clinical vascular episodes; the syndrome may closely mimic primary degenerative dementias such as AD. Clinical clues include fluctuating deficits, bradyphrenia and prominent dysexecutive features. Memory impairment is frequent, although it is more variable, more dependent on attentional factors and more responsive to cueing than in AD. On neurological examination there may be brisk facial and limb reflexes and a short-stepped wide-based apraxic gait or *marche à petit pas*. Other features include parkinsonism and other extrapyramidal syndromes, urinary incontinence or pseudobulbar palsy. A history of vascular risk factors (especially hypertension) should be sought but is of limited discriminating value. Patients undergoing

major surgery (especially cardiac bypass) and those with congestive cardiac failure and orthostatic hypotension are especially vulnerable. However, an identical picture can occur even with a paucity of conventional vascular risk factors, suggesting that as yet undefined genetic and other factors also influence the development of cerebral small vessel disease.

The diagnosis rests on brain imaging findings of extensive, typical peri-ventricular white matter changes which predominantly spare subcortical U fibres and the corpus callosum and lacunes in the deep grey matter (Figure 8.16). MRI is the preferred modality because of its greater sensitivity; however, white matter changes may arise from a variety of different mechanisms and care is needed not to misclassify prominent peri-vascular spaces, which have no pathological significance. Existing brain imaging criteria for subcortical ischaemic vascular dementia have not been prospectively evaluated and do not reliably distinguish cases of 'mixed' dementia: although diffuse atrophy accompanies white matter damage, disproportionate atrophy of mesial temporal structures is a marker of AD. The relationships between cerebrovascular disease, neurodegeneration and atrophy as captured on brain imaging are complex and still poorly understood: cerebrovascular disease can itself lead to cortical atrophy, particularly in association with small vessel (lacunar) disease, which in turn is the clinical VCI syndrome most likely to produce insidious cognitive decline. Promising approaches for identifying concurrent Alzheimer pathology include MRI (in particular T2\* and susceptibility-weighted) sequences with sensitivity for detection of microhaemorrhages associated with amyloid angiopathy, functional brain imaging based on amyloid-binding ligands, and assays of neurodegeneration-associated protein markers (tau and A $\beta$ 1-42) in CSF: these techniques are becoming increasingly widely available. Although cognitive dysfunction (and more specifically, executive and attentional deficits) correlates with cerebral atrophy and with more severe white matter involvement, there is no agreement regarding the threshold, extent or distribution of the vascular lesion load required to produce cognitive impairment. Also uncertain is the relationship to the rate of accumulation of vascular lesions on serial imaging, although the rapid appearance of new lesions raises concern regarding an atypical aggressive process such as vasculitis or an active embolic source.

While MCI on a vascular basis is well-recognised clinically, consensus diagnostic criteria that could form the basis of large-scale observational studies or therapeutic trials have yet to be agreed. However, it is likely that conventional definitions of MCI that emphasise memory impairment will need to be modified to incorporate the early attentional and executive deficits that are clinical hallmarks of small vessel disease. Depression is an important consideration in such patients (as it is in all forms of VCI) because it is strongly associated with cerebral white matter disease and may amplify any cognitive deficit.

Although less common than ischaemic cerebrovascular disease, cerebral haemorrhage presents distinct diagnostic and management challenges, and multiple haemorrhages may simulate multi-infarct dementia. Hypertension is the key risk factor for most clinically significant cerebral haemorrhages; however, recurrent lobar haemorrhages are a marker for cerebral amyloid angiopathy. Pathologically, there is deposition of congophilic material (beta-amyloid peptide) in vessels of the cortex and leptomeninges, and there is a strong association with cerebral leukoariosis and cortical and subcortical microhaemorrhages. The origin of the vascular beta-amyloid is presently unclear. The extent of associated Alzheimer changes is variable, although these commonly coexist. Genetic factors influence the development of cerebral amyloid angiopathy: it is associated with *ApoE* e4 and e2, while the risk of cerebral haemorrhage is increased in association with the e2 allele. Rarely, cerebral amyloid angiopathy occurs on a familial basis with autosomal dominant inheritance, and various mutations leading to the deposition of specific amyloid proteins have been identified (Table 8.8).

A variety of other haematological, autoimmune, metabolic and genetic processes can cause VCI (Chapters 5 and 19). Clues to a process in one of these categories often lie in associated non-cognitive features, and they should be suspected in younger patients with a vascular phenotype but a paucity of conventional risk factors. The antiphospholipid antibody syndrome may produce dementia via ischaemic mechanisms and there may also be additional direct effects of the antibody on neural tissue. Cognitive impairment in sickle cell disease may reflect chronic hypoxia in addition to focal infarction. Of the genetic vasculopathies, CADASIL has attracted much interest recently as the culprit protein (a transmembrane receptor in smooth muscle cells coded by the *Notch3* gene) appears to have a fundamental role in cell signalling, suggesting that this entity may be part of a broader spectrum of related disorders. Various presentations are possible, including psychiatric disturbance and acute encephalopathies, and a history of adult onset migraine is common. Brain MRI (T2 or FLAIR) characteristically shows involvement of white matter in the temporal pole and external capsule (see Figure 5.30), unusual sites for conventional small vessel disease, and skin or muscle biopsy shows periodic acid–Schiff (PAS) staining of vessels and on electron microscopy granular osmophilic deposits adjacent to the basement membrane of arteriolar smooth muscle cells. The diagnosis is confirmed by screening the *Notch3* gene for known mutations; however, this is not straightforward as the gene is large and over 50 different mutations have been described.

The differential diagnosis of VCI is potentially very extensive, because it overlaps with the spectrum of diseases causing subcortical dementia with cerebral white matter change. These include multiple sclerosis, progressive multifocal leukoencephalopathy, HIV dementia, lymphoma, post-irradiation, post-traumatic and post-hypoxic states, hereditary leukodystrophies and rare familial forms

of AD with presenilin mutations. This list can usually be rationalised based on the clinical context. On imaging grounds, associated cortical infarction and involvement of the deep grey matter and brainstem are pointers to a primary vascular aetiology. Investigation of the patient with suspected VCI should include, in addition to the standard investigations listed in Table 8.4, an assessment of other end-organ damage (especially ischaemic heart disease) which may dictate overall prognosis. Brain imaging is essential and MRI is generally more informative than CT. Assessment of the carotid circulation is indicated where there is large-territory ischaemia or other suspicion of a symptomatic stenosis. Thrombophilia or other haematological or metabolic screens may be indicated, especially in younger patients. EEG often shows non-specific bitemporal slowing but preserved alpha rhythm, unless AD or another cortical degenerative process has supervened. CSF examination is indicated in younger patients or where an inflammatory or infective process is suspected and brain biopsy may be required in exceptional cases where cerebral vasculitis cannot be excluded by other means.

The management of VCI rests on primary and secondary prevention of further vascular damage, based on principles similar to those that hold for cerebrovascular disease in general (Chapter 5), and symptomatic treatment of cognitive deficits. Limited experience with the use of neuroprotective agents after stroke has been disappointing. Control of hypertension and other vascular risk factors remains the core management priority to prevent recurrent stroke. Antihypertensive treatment should be introduced cautiously in light of the evidence for impaired autoregulation in patients with subcortical ischaemic damage together with antiplatelet therapy. Although clear guidance is currently lacking, antiplatelet agents should probably be avoided in the presence of microhaemorrhages as these may signify associated amyloid angiopathy and a propensity to lobar cerebral haemorrhage. The benefit of statins on VCI is not clear, probably reflecting a weaker contribution of cholesterol to cerebrovascular disease. Randomised controlled trials suggests that the cholinesterase inhibitors are likely to be of symptomatic benefit in vascular dementia, although this is a difficult issue to resolve partly because of the problem of associated AD and also to the relative lack of suitable outcome measures (which tend to emphasise memory rather than the executive or attentional functions that are more relevant to VCI).

### Dementia in young adults

Dementia is very rare before the fifth decade: in young adults and adolescents, inherited errors of metabolism and other genetic disorders are over-represented and many of these present as a 'dementia-plus' syndrome. The cognitive profile frequently takes the form of a subcortical dementia with prominent behavioural and affective features, or even frank psychosis, which may be misinterpreted as a pseudodementia. As cognitive impairment in young adult life is often constitutional or the result of congenital brain damage or static insults in early life, it is always important to establish whether cognitive dysfunction is progressive: this depends on a detailed history of pregnancy, birth and early milestones, and physical, social and scholastic development in later childhood. Cognitive decline often occurs in the setting of more widespread neurological and systemic disturbance and diagnosis generally depends on additional clinical and laboratory findings.

Effective treatments with the potential for prevention or reversal of deficits are available for some inborn errors of metabolism, such as Wilson's disease (Chapter 6) and the porphyrias (Chapter 19), which although rare should always therefore be considered in the

correct clinical context. The large and diverse group of metabolic conditions also includes the mitochondrial cytopathies (Chapter 10) and a bewildering array of storage disorders (Chapter 19), in which the absence or partial inactivity of an affected enzyme leads to accumulation of abnormal material. The storage diseases can be subclassified in various ways: for example, according to the type of material deposited (e.g. glycolipid, glycosaminoglycan, lipopigment, cholesterol metabolites, polyglycosans), the primary site of cellular deposition (white matter in leukodystrophies, cell bodies in neuronal storage diseases), or the subcellular organelle affected (lysosomes, peroxisomes).

Clinicians may find it more useful to adopt a pragmatic approach based jointly on the availability of a family history and cardinal clinical features. This is the approach outlined in Tables 8.4 and 8.8. Many of these disorders have autosomal recessive inheritance, and family history is therefore often unrevealing; a history of parental consanguinity may therefore be crucial. Other diseases show variable inheritance (e.g. the mitochondrial diseases, as components of the respiratory chain are encoded both by nuclear DNA and maternally inherited mitochondrial DNA; Chapter 10). The presence of pyramidal, extrapyramidal, cerebellar or peripheral nerve signs are key diagnostic clues and help to direct investigations. Additional features such as seizures, retinopathy or deafness further restrict the differential diagnosis while certain features (such as corneal Kayser–Fleischer rings in Wilson's disease, or tendon xanthomas in cerebrotendinous xanthomatosis), if present, are pathognomonic of particular conditions.

Despite recent progress in elucidating the genetic and molecular basis of many inborn errors of metabolism, diagnosis remains challenging. This is compounded by the protean nature of the diseases themselves. Genetic diagnosis is not practical in many cases (e.g. Wilson's disease and Niemann–Pick disease), both because of the limited availability of the relevant tests and the intrinsic heterogeneity of the causative mutations, although this may change with the advent of next generation genetic sequencing techniques. Specialised processing of tissue samples is often required (e.g. muscle for respiratory enzyme analysis in mitochondrial disease; axillary skin for storage bodies in Kufs or Lafora body disease; fibroblast cultures in Niemann–Pick disease; Table 8.8). Despite much recent interest in disease-modifying therapies such as enzyme replacement or bone marrow transplantation in certain diseases (e.g. Gaucher's disease), the availability of such therapies remains limited, and cognitive deficits are unfortunately generally refractory to their effects. Accurate diagnosis is nevertheless of paramount importance in this group both for prognosis and genetic counselling.

In addition to genetically based disorders, non-degenerative acquired causes of dementia are also relatively more common in younger patients. The importance of this group lies in the potential for reversibility in many infective, inflammatory and acquired metabolic conditions. Advances in genetic sequencing techniques are also revealing links between hitherto unrelated conditions. Thus, while certain homozygous mutations in the *TREM2* gene cause a very rare dementia associated with leukoencephalopathy and bone cysts (Nasu–Hakola disease), other heterozygous *TREM2* mutations have recently been shown to be risk factors for sporadic AD.

### Potentially reversible causes of dementia

Although they are individually rare, many causes of dementia are potentially reversible and this group includes many diverse disease processes. A syndrome-based approach to the diagnosis of reversible dementias is presented in Table 8.9. Patients presenting with

these syndromes demand particular vigilance to ensure that a treatable process is not overlooked. Rapid clinical evolution is a feature common to a number of diseases in this category. However, it is important to emphasise that many cases of dementia resulting from a reversible process do not present with such clinical clues: all patients with dementia should therefore be screened for treatable contributions to their cognitive decline.

### Neoplasms and other space-occupying lesions

A variety of intracranial space-occupying lesions may present with insidious cognitive or behavioural decline. Potential causes include tumours, infectious lesions, chronic subdural haematoma and hydrocephalus. Cognitive and behavioural presentations are particularly associated with lesions in the frontal lobes, corpus callosum and midbrain. There may be associated features such as papilloedema or focal neurological signs, seizures, or systemic evidence of infection or primary tumour; however, such clues are often lacking and the detection of a process that may be amenable to surgical intervention is the single most important justification for brain imaging in all patients presenting with dementia. Biopsy or resection of the lesion is usually required for a definitive pathological diagnosis.

There are a number of other mechanisms besides focal cerebral damage by which neoplasms may produce cognitive dysfunction: metabolic disturbances associated with systemic cancers, paraneoplastic syndromes and meningeal infiltration. Cerebral lymphoma is notoriously protean, especially the intravascular variant which can closely mimic cerebral vasculitis and requires brain biopsy for diagnosis. Antineoplastic therapies may also be implicated in both acute and chronic cognitive decline, including cytotoxic drugs (especially methotrexate, or where multiple agents have been used) and cranial irradiation; these different modalities interact and show a dosage effect, and their delayed effects may be difficult to distinguish from tumour recurrence. Leukoencephalopathy and cerebral atrophy may manifest as a late decline in cognitive function up to several years post therapy. Cranial radiotherapy also predisposes to accelerated cerebral atherosclerosis and secondary tumours.

### Epilepsy and dementia

There are a number of mechanisms by which seizures can be associated with cognitive decline and dementia. Seizures themselves may cause cognitive decline, and it is particularly important to identify covert temporal lobe seizures that may cause an amnesic syndrome similar to degenerative dementias such as AD. The syndrome of transient epileptic amnesia is characterised by fluctuations in cognitive function associated with episodes of anterograde amnesia and retrograde amnesia incorporating time periods for which the patient has essentially no recollection. Exacerbation of deficits following sleep is characteristic. Other clinical features of temporal lobe seizures often coexist but these are variable and indeed pure 'amnesic seizures' may occur. Temporal lobe spikes may be evident in the surface EEG; however, a prolonged recording may be required. There may be evidence of hippocampal damage on MRI. Although the pathophysiology is not understood in detail, ictal hippocampal paresis with inability to transfer events into long-term storage is a plausible mechanism.

Cognitive dysfunction (in particular, impaired attention and bradyphrenia) may develop in association with a number of anti-convulsant agents, including phenytoin, phenobarbital, topiramate and valproate (the last may also cause a hyperammonaemic encephalopathy, which in its more severe state can mimic CJD).

<b>Extrapyramidal syndromes</b>		
Tics – motor stereotypies, psychiatric disturbances, may have precipitating factor (e.g. respiratory infection)	ABGA syndrome	MRI: basal ganglia signal change Serum: ABGA titre
Encephalitis lethargica: sleep disturbance, psychiatric disturbances, ocular abnormalities, parkinsonism, dyskinesias; may have precipitating factor (e.g. upper respiratory tract infection)	Encephalitis lethargica* (?post-infectious)	MRI: basal ganglia, thalamic, midbrain signal change CSF: OCBs Serum: ABGA may be positive
<b>Chronic meningitis</b>		
Uveitis, hypothalamic dysfunction, cranial nerve signs or polyradiculopathy, systemic features; often recurrent episodes	Neurosarcoidosis	CXR: various patterns MRI: w.m. lesions ± meningeal enhancement CSF: lymphocytic meningitis
Oral and genital ulcers, uveitis, rash, posterior circulation strokes, racial predilection (especially Turkish/Japanese)	Behçet disease	MRI: brainstem, basal ganglia lesions CSF: lymphocytic meningitis
May have evidence of primary tumour; headache, confusion, cranial nerve and radicular signs	Carcinomatous/lymphomatous/ leukaemic	CT/MRI: may have mass lesions CSF: cytology, immunophenotyping (may need several)
Immunosuppression (incl HIV), systemic features, may have cranial nerve signs, strokes; travel, occupational exposures	TB/fungal/'atypical' infectious agents	CXR: frequently abnormal CT/MRI: meningeal enhancement, may have hydrocephalus, mass lesions (tuberculoma) CSF: lymphocytic meningitis, AFB and fungal cultures, cryptococcal Ag
Tick bite/travel to endemic area, skin lesion, arthritis, may have radiculopathies/mononeuropathies/encephalomyelitis	Lyme disease (neuroborreliosis)	Serum: Lyme serology (may be negative) CSF: pleocytosis (may be absent), Lyme serology
Argyll Robertson pupils (light-near dissociation), strokes, dorsal column signs (tabes dorsalis), HIV infection	Neurosyphilis	Serum: treponemal serology CSF: pleocytosis, treponemal serology
<b>Infectious syndromes with posterior hemisphere signs</b>		
Adolescent or young adult, history of measles, rapid course, florid myoclonus and seizures	SSPE*	EEG: periodic burst-suppression CSF: OCBs (measles-specific Ab)
Immunosuppression/haematological malignancies, often hemiparesis, ataxia	PML*	MRI: confluent posterior w.m. changes CSF: JC virus PCR
<b>Other infectious syndromes</b>		
HIV risk factors, AIDS-related illnesses, advanced immunosuppression, gait disorder, seizures	HIV (AIDS–dementia complex)	MRI: confluent w.m. changes Serum: HIV serology, low CD4 count
Arthralgia, gut symptoms, facial movement disorder (oculomasticatory myorhythmia), supranuclear gaze palsy, myoclonus	Whipple's disease of CNS	CSF: Whipple PCR Duodenal biopsy
<b>Acquired metabolic disturbances</b>		
History of poor nutrition, food faddism, vegan, features of malabsorption; specific features (e.g. Wernicke–Korsakoff, pellagra)	Nutritional deficiency states	Dietary assessment, nutritional and malabsorption (incl coeliac) screens, empirical therapy (e.g. thiamine)

Table 8.9 (continued)

Syndrome/clinical features <sup>§</sup>	Candidate diagnoses	Relevant investigations
Clinical features of endocrine dysfunction	Endocrinopathies	
Clinical features of organ failure; organ transplantation	Uraemia Hepatic encephalopathy Pancreatic encephalopathy Cardiorespiratory failure	Biochemical and metabolic screens, organ-specific imaging findings
Obesity, morning headaches, daytime somnolence, snoring	Obstructive sleep apnoea	Sleep study
<b>Toxicological exposures</b>		
Alcohol dependence, may have cerebellar ataxia, peripheral neuropathy, features of Wernicke–Korsakoff encephalopathy	Alcoholic dementia*	Co-morbidities: nutritional screens, liver function tests, brain imaging (exclude SDH)
History of heroin inhalation ('chasing the dragon'), parkinsonism, ataxia, cortico-spinal signs, subacute encephalopathy	Pyrolysate encephalopathy	MRI: diffuse w.m. increased signal sparing U fibres (esp posteriorly)
Polypharmacy, recent changes in therapy, culprit agents	Iatrogenic	Medication review
Suspicion of overt or covert poisoning (e.g. occupational/environmental, recreational drugs, self-harm), specific systemic features; specific neurological syndromes may occur (e.g. vasculitis with cocaine, amphetamines)	Environmental poisons (e.g. carbon monoxide, heavy metals, solvents, herbicides), illicit drugs	Specific urine and blood screens if available, other specific findings (e.g. blood picture, EMG)

\* Limited potential for reversibility.

The potential for cognitive deficits following surgical resections for intractable epilepsy (chiefly, temporal lobectomy) has long been recognised and must be taken into account during surgical planning and preoperative studies of the lateralisation of cognitive functions (especially language and memory).

A number of disorders predispose to the development of both cognitive dysfunction and seizures: examples include intoxications and drug withdrawal (notably alcohol), intracranial infections, head trauma, stroke, intracranial space-occupying lesions, cerebral vasculitis and degenerative dementias including AD (generally later in their course). In such disorders, care is needed to distinguish the cognitive effects of seizures from the underlying disease process. Complex partial seizures frequently accompany limbic encephalitis, whether infectious, paraneoplastic or autoimmune. Certain epilepsy syndromes are integral to primary disease processes that also produce progressive cognitive decline: these include epilepsy partialis continua in Rasmussen's encephalitis and progressive myoclonic epilepsy in neuronal storage diseases associated with inborn errors of metabolism (Table 8.8).

### Limbic encephalitis

Limbic encephalitis (LE) is typically considered to be a subacute encephalopathy characterised by short-term memory impairment, confusion, alteration of consciousness, complex partial temporal

lobe seizures and psychiatric syndromes. While it is mandatory always to consider, exclude and where doubt remains treat for infectious causes, including herpes simplex encephalitis (Chapter 9), classically LE is considered in the context of autoimmunity. LE was initially described as a paraneoplastic phenomenon associated with small cell bronchial (50%), testicular (>20%) and breast tumours (>13%). Several specific autoantibodies are recognised in this context, including ANNA1 (*anti-Hu*) in bronchial small cell carcinoma; *Anti-Ma2 (anti-Ta)* in testicular tumour; *CRMP5/(anti-CV2)* in lymphoma, thymoma, bronchial small cell carcinoma; *ANNA3* in bronchial small cell carcinoma; and *N type VGCC* in bronchial small cell carcinoma and breast tumours. Paraneoplastic LE is usually associated with the subacute (weeks to months) onset of ante-grade memory impairment, temporal lobe seizures and psychiatric symptoms (particularly depression, aggressive psychosis, hallucinations and personality change). There may be other associated constitutional symptoms resulting from the underlying cancer, and other specific neurological features depending on the particular antibody (e.g. brainstem and eye movement abnormalities are common with *Ma2*). The MRI in paraneoplastic LE typically shows non-enhancing increased signal in the mesial temporal lobes, which can undergo prominent atrophy as the disease progresses. The EEG shows diffuse slowing with epileptiform discharges and there is a CSF pleocytosis and elevated protein in the majority. Serum

antineuronal antibodies are not detected in approximately 40% of cases of histologically proven paraneoplastic LE, and it is important therefore that the diagnosis should not rely on their identification. In the majority (approximately 60%) of cases, the neurological presentation antedates the diagnosis of cancer and usually occurs in the absence of local or distant spread, emphasising the importance of early diagnosis. While a neoplasm may be identifiable on examination – underscoring the importance of a thorough physical examination including the breasts and testes in rapid and unusual dementia syndromes – occult tumours may be very difficult to detect. CT scanning, mammography or ultrasound of testicles/ovaries may detect tumours, supplemented where available by whole body FDG-PET which is very sensitive at detecting occult glucose-avid malignancy. The mechanism of paraneoplastic LE is unclear but is probably related to cell-mediated immunity developing against cancer cells. Paraneoplastic LE may improve following removal of the primary tumour usually with immunosuppression but there is often a considerable residual cognitive impairment and seizures may persist.

While classic antibody mediated syndromes including CNS vasculitis, Susac's syndrome, lupus cerebritis, Sjögren's syndrome and antiphospholipid syndrome may cause cognitive syndromes, over the last decade or so a number of novel antibodies directed against cell-surface antigens have been specifically associated with autoimmune encephalitis. Antibodies against the voltage-gated potassium channel complex are associated with a variety of peripheral hyperexcitability syndromes including cramp fasciculation syndrome and autoimmune neuromyotonia. In Morvan's syndrome, as well as these peripheral features, there is additional CNS involvement, with severe insomnia, seizures, hyperhidrosis, autonomic instability and subacute encephalopathy, often in association with thymoma. Recently it has emerged that antibodies directed against the VGKC complex are more frequently associated with limbic encephalitis, without peripheral manifestations and usually without an underlying tumour. Patients with significantly elevated (e.g. >400 pM, NR <100 pM) VGKC complex antibodies typically present in middle age, males more affected than females, with a subacute onset of behavioural changes, seizures and amnesia. MRI scanning typically but not always shows high signal change in medial temporal lobe structures, there is often significant and treatment resistant hyponatraemia, with normal CSF. Untreated, a significant proportion of patients will develop irreversible cognitive impairment, including an unusual, temporally ungraded dense retrograde amnesia, which may be prevented by prompt recognition and treatment with immune suppression (typically plasma exchange/IVIg followed by steroids). However, some patients may present with *formes frustes*, including REM behaviour disorder and unusual seizures, which may resolve spontaneously. Recent work has demonstrated a number of specific antigenic targets within the VGKC complex which begin to explain the phenotypic diversity: thus, patients with antibodies against the Lgi1 subunits of the channel are most likely to have 'classic' LE with signal change and hyponatraemia, and importantly may present with brief, frequent jerks of the face and hand (so-called faciobrachial dystonic jerks) preceding the development of cognitive impairment. Conversely, individuals with CASPR2 antibodies are more likely to have peripheral manifestations, although they can also have LE.

A distinct neuropsychiatric syndrome with antibodies directed against the NMDA receptor was first described in 2007 in young women with ovarian teratomas presenting with behavioural change, amnesia, movement disorders including choreoathetoid

movements and orofacial dyskinesia, and autonomic disturbance including hypoventilation. The phenotype of this syndrome has since expanded to include women with teratomas or other tumours, men and children; and to include a variety of different cognitive and neuropsychiatric phenotypes including late onset psychosis. As with VGKC complex antibody encephalitis, recognition of this syndrome should prompt a hunt for an occult neoplasm, as resection (with immunosuppression) can result in dramatic improvements. Non-paraneoplastic cases can respond very well to treatment with immunosuppression, although there is a risk of relapse. A number of other antibodies including GAD, glycine and GABA-B antibodies have rarely been associated with autoimmune encephalitis.

### Infective, metabolic, toxic and other causes of dementia

Cognitive dysfunction is a frequent accompaniment of infective, metabolic and toxic disorders, whether systemic or restricted to the CNS. The primary disorders are dealt with at greater length in Chapters 9 and 19: here, basic principles relating to their effects on cognition are summarised. In the majority of cases, cognitive decline is acute and manifests as a delirium; however, in a smaller proportion an insidious deterioration ensues which may be difficult to distinguish from more common degenerative causes of dementia. The exact pathophysiology of cognitive decline is poorly understood in many cases and is probably multifactorial. The cognitive profile itself is rarely diagnostic, and indeed remains poorly characterised for many of the disorders in this large and diverse group. Posterior hemisphere signs may be prominent in some conditions, such as progressive multifocal leukoencephalopathy and subacute sclerosing panencephalitis. However, most diseases in this group can produce a variable combination of behavioural and executive deficits, often with bradyphrenia: the pattern of a subcortical dementia. General clues that one may be dealing with a disease process in one of these categories include an aggressive course, evidence of active systemic disease and younger age. Risk factor profiles based on ethnic or geographical origin (many of these diseases are more common in poorer populations), occupational, travel or sexual habits, clinical infection or infectious contacts, immunosuppression or toxic exposures may raise suspicion of a particular cause. Impairment of cognition in patients with HIV is common and is known as HIV-associated neurocognitive disorder (HAND). In the early days of the HIV epidemic, prior to the introduction of combination antiretroviral therapy (cART), a subcortical dementia (AIDS dementia complex) would often develop, characterised by cognitive slowing and impaired attention and concentration in the early stages. Despite the introduction of cART, the overall prevalence of cognitive impairment has been relatively unchanged, seen in around a half of all patients, but in the cART era the majority of patients have mild cognitive impairment rather than dementia. Current criteria separate asymptomatic neurocognitive impairment from mild neurocognitive disorder (both defined as scoring one standard deviation below the mean in two cognitive domains but with no impairment in activities of daily living in the former). HIV-associated dementia (HAD) (defined as scoring two standard deviations below the mean in two cognitive domains with impairment of ADLs) is much less common and generally has a different cognitive profile now than in the pre-cART era, with more cortical (rather than subcortical) impairment, often with memory problems predominating. Characteristic and discriminating clinical features and investigations for some of these diseases are summarised in Table 8.3.

### Controversial entities

A number of conditions often listed as causes of dementia continue to arouse controversy, because of uncertainty regarding the pathogenetic mechanism or the validity of the association with cognitive decline.

In addition to its well-recognised acute effects on cognition and behaviour, alcohol has an established association with dementia and forms a high proportion of young onset cases in community-based series. However, it is often unclear to what extent cognitive decline in an individual patient is attributable to the toxic effects of ethanol *per se* rather than associated factors such as malnutrition (in particular, thiamine deficiency and Wernicke–Korsakoff syndrome), concomitant drug use, hepatic encephalopathy and other associated medical conditions, head trauma or the interaction of multiple factors. Marchiafava–Bignami disease, a rare degeneration of the corpus callosum, was described initially in male Italian red wine drinkers but is likely to be the result of an uncharacterised nutritional deficiency or osmotic dysmyelination. On balance, it is likely that chronic heavy alcohol intake can itself produce a dementia that includes frontal deficits and difficulty with complex learning and which is accompanied by generalised cerebral atrophy. Improvement in cognitive function may occur with prolonged abstinence, although little information is available concerning the time course or extent of this. A variety of neuropathological changes have been described in alcoholics, including cortical neuronal loss and gliosis, cerebellar degeneration, and atherosclerosis; however, none could be considered pathognomonic. In some cases, alcoholism can be the result of behavioural change caused by an alternate cause of dementia.

Head trauma is linked with ‘dementia pugilistica’, a syndrome of cognitive deterioration, behavioural change and parkinsonism of variable severity that is observed in boxers and other individuals who have sustained significant repeated head injuries. Pathologically, dementia pugilistica shares many features with AD, and indeed head injury is a risk factor for later development of AD in epidemiological studies. The level of risk is influenced by the severity and tempo of the injury (greater with loss of consciousness and with repeated insults) and possibly *ApoE* status (greater in those with the  $\epsilon 4$  allele).

The association between dementia and common autoimmune disorders such as Hashimoto’s thyroidopathy and coeliac disease is not straightforward. Such diseases may lead to cognitive deterioration secondary to a systemic disturbance such as hypothyroidism or malabsorption. The key issue concerns the potential pathogenetic role of autoantibodies in causing cognitive decline in such disorders. Despite a growing literature on ‘Hashimoto encephalopathy’ its nosological status remains to be defined, although there is growing consensus that thyroid antibodies are not causative. While the aetiology remains unclear, it is important to exclude other treatable processes (e.g. cerebral vasculitis or VGKC complex or NMDA-antibody associated syndromes) in all suspected cases of Hashimoto’s encephalopathy.

Normal pressure hydrocephalus (NPH) is considered here insofar as it has been overdiagnosed in patients presenting with cognitive impairment. It is traditionally listed as a cause of reversible dementia, heralded by a clinical triad of gait apraxia, urinary incontinence and cognitive decline. However, the validity of the term has been criticised. NPH appears to be an idiopathic communicating hydrocephalus in a high proportion of cases, although it may follow arachnoiditis, subarachnoid haemorrhage or head trauma. Impaired CSF resorption at the arachnoid granulations is

most often proposed as the pathogenetic mechanism. Supportive radiological features include ventricular enlargement that is disproportionate to the degree of gyral atrophy, occluded cortical sulci, prominence of the third and fourth ventricles with no macroscopic evidence of ventricular obstruction, and (on MRI) an aqueductal CSF flow void. The demonstration of normal CSF pressure and clinical improvement following removal of a diagnostic aliquot of CSF are put forward as additional criteria for the diagnosis. This can be supplemented by prolonged monitoring to document phasic increases in CSF pressure, CSF conductance studies or cisternography. Although the potential for improvement following surgical insertion of a CSF shunt has often been emphasised, the relationship between NPH and cognitive decline, as opposed to gait impairment, remains unclear. ‘Pure’ NPH is uncommon. Many patients diagnosed with NPH have changes of small vessel disease and/or AD at postmortem, and it has been shown that patients with AD may improve transiently following ventricular drainage (the mechanism is not clear). Patients with ‘idiopathic’ NPH, longstanding symptoms, established dementia, or radiological evidence of significant cerebral atrophy or cerebrovascular disease generally fail to improve cognitively following CSF shunting. The shunt procedure itself carries a significant risk of complications such as subdural haematoma in this population. It may be helpful to use molecular means (CSF or amyloid PET) to determine the extent of Alzheimer-related pathology in such patients, as there is evidence that individuals with AD pathology have a poor prognosis following shunting.

## Management of dementia

### Risk factor management

The greatest risk factor for development of dementia is age. However, there are several modifiable risk factors. Moderate exercise reduces the risk of dementia as does modification of vascular risk factors: obesity, hypercholesterolaemia, diabetes, hypertension and smoking.

### Co-morbidity

Delirium is often a harbinger of dementia and patients with dementia have a lower threshold for developing delirium and will take longer to recover than those who are cognitively normal. The usual causes apply, such as infection (usually involving the urinary or respiratory tract), metabolic/biochemical derangement, hypoxic/ischaemic damage or medication. These should all be excluded as a cause and treated actively if identified. Multiple drugs can have a significant adverse effect on cognition.

Depression is both an important treatable cause and compounding feature of dementia, occurring in up to 20% of individuals with AD, vascular dementia and DLB. Over 50% of patients with dementia experience depressive symptoms at some stage. Symptoms should be actively sought and treated in any patient at presentation and during the course of their illness. Tricyclics should be avoided because of their anticholinergic effects. Selective serotonin reuptake inhibitors (SSRIs) are also preferable in FTD, as they may be effective in modifying the behavioural symptoms, in addition to any depressive symptoms. As in all patients, side effects should be looked for and response monitored.

Epileptic seizures occur in patients with dementia more frequently than among healthy elderly individuals. The incidence of seizures among patients with dementia varies with the aetiology of the dementing illness. In patients with AD, approximately 10–20%

have at least one seizure. Seizures usually occur several years post diagnosis, in moderate to severe AD. There is an increased incidence in early onset AD, especially with *PSEN1* mutations. The incidence of seizures in other dementing diseases is less clear. Diagnosis can be delayed by difficulty in description as a result of cognitive impairment. The potential cognitive adverse effects of some antiepileptic drugs must be taken into consideration, and the lowest effective dosage should be used.

The majority of patients with dementia are cared for in the community, at home or in nursing homes. Up to 30% of patients in UK nursing homes have received antipsychotic drugs, usually neuroleptics, although their use is steadily declining. In dementia, particularly DLB, these drugs can have catastrophic consequences; atypical antipsychotics should be used in preference. Even these are not free of the risk of increasing side effects and confusion, therefore treatment titration must be cautious. It is also important to remember the reported increase in stroke risk with risperidone and olanzapine.

### Behavioural management

Coping on a daily basis with challenging behaviour is a major burden for the carer of a patient with dementia. In the early stages, the major behavioural changes are seen in FTD, but other disorders may also produce significant behavioural problems at some stage. The loss of insight seen in some diseases, combined with the change in personality and disinhibition, have a huge impact on the carer, causing strain on the relationship and loss of sense of control. Another problem apparent in mild dementia is significant anxiety, which also may exacerbate behavioural problems.

In more severe dementia, a multidisciplinary assessment is required for behavioural modification. This approach tends to be most successful in patients in nursing homes. Behavioural modification may be achieved by altering the environment, if there is an external precipitant, or by conditioning techniques with positive reinforcement. Strategies may improve performance, for example scheduled toileting or prompted voiding can reduce urinary incontinence. Playing music during meals and bathing can reduce disruptive behaviour. Exercise, massage and pet therapy have all been used to reduce abnormal behaviours.

Hallucinations often occur at home in dimly lit surroundings ('sundowning') and improved lighting may help; as always, intercurrent infections and drugs should be considered as possible exacerbating factors.

Patients may become irritable or angry at being disturbed at times of washing, dressing or eating. A considered response is needed, with maintenance of a respectful friendly approach, removal of exacerbating factors and consideration of behavioural measures such as distraction or 'time out'.

Sleep cycle is often very disturbed – patients may be up all night and sleep all day. This can be extremely distressing for carers. It is important to exclude delirium, and to ensure structure and rewarding activities during the day. A routine should be established with a fixed bedtime, no stimulants and meal before sleep. If these fail, it is reasonable to provide a trial of medication, such as an anxiolytic.

Urinary and faecal incontinence may become a problem for multiple reasons: medical causes such as diabetes mellitus, or cortical loss of bladder control, reduced mobility; or cognitive causes such as poor recognition, disorientation or impaired planning. In addition to prompt treatment of medical problems such as urinary tract infections, simple physical measures can make a significant difference. Regular visits can reduce the likelihood of accidents; avoidance of bedtime drinks, labelling of the toilet to provide cues and

the use of incontinence pads all help. Pharmacological therapies (Chapter 25) may help, but have the potential for worsening confusion and need to be monitored closely.

### Safety

Patients with mild to moderate dementia usually function best in familiar surroundings. It is important to create an appropriate, safe and supportive environment to encourage optimal function. A home safety evaluation and appropriate modifications should be organised. For example, signs may be placed around the house to orientate patients.

Patients may become increasingly unstable on walking, yet be unaware of this because of their cognitive impairment. Wandering is a frequent problem, often associated with lack of stimulation and ensuing frustration. Behavioural measures such as increasing interaction, providing stimulation at day centres, encouraging exercise and increasing the structure of the day may help. At times, locking doors is the only solution.

In patients with significant orobuccal apraxia (e.g. in progressive non-fluent aphasia), a feeding nasogastric tube, or even a percutaneous endoscopic gastrostomy, may be required. Patients and family may opt not to have this, but discussion is important. Broaching the subject early in the course of the illness, if swallow is involved, will enable the patient and carers to make an informed decision.

As dementia progresses, increasing supervision is necessary, eventually becoming continuous. This curtails the carer's ability to continue working, and progressively reduces their independence. Day care centres can provide release for the carers during the week and give structure to the patient.

The issue of fitness to drive creates enormous anxiety for the patient diagnosed with dementia, who perceives removal of a licence as a loss of independence. Driving for patients with frontal impairment can be particularly difficult because of their lack of insight and poor judgement, and families often have difficulty in persuading patients to stop. In contrast, patients with AD often progressively curtail their driving activities as they realise they or their relatives feel unsafe. It is difficult to determine at what point an individual becomes sufficiently impaired to cease driving, and the relationship between the severity of dementia and driving abilities is complex. The UK driving licence law states that if at any time the licence holder becomes aware that he/she has a disability he/she must inform the driver and vehicle licensing authority (DVLA). The guidelines state that in general a patient able to attend to day-to-day needs, with adequate insight and judgement, and not disorientated in time or place may be fit to drive. A licence may be issued on a yearly basis with reassessment on each renewal. If in doubt, assessment at a mobility centre may be required; if serious doubt exists a medical adviser at the DVLA may require a test to be taken.

In practical terms, the issue must be discussed with the patient and family once a diagnosis of dementia is made. The patient should be reminded of their legal obligation to inform the DVLA. If the patient and family do not inform the DVLA, and the physician is concerned, then he/she can inform the DVLA directly. Each case is individual, and the discussion should include carers and the patient.

### Caring for the carer

In the United Kingdom and the United States, 33–60% of carers of patients with dementia are spouses over 75 years, of whom 75% are women. This profile, and the perception of the role of a carer, varies across cultures and socio-economic groups. In most of the Western world, where the extended family is small or may not exist, the

burden of caring can be very high, often focusing almost entirely on a single, often elderly individual.

Compared with age-matched non-carer controls, carers have problems in several areas:

- Depression, stress, low self-esteem and poorer sense of well-being are common and are more severe in young onset dementia and if the premorbid relationship was ambivalent.
- Carers experience poorer physical health, with higher levels of chronic conditions, more drug prescriptions and GP attendances and poorer self-perception of health.
- Social isolation is frequent as carers have less time for themselves for hobbies and going out, and may have difficulty coping with social embarrassment caused by the patient's behaviour.
- The cost of nursing, respite care and lost earnings should not be underestimated, and often has a huge impact on quality of life, compounding the above factors.

This complex relationship requires both formal support from professionals and informal support from friends and relatives. The carer's needs change through the evolution of the illness and often continue after the death of the patient. Local support groups and national associations are extremely important in this regard.

### Planning for the future and end of life issues

If no will is in existence, this should be discussed amongst the family. In order to make a will the patient needs to understand what they are doing and the effect it will have: what they have to leave, and who might make claims on it. Advanced directives concerning treatment should also be considered when patients are competent.

In the later stages of dementia the individual becomes totally dependent in activities of daily living, needing continuous nursing care. Profound loss of memory may lead to inability to recognise familiar surroundings or family and friends. Almost all comprehensible speech may be lost. There are particular issues that emerge at this stage, many with ethical implications, including whether to place the patient in institutional care. Important issues in any setting include:

- **Feeding** Swallowing may be difficult and good nutrition becomes a priority. Individuals at this stage need speech therapist assessment of swallowing, dietitian advice on nutrition and consultation with family as to when and if to institute feeding devices.
- **Medical treatment** Weight loss and immobility contribute to vulnerability to pressure sores and infection. Issues of withholding life-prolonging curative treatment, including cardiorespiratory resuscitation, need to be discussed with the family.
- **Postmortem diagnosis and brain donation** Clinical diagnostic accuracy in patients with dementia is at best 70–80%. Postmortem neuropathological examination can provide an accurate diagnosis with potentially important aetiological information for familial diseases. Families often gain benefit from contributing to research from tissue donation. Examination of the brain and use of tissue, however, can only be performed with written informed consent from the next of kin, even in the case of a coroner's postmortem.

## CHAPTER 9

# Infection in the Nervous System

Robin Howard, Carmel Curtis and Hadi Manji

National Hospital for Neurology & Neurosurgery

Infections that involve the nervous system carry a high morbidity and mortality, particularly in developing countries where the burden of disease is great, diagnosis is difficult and limited resources mean that availability and access to treatment is poor. In the developed world, neurological infection is less frequent but continues to cause significant problems of diagnosis and management. Acute bacterial meningitis and viral encephalitis remain significant causes of morbidity and mortality in all ages everywhere. Increasing global travel means that unfamiliar organisms are encountered unexpectedly. There is also increasing recognition that familiar pathogens may manifest disease in unexpected patterns and settings and emergent pathogens have become important, particularly in the immunosuppressed patient because of HIV and post transplant. The increasing burden of AIDS continues to present worldwide social and economic concern.

Infections of the nervous system can be caused by viruses, bacteria, fungi or protozoa. They may affect the meninges, cerebrospinal fluid (CSF), brain parenchyma, spinal cord, nerve roots, peripheral nerve or muscle. Infections of the central nervous system (CNS) may be divided into meningitis, encephalitis and focal suppuration or inflammation. In meningitis there is inflammation involving the pia and arachnoid mater and the subarachnoid space. Encephalitis is infection and inflammation within the brain parenchyma. Focal infection causes abscess formation within or immediately adjacent to the brain or spinal cord. These patterns may overlap and when infection involves the meninges, brain, spinal cord and nerve roots descriptive compound terms are used: meningoencephalitis, meningomyelitis, encephalomyelitis, meningoradiculitis and meningoencephalomyelitis. Neurological disturbances may also arise as a consequence of direct infection or from a secondary para-infectious immune-mediated mechanism.

The presentation of infections of the nervous system can be highly variable, ranging from acute fulminating meningitis or encephalitis leading to death within hours, to the development of disease many years after the initial infection. The spectrum of neurological manifestation is also highly variable, ranging from meningism and impaired consciousness, to signs of cortical and subcortical dysfunction, or involvement of the spinal cord, nerve roots, peripheral nerve or muscle.

The understanding of neurological infection has been advanced by new techniques of molecular diagnosis, in particular wider

availability of polymerase chain reaction (PCR) assay to detect bacterial and viral nucleic acid in CSF, and improved imaging of brain and spinal cord. There have also been many important recent advances in the development of therapies targeted towards specific pathogens, such as antiretroviral therapy, and in facing the challenges presented by increased antibiotic resistance of pathogens such as pneumococci, tuberculosis and malaria. Even more importantly, the global burden of infections of the nervous system has been greatly reduced by the development of effective strategies of prevention for conditions such as poliomyelitis, leprosy and malaria.

## Bacterial meningitis

Bacterial meningitis is caused by a primary infection within the subarachnoid space that leads to acute inflammation of the meninges (pia and arachnoid mater). It can be caused by a variety of organisms which vary in frequency according to the age of the host and other risk factors.

## Epidemiology

The incidence of bacterial meningitis is 2–6/100 000 per annum, with peaks in infancy, adolescence and the elderly. Common causes of meningitis by age and risk factors are shown in Table 9.1. The incidence of *Haemophilus influenzae* type b, group C meningococcal (*Neisseria meningitidis*) and pneumococcal (*Streptococcus pneumoniae*) meningitis have declined dramatically with the introduction of vaccination, particularly in young children. The burden of bacterial meningitis is now borne by the older population. The most common infective species in adults in the United States are now *S. pneumoniae* (58.0%) followed by group B streptococcus (18.1%), *N. meningitidis* (13.9%), *H. influenzae* (6.7%) and *Listeria monocytogenes* (3.4%). The overall case fatality rate is 14.3% and has not changed significantly over the last decade.

## Pathogenesis

Bacterial infection reaches the CNS either by direct invasion, haematogenous spread or embolisation of infected thrombi. In addition, there may be direct extension from contiguous structures via the diploic veins or erosion of an osteomyelitic focus and infection may be iatrogenic (e.g. following external ventricular drainage, ventriculo-peritoneal shunt, intracranial pressure monitor or surgery).

**Table 9.1** Common causes of bacterial meningitis by age and risk factors.

Neonates (<3 months)	Group B streptococcus <i>Escherichia coli</i> <i>Listeria monocytogenes</i>
Infant and child (>3 months)	<i>Streptococcus pneumoniae</i> (pneumococcus) <i>Neisseria meningitidis</i> (meningococcus) <i>Haemophilus influenzae</i> type b
Adults <50 (healthy and immunocompetent)	<i>S. pneumoniae</i> <i>N. meningitidis</i>
Adult >50	<i>S. pneumoniae</i> <i>N. meningitidis</i> <i>L. monocytogenes</i> Aerobic Gram-negative organisms
Pregnancy	<i>L. monocytogenes</i>
Immunosuppressed (e.g. malignancy, alcohol, diabetes mellitus, septicaemia)	<i>S. pneumoniae</i> <i>N. meningitidis</i> Gram-negative bacilli <i>L. monocytogenes</i> Group B streptococcus <i>Staphylococcus aureus</i>
Impaired T-cell immunity (HIV, immunosuppressant medication, e.g. corticosteroids, post-transplant, TNF-alpha inhibitors, myeloproliferative disorders)	<i>S. pneumoniae</i> <i>N. meningitidis</i> Gram-negative bacilli <i>L. monocytogenes</i> Group B streptococcus <i>S. aureus</i>
Rarer causes	Non-typhoidal salmonellae <i>Shigella</i> spp. <i>Clostridium</i> spp. <i>N. gonorrhoeae</i>
Foreign bodies within the CNS (e.g. CSF shunts)	Coagulase-negative staphylococci <i>Propionibacterium</i> spp.
Splenectomy or splenic dysfunction, as in sickle cell disease	<i>S. pneumoniae</i> <i>H. influenzae</i> type b Non-typhoidal <i>Salmonellae</i>
Postoperative meningitis	Gram-negative bacilli including <i>Pseudomonas aeruginosa</i> , <i>S. aureus</i>

CSF, cerebrospinal fluid.

In community-acquired meningitis, the transmission of pathogenic bacteria occurs by respiratory droplet spread or close contact with a carrier. The process by which these bacteria gain access to the CNS is complex. Bacteria initially colonise the nasopharynx by attaching to epithelial cells using outer adhesive pili and membrane

proteins. The risk of colonisation of the respiratory epithelium is increased by damage caused by irritants such as a preceding viral illness or cigarette smoke. Their capsular polysaccharides help to overcome host defence mechanisms including impairment of mucosal immunoglobulin A (IgA). The bacteria are carried across the epithelial cell into the intravascular space where they are relatively protected from the complement-mediated humoral response because of their polysaccharide capsule.

Bacteria that survive in the bloodstream gain access to the CSF via the choroid plexus epithelium or cerebral capillaries. They cross between endothelial cells by disrupting intercellular tight junctions or causing endothelial cell injuries. Once the bacteria reach the CSF they are in an immunologically privileged site where there is minimal complement-mediated humoral response. Bacteria multiply rapidly within the CSF and bacterial wall components released by lysis induce an inflammatory process involving the meninges and brain substance. This, in turn, leads to increased permeability of the blood-brain barrier allowing further leakage of plasma proteins into the CSF which contributes to the inflammatory and purulent exudates within the subarachnoid space (an immunologically privileged site). There is initially a temporary increase in cerebral blood flow leading to disruption of cerebral autoregulation and an increase in intracranial pressure. Worsening exudates infiltrate the arterial walls leading to intimal thickening and large vessel constriction, together with an inflammatory vasculopathy eventually culminating in cerebral ischaemia. The development of systemic shock leads to a reduction in systemic arterial blood pressure and, because of the impairment in cerebral autoregulation, a consequent reduction in cerebral blood flow which exacerbates the cerebral ischaemia or infarction. There may also be secondary thrombosis of the major venous sinuses and thrombophlebitis of the cortical cerebral veins. Finally, the purulent exudate can obstruct the resorption of CSF by the arachnoid villi or the flow through the ventricular system leading to obstructive or communicating hydrocephalus with interstitial cerebral oedema.

### Clinical presentation

Meningitis is characterised by the presence of fever, headache, altered mental state and neck stiffness. There is usually associated nausea, vomiting, photophobia and progressive lethargy, stupor or coma; seizures may occur. Meningitis may evolve as a fulminating illness over a few hours, particularly in children, but progression is variable and less commonly can be a progressive (subacute) infection worsening over several days, particularly in the elderly and the immunosuppressed. Meningism is characterised by the presence of neck stiffness on passive flexion and Kernig's sign is positive when the thigh is flexed at the hip and knee at 90° and subsequent extension of the knee is painful (leading to resistance). Brudzinski's sign is positive when flexion of the neck results in spontaneous flexion of the hips and knees when the patient is in a supine position. Seizures may be focal or generalised and may occur either at presentation or at any time during the course of bacterial meningitis in 40% of patients. They may arise from focal arterial or venous infarction, haemorrhage, localised cerebral oedema or as a consequence of systemic features including pyrexia, septicaemic shock, toxicity or other metabolic derangement. Meningitis may lead to vascular occlusion and subsequent infarction of the brain or spinal cord, progressive cranial nerve lesions and hydrocephalus secondary to impaired CSF absorption and obstruction. Organ failure, hearing loss and limb infarction may also occur.

**Table 9.2** Possible imaging findings in CNS infection.

Imaging appearance	Possible infective cause	Differential diagnosis
Mass lesion	Abscess Subdural empyema Cerebritis	Tumour MS Acute disseminated encephalomyelitis Lymphoma
Temporal lobe signal change	HSV-1 or 2	Autoimmune limbic encephalitis (VGKC antibody) Paraneoplastic
Extensive white matter signal change	HSV HHV6	PML PRES ADEM
Brainstem	<i>Listeria</i> infection Bickerstaff encephalitis Viral encephalitis (VZV, HSV-2, WNV)	CPM Wernicke PRES Autoimmune encephalitis Whipple's disease CLIPPERS
Basal ganglia	<i>Toxoplasma gondii</i> , encephalitis (WNV, EEE, WEE, Jap B)	
Infarction	Infective endocarditis VZV Fungal (aspergillus, mucormycosis)	Vasculitis
Multiple enhancing lesions	Abscess <i>T. gondii</i> Tuberculomas <i>Cryptococcus</i> Neurocysticercosis	Multiple metastases Vasculitis

ADEM, acute disseminated encephalomyelitis; CLIPPERS, chronic lymphocytic inflammation with pontine perivascular enhancement responsive to steroids; CPM, central pontine myelinolysis; EEE, Eastern equine encephalitis; HHV, human herpes virus; HSV, herpes simplex virus; Jap B, Japanese B encephalitis; PML, progressive multifocal leukoencephalopathy; PRES, posterior reversible encephalopathy syndrome; VGKC, voltage-gated potassium channel; VZV, varicella zoster virus; WEE, Western equine encephalitis; WNV, West Nile virus.

### Investigation

Bacterial meningitis is usually accompanied by an elevated peripheral white cell count and raised inflammatory markers. In the presence of septicaemia, platelet consumption may occur with loss of clotting factors. There may be associated hypocalcaemia, hyponatraemia and impaired renal function with metabolic acidosis. Imaging should be undertaken urgently to exclude mass lesions, hydrocephalus or cerebral oedema which are contraindications to lumbar puncture. The cornerstone of the diagnosis of meningitis remains a positive CSF Gram stain and culture, additional support for the diagnosis can be made by positive blood cultures (50% cases), a positive throat swab (in cases of *N. meningitidis*), CSF biochemical analysis, and PCR of blood or CSF. However, there is a considerable risk that lumbar puncture may cause coning in the presence of cerebral oedema. Lumbar puncture should be avoided if the patient has:

- Impaired consciousness (Glasgow Coma Scale [GCS] <12, or fall in GCS of  $\geq 2$ )
- Signs of raised intracranial pressure or incipient herniation

- Focal neurological signs
- Papilloedema
- Prolonged focal seizures within 2 weeks of presentation
- Signs of shock or bleeding diathesis
- Purpuric or petechial rash
- Known immunocompromised state
- Evidence of obstructive hydrocephalus, cerebral oedema or herniation on computed tomography (CT) or magnetic resonance image (MRI) scan of brain.

Imaging may also provide important clues to the aetiology of the infective process (Table 9.2).

Gram staining of the CSF is positive for meningococcus in approximately 50% of patients with acute meningococcal meningitis. Blood cultures may be helpful but are not sensitive. CSF tests may directly identify an organism and its nucleic acid or surface constituents by staining, culture or capsular antigen detection (less helpful in adults). PCR is particularly sensitive in CSF for *S. pneumoniae* and *N. meningitidis*. The CSF findings in different forms of meningitis are summarised in Table 9.3.

**Table 9.3** Comparison of CSF findings in different forms of meningitis.

	Normal	Acute bacterial	Viral meningitis	TB meningitis	Fungal meningitis
Appearance	Clear colourless	Turbid	Clear / opalescent	Clear / opalescent	Clear
Pressure (mm H <sub>2</sub> O)	Normal (<180)	Increased	Normal or increased	Increased	Normal or increased
White cell count (cells/mm <sup>3</sup> )	0–5	100–50 000	5–500	5–500	20–500
Neutrophils (%)	None	>80%	<50%	<50%	<50%
Glucose	>3.5 mmol/L (75% blood glucose)	Low (<50% blood glucose)	Normal	Low (<50% blood glucose)	Low (usually between 50% and 75% blood glucose)
Protein (g/L)	<0.4	>0.9	0.6–0.9	0.6–5	0.6–5
Others		Gram stain positive <90% Culture positive <80% Blood culture positive <60% PCR	Culture positive <50% PCR, if cellular	ZN stain positive <90% Culture positive 50–80%	Gram stain negative Culture positive 25–50% India ink

Previous or partial antibiotic treatment of bacterial meningitis usually leads to reduction in CSF cell count and protein level, shift from polymorphonuclear to lymphocytic CSF and marked reduction in the yield on Gram stain and culture. PCR, polymerase chain reaction.

## Management

In patients with severe meningitis, the first priority is to commence empirical antibiotic treatment, usually immediately after sending a blood culture. Empirical therapy in the absence of staining and culture depends on the age and immune status of the patient and any other underlying risk factors:

- In any child or adult with suspected meningococcal meningitis, primary care physicians are recommended to commence benzylpenicillin before transfer to hospital. If the situation is less urgent it is preferable to undertake a lumbar puncture, if safe, and send CSF for staining and culture before antibiotics are commenced.
- In healthy immunocompetent adults with suspected bacterial meningitis, hospital treatment should be initiated with a third generation cephalosporin (2 g ceftriaxone 12-hourly IV) and not penicillin (because of potential pneumococcal resistance) and in those older than 50 years amoxicillin and gentamicin to cover *Listeria* infection (2 g amoxicillin 4-hourly, 7 mg/kg gentamicin once daily)
- When there is the possibility of nosocomial infection (i.e. acquired in hospital, such as following surgery, trauma or in the presence of a shunt), ceftazidime (2 g 8-hourly) is preferred because it is more active against *Pseudomonas aeruginosa* than other third generation cephalosporins. Vancomycin (15 mg/kg 8-hourly) is added to cover highly resistant staphylococcus.
- If the patient has penicillin or cephalosporin allergy, chloramphenicol (12.5 mg/kg 6-hourly) should be given with vancomycin (add co-trimoxazole if *Listeria* is suspected).
- Dexamethasone (10 mg every 6 hours) should be given concurrently with the antibiotics and continued for 4 days in all cases. This is primarily effective if Gram stain or culture is positive for

pneumococcus but may be beneficial for other causes of bacterial meningitis.

- Aciclovir (10 mg/kg IV 8-hourly) should be commenced if viral encephalitis resulting from herpes simplex virus (HSV) is considered possible.

Specific antibiotic treatment for acute bacterial meningitis is summarised in Table 9.4 but therapy depends on demonstration of appropriate microbiological sensitivities.

## Specific causes of bacterial meningitis

### *Neisseria meningitidis* (meningococcal meningitis)

This is a Gram-negative diplococcus. It is the most common identified cause of meningitis in children and young adults, with an incidence of 1–1.5/100 000/year. In the United Kingdom, meningococcal disease remains the leading infectious cause of death in childhood with a mortality of approximately 10%. It occurs throughout the year but the majority of cases are in the winter and early spring. Transmission occurs by droplet spread, particularly with close contact, and 5–10% of all adults are asymptomatic nasopharyngeal carriers of these pathogenic bacteria.

Meningococcus is classified into subgroups according to the immunoreactivity of the capsular polysaccharide. While there are at least 13 serogroups, most cases of meningococcal disease are caused by subgroups A and C (geographically dependent) for which a polysaccharide vaccine is effective. In November 1999 the United Kingdom established a programme for vaccinating all infants with conjugate sero-group C vaccine. In 2014, two subgroup B meningococcal vaccines were approved for use and from 2015 quadrivalent conjugate vaccine against meningococcal subgroups A, C, W135

**Table 9.4** Treatment of bacterial meningitis.

	First line treatment	Alternative treatment
<i>Neisseria meningitidis</i> (meningococcus)	Ceftriaxone 2 g (IV) 12-hrly for 7 days or Cefotaxime 2 g (IV) 6-hrly for 7 days	Benzylpenicillin (penicillin G) 2.4 g (IV) 4-hrly for 7 days or Chloramphenicol 12.5 mg/kg 6-hrly or Amoxicillin 2 g (IV) 4-hrly for 7 days
<i>Streptococcus pneumoniae</i> (pneumococcus)	Ceftriaxone 2 g (IV) 12-hrly for 14 days or Cefotaxime 2 g (IV) 6-hrly for 14 days	Benzylpenicillin <2.4 g (IV) 4-hrly for 14 days
<i>Haemophilus influenzae</i> type b	Ceftriaxone 2 g (IV) 12 hrly for 14 days or Cefotaxime 2 g (IV) 6-hrly for 14 days	Chloramphenicol 12.5 mg/kg 6-hrly or Meropenem 2 g (IV) 8-hrly for 14 days
Streptococcus Group B or <i>milleri</i> group	Ceftriaxone 2 g (IV) 12-hrly for 14 days or Cefotaxime 2 g (IV) 6-hrly for 14 days	Benzylpenicillin 2.4 g (IV) 4-hrly for 14 days and Gentamicin 8-hrly for 7 days
<i>Listeria monocytogenes</i>	Amoxicillin 2 g (IV) 4-hrly for 3 weeks and gentamicin for 7 days	Co-trimoxazole 3 mg/kg (IV) 6-hrly for 21 days
<i>Staphylococcus aureus</i> – non-MRSA	Flucloxacillin 2 g (IV) 6-hrly for 4 weeks	Ceftriaxone 2 g (IV) 12-hrly for 4 weeks
Methicillin-resistant <i>Staphylococcus aureus</i> – MRSA	Vancomycin 1 g (IV) 12-hrly for 4 weeks	Linezolid 600 mg (IV) for 28 days maximum (limited clinical experience)
Gram negatives (excluding <i>Pseudomonas</i> ) i.e. <i>E. coli</i> , <i>Klebsiella</i> spp. and <i>Proteus</i> spp.	Ceftriaxone 2 g (IV) 12-hrly for 3–4 weeks or Cefotaxime 2 g (IV) 4-hrly for 3–4 weeks	Meropenem 2 g (IV) 8-hrly for 14 days (for more resistant isolates)
<i>Pseudomonas aeruginosa</i>	Ceftazidime 2 g (IV) 8-hrly for 3 weeks	Meropenem 2 g (IV) 8-hrly for 3 weeks

and Y will be undertaken routinely in all infants. Risk factors for meningococcal infection include close contact with carriers or infected individuals, low socio-economic status, poor housing and impairments of both humoral and cell-mediated immunity.

Clinical manifestations of meningococcal infection may develop within minutes or hours. In approximately 40% of patients there is isolated meningitis; 10% have septicaemia alone and the remainder a mixed pattern. Isolated meningococcal meningitis carries a better prognosis than meningococcal septicaemia or a mixed picture. Clinically, fulminant meningitis is characterised by pyrexia, headache and meningism associated with nausea and vomiting, photophobia and progressive lethargy. In early meningococcal meningitis there is a diffuse erythematous macular papular rash which eventually develops into the characteristic non-blanching petechiae found across the trunk and lower extremities in the mucous membranes, conjunctiva and occasionally on the palms and soles. These lesions should be distinguished from other infective disorders that cause a purpuric rash, including enterovirus meningitis and bacterial endocarditis. The development of meningococcal septicaemia is associated with progressive vasomotor disturbance culminating in profound hypotension, tachycardia and a rising respiratory rate indicating pulmonary oedema or raised intracranial pressure resulting from cerebral oedema.

Waterhouse–Friderichsen syndrome is a form of fulminant meningococcal disease, in which severe septicaemia is complicated by the development of bilateral haemorrhage into the adrenal glands and disseminated intravascular coagulation leading severe sudden febrile illness associated with septic shock, petechiae, purpura and coma.

**Management** Patients with probable fulminant meningococcal meningitis should be treated immediately in primary care settings with parenteral benzylpenicillin (2.4 g) given intramuscularly or preferably intravenously because of uncertain absorption in patients with shock (Table 9.4). They should be transferred immediately to an accident and emergency department. In secondary care settings first line treatment is 2 g ceftriaxone IV stat; alternatively cefotaxime can be used. Antibiotics should be given prior to any diagnostic procedure if there is a petechial or purpuric rash or shock.

Septicaemic shock should be treated with appropriate volume replacement, elective intubation and ventilation. Patients may require inotropic support and metabolic abnormalities, coagulopathy and anaemia should be promptly treated. In the presence of raised intracranial pressure it may be necessary to administer mannitol, muscle relaxation and appropriate intensive care nursing.

**Contacts** Meningococcal meningitis is a notifiable disease in the United Kingdom and there is a high risk of family members developing the disease. All household close contacts should therefore be treated to eradicate nasopharyngeal carriage. It is recommended that 600 mg rifampicin 12-hourly should be given as prophylaxis for 2 days. Ciprofloxacin (750 mg as a single dose) is also effective.

**Immunisation** Meningococcal vaccination is currently available and contains polysaccharides to monovalent subgroup B and quadrivalent conjugate serogroups A, C, Y and W135.

**Outcome** Complications of the acute infection are common and occur in more than 35% of patients, they include cerebral oedema, hydrocephalus, vasculitis, venous thrombosis, ventriculitis, labyrinthitis and spinal cord involvement. The mortality rate is approximately 25% although this rises to 40% in those with meningococcal septicaemia coexisting with meningitis. Of survivors, 20% have neurological sequelae such as hearing loss, loss of limbs secondary to large vessel vasculitis and neurological disability resulting from cerebral ischaemia.

### ***Streptococcus pneumoniae* (pneumococcal meningitis)**

This is the most common cause of meningitis in adults over the age of 18 years and carries a case fatality rate of approximately 20%. The organism is a Gram-positive coccus and spread occurs by respiratory droplet infection. The primary site of colonisation is the nasopharynx and the carrier state is common. *S. pneumoniae* meningitis can have a more insidious onset and is commonly caused by local extension from otitis media, or a paranasal source of infection, following a skull base fracture or sinus injury with dural tear. Other predisposing features include pneumonia, alcoholism, diabetes, immunodeficiency states (e.g. splenectomy, hypogammaglobulinaemia, HIV). Clinical presentation is similar to other forms of pyogenic meningitis but a coexisting pneumococcal pneumonia may be present. The course may be aggressive with rapid progression to coma and respiratory arrest. Neurological complications are similar to those described for meningococcal meningitis and include cerebral oedema, hydrocephalus, vasculitis, venous thrombosis, ventriculitis, labyrinthitis and spinal cord involvement. Residual sequelae occur in more than 30% of patients and include seizures, focal neurological deficits (cranial nerve palsies, hemiparesis), sensorineural hearing loss, stroke and intellectual impairment.

**Management** Conventional treatment is with penicillin, ampicillin and ceftriaxone or cefotaxime but this treatment has been complicated by the development of penicillin and cephalosporin resistant strains. If penicillin-resistance is suspected then vancomycin should be added. However, vancomycin itself only crosses the blood-brain barrier poorly and therefore should not be used in isolation. Adjuvant dexamethasone (10 mg 6-hourly IV for 4 days) improves the outcome and should be commenced before or with the first dose of antibiotics. Failure to improve despite antibiotic treatment implies either the development of cerebral complications, a persistent primary focus or an inadequate or inappropriate regimen of antibiotics. In the United Kingdom, pneumococcal vaccine is recommended for all infants as part of the routine childhood immunisation programme, for those over the age of 65 and for children and adults at clinical risk (asplenia or splenic dysfunction, chronic respiratory, cardiac, renal or liver

disease, diabetes, immunosuppressive or individuals with CSF leaks). Primary immunisation with conjugate vaccine (PCV 13) is recommended in childhood but polysaccharide vaccine (PPV 23) is used in those over 65 years or in the at risk group over 2 years.

### ***Haemophilus influenzae* type b**

This is a small Gram-negative coccobacillus. Prior to the introduction of *Haemophilus influenzae* type b (Hib) vaccination this was the most common cause of meningitis in children with a fatality rate of approximately 5% and permanent neurological damage in some 30% of cases. Meningitis occurs as a consequence of respiratory droplet spread and adults remain vulnerable to the non-encapsulated strains. Risk factors include otitis media, splenectomy, head trauma, previous neurosurgery or a CSF leak. Presentation may be with acute meningitis but an associated vasculitis may occur, leading to focal signs.

**Management** The primary treatment of *H. influenzae* is ceftriaxone or cefotaxime because of the significant incidence of penicillin resistant strains in up to 40%. Chemoprophylaxis is recommended for non-immune household contacts, 600 mg rifampicin once daily for 4 days. Vaccination is recommended for all children with the first dose being given at 2 months.

### ***Listeria monocytogenes***

This is a beta-haemolytic Gram-positive rod with 12 subtypes based on antigenic properties. It is an intracellular pathogen that lyses phagocytic cells before entering the bloodstream. The overall case fatality rate is around 15%. Outbreaks are associated with contaminated food including soft cheese, unpasteurised milk and occasionally raw meat. Predisposing factors include pregnancy, advanced age, the neonatal period or immunosuppression, and listeria is more common in patients with malignancy, renal failure or following organ transplantation or steroid treatment. Listeria may cause a meningitis or meningoencephalitis but seizures, disturbances of consciousness and movement disorders may also occur. A brainstem meningoencephalitis develops in <10%, this presents with a prodromal phase followed by progressive ponto-medullary involvement with cranial neuropathy, pyramidal and sensory signs. The differential diagnoses of brainstem meningoencephalitis are listed in Table 9.5.

**Management** Treatment is with amoxicillin for 21 days; however, gentamicin for 7 days is recommended in addition to enhance bacteriocidal activity. If there is a penicillin allergy then co-trimoxazole (Septrin) is recommended but chloramphenicol should be avoided because of the high risk of relapse.

### **Group B streptococcus**

Group B streptococcus (*Streptococcus agalactiae*) is an important cause of neonatal sepsis and meningitis. It also causes purulent meningitis in adults with a case fatality rate of approximately 5%. Risk factors in neonates include premature birth or low birth weight, prolonged rupture of membranes, intrapartum fever or maternal group B streptococcus infection during pregnancy. In non-pregnant adults, group B streptococcal meningitis is associated with advanced stage diabetes, cirrhosis and systemic malignancy; it can be acquired nosocomially. The treatment is with benzylpenicillin.

**Table 9.5** Differential diagnosis of brainstem meningo-encephalitis.

Virus	Enterovirus EBV/CMV Tick-borne encephalitis, <i>Coxiella</i>
Bacterial	<i>Listeria</i> , <i>Mycoplasma</i> <i>Legionella</i> , <i>Brucella</i> <i>Borrelia</i>
Non-infectious	Multiple sclerosis Sarcoid Behçet's Acute disseminated encephalomyelitis Vasculitis Carcinomatous meningitis Bickerstaff's encephalitis Fisher's syndrome CLIPPERS

CMV, cytomegalovirus; CLIPPERS, chronic lymphocytic inflammation with pontine perivascular enhancement responsive to steroids; EBV, Epstein-Barr virus.

### Gram-negative meningitis

Gram-negative meningitis (excluding *N. meningitidis*) may arise spontaneously, when the onset is often acute, and the condition follows an aggressive course. More commonly, Gram-negative meningitis may follow neurosurgical intervention when the onset and progression is insidious and gradual. Nosocomial infection is usually caused by *Klebsiella* spp. (approximately 40%), *Escherichia coli* (<30%) or *Pseudomonas aeruginosa* (<20%) with *Serratia* spp., *Proteus* spp. and *Salmonella* spp. meningitis occurring less commonly. Meningitis may be associated with seizures, confusion and focal signs including cranial nerve palsies. The diagnosis is made on CSF Gram stain and culture but this is only helpful in <50% of untreated patients. The limulus lysate assay can detect endotoxin but is limited in sensitivity and has little clinical role. Treatment of organisms with minimal resistance is with a third generation cephalosporin (Table 9.4).

### Gram-positive meningitis (non-pneumococcal, non-group B)

Gram-positive meningitis usually results from a CNS shunt infection. Nosocomial shunt infections are usually caused by coagulase-negative staphylococci or *Propionibacterium acnes*. Spontaneously occurring *Staphylococcus aureus* meningitis may be predisposed by coexisting disease including diabetes mellitus, carcinomatosis, alcohol and intravenous drug abuse. It is usually associated with a focus of infection outside the CNS (e.g. endocarditis or osteomyelitis). The diagnosis is made on the basis of CSF staining and culture. Treatment depends on drug resistance. For fully sensitive staphylococci, treatment with high dose flucloxacillin or ceftriaxone is appropriate, with vancomycin or linezolid being used for methicillin resistant *S. aureus* (MRSA). There is a high mortality rate of approximately 50% with a further >10% experiencing neurological sequelae. *Streptococcus suis* is the second most common cause of community-acquired meningitis in South-East Asia and is associated with contact with pigs or raw pork. Treatment is with benzylpenicillin or ceftriaxone for 14 days. Other streptococci implicated in meningitis include group D streptococci (including

*S. milleri* group) as a result of local invasion or haematogenous spread. Treatment with ceftriaxone is recommended.

### Nosocomial meningitis

Nosocomial bacterial meningitis results from invasive procedures, such as craniotomy (0.8–1.5%), placement of internal (4–17%) or external (8%) ventricular catheters, lumbar puncture, intrathecal infusion or spinal anaesthesia, complicated head trauma or metastatic infection in patients with hospital acquired Gram-negative sepsis.

The initial choice of antibiotic treatment depends on the age of the patient and any underlying risk factors. In the neonate in whom there is a possibility of group B streptococcal infection or *Listeria*, then ampicillin and cefotaxime should be used. For anyone over the age of 3 months, ceftriaxone is the preferred treatment; cefotaxime is an alternative. Vancomycin should be added if there is a significant risk of *S. pneumoniae* with penicillin resistance and in those over 50 years.

Meningitis may occur as a complication of closed head trauma, particularly if there is a basal skull fracture causing the subarachnoid space to be in communication with a paranasal sinus cavity. The onset may be delayed for several days after the initial injury. Leakage of CSF is a further risk factor and is often unrecognised. Head trauma is the most common cause of recurrent meningitis and, in those over 50 years, the incidence of meningitis after moderate or severe head trauma is approximately 1.4%, usually resulting from a persistent dural tear and CSF leak. Open compound cranial fractures occur in 5% of head injuries and have been associated with rates of meningitis of 2–11% but prophylactic antibiotics are not indicated.

The specific bacteria causing nosocomial meningitis vary according to the pathogenesis and timing of the infection after the predisposing event. In the early stages after neurosurgical or ENT procedures the causative organism is generally pneumococcus but following prolonged hospitalisation after neurosurgery, penetrating trauma or skull base fracture infection meningitis is usually caused by staphylococci or aerobic Gram-negative bacilli. In those with a foreign body (e.g. external ventricular drain), infection is often caused by cutaneous organisms such as coagulase negative staphylococcus. CSF examination may be misleading and cell count may be normal even in culture positive meningitis. The choice of antibiotics depends on the pathogenesis of the infection. Following basilar skull fracture or ENT surgery a third generation cephalosporin and vancomycin are recommended but if there has been prolonged hospitalisation ceftazidime and vancomycin or meropenem are indicated.

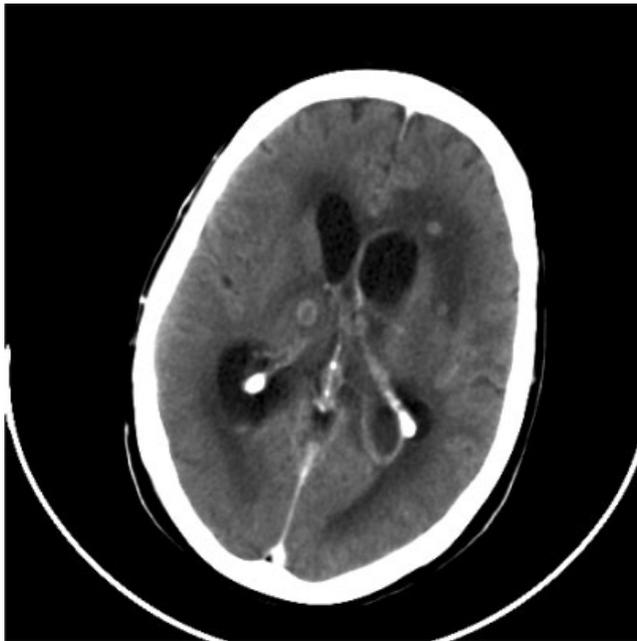

## Focal CNS infection

### Cerebral abscess

Cerebral abscess is a focal suppurative (pus forming) infection occurring within the cerebral parenchyma. It develops as a result of contiguous spread of infection from paranasal sinuses, mastoiditis, otitis media, osteomyelitis, following postoperative and post-traumatic infections or, rarely, as a consequence of penetrating craniocerebral injuries. Less commonly, it may arise as a result of haematogenous spread from distant sites including teeth and lungs. No cause is found in around one-fifth of cases. The causative agents depend on the underlying abnormality, and the age and immunological status of the patient but 80–90% of all bacterial abscesses are polymicrobial. These are summarised in Table 9.6.

**Table 9.6** Microbiological pathogens in brain abscesses.

Source/predisposition	Pathogens
Paranasal sinuses, otitic, mastoiditis or dental infection	Streptococci (esp. Group D strep including <i>Strep. milleri</i> ) 60–70%, Enterobacteriaceae 20–40%, anaerobes, fusobacteria. More rarely <i>Actinomyces</i> spp., <i>Listeria monocytogenes</i>
Post-neurosurgery and penetrating head injury	<i>Staphylococcus aureus</i> , aerobic Streptococci, Enterobacteriaceae <i>Pseudomonas aeruginosa</i>
Pulmonary	Streptococci, <i>Nocardia</i> spp., Actinomycosis, <i>Prevotella</i> spp.
Infants	<i>S. aureus</i> , Enterobacteriaceae, <i>Pseudomonas aeruginosa</i>
Endocarditis	<i>Strep. viridians</i> , <i>S. aureus</i> , Enterococci spp.
Immunocompromised (immunosuppressant medication, post transplant, HIV, diabetes mellitus, IV drug user)	<i>Pseudomonas aeruginosa</i> , <i>Mycobacterium tuberculosis</i> , Enterobacteriaceae, <i>Nocardia</i> , <i>Listeria</i> , fungi ( <i>Cryptococcus</i> , <i>Candida</i> , <i>Aspergillus</i> ) and <i>Toxoplasma gondii</i>
HIV	<i>Toxoplasma gondii</i> , <i>Cryptococcus neoformans</i> , <i>Mycobacterium tuberculosis</i>

**Figure 9.1** CT scan showing multiple bacterial abscesses and ventriculitis in a 53-year-old woman with Gram-negative septicaemia.

Most commonly, cerebral abscesses that arise from dental, frontal or ethmoid sinuses tend to involve the frontal lobe while those arising from the sphenoid sinuses or otitic infection particularly involve the temporal lobes. Cerebral abscesses resulting from haematogenous spread tend to occur as multiple rather than single abscesses (Figure 9.1), often in the region of greatest blood flow, within the basal ganglia.

### Clinical features

The peak frequency is 35–45 years but abscesses can occur at any age. Although the characteristic onset is subacute and indolent with fever, headache, nausea, vomiting, seizures or focal neurological signs, there may be a rapid course of neurological symptoms

suggesting a tumour or cerebral infarction. Fever is variable and may be absent in around half of cases, and usually those who are older; fever tends to resolve rapidly with steroids. Rupture of an abscess into the ventricles may cause a dramatic severe headache and emerging signs of meningism. Cerebellar abscess may cause obstruction to CSF flow and acute hydrocephalus.

### Investigations

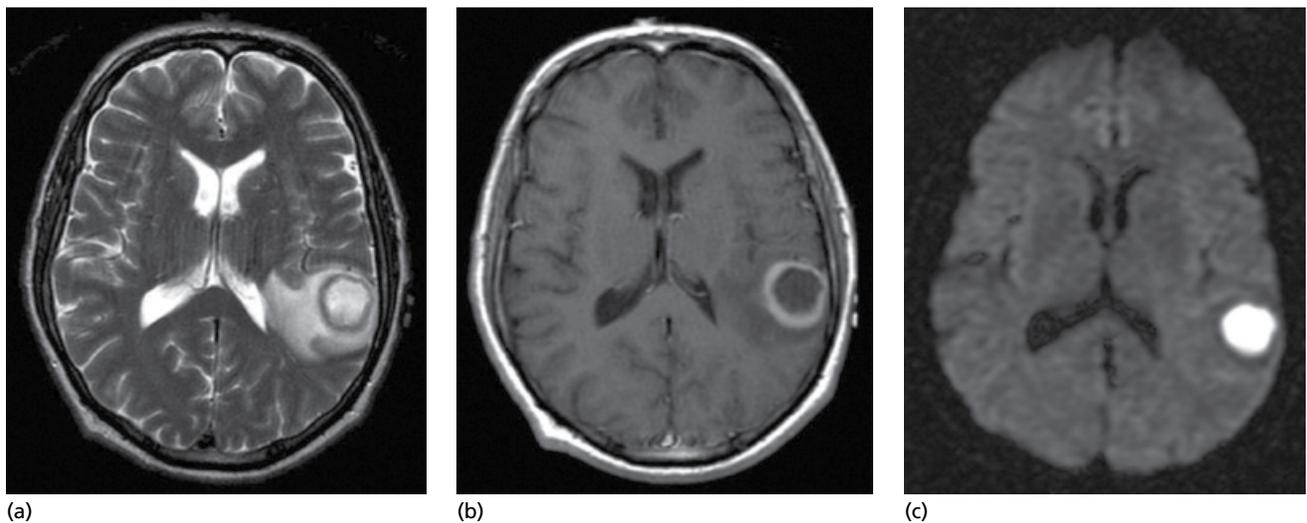

Following imaging, the gold standard investigation is aspiration of the abscess, urgent Gram stain, microscopy and culture. Depending on the age and immune status of the patient, analysis of the pus may include auramine stain for acid-fast bacilli, toxoplasma microscopy, fungal culture or PCR if culture fails to grow an organism. All specimens should have histopathology reporting. Routine haematology usually shows a raised ESR and white cell count. Blood cultures are positive but only in about 10%. CT scan may show a thin enhancing ring of uniform thickness with smooth margins which tends to be thicker nearer the cortex and thinner near the ventricles. MRI with enhancement is more sensitive and will show the extent of surrounding oedema more accurately than CT. Pyogenic abscesses exhibit restricted diffusion within the central pus (Figure 9.2). This is an important finding which allows distinction from other cystic lesions such as metastases. Lumbar puncture is contraindicated in patients with mass lesions and yield is usually low because of the focal nature of the abscess.

### Treatment

Treatment is urgent, with surgical drainage being most effective but also necessitating administration of appropriate antibiotics and control of cerebral oedema (Table 9.7).

### Surgical intervention

Pus evacuation using image guidance techniques usually utilising a mini-craniotomy is the optimum method and it carries a low risk, and should provide a microbiological diagnosis. Simple pus aspiration is easier than attempts at abscess excision and carries a smaller risk of subsequent seizures. Despite appropriate antibiotic therapy, recurrent abscesses are common. Cerebral oedema should be treated with dexamethasone, hyperventilation and/or mannitol.

**Figure 9.2** Left temporal abscess MRI: (a) T2-weighted, (b) T1 weighted post-contrast and (c) diffusion weighted images. Note the central T2 hyperintensity, relatively T2 hypointense, enhancing margin and central restricted diffusion.

**Table 9.7** Antibiotic treatment of cerebral abscess.

Unknown source (covers sensitive streptococci, sensitive staphylococci, minimally resistant Gram- negatives and anaerobes)	Ceftriaxone/cefotaxime plus metronidazole
Streptococcus (resistant)	Add vancomycin or linezolid (limited clinical experience)
MRSA risk	Add vancomycin or linezolid (limited clinical experience)
Highly resistant Gram-negative organisms risk	Meropenem
<i>Pseudomonas aeruginosa</i> risk	Ceftazidime or meropenem

### Prognosis

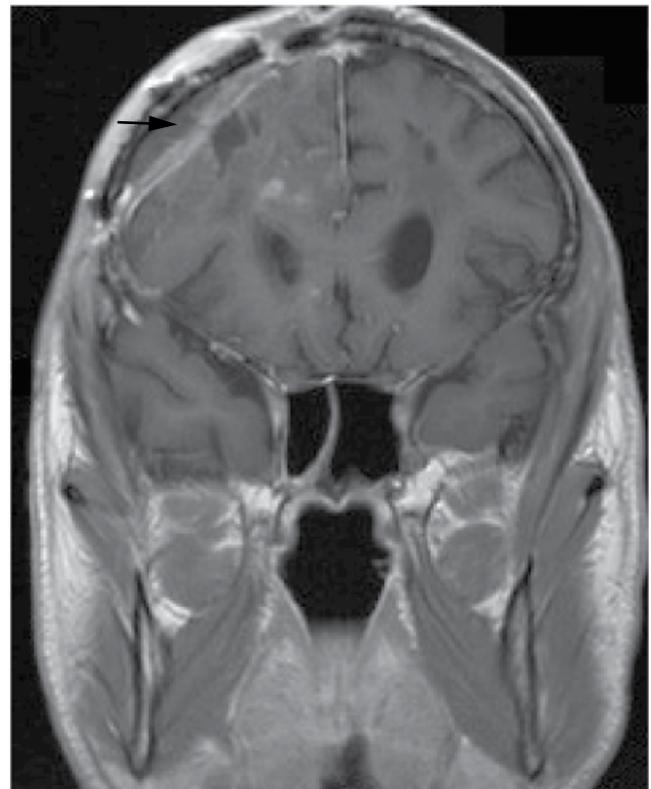

The prognosis depends on the clinical state of the patient and the organism isolated or suspected. Survival is excellent for those fully alert and conscious who receive appropriate treatment but declines to 40% if a patient is unrousable at initial assessment. Intraventricular rupture carries a mortality of up to 80%.

### Subdural empyema

Subdural empyema occurs when intracranial suppuration develops between the dura and the arachnoid (Figure 9.3). This is usually a consequence of ear or paranasal sinus infection, particularly involving the frontal ethmoid sinuses. Empyemas also follow skull osteomyelitis, penetrating head trauma, neurosurgery and infection of a subdural effusion following childhood meningitis. Empyema from haematogenous spread does occur, but is rare.

### Pathophysiology

Infection gains entry to the subdural space by direct extension through the bone and dura (e.g. ear and sinus infection, cranial osteomyelitis, penetrating head trauma) or by spread from septic thrombosis of the venous sinus particularly the superior sagittal sinus. Rarely, subdural empyema may result from metastases from infected lungs by haematogenous spread.

**Figure 9.3** Large subdural empyema in a patient with a previous craniotomy for grade 2 glioma (coronal T1 MRI) (arrow).

### Causative agents

Infection is usually secondary to paranasal sinus disease from viridans streptococci, aerobic streptococci (including *Strep. milleri* group [now called *Strep. anginosus* group]) and anaerobes. Less often subdural empyema may be caused by *S. aureus*, *Pseudomonas aeruginosa* or Enterobacteriaceae including *Proteus*, *Klebsiella* and *E. coli*. However, no organism is isolated in 20–50% of patients.

Clinically, there is an acute onset with rapid progression to extensive hemispheric involvement or mass effect with tentorial herniation; occasionally a more gradual meningitis-like conditions may evolve over several weeks. The onset is with pyrexia in >80%, localised cranial pain, focal or generalised headache, but meningism may develop and focal neurological deficits evolve into hemiparesis. Seizures occur in <50% of patients and there may be progressive obtundation. Venous extension of the infection may lead to the development of meningitis, brain abscess or septic intracranial venous thrombosis. The diagnosis is made by CT or MRI with enhancement. The management is immediate surgical decompression with antibiotic cover. There is debate about whether to undertake craniotomy drainage or multiple burr holes. Because many patients with empyema have a mixed culture of organisms, two or more antibiotic agents are required. For initial therapy where no information exists on the source of infection, ceftriaxone and metronidazole are recommended; if Gram-positive resistance is a concern then vancomycin should be added and treatment should be continued for at least 4 weeks. The outcome of surgically treated subdural empyema and intracerebral abscess has been transformed by image-guidance surgical techniques and antibiotics.

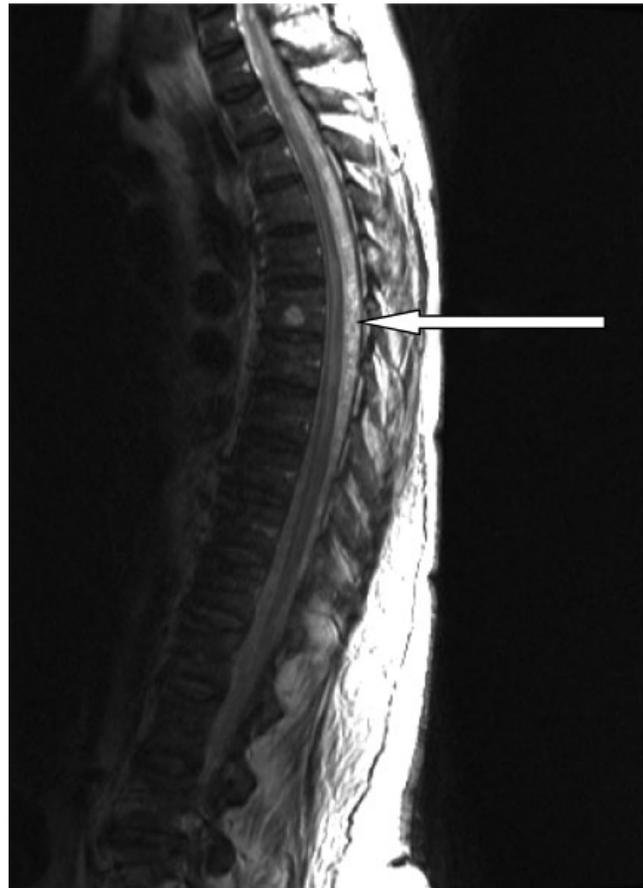

### Intracranial epidural abscess

Intracranial epidural abscess develops as a result of infection between the outer most layer of the meninges (dura) and the overlying skull. These abscesses are associated with cranial osteomyelitis complicating ear, sinus or orbital infection or neurosurgical intervention. Infection is rarely metastatic. Epidural abscesses are commonly caused by streptococci (including *Strep. anginosus* group). The diagnosis and management are similar to subdural empyema. The onset is generally insidious with localised cranial pain following generalised headache. The abscess may be accompanied by superficial subcutaneous infection and oedema. Patients develop focal or generalised seizures, focal neurological deficit or alterations in their mental state. Epidural abscess near the petrous bone affecting the V and VI cranial nerve may cause Gradenigo's syndrome characterised by unilateral facial pain and lateral rectus weakness. Extension inwards across the dura, along the emissary veins leads to subdural empyema, meningitis, brain abscess or venous sinus thrombosis. CT imaging may be normal, but usually these abscesses will be seen on MRI. Small epidural abscesses can be managed by antibiotics alone, following the guidelines indicated earlier but larger abscesses require surgical drainage.

### Spinal epidural abscess

Spinal epidural abscess is an infection of the epidural space of the spinal cord (Figure 9.4). It is usually caused by osteomyelitis or metastatic spread of infection from injuries to the back associated with skin wounds, bacteraemia or septicaemia. It may rarely occur following spinal surgery, lumbar puncture or epidural/spinal anaesthetic. Patients present with fever and back pain which may be severe and localised or radicular. Typically, the patient develops a fever and signs of progressive spinal cord compression leading to paraparesis, sensory loss and sphincter involvement, with localised spinal tenderness. Rarely, there may be a more chronic and indolent onset with a history suggesting a spinal cord neoplasm or a tuberculous abscess.

*S. aureus* is the most common cause of spinal epidural abscess, found in 50–90% of patients, although a few may be caused by aerobic streptococci, Gram-negative bacilli and, more rarely, anaerobic organisms. CSF shows a clear pleocytosis but this is usually modest with <100 white cells/mm<sup>3</sup> and these may be both polymorphonuclear and lymphocytes. The protein is usually high. Surgical treatment with laminectomy and drainage with prolonged antibiotic cover is

**Figure 9.4** Extensive posterior epidural abscess on T2-weighted sagittal MRI.

indicated. There is a danger of vascular compromise to the cord causing infarction and permanent cord injury. Recovery may be slow with residual incomplete cord compression caused by formation of a fibrous and granulomatous reaction at the operative site.

### Spinal subdural abscess

Subdural spinal abscess may be acute or chronic and caused by osteomyelitis or metastatic spread of infection and may be impossible to distinguish from the more common epidural infection. Presentation is similarly with fever, back and neck pain and rapidly developing signs of spinal cord compression. The onset is variable and may be over days or weeks. The causative agent is *S. aureus* in >50% of patients. A clue to the presence of subdural empyema comes from imaging, which tends to show that these lesions have a less sharp margin and a greater vertical extent than epidural abscess.

### Spinal cord intramedullary abscess

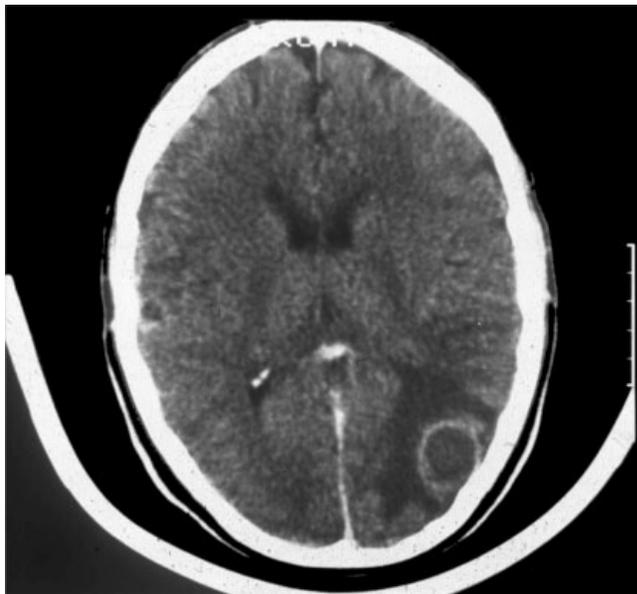

Spinal cord intramedullary abscess is rare. It may present with a syringomyelia-like picture. The spinal cord is usually involved by direct spread from a contiguous abscess in the skin or if there is spinal dysraphism leading to an open track. Surgical drainage may be necessary.

### Infective endocarditis

Infective endocarditis is caused by direct bacterial colonisation of the endothelial surface of the heart, usually on the valves. Endocarditis affecting a native valve is usually associated with

congenital, rheumatic or degenerative valve disease but occurs on previously normal valves in intravenous drug users. Endocarditis develops on around 6% of prosthetic valves over 5 years. Approximately 30% of patients with endocarditis have neurological complications and often these are the presenting features. Most cases of native valve endocarditis are caused by *Streptococcus viridans* group, Enterococci or *Staphylococcus aureus*; the latter is common in endocarditis amongst intravenous drug users. Native valve endocarditis typically affects left heart valves, except in intravenous drug users, where right heart valves tend to be infected; the reasons are unclear.

Clinical presentation is characterised by fever, systemic symptoms including weight loss and anorexia, new or changing heart murmurs or peripheral vasculitic signs including petechiae, splinter haemorrhages or Osler nodes. Neurological complications are common and brought about either by bacteraemia leading to meningitis, cerebritis or a parameningeal focus or by recurrent emboli which may be infective. Cerebral emboli commonly involve the anterior cerebral circulation and are frequently multiple with up to 10% becoming haemorrhagic. There is often a preceding transient ischaemic attack and concurrent systemic emboli are common. Septic emboli may cause cerebral infarction, meningitis or parenchymal abscess but they also lead to the development of mycotic aneurysms which occur when an infected arterial wall becomes weakened (Figure 9.5). Mycotic aneurysms usually develop at arterial bifurcation or in distal arterial vessels and carry a high risk of rupture into the parenchyma and subarachnoid space leading to stroke, causing focal neurological deficits, meningism, declining consciousness and coma. Cerebral abscesses may be multiple and also lead to severe focal or generalised neurological deficits. Bacterial meningitis is common in endocarditis and carries a poor prognosis. Meningitis may lead to cerebral vasculitis, a condition seen particularly in staphylococcal infection. Ocular involvement may occur with vasculitis involving the retina, optic nerve, oculomotor nerves or brainstem. Central retinal artery occlusion, ophthalmoplegia or field loss may follow.

**Figure 9.5** CT scan showing mycotic aneurysm in *Streptococcus viridans* endocarditis.

Endocarditis should be carefully considered in any patient with a focal or generalised neurological deficit and unexplained pyrexia. The diagnosis depends on appropriate cardiac imaging including transthoracic and transoesophageal echocardiography, serial blood cultures and urine microscopy for red cells. Neurological investigation includes imaging of the brain and intracranial vessels with CT and/or MRI, and CSF examination; catheter angiography may be needed in cases of parenchymal or subarachnoid haemorrhage.

Treatment involves the urgent initiation of organism-specific antibiotics and depends on bacterial sensitivities and underlying risk factors. There should be close liaison with a bacteriologist. The 2012 British Society of Antimicrobial Chemotherapy guidelines recommend the following.

- Native valve *S. viridans* endocarditis should be treated with benzylpenicillin (or ceftriaxone) and gentamicin in regimens varying between 2 and 6 weeks depending on penicillin resistance. Longer courses are given for prosthetic valve *S. viridans* endocarditis. Vancomycin is used if there is penicillin allergy.
- Native valve staphylococcal endocarditis requires a 6-week course of flucloxacillin; if there is MRSA, vancomycin and rifampicin are used.
- Prosthetic valve staphylococcal endocarditis requires the addition of gentamicin and rifampicin to flucloxacillin or vancomycin.

The management of cerebral emboli and mycotic aneurysms is difficult. Longer courses of endocarditis treatments are recommended in cases of cerebral complications. Anticoagulation should be avoided because of the high risk of haemorrhagic transformation. Neurosurgical intervention is rarely indicated, endovascular procedures are occasionally undertaken. However, a conservative approach is usually justified depending on the size and location of the aneurysm. Despite advances in antibiotic management and supportive care, the prognosis of endocarditis once there is CNS infection is poor, with mortality of <20%.

## Granulomatous infections of the nervous system

### CNS tuberculosis

#### Tuberculous meningitis

*Mycobacterium tuberculosis* infection occurs by person-to-person droplet spread. The organism is inhaled into the lower portion of the lungs and there multiplies locally before disseminating through lymphatic and haematological spread into other organs. The general decline of tuberculosis in Europe has led to a marked reduction in the incidence of tuberculous meningitis (TBM) but the condition is still frequent in developing countries and in patients who are immunosuppressed, particularly because of HIV. However, there has been a recent increase in TB in the United Kingdom and other nations in the European Union. TBM develops secondary to a small caseating subpial and subependymal foci in the brain and spinal cord adjacent to the CSF (Rich foci). In some individuals, foci rupture and release bacteria into the subarachnoid space causing meningitis. In others, foci enlarge to form tuberculomas without meningitis. Both tuberculomas and parenchymal tuberculosis occur as a result of haematogenous spread. They may develop in the absence of pulmonary tuberculosis.

TBM is characterised by inflammatory meningeal adhesive exudates leading to a florid small and medium vessel vasculitis which culminates in occlusion of cerebral arteries and infarction. There is also a disturbance of CSF flow because of impairment of absorption

**Table 9.8** Poor prognostic factors in tuberculous meningitis.

Disease severity
Impairment of consciousness
Presence of neurological deficits, seizures or abnormal movements
Extremes of age
Co-existing miliary disease
CSF protein with spinal block
Very low CSF glucose
CT scan showing abnormalities
HIV positive, low CD4 (below 50/mm <sup>3</sup> )
Illness longer than 14 days

CSF, cerebrospinal fluid; CT, computed tomography.

at the arachnoid villi and blockage at the aqueduct and 4th ventricular outlet. In tuberculous meningitis, vasculitis particularly affects the vessels at the base of the brain – the internal carotid and proximal middle cerebral arteries – and perforating arteries to the basal ganglia and internal capsule. TBM was almost invariably fatal before the development of antituberculous chemotherapy. Tuberculosis in immunosuppressed adults, especially those with HIV infection, is likely to be disseminated and involve the CNS. Other risk factors for TBM include alcoholism, diabetes mellitus, malignancy, corticosteroid treatment and tumour necrosis factor (TNF) blocking drugs. Table 9.8 summarises factors of prognostic significance in the outcome of CNS tuberculosis.

**Clinical manifestations** TBM is often preceded by a prolonged prodrome (>6 days) of non-specific malaise, anorexia, low grade fever, myalgia, photophobia and headache. Neck stiffness is usually absent. The development of meningitis may be insidious, with worsening headache, nausea, vomiting, focal or generalised seizures and progressive impairment of consciousness. Cranial nerve palsies are common and often initially involve eye movements resulting from IIIrd, IVth or VIth nerve palsy. There may be facial weakness (VII), optic neuropathy (II), progressive hearing loss (VIII) and eventual bulbar involvement (X–XII). Fundal examination may show papilloedema, optic atrophy or the presence of choroidal tubercles. Visual impairment may also develop because of involvement of the optic chiasm, tuberculomas compressing the optic pathways or optic nerve toxicity resulting from treatment with ethambutol. Other neurological signs include hemiparesis and hemiplegia as a consequence of vasculitic infarction or space-occupying tuberculomas. Movement disorders may be manifest as tremor, myoclonus, chorea, hemiballismus or dystonia and cerebellar ataxia may occur from direct involvement or vasculitic infarction. Vasculitis usually occurs in the distribution of the anterior circulation, particularly affecting the deep structures, but occasionally involves the posterior territory. The major complications of TBM are:

- Hydrocephalus
- Stroke
- Tuberculoma formation.

**Diagnosis** The diagnosis of TBM or focal parenchymatous involvement can be difficult clinically. Tuberculin skin test is variable in its response and unreliable as there may be anergy even in the presence of miliary tuberculosis. Interferon gamma release assays

are increasingly used but cannot differentiate active from latent disease and are negative in 25% of cases. CSF examination is characterised by the presence of an elevated opening pressure in 50%, lymphocytic pleocytosis with a high protein and low glucose. The white cell count is usually 5–500/mm<sup>3</sup> and should not generally exceed 1000/mm<sup>3</sup> but there may be a significant proportion of polymorphonuclear cells in the initial stages. The protein is generally elevated up to 1 g/L but may be greater than this particularly if there is a spinal block. The glucose concentration is low (often <2.2 mmol/L) and this is usually below 50% of the serum glucose.

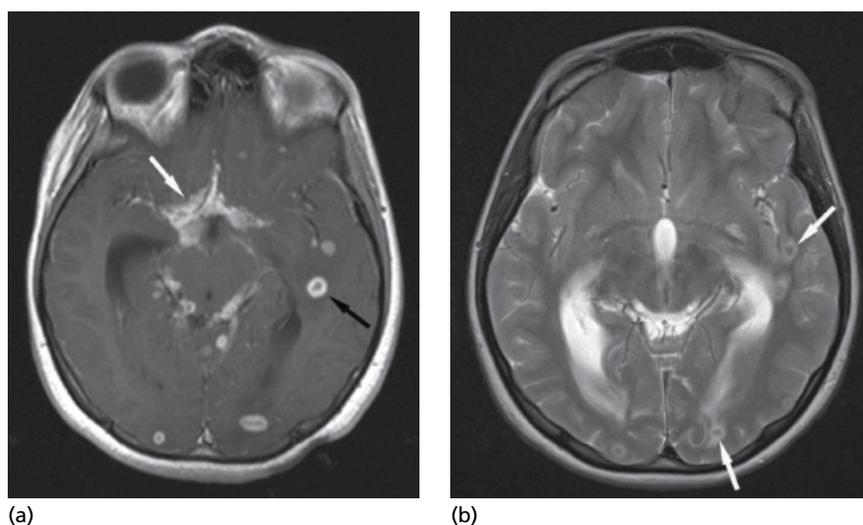

A tissue diagnosis (by histopathology and culture) should be attempted whenever possible, either by meningeal biopsy or through diagnostic sampling from extraneural sites of disease (e.g. lung, gastric fluid, lymph nodes, liver or bone marrow). PCR can be performed directly on clinical specimens in untreated patients but is less sensitive than culture, particularly in extrapulmonary specimens. All patients with suspected or proven tuberculosis should be offered HIV testing.

**CSF bacteriology** No specific test has high sensitivity. Direct examination of the CSF for acid–alcohol fast bacilli (AFB) using Ziehl–Neelsen or auramine staining requires large volumes of CSF (minimum 10 mL) and is dependent on the experience of the microscopist. AFB are only seen in approximately 10% of cases with appropriate staining. CSF culture is the diagnostic investigation but requires up to 6 weeks, has a yield of 10–60% and is therefore of only limited value in clinical practice. CSF culture has the advantage of indicating drug sensitivities if the samples are taken before treatment has commenced.

Nucleic acid amplification techniques (NAATs) for the diagnosis of TBM are 98% specific but only 56% sensitive. Therefore, NAATs can confirm the diagnosis but cannot exclude it. The use of real-time PCR can improve the sensitivity but is expensive. The only way to diagnose drug resistant TBM is through CSF NAATs and the detection of genetic mutations that confer drug resistance. However, at present, this approach is limited by the low sensitivity of CSF NAATs and uncertainty about which mutations best predict resistance for some drugs.

**Radiology** Approximately 50% of patients with TBM show evidence of previous tuberculosis on chest X-ray, with up to 10% having miliary tuberculosis. CT brain scanning is commonly abnormal with marked enhancing exudate in the basal cisterns. There may also be hydrocephalus, parenchymal enhancement, evidence of cerebral infarction or cerebral oedema or focal tuberculoma. MRI is sensitive in showing meningeal enhancement, focal parenchymal abnormalities or the development of communicating or obstructive hydrocephalus (Figure 9.6).

**Management of tuberculous meningitis** TBM, like all bacterial meningitides, is a medical emergency. Treatment delay is strongly associated with death and empirical antituberculous treatment should be started promptly in all patients in whom the diagnosis of TBM is suspected without awaiting microbial or molecular confirmation. Chemotherapy for CNS tuberculosis consists of an intensive phase of treatment followed by a continuation phase. This is aimed at eradicating the causative organisms and management of the complications caused by the inflammatory response including hydrocephalus, vasculitis and raised intracranial pressure. The standard treatment of TBM is with an intensive primary phase of treatment followed by a continuation phase as summarised in Table 9.9 and

**Figure 9.6** TB: basal meningitis and multiple tuberculomas. (a) T1-weighted post-contrast MRI showing extensive enhancing material within the basal cisterns encasing the vessels of the circle of Willis (white arrow) and multiple ring enhancing tuberculomas typified by the left temporal lesion (black arrow). (b) T2-weighted MRI showing hydrocephalus and multiple tuberculomas with characteristic hypointense centre and hyperintense rim (white arrows).

**Table 9.9** Treatment of tuberculous meningitis – initial phase using four drugs for 2 months.

	Adult daily dose	Comment	Side effects
Isoniazid	300 mg	Essential drug Penetrates CSF freely and has potent early bacteriocidal activity Add pyridoxine to avoid peripheral neuropathy	Hepatitis, haemolytic anaemia, aplastic anaemia, peripheral neuropathy, optic neuritis, mania, fits
Rifampicin	450 mg (wt <50 kg) 600 mg (wt >50 kg)	Essential drug Bacteriocidal but poor CSF penetration (10%)	Hepatitis, thrombocytopenia, headache, confusion, drowsiness
Pyrazinamide	1.5 g (wt <50 kg) 2.0 g (wt >50 kg)	Bacteriocidal with good penetration	Hepatitis, anorexia, flushing
<b>Fourth drug: use one of</b>			
Streptomycin	20–40 mg/kg	Neither penetrates CSF well in absence of inflammation (10–50%)	Avoid in pregnancy and renal impairment Neuromuscular blockade
Ethambutol	15 mg/kg		Retrolbulbar neuritis, peripheral neuropathy, confusion
Ethionamide	500–750 mg	Penetrate healthy and inflamed meninges but no evidence of advantage over other drugs	

Table 9.10. Treatment should commence with isoniazid, rifampicin, pyrazinamide and ethambutol for 2 months and this should be followed by a 9–12 month continuation phase of treatment with isoniazid and rifampicin or pyrazinamide. There remains some debate about the duration of treatment. Expert opinion should be sought where possible: TBM has a poor prognosis.

Isoniazid and pyrazinamide are bacteriocidal and show good penetration through inflamed meninges, easily achieving therapeutic concentrations. Rifampicin, ethambutol and streptomycin have poorer penetration and achieve lower CSF concentrations (maximum concentration around 30% of plasma) but the high mortality from

rifampicin resistant tuberculosis confirms its role. The fourth drug (ethambutol) is added to cover the possibility of isoniazid resistant bacteria. All antituberculous treatment carries significant risks of toxicity. Treatment with a fourth drug during the initial phase remains indicated despite the poor ability of streptomycin and ethambutol to cross the blood–brain barrier. Ethambutol-induced optic neuropathy is a concern but is infrequent. The dose conventionally follows those used in pulmonary TB but remains controversial.

There is an increasing incidence of tuberculosis caused by organisms resistant to conventional treatment. The risk of drug resistance must be assessed individually for all patients with CNS

**Table 9.10** Treatment of tuberculous meningitis— continuation phase using two drugs for 9–12 months.

Isoniazid	
Rifampicin	
Pyrazinamide	
<b>Suspected or proven multidrug resistance:</b>	
Aminoglycoside	Kanamycin, amikacin, capreomycin
Ethionamide	
Prothionamide	
Fluoroquinolones	Moxifloxacin, levofloxacin
Linezolid	

tuberculosis. Suspected isoniazid resistant disease should be treated with conventional four-drug first line therapy followed by 12 months treatment with rifampicin, isoniazid and pyrazinamide. If high level isoniazid resistance is proven the isoniazid should be exchanged for levofloxacin or moxifloxacin for 12 months treatment. With suspected or proven multi-drug resistance initial therapy should be with a fluoroquinone (levofloxacin or moxifloxacin), pyrazinamide, ethionamide or prothionamide and an injectable agent (kanamycin, amikacin or capreomycin) followed by a maintenance course for 9–18 months.

**Corticosteroids** Adjunctive corticosteroids reduce death and disability from TBM by about 30% and are recommended for all patients with the disease. Treatment should be with 0.4 mg/kg dexamethasone, intravenously initially, gradually reducing and switching to oral, stopping after 6–8 weeks. Alternative treatment is with 2–5 mg/kg prednisolone intravenously initially and then reducing and switching to oral over 4 weeks. More prolonged courses may be considered if there is cerebral oedema, spinal block, severe tuberculous meningitis, spinal arachnoiditis or cerebral vasculitis.

**Surgical intervention** Surgical intervention may be required in the presence of obstructive hydrocephalus that has not responded to medical treatment. This usually consists of an external ventricular drain initially but may eventually necessitate a ventriculo-peritoneal shunt. Shunt complications are common (<30%) thus endoscopic 3rd ventriculostomy has become an alternative surgical treatment option. Success rates for this procedure are approximately 65%, with failure being caused by distorted anatomy of the 3rd ventricular floor in the acute phase of the disease.

**Outcome** The outcome of TBM has remained poor and the mortality is still >20%, with severe neurological sequelae occurring in up to 30% of survivors. Early drug treatment is essential, particularly before the development of impaired consciousness and coma. Late neurological disability is predicted by the presence of extrameningeal tuberculosis, cranial nerve palsies, limb weakness and multiple neurological abnormalities including hydrocephalus, cerebral infarction, expanding tuberculomas and hyponatraemia.

### Parenchymal CNS tuberculosis

**Tuberculous granuloma (tuberculoma)** Tuberculous granulomas can be found in the cerebrum, brainstem, cerebellum, spinal cord, subarachnoid or epidural space but are generally supratentorial; they may be multiple in up to two-thirds of patients and may coexist with TBM in about 10% of patients. They present as space-occupying

**Figure 9.7** Anteriorly placed tuberculous spinal abscess (arrow).

lesions with headache, intracranial hypertension, seizures and papilloedema. There may be motor, cerebellar or brainstem signs. Imaging confirms the presence of an enhancing space-occupying lesion, occasionally with central calcification. They usually resolve with conventional antituberculous treatment but there may be an initial phase of paradoxical expansion even with appropriate therapy. Occasionally, surgical intervention is indicated.

### Tuberculous abscess

Tuberculous abscess results from liquifaction of the central core of the tuberculoma. The lesions often enlarge and become multilocular and have mass effect associated with oedema. They tend to resemble pyogenic abscesses rather than tuberculomas and are difficult to distinguish clinically. They do not always respond well to antituberculous chemotherapy; surgical excision may be necessary.

### Spinal tuberculosis (tuberculous spondylitis)

Tuberculosis may involve the spinal vertebral bodies, with a predilection for the anterior elements (Figure 9.7). In adults, at least two contiguous levels and their intervening disc space are involved, particularly in thoracic and lumbar regions. Paraspinal soft tissue

involvement is common and a paravertebral tuberculous abscess (Pott's abscess) may occur in up to 30% of patients with tuberculous spondylitis. Spinal collapse is also frequent and leads to gibbus, extrinsic cord compression and paraparesis.

Tuberculous spinal meningitis may be localised to the spinal cord. In this condition there is a gross granulomatous exudate in the subarachnoid space, which causes a vasculitic response in the spinal vessels, particularly the anterior spinal artery, culminating in ischaemia or infarction of the spinal cord. There may also be a progressive radiculopathy, myelopathy or transverse myelitis. Intramedullary spinal cord tuberculous abscess or, rarely, tuberculoma may occur within the substance of the spinal cord mimicking a tumour. Tuberculous radiculomyelopathy or transverse myelitis often present acutely but may be slower in onset. They may be characterised by radicular pain, bladder disturbance or progressive paraparesis. CSF shows a high protein content with lymphocytic pleocytosis and a low glucose. MRI scan shows contrast enhancements surrounding the spinal cord and roots and often a diffusely increased intramedullary signal. Spinal cord disease is treated with prolonged standard antituberculous treatment and systemic steroids. If there is significant bone destruction, bracing and/or surgical decompression may be necessary.

### Leprosy (Hansen's disease)

Leprosy is a common condition worldwide, but occurs predominantly in Africa (particularly Sudan and Nigeria), South America (particularly Brazil), South-East Asia, Nepal, India, Pakistan, Bangladesh and China. The prevalence is difficult to establish because of incomplete reporting. The disease remains widely feared and poorly understood but it is not highly contagious and curative treatment is available. However, early diagnosis and appropriate management are necessary to minimise the risk of irreversible neuropathy, deformity and disability. Leprosy is due to *Mycobacterium leprae* which causes granulomas to form in the peripheral nerves and skin. The organism is an intracellular AFB that resembles the tubercle bacillus. It multiplies at a cool temperature (27°C and 33°C) and therefore favours distal parts of the human body. There is a prolonged incubation period of 2–5 years but this may be as long as 20 years. The organism has a predilection for Schwann cells associated with thinly myelinated axons. The infective risk of leprosy is relatively low, even after exposure, and the means of transmission are not fully understood. The disease is probably transmitted from person to person by aerosol with a high subclinical rate of infection. Household and prolonged close contact seem important. There is anecdotal evidence that it may be transmitted by inoculation, such as by contaminated tattoo. Primary infection is followed by haematogeneous spread to preferential sites including skin, peripheral nerves, upper respiratory tract, anterior chamber of the eye and the testes.

The pattern of illness is determined by the host's immune response to the mycobacterial antigen. When there is an active cell-mediated immune reaction directed against *M. leprae*, tuberculoid leprosy develops which is restricted to a few peripheral nerves. However, a poor immune response leads to lepromatous leprosy in which there is an extensive proliferation of bacilli. Some patients have borderline patterns with features of both tuberculoid and lepromatous. The World Health Organization (WHO) now uses a simplified classification scheme that relies on clinical examination and skin scrapings, dividing cases into paucibacillary and multibacillary leprosy. Paucibacillary leprosy is defined as five or fewer skin lesions without detectable bacilli on skin smears while in multibacillary leprosy there are six or more lesions and skin smear may be positive. The risk of transmission from close contact is much greater in the multibacillary form.

### Clinical features

Leprosy is characterised by hypoaesthetic skin lesions, thickened peripheral nerves and positive skin smear showing AFB.

In tuberculoid leprosy, the earliest skin lesions are single or few with clearly demarcated asymmetrical hypopigmented or erythematous skin lesions which are hypoaesthetic and are scattered across the body with no obvious preferential areas. They have a sharp edge but vary in size. Patients may complain of a numb patch or patches and/or minor and typically painless skin lumps.

In lepromatous leprosy, there is a more diffuse involvement of the skin with extensive hypopigmented, nodular or maculopapular infiltration affecting the body, the skin of the face and the earlobes, with progressive loss of the eyebrows and eyelashes. Over the course of years, there may develop coarse thickening of the features, particularly the earlobes, nose and cheeks, giving rise to the characteristic leonine facies. The larynx may also be involved. The testes become atrophic; gynaecomastia and sterility may follow. Visual impairment occurs because facial weakness and anaesthesia of the conjunctiva and cornea lead to corneal ulceration and scarring culminating in exposure keratitis. There also may be an iridocyclitis and cataracts secondary to intraocular involvement by the bacilli.

### Peripheral nerve involvement

In tuberculoid leprosy, there is involvement of the small superficial nerves in the cooler part of the body and at points where they are exposed, leading to pain and temperature, touch and pressure impairment over affected skin areas but nerve thickening is less common than in lepromatous disease.

The most frequently affected peripheral nerves (nerves of predilection) are:

- Ulnar nerve
- Posterior tibial nerve and sural (at the medial malleolus of the tibia)
- Common peroneal nerve (at the knee where it winds around the neck of the fibula)
- Median (at the wrist)
- Facial (crossing zygomatic arch)
- Trigeminal nerve involvement of ophthalmic division of the trigeminal nerve leading to corneal and conjunctival sensory loss, ulceration and blindness
- Greater auricular (posterior triangle of the neck)
- Supraorbital
- Superficial radial (cutaneous at the wrist).

Lepromatous involvement of the peripheral nerves is insidious over many years. Peripheral nerve thickening affects sensori-motor and autonomic nerves to a varying extent and may cause either a focal or diffuse mononeuritis multiplex or a progressive symmetrical distal peripheral neuropathy. Sensory impairment is more common than motor but there may be atrophy and weakness leading to claw hands or bilateral foot drop.

Immunological reactions are systemic inflammatory complications that occur either before, during or after treatment and affect 30–50% of patients. There are two types of reaction: type I occurs in patients with borderline disease and seems to be caused by an intensification of the cellular immune response to *M. leprae*. It is manifest as a worsening erythema or swelling of an existing lesion; inflammation leading to severe nerve injury with pain and tenderness in a peripheral nerve distribution with subsequent paralysis and deformity; peripheral oedema and ulcerated skin lesions. Type 2 reaction (erythema nodosum leprosum) occurs in lepromatous disease. It is characterised by the acute eruption of numerous painful nodules which can form pustules or ulcerate. There may also be pyrexia, headache, generalised pain, tender lymphadenopathy,

iridocyclitis, muscle tenderness and swollen joints. The mechanism of type 2 reactions is uncertain but has previously been thought of as an immune complex disorder.

### Borderline leprosy

In borderline leprosy there are features of both tuberculoid and lepromatous forms. Hypoaesthetic skin lesions occur but they differ slightly in appearance from lepromatous leprosy. Borderline patients are particularly vulnerable to nerve damage and may develop severe deformities including trophic ulceration. The affected nerve trunk is often swollen and painful.

### Primary neuritic leprosy

This is seen in India and Nepal and presents as peripheral nerve involvement without the characteristic skin lesions. Skin smears are negative for AFB. Neurological manifestations are caused by asymmetrical involvement of one or several peripheral nerve trunks and sensory changes develop before motor features. Isolated nerve thickening may occur. Skin lesions may develop later in the course of the illness.

### Diagnosis

This is difficult and primarily clinical. Nerve conduction studies show axonal loss and demyelination with focal slowing across thickened nerve segments suggesting segmental demyelination. There is loss of the sensory action potentials. A skin smear is used to assess the density of AFBs – they are always found in the multi-bacillary form but only in 30% of borderline disease. Skin biopsy is essential for correct classification and diagnosis when skin smears are negative. Nerve biopsy of a thickened sensory nerve (usually sural or radial cutaneous nerve) may also yield a diagnosis. The Lepromin skin test assesses the patient's cell-mediated immunity against *M. leprae* and is strongly positive in tuberculoid leprosy but is negative in lepromatous leprosy. This test is of no value in patients who have received bacille Calmette–Guérin (BCG) vaccination or who have had previous subclinical disease. Serology tests use radioimmune assay and ELISA based on the detection of antibodies to *M. leprae* antigen. The *M. leprae* genome has now been entirely sequenced and it is possible to detect the organism using PCR amplification in skin and nerve biopsies.

### Management

Accurate classification is essential to establish the correct treatment. Multi-drug therapy with a combination of rifampicin, dapsone and clofazimine is effective in both multibacillary and paucibacillary leprosy and nerve function appears to improve with early treatment. The skin lesions in paucibacillary leprosy resolve within a year but in patients with multibacillary leprosy they persist for much longer. However, with prolonged treatment relapse rates are low. Dapsone, the original drug treatment, is only slowly bactericidal and needs to be given daily. It is limited in its effectiveness and there is a high incidence of resistance if the drug is used alone. Side effects are rare but malaise, haemolytic anaemia and leukopenia can occur. Rifampicin is a strongly bactericidal drug which is rapidly effective. Because of the slow rate of replication of *M. leprae* the drug need be given only once a month but resistance may occur on monotherapy. Clofazimine is weakly bactericidal but is highly effective in controlling lepromatous leprosy, particularly in suppressing the inflammation of erythema nodosum.

Patients with paucibacillary leprosy are generally treated with two drugs. The WHO recommends rifampicin 600 mg once a month (supervised) and dapsone 100 mg/day (unsupervised) for 6 months. This regimen should be followed by treatment with dapsone as

monotherapy for 3 years in patients with tuberculoid leprosy or 5 years in patients with borderline lepromatous leprosy. The National Hansen's Disease Program (NHDP) recommends rifampicin 600 mg/day and dapsone 100 mg/day for 12 months. Patients with multibacillary leprosy receive three drugs. The WHO recommends dapsone 100 mg/day (unsupervised), clofazimine 50 mg/day (unsupervised) and rifampicin 600 mg once a month plus clofazimine 300 mg once a month (unsupervised) for 12 months. The NHDP recommends dapsone 100 mg/day, rifampicin 600 mg/day and clofazimine 50 mg/day for 24 months. All treated patients should be followed up for reactions or relapses for many years after completing treatment. There is a small but increasing incidence of resistance to dapsone, notably in Vietnam. The neuropathy is often treated with oral steroids; 60% of patients usually regain some nerve function but this can take many months.

Mild immunological reactions can be managed with supportive care and antimicrobial treatment should be continued. Severe reactions with neuritis or erythema nodosum, cropping of facial lesions and ocular involvement require corticosteroids (prednisolone 40–60 mg/day tapered when the reaction is controlled – this may be up to 3 months in borderline disease and up to 9 months for lepromatous forms). Second line treatment includes ciclosporin for severe type 1 reactions and thalidomide (300–400 mg/day) for type 2 leprosy reactions, although teratogenicity limits its use in women of child-bearing age.

The social stigmata associated with deformity and scarring from leprosy remain a considerable worldwide problem despite extensive health education programmes run by WHO and other community projects. Leprosy control has been integrated into general health services in endemic areas, increasing access to diagnostic and treatment facilities. Despite these advances leprosy remains feared – difficulty in achieving diagnosis and poor compliance with treatment remain a major concern.

### Brucellosis (undulant fever)

Brucellosis is a zoonotic infection caused by Gram-negative coccobacilli, *Brucella melitensis*, *B. abortus* and *B. suis*, harboured in sheep, cattle and pigs, respectively. Camels' milk can also become infected. Transmission of brucellosis to humans occurs through consumption of infected and unpasteurised milk, through direct contact with animals, living or dead, and through direct inhalation of aerosol particles. It is a granulomatous disease, either acute or indolent in character. There is a non-specific prodrome with a variable and irregular (undulant) fever and flu-like symptoms of malaise, night sweats, malodorous perspiration, arthralgia and myalgia. Lymphadenopathy and hepatosplenomegaly follows; this either resolves or is followed by localised single organ infection. Osteoarticular disease is the most common and this can manifest as polyarthritis, sacroileitis or spondylitis.

The nervous system is affected in about 5% of patients; meningitis and meningo-encephalitis are the most common presentation with meningism, confusion and impaired level of consciousness. Cranial nerve deficits occur as a consequence of granulomatous involvement at the skull base, with facial weakness, sensorineural hearing loss and ocular symptoms from retrobulbar neuritis, papilloedema, optic neuropathy and ophthalmoplegia, all of which may occur. *Brucella* meningitis can lead to hydrocephalus and raised intracranial pressure. Brain and spinal cord abscesses can develop. There may be a granulomatous endarteritis or focal vasculitis causing stroke, myelitis or a radiculopathy. Polyneuropathy may also develop. Endocarditis is the principal cause of death. This organism is regarded as a biohazard and the laboratory should be warned of the possibility of a case of brucellosis. The diagnosis is often made serologically but culture

is the gold standard. However, blood cultures are positive in only 40% of acute cases, with bone marrow cultures offering an additional 20% yield. CSF is positive 25% on culture or serological tests include tube agglutination and enzyme linked immunosorbent assay. There is no standardised PCR test yet available. CSF shows an elevated protein with a lymphocytic pleocytosis and a low glucose; occasionally oligoclonal bands are present. MRI may show contrast enhanced inflammatory changes in the spinal cord or brain.

Brucellosis is treated by various combinations of antibiotics; there is a high relapse rate with a single drug. WHO guidelines recommend doxycycline for 6 weeks (though not in pregnancy) with either streptomycin for 2-3 weeks or rifampicin for 6 weeks. Alternative drug combinations are co-trimoxazole with a quinolone, such as ciprofloxacin or moxifloxacin. *Brucella* meningitis should be treated with three drugs for 2-6 months. Regimens include doxycycline, rifampin and either ceftriaxone or co-trimoxazole. Ceftriaxone-based regimens may be more successful and allow shorter duration of therapy but therapy is generally prolonged (months) and needs to be individualised according to clinical signs and symptoms; in general, it should be continued until CSF parameters have returned to normal. The role of corticosteroids is uncertain and they are not part of routine therapy. Steroids may be appropriate in the setting of neurobrucellosis complicated by iritis, papilloedema, myelopathy, polyneuropathy and/or cranial nerve palsies.

Surgical drainage of brucella abscesses may be necessary.

## Spirochete CNS infections

### Syphilis

Syphilis is increasing in prevalence in the United Kingdom, in particular amongst homosexual men with HIV. It is a chronic systemic infection caused by the spirochete *Treponema pallidum* subsp. *pallidum*. It is transmitted through contact with an infected lesion (usually sexual contact), from mother to fetus during pregnancy (congenital syphilis) and through contaminated blood products. It readily penetrates intact mucus membranes and abraded skin, rapidly reaching the bloodstream and lymphatics.

Syphilis is characterised by four stages:

- 1 **Primary** Local primary chancre with regional lymphadenopathy
- 2 **Secondary** Multisystem involvement with generalised mucocutaneous lesions
- 3 **Latent** Previous infection with positive serological tests but no symptoms or signs
- 4 **Late (tertiary)** Involvement of the heart, bone, skin and CNS, many years after primary infection. The most common manifestations of late syphilis are cardiovascular (especially aortitis), CNS (general paralysis and tabes dorsalis) and gummatous (granulomatous, nodular lesions affecting a variety of organs, particularly skin and bones.)

Primary syphilis usually develops within a few days of exposure but may be delayed up to 90 days. It is characterised by a painless ulcer known as a chancre at the site of inoculation, with local lymphadenopathy. A chancre is highly infectious, but heals spontaneously over the course of some weeks.

Secondary syphilis usually develops 6-12 weeks after the chancre heals and consists of a characteristic generalised maculopapular rash involving the palms, soles and mucosal surfaces, with diffuse generalised lymphadenopathy, fever, weight loss and malaise. The patient is highly infectious during secondary disease. Secondary syphilis also causes meningitis. There may also be proctitis, hepatitis, gastritis, nephrotic syndrome and iridocyclitis.

The secondary infection resolves spontaneously, to become latent with a prolonged quiescent phase for a decade or more. About

one-third of patients with latent syphilis who remain untreated develop tertiary disease and one-third of these develop symptomatic neurosyphilis. In a study of patients with untreated syphilis, 10% developed cardiovascular syphilis, 16% gummatous and 6.5% symptomatic neurosyphilis. With HIV infection, all stages of syphilis tend to be accelerated.

Syphilitic meningitis usually develops within the first year after infection but the onset may be delayed. The onset is with progressive headache, confusion and meningism. There may be progressive cranial nerve (particularly VII and VIII) involvement and focal signs such as aphasia, hemiparesis and focal epilepsy. Ocular involvement includes uveitis, vitritis, retinitis and optic neuritis. Focal meningial inflammation may give rise to syphilitic gummas (see Intracerebral gumma) or a diffuse hyperplastic pachymeningitis affecting the cortex or spinal cord. Spinal involvement leads to back pain, muscle wasting and weakness (occasionally resembling motor neurone disease), urinary incontinence and sensory impairment.

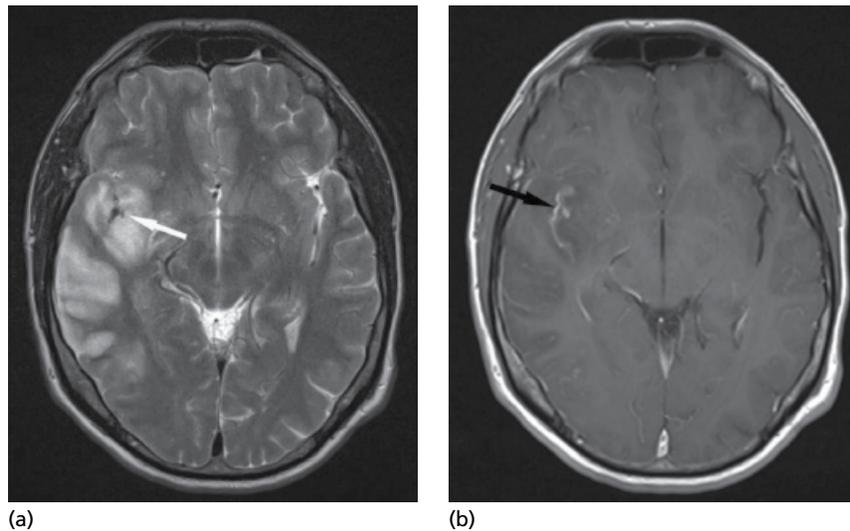

Pachymeningitis refers to a localised, inflammatory thickening of the dura which has a number of causes:

- Infective
  - neurosyphilis
  - CNS tuberculosis: tuberculous pachymeningitis
  - CNS cryptococcosis
  - bacterial meningitis
- Inflammatory
  - Wegener's granulomatosis
  - polyarteritis nodosa
  - rheumatoid arthritis
- Neurosarcoidosis
- IgG4 disease
- Haemodialysis
- Mucopolysaccharidoses
- Idiopathic hypertrophic pachymeningitis.

Meningo-vascular syphilis is a form of early symptomatic neurosyphilis. It develops within 10 years of infection and is caused by syphilitic meningitis causing an infectious obliterative endarteritis and periarteritis with meningitis and spinal arachnoiditis (Figure 9.8). Impairment of CSF absorption may lead to hydrocephalus, with headache or confusion; there may be signs of focal cortical involvement brought about by ischaemic stroke including aphasia, hemiplegia, hemisensory disturbance or multiple cranial nerve palsies leading to diplopia, vertigo and dysarthria. Spinal cord involvement caused by meningo-myelitis is characterised by the slow evolution of a spastic paraparesis with bowel and bladder involvement and lower limb sensory loss. There may also be a more acute transverse myelitis caused by infarction caused by anterior spinal artery occlusion. Meningo-vascular syphilis should be considered in the differential diagnosis of ischaemic stroke in a young person. The CSF changes in meningo-vascular neurosyphilis are generally less severe than those in acute meningitis with a lymphocytic pleocytosis of 10-100 cells/mm<sup>3</sup> and a protein of 1-2 g/L.

### Late neurosyphilis

**Tabes dorsalis** Tabes dorsalis has the longest latent period between primary infection and the onset of symptoms of late neurosyphilis with an average duration of 20 years although the time to onset can be much shorter. There is involvement of the posterior columns and root entry zones with diffuse inflammatory infiltration and atrophic change. Symptoms include characteristic lightning pains in the legs - intensely painful, sharp shooting paraesthesiae and pain - often associated with episodic acute abdominal pain, known as tabetic crises. The proprioceptive loss leads to a severely ataxic gait

**Figure 9.8** Meningovascular syphilis: T2-weighted and post-contrast T1-weighted images (a and b, respectively) showing right temporal lobe infarction. A thrombosed right middle cerebral artery branch can be seen (white arrow) with enhancement of the vessel and adjacent leptomeninges (black arrow).

with characteristic stamping. There is also impaired deep pain sensation in the limbs and the development of bladder, bowel and sexual dysfunction. Progressive posterior column impairment leads to neuropathic (Charcot) joints, a severe destructive arthropathy caused by repeated trauma, ulcers may develop around these joints. Cranial nerve abnormalities are associated with tabes including optic atrophy and pupillary abnormalities.

**General paralysis** General paralysis is a recrudescence of infection (GPI) caused by direct invasion of the brain by spirochetes leading to frontal and temporal atrophy. GPI develops >15 years after the initial infection. There is a progressive cognitive impairment with memory loss and disintegration of personality and behaviour leading to severe dementia. Psychiatric problems include emotional lability, paranoia, delusions of grandeur and hallucinations. There may be a coarse tremor of the tongue and similar tremor of the extremities with pyramidal signs including hyper-reflexia. Pupillary abnormalities are characterised by the Argyll Robertson pupil, a tiny irregular pupil, fixed to light but with a preserved accommodation reflex.

#### Intracerebral gumma

Gummas are granulomatous masses formed by a chronic cellular hypersensitivity reaction resulting from late benign syphilis. Gummas form in skin, bone, abdominal viscera and the brain. Intracerebral gummas may act as mass lesions causing compression of adjacent structures, raised intracranial pressure or epilepsy. Cutaneous and intracerebral gummas usually heal rapidly after penicillin therapy with little scarring.

#### Diagnosis

The diagnosis of neurosyphilis is initially clinical but if neurosyphilis is suspected on the basis of positive serology CSF examination is mandatory. *T. pallidum* cannot be cultured. Diagnosis depends on identifying the spirochete by direct visualisation or by serology. In primary and secondary syphilis, direct visualisation is achieved by dark field microscopy of tissue samples from skin and mucous membranes. The diagnosis of latent syphilis and neurosyphilis relies on serological tests. These are either non-specific antigen tests such as the Venereal Disease Research Laboratory (VDRL) and rapid plasma

reagin (RPR) or specific tests based on the detection of IgG and IgM directed against treponemal antibodies such as the fluorescent treponemal antibody absorption test (FTA-Abs), *Treponema pallidum* particle agglutination assay (TPPA) and the syphilis enzyme-linked immunosorbent assay (ELISA). The non-specific tests such as VDRL and RPR may be non-reactive in late syphilis, particularly in tabes dorsalis. It is thus essential to undertake specific treponemal tests to establish a diagnosis. The specific tests (TPPA, FTA, ELISA) remain reactive for life regardless of treatment.

The definitive diagnosis of neurosyphilis depends on the presence of a positive serum treponemal test and a reactive CSF with pleocytosis, increased protein and IgG and possibly also oligoclonal bands. In asymptomatic early neurosyphilis, the CSF shows a lymphocytic pleocytosis (typically 5–100 cells/mm<sup>3</sup>), an elevated protein concentration (<1 g/dL) and a reactive CSF-VDRL. The CSF changes in symptomatic meningitis are more severe with CSF lymphocyte counts of 200–400 cells/mm<sup>3</sup> and protein of 1–2 g/dL with a reactive CSF-VDRL. In parietic neurosyphilis, the lymphocytic pleocytosis persists (25–75 cells/mm<sup>3</sup>) with a raised protein (0.5–1 g/dL). In tabes, the CSF may be entirely normal or show only a mild elevation in protein concentration (0.5–0.75 g/dL).

Positive VDRL/RPR in CSF may indicate neurosyphilis but there is a high incidence of false positive findings, particularly because of previous infection with yaws, caused by the spirochete *T. pallidum pertenue*. The CSF-FTA Ab test is sensitive but not specific, particularly in asymptomatic neurosyphilis but a non-reactive CSF VDRL and FTA-Abs largely excludes the diagnosis of neurosyphilis.

In early neurosyphilis, the CSF findings may be difficult to interpret if there is coexisting HIV infection because HIV itself causes mild CSF pleocytosis and mild elevation of CSF protein levels.

#### Treatment

Standard treatment for early syphilis is intramuscular benzathine penicillin G 2.4 megaunits (MU) given in a single dose. Alternatives are procaine benzylpenicillin 0.6 MU intramuscularly daily for 10 days, or doxycycline 100 mg orally 12-hourly for 14 days for patients who are allergic to penicillin or who refuse parental therapy. Late latent, cardiovascular or gummatous syphilis requires intramuscular benzathine benzylpenicillin in three doses of 2.4 MU

at weekly intervals. Alternatives are procaine benzylpenicillin 0.6 MU intramuscularly daily for 17 days or doxycycline 100 mg orally 12-hourly for 28 days for patients who are allergic to penicillin or who refuse parenteral therapy.

Treatment of neurosyphilis (including neurological and ophthalmological involvement in early syphilis) is with intramuscular procaine benzylpenicillin 1.8–2.4 MU given intramuscularly once daily and probenecid 500 mg 6-hourly for 17 days. Alternatives are benzylpenicillin 18–24 MU daily given as 3–4 MU intramuscularly every 4 hours for 17 days. These regimens can be used following desensitisation to beta-lactams for patients who have serious penicillin allergy. Limited data suggest that ceftriaxone (2 g intramuscularly or IV for 10–14 days) or high dose doxycycline (200 mg orally 12-hourly for 28 days) could be used as alternatives. HIV positive patients should be given the same treatment regime.

Treatment of early syphilis may be associated with a Jarisch–Herxheimer systemic reaction – the sudden onset of severe systemic features including fever, chills, headache and tachycardia – due to rapid destruction of treponemes. All patients being treated for syphilis should be pretreated with prednisolone 60 mg for 24 hours.

Antibiotics do not reverse the cardiovascular and neurological manifestations of late non-cutaneous gummatous syphilis but may prevent further progression.

The CSF should be re-examined after treatment has been completed to show a fall in the pleocytosis and then at 6-monthly to 1-year intervals until the cell count and protein levels have returned to normal although this is rarely undertaken in practice.

## Zoonoses

### Lyme neuroborreliosis

Lyme disease is caused by *Borrelia burgdorferi* which is a helical motile spirochaete. Neuroborreliosis is the most common complication of Lyme disease in the United Kingdom. The infection is a zoonosis; the spirochaete is maintained in populations of large and small mammals, such as deer, field mice and birds and transmitted by the tick bite of the hard-bodied *Ixodes* tick. Bites are small and

easily overlooked. Within Europe, Lyme disease is a significant problem in Germany, Austria, France, Switzerland and Sweden where the annual incidence has been as high as 69/100 000. In the United Kingdom, the south-west regions are endemic areas. In North America, most cases occur in the north-east and mid-Atlantic regions, with 15 000 cases reported each year. Lyme also occurs widely in Asia.

Lyme disease affects all ages, with time outdoors being the most significant risk factor (e.g. forest workers). An occupational and travel history with a focus on hobbies such as shooting and rambling is therefore crucial. The infection occurs between May and September in Europe when the tick feeds, as they become inactive in cold weather. The substantial clinical differences between infections in the United States and Europe arise as a result of the differing strains – *B. burgdorferi sensu stricto* in North America and *B. garinii* and *B. afzelii* in Europe and Asia. Lyme disease also occurs in the southern hemisphere.

### Clinical features of early neuroborreliosis

**Local infection** After a tick bite, 50–90% of patients develop the pathognomic skin lesion erythema migrans, 3–30 days later. Typically, the lesion is not painful or pruritic and enlarges centrifugally over the ensuing days. The rash may be accompanied by malaise, fever, headache, meningism, arthritis and lymphadenopathy (Table 9.11).

### Early disseminated infection

Haematogenous dissemination within a few days or weeks after the initial inoculation results in:

- Cardiac involvement in 5–10% with conduction abnormalities such as complete heart block requiring temporary pacing.
- Neurological complications which include an aseptic lymphocytic meningo-encephalitis, cranial neuropathy and a painful radiculoneuropathy, singly or in combination.

Although some of these early disseminated syndromes may resolve without therapy, 10% will go on to develop late chronic disease that is less responsive to antibiotic therapy, hence the necessity for early diagnosis and treatment.

**Table 9.11** Clinical spectrum of Lyme disease.

Infection stage	Incubation period	Clinical features
Early local infection	<1 month	EM Lymphocytoma cutis Flu-like illness Headache
Early disseminated infection	<3 months	Multifocal EM, arthritis, myalgia, myositis, Cardiac (conduction block, pericarditis, myocarditis) Conjunctivitis Meningitis, meningoencephalitis Cranial neuropathy (VII) Acute painful radiculoneuropathy
Late stage	>3 months	Acrodermatitis chronica atrophicans Arthritis Keratitis, uveitis Chronic encephalomyelitis Chronic polyneuropathy Possible motor neurone disease like syndrome

EM, erythema migrans.

### Cranial neuropathy

A facial palsy occurs in 50–75% of patients with early disseminated disease. Clues that may lead to the suspicion of Lyme disease are a facial palsy during the summer months in endemic areas with systemic symptoms such as headache, meningism and arthritis. In one-third, the facial palsy is bilateral – highly unusual in Bell's palsy (Chapter 13). This narrows the differential diagnosis to a limited number of conditions:

- Guillain–Barré syndrome (GBS)
- Meningitis (e.g. due to HIV)
- Chronic meningitic disorders such as sarcoidosis
- Malignant meningeal infiltration
- Amyloidosis

Involvement of the IIIrd, Vth, VIth and VIIIth cranial nerves has also been described.

### Acute radiculoneuropathy

This complication is more common in European Lyme disease than in North America. Patients present with severe radicular pain, which may affect the limbs or trunk, resembling mechanical root pain. Weakness, sensory loss and areflexia develop over the next few days, preferentially affecting the lower limbs. When acute and severe, the clinical picture may resemble GBS although demyelination on neurophysiological studies is unusual in neuroborreliosis and the CSF pleocytosis seen typically in Lyme disease should raise doubts about the diagnosis of GBS, in which cells are typically absent in CSF. The differential diagnosis of such a painful radiculoneuropathy with a pleocytic CSF includes:

- Herpes zoster with or without a rash (zoster sine herpette)
- Cytomegalovirus infection, in the context of immunosuppression
- Malignant infiltration
- Sarcoidosis
- Vasculitis
- Proximal diabetic radiculoplexoneuropathy (diabetic amyotrophy)
- Diabetic truncal radiculopathy.

### Other syndromes

Anecdotal reports have described brachial and lumbosacral plexopathies similar to neuralgic amyotrophy (Parsonage–Turner syndrome; see Acute brachial neuritis, Chapter 10) associated with borrelia. A few cases of a motor neurone disease-like phenotype have been described with exclusively lower motor neurone signs; however, these patients usually have a cranial or polyradiculopathy due to borrelia which is associated with clear serological evidence of acute infection. While borreliosis is often considered in the differential diagnosis of motor neurone disease, the serology is generally equivocal and the condition does not respond to appropriate treatment.

### Clinical features of late neuroborreliosis

A few patients with early untreated Lyme disease go on to develop a chronic disorder and, occasionally, this may be the first presentation of neuroborreliosis. Problems include:

- Acrodermatitis chronica atrophicans.
- Chronic axonal neuropathy: distal sensory symptoms, radicular involvement and/or restless legs. Neurological examination is either unremarkable or minor sensory abnormalities are found. Neurophysiological abnormalities are consistent with a patchy sensori-motor axonal neuropathy. The CSF is normal. Nerve biopsies are unhelpful but can reveal minimal changes of an axonal neuropathy.

**Table 9.12** American Academy of Neurology guidelines for the diagnosis of nervous system Lyme borreliosis.

<p>Diagnosis of definite nervous system Lyme disease requires:</p> <ol style="list-style-type: none"> <li>1 Possible exposure (in wooded, brushy or grassy areas) to appropriate ticks in an area where Lyme disease occurs. A history of tick bite is not necessary</li> <li>2 One or more of the following:             <ol style="list-style-type: none"> <li>i Erythema migrans, the pathognomonic rash, or histopathologically proven borrelia lymphocytoma or acrodermatitis</li> <li>ii Immunologic evidence of exposure to <i>Borrelia burgdorferi</i> (e.g. positive serology)</li> <li>iii Culture, histologic or PCR proof of the presence of <i>B. burgdorferi</i></li> </ol> </li> <li>3 Occurrence of one or more of the following neurologic disorders after exclusion of other potential aetiologies. If CNS disease is suspected, CSF should be examined for intrathecal antibody production, culture or PCR</li> </ol> <p>Causally related neurologic disease:</p> <ol style="list-style-type: none"> <li>i Lymphocytic meningitis, with or without cranial neuritis or painful radiculoneuritis</li> <li>ii Encephalomyelitis</li> <li>iii Peripheral neuropathy</li> </ol>

- Chronic meningitis, progressive myeloradiculopathy or encephalomyelitis.
- Subacute chronic progressive encephalomyelitis which may mimic multiple sclerosis.

### Post Lyme syndrome

Despite effective antibiotic treatment, some patients complain of persistent fatigue, myalgia, paraesthesias, memory difficulties and depression. Post Lyme syndrome remains contentious. In any event, serological tests continue to remain positive after treatment so there is no diagnostic test.

### Diagnosis

The diagnosis of neuroborreliosis can be difficult for several reasons. The diagnosis remains clinical with laboratory support provided by serological tests and CSF examination. Features worth noting in the history are exposure in an endemic area, and associated systemic symptoms. The American Academy of Neurology has produced practice parameters for the diagnosis of patients with nervous system Lyme disease (Table 9.12).

Culture is the gold standard but is difficult to achieve and is a reference laboratory service. Punch biopsy or aspiration of the erythema migrans lesion has the highest positive rates of 40–80%. Less than 10% of CSF cultures are positive, reflecting the low density of organisms. Serology provides the basis for the laboratory support of the clinical diagnosis with a number of caveats:

- 1 The demonstration of positive antibody is evidence of exposure rather than active disease. Furthermore, these will remain positive even after adequate treatment regimens and cannot be used to assess treatment response.
- 2 Serology may be negative, especially in early disease because IgM antibodies take 2 weeks to develop and IgG antibodies 4–6 weeks after inoculation. Patients prescribed inadequate doses of antibiotics

early in the course of the illness may remain antibody negative despite persistence of viable organisms.

- 3 False positive results may occur because of cross reactions with infections such as EBV, syphilis, rickettsial and bacterial infections and autoimmune disorders.

The current recommendation is to use a two-tier system for serodiagnosis – screening with an ELISA or immunofluorescence assay (IFA) which is rapid and sensitive. Positive tests are followed up by a more specific Western blot analysis. Western blots are considered positive in acute disease if two of three selected bands are positive. In disease of longer duration five out of ten positive bands are required. A follow-up serology test may be required 2–4 weeks later to confirm seroconversion.

CSF examination is abnormal in most cases of neuroborreliosis – the exception being the chronic axonal neuropathy described earlier. There is usually a lymphocytic pleocytosis of up to a few hundred cells with an elevated protein level. The glucose is usually normal or slightly reduced. Intrathecal antibody production against *B. burgdorferi* is a useful indicator of infection; however, like blood serology, it may be a marker of past infection and remains positive after treatment. It is therefore necessary to assess CSF cytochemical parameters for evidence of active infection or a treatment response. PCR has proved disappointing with less than 50% of patients with meningitis demonstrating a positive response. As with serology, a positive PCR can be a marker of prior infection without viable organisms being present in the CSF.

### Treatment

Although early disseminated neurological syndromes may resolve spontaneously, 10% go on to develop late complications. The current recommendation is that early and late neurological and cardiovascular borreliosis be treated with intravenous third generation cephalosporins such as ceftriaxone 2 g once daily for 2–4 weeks. Because it has not yet been determined whether a 2-week course is as effective as a 4-week course it seems reasonable to err on the side of caution. The alternative is another third generation cephalosporin, cefotaxime 2 g 8-hourly, which is less convenient. Intravenous penicillin G 3–4 mU six times daily (18–24 mU/day), provided renal function is normal, is another alternative. Oral doxycycline 100 mg 12-hourly was found to be effective for neuroborreliosis including meningitis in one European study and is an alternative. It may be argued that facial palsy is a peripheral disorder and oral antibiotics will suffice. However, many patients have symptoms of meningism and the CSF is abnormal. It is therefore reasonable to consider lumbar puncture in patients presenting with facial palsy in endemic areas before deciding on the most appropriate treatment regimen.

### Leptospirosis

Leptospirosis is a widespread and prevalent zoonosis caused by the spirochete *Leptospira interrogans* carried in domestic animal and rodent urine. Risk factors for infection include occupational exposure – (farmers, abattoir workers, vets and sewer workers), recreational activities (freshwater swimming, canoeing) and household exposure (pet dogs, domesticated livestock). Although clinical manifestations vary in severity, presentation is gradual and non-specific with a flu-like illness, pyrexia, nausea, vomiting and myalgia. Systemic involvement may rapidly develop with chest and abdominal pain. Aseptic meningitis is characterised by headache, photophobia and meningism progressing to encephalopathy with seizures. Ocular features include conjunctival injection, optic

neuritis and uveitis. In the most severe form of the condition (Weil disease) there is hepatic and renal impairment with a bleeding diathesis. Less commonly, leptospirosis may result in acute disseminated encephalomyelitis or cerebrovascular disease manifest as vasculitic ischaemia or haemorrhagic complications. Cranial neuropathy, peripheral nerve involvement including radiculopathy, mononeuritis multiplex and an axonal or demyelinating peripheral neuropathy may occur.

CSF in the meningitic state shows a mononuclear pleocytosis usually around 100/mm<sup>3</sup> but may rise to >10 000/mm<sup>3</sup>. The protein concentration may also be elevated. The diagnosis depends on culture requiring special media and growth is very slow. Diagnosis can also be made by serology with rising titres and specific agglutination tests.

The meningitic illness is usually self-limiting. *Leptospira* are sensitive to antibiotics during the initial febrile phase and treatment is with intravenous benzylpenicillin 6 mU/day or ceftriaxone or doxycycline but there is a risk of Jarisch–Herxheimer reaction.

### Anthrax

Anthrax is caused by *Bacillus anthracis*, a Gram-positive rod that can exist for prolonged periods as a dormant spore in the soil. When introduced subcutaneously spores become vegetative organisms and multiply with the production of exotoxins which lead to extensive tissue necrosis and brawny oedema. Spores may be disseminated into the alveoli where they are phagocytosed into alveolar macrophages and transported to mediastinal lymph nodes. Following secondary haematological spread, they cause a haemorrhagic mediastinitis and overwhelming toxæmia with hypotension and hypoxaemia.

Haemorrhagic meningitis develops in about half of the cases of inhaled anthrax. Some patients develop severe parenchymal brain haemorrhage; coma rapidly supervenes and the prognosis is grave. The diagnosis is established by isolation of *B. anthracis* using culture, PCR or immunohistochemistry.

Treatment of localised cutaneous anthrax is with ciprofloxacin or doxycycline. Meningitis caused by anthrax is treated with IV ciprofloxacin and two additional antibiotics with good CNS penetration (e.g. rifampicin, vancomycin, ampicillin or meropenem).

### Psittacosis

Psittacosis is infection with *Chlamydophila psittaci* transmitted from birds to humans, usually following inhalation of organisms in dried faeces, for example during cage cleaning. It generally presents with a pyrexial pneumonic illness. Neurological involvement is uncommon but there may be a brainstem encephalitis, cerebellar disturbance or uveomeningitic syndrome or it may be associated with the development of Guillain–Barré syndrome. Diagnosis is established by serology. First line treatment is with doxycycline (100 mg 12-hourly), tetracycline or erythromycin.

### Cat scratch disease

Cat scratch disease is a zoonosis spread by exposure to cat bites or scratches or flea bites. It is caused by *Bartonella henselae* and is characterised by regional lymphadenopathy. Ocular manifestations include a form of conjunctivitis with granuloma formation (Parinaud's oculoglandular syndrome), neuroretinitis with visual loss from optic nerve oedema and macular exudates. Neurological involvement includes encephalopathy, transverse myelitis or radiculitis and occasionally cerebellar ataxia. Treatment is with azithromycin, clarithromycin or rifampicin.

## Infections of the nervous system associated with toxin production

### Diphtheria

Diphtheria is now extremely uncommon in developed countries as a consequence of immunity induced by mass immunisation with diphtheria toxoid. However, sporadic cases still occur and there is a risk that a decline in population immunity may render the individual at greater risk given that immunisation does not necessarily confer life-long immunity.

Diphtheria is caused by the toxin of *Corynebacterium diphtheriae* (and less often *C. ulcerans*), an aerobic Gram-positive bacteria which most commonly causes local mucosal necrosis with the formation of a thick 'pseudomembrane' of fibrin, epithelial cells, bacteria and neutrophils affecting the skin and the throat. The toxin may disseminate leading to myocarditis and neurological complications. The incubation period is 1–7 days (usually 2–4 days) and infection is generally manifest as inflammation or pseudomembrane formation over the pharynx or skin.

Systemic involvement caused by dissemination of the toxin leads to neurological complications characterised by cranial nerve involvement and peripheral neuropathy. Palatal and posterior pharyngeal wall paralysis commonly follows pseudomembrane formation and is associated with progressive cranial neuropathy leading to bulbar weakness, with dysarthria, dysphagia and aspiration; ocular involvement may also occur. A mixed sensorimotor demyelinating peripheral neuropathy develops later in the course of the disease, often many months after the onset. There is usually proximal weakness extending distally with severe paralysis and areflexia. Diaphragm and respiratory muscle weakness may develop requiring tracheal intubation and prolonged ventilation. Distal sensory impairment affects all modalities. Autonomic involvement is common, with sinus tachycardia, postural hypotension and urinary retention.

The diagnosis is initially clinical and confirmed by nose or throat swabs, membrane sampling for *C. diphtheriae* and toxin detection. Serological testing for antibody to the toxin can also help support the diagnosis in cases where culture is negative but does not stand alone as a definitive test.

### Management

Treatment involves the immediate administration of diphtheria antitoxin to neutralise circulating toxin, antibiotic treatment against *C. diphtheriae* (penicillin or erythromycin) and supportive management of cardiac, respiratory, bulbar and secondary infective complications. It is essential to recognise that immunity can wane and booster immunisation should be offered every 10 years. Public health notification is essential: diphtheria is contagious. Contacts are at considerable risk and throat swabs should be collected and antibiotic prophylaxis offered.

### Botulism

Botulism is caused by a highly potent neurotoxin elaborated by *Clostridium botulinum*, an anaerobic Gram-positive rod which survives in the soil by forming spores. There are eight antigenically distinct strains of toxin (A–G) but each strain of *C. botulinum* produces only a single toxin. In food-borne botulism, the toxin is absorbed from the gastrointestinal tract and haematogenously disseminated. Toxin binds irreversibly to the presynaptic membrane of peripheral neuromuscular and/or autonomic nerve junctions to inhibit acetylcholine release. Recovery depends on the sprouting of

new nerve terminals. Wound botulism has a longer incubation period but the symptoms and signs are similar to food-borne botulism. This condition also follows subcutaneous or intramuscular injection (skin or muscle popping) of black tar heroin contaminated with *C. botulinum* spores when being cut or diluted prior to street sale.

### Forms of botulism

- Infantile
- Food-borne
- Wound
- Iatrogenic
- Inhalation (possible bioterrorism).

The mean incubation period of food-borne botulism (where the food is contaminated with the toxin) is 12–36 hours. Classically, patients develop non-specific gastrointestinal symptoms, a descending flaccid paralysis, cranial nerve symptoms, autonomic disturbance and ventilatory failure. They remain afebrile and have normal sensation.

Local botulinum toxin injected therapeutically or for cosmetic reasons is generally safe but weakness of muscles adjacent to injection site can be significant (e.g. worsening of dysphagia in motor neurone disease following injection of the salivary glands). Life-threatening toxicity can also occur with paralytic symptoms resulting from spread of toxin. Patients may complain of dysphagia, ptosis, difficulty holding up the head and leg weakness. Occasionally, respiratory difficulties may occur.

### Clinical presentation

Patients are afebrile but may have nausea, vomiting, anorexia and abdominal pain. Cranial nerve deficits develop early including blurred vision, diplopia, dysarthria, dysphagia, dysphonia, facial weakness, ptosis and external ophthalmoplegia with mydriasis occurring because of accommodation paresis. There is flaccid limb weakness affecting the arms more than the legs and progressive respiratory impairment and arrest. Autonomic involvement is characterised by a dry mouth, unreactive pupils, paralytic ileus, gastric dilatation, bladder distension, orthostatic hypotension and constipation. Respiratory muscle weakness may be severe and prolonged. There is an important differential diagnosis which is summarised in Table 9.13.

### Diagnosis

Botulism is a clinical diagnosis which may or may not be supported by laboratory findings. CSF and blood examination are normal. *C. botulinum* may be isolated from the wound site, stool or food.

**Table 9.13** Differential diagnosis of botulism.

Guillain–Barré syndrome and Fisher variant
Myasthenia gravis and myasthenic syndrome
<i>Borrelia</i> (neuroborreliosis)
Diphtheritic polyneuropathy
Tick bites
Curare poisoning
Poliomyelitis
Organophosphate poisoning
Nerve gases (Chapter 19)

**Table 9.14** Management of botulism.

Early administration of antitoxin	Antitoxin should not be delayed pending laboratory results Monitor for signs of allergic reaction to the antitoxin Antitoxin will not reverse established paralysis but should prevent progression Repeated doses can be considered after consultation with an expert if symptoms progress
Wound debridement	Search for and debride any wound no matter how small Examine carefully to ensure that small abscesses or sinuses have not been missed
Give antibiotics if wound present	Benzylpenicillin and metronidazole should be continued until the wound has healed completely
Supportive care	Patients should be admitted to ITU with close bulbar and respiratory monitoring Intubation and ventilation should be undertaken as necessary
Notify public health authorities immediately	Food-borne botulism is a public health emergency

The toxin is detected in serum, stool and food by bioassay using mice, but detection rates are less than 70% in food-borne cases and less than 50% in wound botulism. Immunoassays to detect toxins in the stool and food are being developed but have not been validated.

### Neurophysiology

Nerve conduction studies are normal but repetitive stimulation shows a decremental response at low rates but an incremental response occurs at higher rates. Needle electromyography confirms small polyphasic motor units and single fibre studies show jitter and block.

### Management

The management of botulism is summarised in Table 9.14. The mortality of patients with food-borne botulism is approximately 10%, wound botulism 15% and infant botulism 5%.

### Tetanus

Tetanus is a disease preventable by immunisation. It is rare in the United Kingdom but common worldwide and probably kills 500 000 adults per year. Tetanus is caused by the neurotoxin tetanospasmin, elaborated by the anaerobic Gram-positive rod *Clostridium tetani*. This is a ubiquitous organism found in soil and faeces which persists as resilient spores capable of surviving many years and resistant to most disinfectants and boiling for 20 minutes. The spores germinate under appropriate anaerobic conditions. The toxin is produced in the wound and binds to peripheral motor nerve terminals before being transported via retrograde axonal

transport into the spinal cord and/or brainstem. The toxin ultimately migrates to the presynaptic terminals. It inhibits release of gamma-aminobutyric acid (GABA) and glycine, important inhibitory neurotransmitters. In the absence of the inhibitory influence of GABA and glycine, alpha motor neurones fire rapidly, producing muscle spasms and rigidity. Preganglionic sympathetic neurones are also affected, resulting in increased catecholamine levels and sympathetic over-activity. Tetanospasmin can also produce weakness through blockade of acetylcholine release in a manner analogous to that of botulinum toxin.

### Epidemiology

Tetanus occurs in neonates because of contamination of the umbilical stump. Children and adults may develop tetanus as a consequence of infected wounds, skin lacerations, as a consequence of intramuscular injections or drug abuse and occasionally after abdominal surgery. In adults incidence is greatest at ages >65 years, usually as a result of inadequate reimmunisation and waning immunity.

### Clinical features

The incubation period varies from a few days to several weeks depending on the site of spore inoculation. There may be localised spasm and rigidity in the region of the wound. The onset may be with back pain, increased muscle tone and rigidity of the masseter muscles leading to trismus (lockjaw) and a similar rigidity of the facial muscles (risus sardonicus). There is a localised stiffness near to the injury with sustained rigidity of the axial muscles with involvement of the neck, back and abdomen and, in severe cases, reflex spasms and opisthotonus. Paroxysmal contractions of muscles appear in response to slight stimuli, and in severe cases are bad enough to cause limb fractures, tendon avulsion and rhabdomyolysis. Spasms of respiratory muscles lead to asphyxia, vocal cord obstruction and aspiration associated with increased bronchial secretions, hypersalivation and dysphagia.

Autonomic manifestations are common in severe tetanus with profuse sweating, hypersalivation and extreme hyperpyrexia. Fluctuations of blood pressure and heart rate are cardinal features and these may be followed by arrhythmias and circulatory failure. There may be transient glycosuria. There is also excessive bronchial secretion, gastric stasis, diarrhoea, acute renal failure and volume depletion.

### Diagnosis

The diagnosis is predominantly clinical, from the history of the spasms and examination findings. Culture of *C. tetani* from a wound is confirmatory. Serology can also have a supportive role in diagnosis, with serum tests for tetanus toxin and tetanus toxin antibody.

### Differential diagnosis

- Strychnine poisoning: strychnine is a competitive antagonist for glycine and poisoning causing spasms and rigidity, typically in the abdominal muscles.
- Dystonic drug reactions cause stiffness and involuntary muscle spasms.
- Autoimmune limbic encephalitis (particularly anti-N-methyl-D-aspartate [NMDA] receptor encephalitis) can cause severe involuntary spasms of the face and limbs.
- Non-organic spasms and rigidity may also be mistaken for tetanus.

**Table 9.15** Management of tetanus.

Neutralise any unbound toxin	TIG intramuscular in multiple sites at 5000–10 000 IU. In the event of reduced availability of TIG, intravenous human normal immunoglobulin can also be used
Debridement of the wound	This encourages eradication of tetanus bacteria and arrest of toxin release
Antibiotics	Metronidazole 500 mg 4 times daily for 7–10 days
Supportive therapy during the acute phase	Nursing in a calm, quiet environment with cardiorespiratory monitoring Fluid balance, nutrition and the control of muscle spasms with diazepam, midazolam Tracheal intubation, ventilation and neuromuscular blockade with vecuronium
Immunisation	Immunisation is recommended following recovery from tetanus Primary childhood immunisation programmes as five doses of combined DPT in the UK given at 2 months, 4 months, 6 months, 3–5 years and 13–18 years Boosters are recommended every 10 years

DPT, diphtheria, pertussis and tetanus; TIG, tetanus immunoglobulin.

### Treatment

Treatment in the ICU has resulted in a marked improvement in prognosis for patients with tetanus but the mortality is still approximately 10%. Severe muscular rigidity may last for weeks and assisted ventilation may be required for several weeks. Complete recovery is typical, although mild painful spasms can persist for months. Management is summarised in Table 9.15.

## Miscellaneous infections of the nervous system

### Mycoplasma

Mycoplasma are among the smallest free living organisms; they have no cell wall and grow in both aerobic and anaerobic conditions. They are difficult to identify and isolate. Pathogenic mechanisms are immune-mediated rather than caused by direct infection. Antibodies produced against the glycolipid antigens of *Mycoplasma pneumoniae* probably act as autoantibodies as they cross-react with human brain cells and erythrocytes.

The most common manifestations of mycoplasma infection include atypical pneumonia, skin rashes, gastrointestinal involvement, arthritis, glomerulonephritis, uveitis and cardiac disease. Neurological involvement is unusual and occurs most commonly in children as encephalitis. Other manifestations include aseptic meningitis, peripheral neuropathy, brainstem encephalitis, cranial nerve palsies and cerebellar ataxia. Acute transverse myelitis, although rare, can be severe (often affecting the high cervical cord); some patients suffer permanent sequelae, including tetraplegia.

There may be a haemolytic anaemia with positive Coombs test and an elevated reticulocyte count. The CSF typically shows a lymphocytic pleocytosis with elevated protein but normal glucose. Isolation of *M. pneumoniae* from the CSF is exceptional, antigen detection is occasionally positive but unreliable, PCR is more

sensitive and specific but has a low diagnostic yield. Treatment is often empirical for atypical pneumonia. Specific anti-mycoplasma treatment includes doxycycline, erythromycin, azithromycin or a fluoroquinolone such as levofloxacin or moxifloxacin. Prolonged treatment may be necessary because of the organism's ability to reside intracellularly.

### Whipple's disease

Whipple's disease is a multi-system disorder that usually presents with systemic and gastrointestinal features before neurological involvement. However, the condition may occasionally present with neurological features or these may be the only manifestation. Whipple's is caused by a Gram-positive bacillus *Tropheryma whippeli* which is ubiquitous and slow-growing.

Patients usually develop weight loss with abdominal pain, diarrhoea and steatorrhoea. Joint pain occurs, a consequence of a seronegative migratory arthropathy. There may be a low grade chronic pyrexia with lymphadenopathy, splenomegaly and hyperpigmentation. Cardiac involvement includes culture negative endocarditis and constrictive pericarditis.

CNS involvement occurs in 40% of patients, often late in the disease, after many months or years. The most common manifestation is slowly progressive cognitive change with memory loss, behaviour and personality change, evolving into frank dementia. Ocular involvement is also frequently seen with inflammatory changes causing retinitis or uveitis but there may also be papilloedema and progressive optic atrophy. Supranuclear vertical gaze palsy may occur with a characteristic movement disorder of oculomasticatory myorhythmia in which there is an associated repetitive movement of the masticatory muscles that persists during sleep or oculofacial skeletal myorhythmia that involves the facial and neck muscles. Seizures and myoclonus occur about 25% of cases in whom there is neurological involvement. There may also be a progressive ataxia. Rarely, the level of consciousness may be affected with progressive obtundation and even coma. Thalamic involvement causing polydipsia, hyperphagia, insomnia or hypersomnia have been described.

*Tropheryma whippeli* can be identified on biopsy of the jejunal mucosa which shows macrophages filled with periodic acid–Schiff (PAS+) staining intracellular inclusions that contain the organism. Similar staining may be seen in biopsies of lymph nodes, heart valves and cerebral tissue and in the CSF. Diagnostic PCR assay for *T. whippeli* is used widely to establish and confirm the diagnosis of Whipple's disease. CSF is characterised by pleocytosis with an elevated protein. MRI may show diffuse high signal on T2-weighted (T2W) images particularly affecting the frontal cortex, basal ganglia and periventricular white matter but the hypothalamus and cortex may also be involved. Occasionally, mass lesions may develop with ring enhancement. There may also be diffuse atrophy or focal abnormalities and, occasionally, hydrocephalus.

Management remains unsatisfactory. Conventionally, patients have been treated with parenteral penicillin and streptomycin followed by long-term tetracycline. Relapses occur and the outlook for recovery with neurological involvement is particularly poor. Newer recommendations suggest that more intense and vigorous treatment is indicated in the presence of neurological involvement because of the likelihood of clinical relapses. The initial phase should be treated with intravenous antibiotics that are active against *T. whippeli* and penetrate the blood brain barrier (Ceftriaxone 2g daily or Penicillin G 4mu 4 hrly) for 4 weeks followed by maintenance with co-trimoxazole or doxycycline and hydroxychloroquine. Meropenem is also considered an alternative to ceftriaxone. Although antibiotics are usually

given for 1 year it has been argued that with neurological involvement treatment should be given indefinitely because of the high likelihood of relapse when therapy is stopped.

### Melioidosis

Melioidosis is an infection caused by a facultative Gram-negative bacteria *Burkholderia pseudomallei* which occurs in South Asia (particularly Thailand), China and Australia. Transmission is by percutaneous inoculation during exposure to contaminated water or wet season soil. The predominant manifestation is a cavitating, nodular and fibrotic pneumonia but it may cause an encephalomyelitis often affecting the brainstem, occasionally with abscess formation. Treatment is with ceftazidime or meropenem.

### Tick-borne disease

Ticks are small arachnids which are external parasites feeding on the blood of hosts including mammals and amphibians. They harbour disease-causing agents and act as vectors transmitting diseases including:

- *Bacteria*
  - Lyme disease (*B. burgdorferi*)
  - Relapsing fever (other species of borrelia)
  - Ehrlichiosis
  - Tularemia
- *Rickettsiae or rickettsiae-like*
  - Rocky Mountain spotted fever
  - Q fever
- *Viruses*
  - Tick-borne meningoencephalitis
  - Colorado tick fever
  - Crimean–Congo haemorrhagic fever
- *Protozoa*
  - Babesiosis
- *Toxins*
  - Tick paralysis.

### Ehrlichiosis

Ehrlichiae are obligate intracellular bacteria that grow within membrane-lined vacuoles in leukocytes (affecting either monocytes or granulocytes). In adults, the condition may present with malaise, myalgia and headache with a characteristic rash. Leukopenia and thrombocytopenia are common. Neurological manifestations include mental state changes, meningitis, seizures and coma. Diagnosis is established by a fluorescent antibody test. Treatment is with doxycycline.

### Tularaemia

Tularaemia is a tick-borne infection caused by *Francisella tularensis*. It may cause severe typhoid-like or pneumonic disease. Neurological manifestations include meningitis and rhabdomyolysis. Treatment is with aminoglycosides or ciprofloxacin.

### Rickettsial disease

Rocky Mountain spotted fever (RMSF) occurs in North, Central and South America and is caused by a minute polar staining Gram-negative bacillus (*Rickettsia rickettsii*) that occurs in freshly laid eggs of infected ticks. Attachment by the tick to the skin for more than 6 hours is required before rickettsiae are transmitted. There is subsequent invasion and multiplication within endothelial smooth muscle cells leading to the development of a vasculitis. The onset is with a maculopapular rash.

Severe RMSF is associated with encephalitis and systemic signs including purpura, hypovolaemia, hypotension, prerenal failure and cerebral and pulmonary oedema. There may be non-specific muscular weakness which can progress to rhabdomyolysis.

Other rickettsial-like infections including *Coxiella burnetii* (Q fever) develop over 10–14 days and tend to be slightly less severe but are also associated with a purpuric rash, seizures, aseptic meningitis and encephalitis. There is also a chronic form characterised by endocarditis. Treatment with doxycycline is given until the patient has been afebrile for >2 days. Tetracycline and chloramphenicol are alternatives.

## Viral infections of the nervous system

Viruses can cause a variety of diseases in the CNS. The most important are viral meningitis, encephalitis and encephalomyelitis.

### Viral meningitis

Viruses cause an isolated aseptic meningitis characterised by symptoms and signs of meningeal irritation with a CSF pleocytosis in the absence of bacterial, fungal or parasitic infection – hence the term aseptic. There is no parenchymatous brain or spinal cord inflammation. However, in most cases there is mixed meningo-encephalitic or encephalomyelitic involvement.

### Aetiology

Non-polio enteroviruses are by far the most common cause of viral meningitis, these include coxsackie and echovirus strains (Table 9.16).

Viral meningitis is a relatively uncommon complication of systemic viral infection. Most viruses gain access to the body from the oropharynx. They are amplified (multiply) in lymphatic tissue, spread to the bloodstream (viraemia) and cross the choroid plexus or capillary endothelial cells to reach the CNS. Rarely, viruses may enter the CNS by direct transmission through axons.

**Table 9.16** Main causes of viral meningitis.

Enterovirus:
• Echovirus
• Coxsackie A, B
• Enterovirus 70, 71
Mumps
Measles
Parvovirus B19
Herpes viruses
• Herpes simple virus 2 (HSV-2)
• Varicella zoster virus (VZV)
• Epstein–Barr virus (EBV)
• Cytomegalovirus (CMV)
• Human herpes virus 6 (HHV-6)
Arboviruses (e.g. West Nile virus)
Influenza
Parainfluenza
Acute HIV infection
Adenovirus

**Table 9.17** Differential diagnosis of aseptic meningitis.

<b>Infections</b>
Viruses
Viral meningitis
<b>Bacterial</b>
Partially treated bacterial meningitis
Bacterial endocarditis
<i>Bruce</i> llosis, <i>Listeria</i> osis, <i>Mycoplasma pneumoniae</i>
Spirochete infection (syphilis, leptospirosis, <i>Borrelia</i> )
Mycobacterium (TBM)
Whipple's disease
Parameningeal infection – abscess, empyema, osteomyelitis, sinusitis, subdural empyema
Rickettsial infection
Fungi
Parasites – malaria
<b>Vasculitis</b>
Inflammation – sarcoid, Behçet's
Collagen vascular – SLE, RA, polyarteritis nodosa, mixed connective tissue disease, Sjögren's, Wegener's, lymphomatoid granulomatosis
Uveo-meningitic syndromes – Vogt–Koyanagi–Harada syndrome
<b>Meningeal carcinomatosis</b>
Leukaemia/lymphoma
<b>Vascular</b>
Previous subarachnoid haemorrhage
<b>Chemical meningitis</b>
Contrast materials
<b>Drugs</b>
Non-steroidal anti-inflammatory drugs
Antineoplastic drugs
Immunosuppressants – azathioprine
Antibiotics – septrin, sulfasalazine, ciprofloxacin, amoxicillin
Intravenous immunoglobulin G

RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; TBM, tuberculous meningitis.

### Clinical features

In viral meningitis there may be a flu-like prodrome followed by the sudden onset of intense frontal headache, fever and neck stiffness associated with photophobia, malaise, myalgia and severe nausea and vomiting. Although there is pyrexia, neck stiffness and meningeal signs, patients are generally less unwell than those with bacterial meningitis. A pruritic rash, pleurodynia or myocarditis may be present. There is a wide differential diagnosis of aseptic meningitis which is summarised in Table 9.17.

### Diagnosis

The peripheral white cell count is usually normal but may be increased or decreased. Liver function tests may be abnormal. The

CSF is clear and colourless with a normal to moderately elevated pressure; the cell count is usually  $<300$  cells/mm<sup>3</sup> but may be up to 1000 cells/mm<sup>3</sup>; mononuclear lymphocytes predominate, although polymorpholeukocytes may be present particularly in the early stages. CSF glucose is usually normal but may be slightly depressed. CSF protein is normal or mildly elevated.

### Viral isolation

Viral isolation is undertaken from the throat, urine or stool and antibody studies are possible in serum or CSF. The detection of viral RNA or DNA is now undertaken using PCR in the serum or CSF. Not infrequently no virus is isolated in presumed viral meningitis.

### Management and prognosis

Treatment is supportive but it is usual to admit a patient to exclude bacterial meningitis. A clinical diagnosis of viral meningitis is not secure; substantial errors have occurred by presuming a viral infection, when the underlying infection has been pyogenic or tuberculous.

Herpes virus meningitis should be treated with aciclovir (famciclovir, valaciclovir, ganciclovir and foscarnet are alternatives). The only therapy of clinical use for enterovirus meningitis is immune serum globulin. The prognosis in viral meningitis is good, with spontaneous recovery usually occurring within 1–2 weeks. However, there may be residual deficits in up to 5% including malaise, fatigue, mild intellectual and language difficulties, seizures, isolated cranial nerve lesions and optic neuritis.

### Chronic and recurrent meningitis

Meningitis may be recurrent either because the patient is predisposed to repeated bacterial infection, recurrent non-purulent infection or because of a non-infective aetiology. Chronic meningitis may be defined as meningitis that persists for 4 weeks or more without showing any recovery. The condition often presents with a more encephalitic-like picture of progressive impairment of cognition and consciousness following a fluctuating course. Any of the conditions listed in Table 9.18 may cause a chronic meningitis or recurrent meningitis.

### Mollaret's meningitis

This is a rare condition in which recurrent self-limiting episodes of pyrexia and lymphocytic meningism occur but may be separated by asymptomatic periods lasting weeks or months. The attacks resolve spontaneously in days with no residual deficit and they usually cease within a few years. During attacks the CSF shows a mild elevation in the protein and pleocytosis (200–several thousand cells/mm<sup>3</sup> which are predominantly monocytes with aggregated 'giant cells' (Mollaret's cells) with a background of polymorpholeukocytes and plasma cells). The cause of the condition is HSV-2, although HSV-1 has been implicated in some cases, presumably related to a viral reservoir in dorsal root ganglia.

### Encephalitis

Encephalitis is acute inflammation of the parenchyma of the brain which is usually diffuse and may involve the meninges. Most common viral infections can, if rarely, lead to viral encephalitis. Encephalitis may also be caused by a parainfectious or autoimmune process. Encephalitis causes focal or multi-focal neurological deficits or seizure activity. Acute disseminated encephalomyelitis (Chapter 11) may occur as an immunologically mediated parainfectious phenomenon following a variety of infections or after vaccination. Encephalopathy refers to disruption of brain activity in the absence of a direct inflammatory process in the brain parenchyma.

**Table 9.18** Causes of chronic or recurrent meningitis.

**Continuing sepsis, potential access to CNS (e.g. skull base or middle ear defect) or immunosuppression (e.g. hypogammaglobulinaemia)**

**Chronic meningeal infection**

*Brucella*, syphilis, *Borrelia*

Fungi – cryptococcus, coccidioidomycosis, histoplasmosis, blastomycosis

HIV

**Para-meningeal infection**

**Periodic reactivation of latent infection**

HSV, VZV, EBV, CMV

Toxoplasmosis

**Immunosuppression**

Sarcoidosis, Behçets, Vogt–Koyanagi–Harada syndrome

**Medication**

Non-steroidal anti-inflammatory drugs

Antineoplastic drugs

Immunosuppressants – azathioprine

Antibiotics – septrin, sulfasalazine, ciprofloxacin, amoxicillin

IVlg

Valacyclovir

Antiepileptic medication – lamotrigine, carbamazepine

**Lymphoma**

**Immune reconstitution in highly active retroviral treatment in AIDS**

**Chemical meningitis**

**Mollaret's meningitis**

Within the United Kingdom and North America, after the neonatal period, the most common severe forms of infectious encephalitis are shown in Table 9.19. Worldwide, the most common causes of encephalitis are arboviruses (e.g. Japanese encephalitis and West Nile virus). Table 9.20 summarises the more characteristic patterns of neurological involvement in encephalitis. Table 9.21 summarises viruses that can affect the CNS.

### Pathophysiology

There are several mechanisms by which viruses can cause encephalitis. Organisms that cause encephalitis require the ability to infect brain tissue (neurotropism) but not necessarily the ability to infect neurones (neuronotropism). They usually enter the CNS via direct haematogenous dissemination but may infect the brain via retrograde neuronal spread.

**Table 9.19** Most common causes of viral encephalitis.

Cognitive impairment	HIV HSV Measles
Myorhythmia	<i>Tropheryma whipplei</i>
Parkinsonism	Japanese encephalitis St Louis encephalitis West Nile virus

Arbovirus encephalitides are zoonoses in which the virus life cycle takes place both in the biting arthropod and an invertebrate host. The virus is then transmitted by an insect bite and undergoes local replication in the skin before spreading to the brain and causing human encephalitis. Pathological examination shows involvement of the grey matter with perivascular inflammation, neural destruction, neuronophagia and tissue necrosis.

Parainfectious and autoimmune encephalitides are discussed in Chapters 11 and 20.

### Incidence

In the United States, the annual incidence of viral encephalitis is between 3.5 and 7.4/100 000 of the population. In the United Kingdom, the reported incidence is lower. HSV-1 is the most frequent cause but varicella zoster virus (VZV), enterovirus and influenza A are also common. There remains considerable geographical variation and arbovirus encephalitis is common in the Americas and Asia, and rare in Europe.

### Clinical features

The clinical manifestations of encephalitis are often most severe in infants and those over the age of 65. Fever is present in >90% of patients, seizures are common and help to distinguish acute infective encephalitis from acute disseminated encephalomyelitis. The presence of headache, pyrexia and meningism suggest leptomeningeal irritation while parenchymatous involvement leads to focal neurological signs, seizures and alteration of consciousness progressing to stupor and coma. Behavioural and speech disturbances may develop and abnormal movements are associated with lesions in the basal ganglia and pituitary, involvement of the hypothalamus may cause hypothermia. Common patterns of encephalitis related to individual viruses are summarised in Table 9.21.

### Diagnosis

In assessing a patient with suspected viral encephalitis it is essential to take a detailed history of travel and to note the season of onset, geographical location, recreational activities, occupation and vaccination history or any contact with animals and any evidence of immunosuppression. CSF examination should be undertaken if possible and HSV PCR should be performed on all CSF samples. MRI appearances may be characteristic in herpes simplex encephalitis (see Herpes simplex virus) but are non-specific in other causes. Immunological studies (e.g. voltage-gated potassium channel and NMDA antibodies) may provide a definitive diagnosis in autoimmune encephalitides.

### Herpes simplex encephalitis

Herpes simplex encephalitis (HSE) is the most common cause of sporadic fatal viral encephalitis. There is a bimodal age distribution with most patients being below 20 or above 50 years. Ninety per cent are caused by HSV-1 and up to 10% by HSV-2, the later often associated with immuno-compromise or occurring in the neonate. Primary infection usually develops in the oropharyngeal mucosa before the virus is transported by retrograde transneuronal spread via the trigeminal nerve to establish latency in the olfactory bulb or trigeminal ganglion. Molecular analysis of paired oral and brain sites have indicated HSE can occur as the result of a primary infection, a reactivation of latent HSV in the trigeminal ganglion or reinfection by a second HSV. The reason for reactivation is unknown. The presence of labial herpes has no diagnostic specificity to HSE. The herpes virus leads to inflammation, infection and necrotising lesions particularly in the inferior and mesial temporal lobes which may also involve the orbital frontal cortex and limbic structures.

The onset of HSE is with symptoms of meningo-encephalitis including fever, headache and alteration of consciousness which may develop gradually or rapidly over a matter of hours, occasionally associated with neck stiffness. The most common manifestations are personality change, dysphasia with progressive behavioural disturbance and occasional psychotic features. Less typical features include the development of hemiparesis or a visual field defect (particularly superior quadrantic). Focal or generalised seizures are often associated with olfactory or gustatory hallucinations. HSE only develops in an immunocompromised patient following bone marrow transplant or in AIDS.

**Investigation** CT scanning is usually normal within the first 4–6 days. EEG is non-specific but may allow early localisation. MRI is more sensitive, demonstrating high signal intensity lesions on T2W diffusion-weighted and FLAIR images early in the course.

The MRI characteristically shows high signal areas of focal oedema on T2 images in the medial and inferior temporal lobes, extending into the insular cortex and frontal lobe; the changes may

be unilateral or bilateral and extensive. Midline shift may be present if there is significant vasogenic oedema (Figure 9.9).

The EEG is characterised by periodic stereotyped, lateralised sharp and slow wave complexes occurring at regular intervals between 2 and 3 seconds.

The CSF is abnormal in >95% of patients. CSF is generally under an increased opening pressure and may show a mild to moderate lymphocytic pleocytosis of 5–500/mm<sup>3</sup>; there may be a mild to moderate elevation in the protein (0.6–0.9 g/L) and a normal or mildly decreased glucose. In approximately 5% of patients CSF examination is normal.

Demonstration of intrathecal production of anti-HSV antibodies, has been replaced by PCR for HSV-1 DNA that is very sensitive (98%) and specific (94%), when compared to the gold standard of brain biopsy which was commonly undertaken in the past.

False negative PCR results can occur during the first days of the disease and, in cases of doubt, a repeat LP after 1–2 days is indicated. The optimal chance of obtaining positive PCR is 2–10 days after onset of illness. It should be positive after about 5 days of infection but clears again after 14 days of illness. PCR may also be used to guide the duration of treatment with aciclovir. PCR has also become increasingly valuable in the diagnosis of virus encephalitides from other causes such as cytomegalovirus CMV, VZV, influenza and enterovirus. Brain biopsy is now rarely undertaken but may be considered if diagnostic uncertainty remains.

**Treatment** HSE remains a serious infection of the CNS. Aciclovir has reduced the mortality of HSE from 70% to <25%. Despite early and appropriate treatment two thirds of patients may be left with significant residual deficits. Empirical therapy with IV acyclovir (10 mg/kg 8-hourly for 14–21 days) should be commenced as soon as the diagnosis is considered with dose adjustments for renal insufficiency.

### Other causes of encephalitis

**Varicella zoster virus** VZV is a large herpes virus. Primary infection causes chickenpox and secondary reactivation leads to dermatomal shingles or disseminated herpes zoster. Chickenpox (varicella) is usually a self-limiting exanthematous disorder characterised by a diffuse vesicular rash in different stages of development on the face, trunk and extremities. It may be associated with pneumonitis or secondary bacterial infection. Neurological complications include severe encephalitis, meningitis, myelitis and cerebellar ataxia. Rarely, an acute toxic encephalopathy or Reye's syndrome may occur.

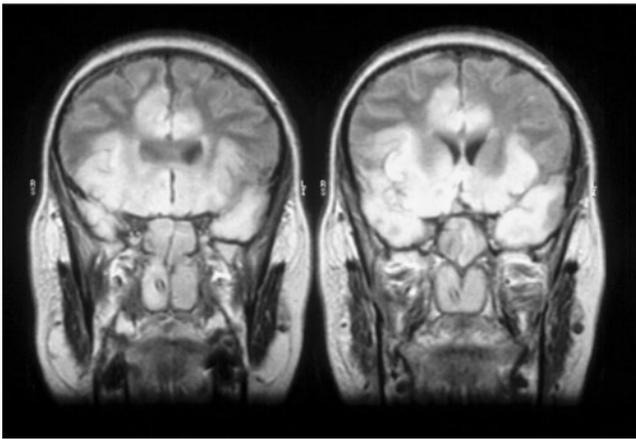

VZV encephalitis is treated with aciclovir (10–15 mg/kg 8-hourly for 10–14 days) although ganciclovir is also effective.

**Shingles** The most common acute peripheral nervous system infection in the United Kingdom is herpes zoster or shingles, caused by reactivation of VZV. VZV becomes latent in the ganglia of sensory and autonomic peripheral and cranial nerves following primary infection in chickenpox. Shingles is associated with reduced cell-mediated immunity through ageing, drugs, malignancy and HIV, but there may be no underlying risk factors. Patients typically experience tingling pain in one or more dermatomes a few days before the development of a vesicular rash. The thoracic dermatomes are most commonly affected. The rash of shingles starts as erythematous papules which rapidly evolve into grouped vesicles or bullae. The vesicles become pustular or haemorrhagic after 3–4 days. Zoster is generally limited to one dermatome but can spread to neighbouring dermatomes and occasionally scattered lesions occur in immunocompetent patients. Shingles most commonly affects the thoracic or lumbar dermatomes. The most common feature of shingles is pain which occurs in approximately 75% and may precede

**Table 9.21** Viruses that may infect the CNS (excluding arboviruses).

Family of virus	Virus		
Herpes virus	HSV-1 HSV-2 VZV CMV EBV		See text
	HHV-6, HHV-7		Linked with meningoencephalitis, GBS and retinitis Occasionally found in CSF of patients with AIDS but significance unknown Treatment is with ganciclovir, foscarnet is an alternative
Orthomyxovirus	Influenza		May present as a frontal lobe or limbic syndrome without disturbance of consciousness Guillain-Barré like neuropathy, myelitis, ADEM Treatment – oseltamivir
	Avian flu A (H5N1)		Characterised by diarrhoea, seizures and progression to severe encephalopathy leading to coma and death CSF protein is elevated
Picornavirus	Enterovirus (non-polio) Coxsackie Echo Polio		Enterovirus infection is usually asymptomatic or manifest as an erythematous or maculopapular rash. Aseptic meningitis may occur Usually associated with a good prognosis but enterovirus 71 may present with herpangina, hand, foot and mouth disease, myoclonus, tremor and cranial nerve involvement May be complicated by acute flaccid paralysis or long-standing chronic meningo-encephalitis particularly in the young or patients who are immunosuppressed Enterovirus can be isolated from CSF faecal, throat and serum specimens
	Paramyxoviruses		
	Mumps	Worldwide (winter and spring)	Usually starts several days after parotitis and usually resolves without sequelae except for occasional hydrocephalus due to ependymal cell involvement
	Measles	Worldwide (winter and spring)	Rash, myelitis, encephalitis Treatment – ribavirin (particularly in SSPE)
	Nipah virus	Asia (all year)	Rare. Contracted from infected pigs Presents with encephalitis and focal cerebellar or brainstem signs Segmental myoclonus and systemic involvement is characterised by hypertension and tachycardia Encephalitis may be delayed for several months after exposure to the virus MRI shows increased signal in cortical white matter
Arenavirus	Lassa fever	Africa	
	LCMV	Europe, Americas, Australia, Japan (usually winter)	
	Rabies		See text
Filovirus	Marburg Ebola	2014 outbreak – West Africa (Guinea, Liberia, Sierra Leone)	Person to person contact with virus containing body fluids Non-specific influenza which can progress to multi-organ failure and shock. Haemorrhagic involvement of multiple organs Headache, confusion, seizures and cerebral oedema reflecting systemic involvement Recurrent infections due to residual virus in privileged sites (e.g. eye) can lead to recurrent viral meningitis
Polyomavirus	JC BK		PML in immunosuppressed (e.g. HIV) Encephalitis in immunodeficiency

ADEM, acute disseminated encephalomyelitis; GBS, Guillain-Barré syndrome; LCMV, lymphocytic choriomeningitis; SSPE, subacute sclerosing panencephalitis; PML, progressive multifocal leukoencephalopathy.

**Figure 9.9** Fulminant herpes simplex encephalitis: extensive temporal lobe and diffuse parenchymal inflammation (coronal FLAIR MRI).

the rash. It is often severe and allodynia may develop. Occasionally, shingles may occur with pain but no rash (herpes zoster sine herpete). Zoster may be associated with a number of complications. Post-herpetic neuralgia increases in frequency with age and occurs in 20% of patients over 80 years. Herpes zoster ophthalmicus (HZO) affects the ophthalmic division of the trigeminal nerve and may be associated with conjunctivitis, episcleritis, iritis and most patients also develop corneal involvement (keratitis). Vesicular lesions on the nose (Hutchinson's sign) are associated with HZO and indicate involvement of the nasociliary branch of the trigeminal nerve which also innervates the globe. VZV has also been associated with the development of acute retinal necrosis which may lead to rapid loss of vision caused by iridocyclitis, vitritis, necrotising retinitis and occlusive retinal vasculitis.

Herpes zoster oticus (Ramsey-Hunt syndrome) is caused by VZV reactivation in the geniculate ganglion with subsequent spread of the inflammatory process to involve the auditory cranial nerve. The condition is characterised by its ipsilateral facial paralysis, ocular pain and vesicles in the auditory canal and auricle. Taste perception, hearing and lacrimation may be affected. Multiple cranial nerves may be involved, especially V, IX and X. Facial paralysis is more severe than in Bell's palsy and carries a worse prognosis for recovery. Other complications of zoster include the development of aseptic meningitis, peripheral motor neuropathy and Guillain-Barré syndrome. Transverse myelitis and radiculopathy may be caused by zoster but they may develop more than 6 months after the onset of zoster. Zoster associated encephalitis may occur months after acute shingles or in the absence of a clinically evident infection. However, it is often associated with extensive zoster particularly in the immunocompromised and in patients with HIV.

VZV can cause stroke resulting from a granulomatous vasculitis of large and small arteries. It is thought to occur by direct viral invasion of the media of cerebral arteries by VZV with extension along the intracranial branches of the trigeminal nerve. Extensive stroke may occur as a result of multifocal occlusion of the anterior and middle cerebral arteries. Immunocompromised patients are at particular risk of infection by VZV, particularly those with HIV, bone marrow and solid organ transplants recipients or patients receiving chemotherapy.

Antiviral therapy is indicated to promote more rapid healing of skin lesions, to lessen the severity and pain associated with acute neuritis and to reduce the incidence and severity of post-herpetic neuralgia. Antiviral drugs should be given to all patients within

72 hours of treatment using valaciclovir (1000 mg 8-hourly) or famciclovir (500 mg 8-hourly) for 7 days. Aciclovir (800 mg five times daily) needs to be given more frequently. Steroids are indicated if there is vasculitis but there is no evidence to support their routine use in shingles to improving quality of life or reducing the incidence of post-herpetic neuralgia. The management of post-herpetic neuralgia is discussed in Chapter 23 and includes the use of tricyclic antidepressants, gabapentin, pregabalin, opioids and topical treatments but side effects are common.

**Cytomegalovirus** CMV is a ubiquitous herpes virus that only affects humans. The virus often persists in the throat following infection and may become latent for many years. Infection is usually transient and asymptomatic but it may cause cytomegalic inclusion disease in the newborn infant and neurological disease in the immunocompromised adult, particularly following organ transplant or in patients who are HIV-positive in whom the most common complications are lumbo-sacral polyradiculopathy and retinopathy. Peripheral nerve vasculitis, encephalitis and myelitis are also described in the context of HIV infection. Treatment is with ganciclovir (5 mg/kg 12-hourly) and foscarnet (60 mg/kg 8-hourly).

**Epstein-Barr virus** EBV is a lymphotropic herpes virus which, like all herpes viruses, may establish latency before being reactivated. It replicates in B cells, causes infectious mononucleosis and is associated with lymphoproliferative disorders – Burkitt's and Hodgkin's lymphomas, hairy cell leukaemia, lymphocytic lymphoma and nasopharyngeal carcinoma. In patients with HIV, primary CNS lymphoma is associated with EBV infection. Neurological complications include aseptic meningitis, encephalitis, acute cerebellar ataxia, cerebritis, transverse myelitis, polyneuropathy (including Guillain-Barré), mononeuropathy (including brachial plexopathy) and cranial nerve palsies (especially facial nerve). These may occur as a consequence of direct viral infection or as a parainfectious phenomenon. EBV causes <5% of viral encephalitis and is associated with impaired level of consciousness, seizures and focal deficits. Although recovery is usual, permanent deficit may occur with residual chorea and cognitive impairment. Management is supportive; there is no evidence of benefit from aciclovir.

#### **Arboviruses (arthropod-borne viruses)**

Arthropod-borne viruses are adapted to particular reservoir hosts and are spread from animal to animal via the bite of an infected arthropod, usually a mosquito or tick (Table 9.22). Specific arboviruses can be predicted on the basis of geographical location and the demographic pattern of infection. Subacute inoculation by mosquito or tick vector is followed by local tissue and lymph node replication, viraemia and finally invasion of deep soft tissues, organs and CNS. Arbovirus encephalitis predominantly affects cortical grey matter but it may also involve the brainstem and thalamic nuclei. Arboviruses can occasionally cause meningitis or meningo-encephalitis.

**Japanese encephalitis** Japanese encephalitis is caused by the mosquito-borne Japanese encephalitis arbovirus. The disease is most prevalent in South-East Asia and the Far East. Japanese encephalitis is the most common arbovirus worldwide, particularly affecting children and young adults. Most infections are asymptomatic. The prodrome is non-specific with fever, headache and malaise. There may be an acute, severe fulminant encephalitic presentation with fever, vomiting, convulsion and impaired consciousness leading to coma. Mortality is high, up to 50%, with a high incidence of residual

**Table 9.22** Arboviruses that may infect the CNS.

Togavirus (Alphavirus)	Eastern Equine	Eastern and Gulf USA (summer)	Severe, rapidly progressive, virulent encephalitis that affects children High mortality (<35%)
	Western Equine	Western USA (summer)	Encephalitis, predominantly affects children Mortality <10%
	Venezuelan	South and Central America (rainy season)	Occurs in large outbreaks but usually self-limiting and encephalitis is rare but neurological sequelae in <20%
Flavivirus	St Louis	USA (Summer)	Most common vector transmitted cause of aseptic meningitis in the USA Aseptic meningitis accounts for approximately 15% of all symptomatic cases Often asymptomatic and characterised by a mild febrile illness but severe encephalitic illness (characterised by tremor, seizures, headache, vomiting and stupor) can occur in the older age group when mortality may rise to 20% Urinary symptoms common (dysuria, urgency, incontinence) Sequelae occur in 10% including memory loss chronic fatigue, sleep disturbance, headaches and occasional seizures SIADH
	Japanese	See below	
	West Nile	See below	
	Far East	Eastern Russia (summer)	Associated with partial epilepsy and high mortality (<20%)
	Central European	Central Europe (tick-borne)	Flaccid proximal weakness
	Powassan	Canada (summer and autumn, tick-borne)	Severe encephalitis Residual cognitive impairment common High fatality rate
	Dengue	Tropics (SE Asia and Indian subcontinent) (transmitted by mosquito)	Presents with severe influenza like illness or haemorrhagic fever Headaches, arthralgia and myalgia Less commonly this can give rise to encephalitis or encephalopathy and rarely transverse myelitis or polyneuropathy resembling Guillain-Barré syndrome Haemorrhagic form also causes intracerebral haemorrhage, hepatic failure and Reye syndrome-like illness Low risk of sequelae and low mortality with appropriate supportive management.
	Zika	Americas (Brazil) Africa SE Asia	Transmitted by mosquito ( <i>Aedes aegyptus</i> ) Acute low grade fever with maculopapular rash Associated with Guillain-Barré syndrome Microcephaly and foetal loss when acquired during pregnancy
	Yellow Fever	West & Central Africa, South America	Mosquito-borne viral haemorrhagic fever, hepatic dysfunction, renal failure, coagulopathy, shock, metabolic encephalopathy and coma. No direct neuroinvasion or encephalitis (high mortality rate)
	Murray Valley	Australia (mosquito-borne)	Mostly in children Rapid progression in infants
	Kunjin Rocio Russia	Australia Brazil Russia (tick-borne)	In cooler northern climates, flaviviruses transmitted by ticks rather than mosquito
Bunyavirus	La Crosse	Central USA Predominantly a viral encephalitis of children which tends to be mild and self-limiting with a low mortality Occasionally fulminant onset with seizures and focal weakness	

CSF, cerebrospinal fluid; ELISA, enzyme-linked immunosorbent assay; JE, Japanese encephalitis virus; PCR, polymerase chain reaction; SIADH, syndrome of inappropriate antidiuretic hormone.

neurological sequelae including deafness, focal deficits and cognitive impairment.

In adults, extrapyramidal involvement may occur with a transient parkinsonian-like syndrome, tremor, choreo-athetotic head nodding or axial rigidity. A flaccid paralysis can occur because of damage of anterior horn cells.

The diagnosis is established by IgM capture ELISA of serum or CSF. Japanese encephalitis virus may be isolated or the genetic viral sequence may be identified in tissue, blood or CSF. Imaging may show bilateral lesions in the basal ganglia, putamen and thalamus. The pons, cerebellum and spinal cord may also be involved. There is no specific antiviral treatment. Vaccination is recommended with three doses of inactivated Japanese encephalitis virus.

**West Nile virus** West Nile virus (WNV) is related to Japanese encephalitis. It is the most widely distributed arbovirus occurring in North and Central America, Africa, the Middle East, Europe and Australasia. It is transmitted by mosquito bites of the genus *Culex*.

Infection may be asymptomatic in <40%. Presentation is usually with a self-limiting pyrexia, malaise, myalgia and anorexia. A maculopapular rash is associated with dysaesthesiae and systemic involvement may also include arthralgia, hepatosplenomegaly and pancreatitis. Neurological involvement occurs in <15% and is characterised by encephalitis, encephalomyelitis, aseptic meningitis, flaccid paralysis, tremor, myoclonus and parkinsonism. Flaccid weakness is generally caused by anterior horn cells involvement and this may lead to bulbar and respiratory muscle weakness. Guillain-Barré syndrome and axonal neuropathy may occur. WNV has been associated with a wide range of systemic and other neurological complications. Imaging changes are non-specific with signal intensity abnormalities in the brain (particularly the basal ganglia and thalamus), brainstem and spinal cord.

The diagnosis is established by demonstrating either specific IgM antibodies by ELISA or viral nucleic acid by PCR in sera, tissue or CSF. The treatment of WNV infection is supportive and no human vaccine is available.

Serious adverse outcome is limited to neurological involvement with a mortality rate of 2% with meningitis and 12% with encephalitis. Long-term residual weakness commonly follows WNV poliomyelitis.

### Viral haemorrhagic fevers

Viral haemorrhagic fevers (VHF) are characterised by coagulation deficits, a capillary leak and shock. The condition is caused by heterogeneous group of viruses discussed earlier: Rift Valley fever; Crimean-Congo haemorrhagic fever; Lassa fever; yellow fever; dengue; ebola and marburg virus infection.

### Polio and the post-polio syndrome

Despite a global policy aimed at eradication, pockets of wild polio still exist and there is a low reported incidence of vaccine-induced polio in infants and adults. Present policies are directed towards mopping up residual sources with the eventual discontinuation of routine immunisation. Acute poliomyelitis is rarely encountered in the United Kingdom following its successful eradication; however, imported poliomyelitis still occurs and it is necessary to distinguish acute poliomyelitis from other causes of acute flaccid paralysis (Table 9.23).

Poliomyelitis is caused by an enterovirus of high infectivity whose main route of infection is via the human gastrointestinal tract. There are three subtypes but, before the introduction of polio vaccine, type I accounted for 85% of paralytic disease. Epidemics of

**Table 9.23** Causes of acute flaccid paralysis.

<b>Infection</b>
Viral
Enterovirus – poliomyelitis (wild and vaccine associated), enterovirus 71, Coxsackie A
Flavivirus – Japanese, West Nile encephalitis
Herpes virus – CMV, EBV, VZV
Tick-borne encephalitis
HIV related (associated with opportunistic infections, particularly CMV)
Other neurotropic viruses – rabies
Bacterial
Borrelia, mycoplasma, diphtheria, botulism
<b>Neuropathy</b>
Acute inflammatory polyneuropathy (AIDP)
Acute motor axonal neuropathy (AMAN)
Critical illness neuropathy
Lead poisoning, other heavy metals, porphyria, hyperkalaemia
<b>Spinal cord</b>
Acute transverse myelitis, acute spinal cord compression, trauma, infarction
<b>Neuromuscular junction</b>
Myasthenia gravis
<b>Muscle</b>
Polymyositis
Viral myositis
Post infectious myositis
Critical illness myopathy
<b>Non-organic</b>

polio occurred, most commonly during the summer months, in the temperate climates of the northern hemisphere and the incidence was greatest where children bathed together.

The incubation period is 7–14 days. The acute illness is characterised by minor flu-like symptoms, followed by a meningitic phase as the virus reaches the CNS. The onset of spinal poliomyelitis is associated with myalgia and severe muscle spasms and the subsequent development of an asymmetrical, predominantly lower limb, flaccid weakness which becomes maximal after 48 hours. A purely bulbar form, with minimal limb involvement, also occurs carrying a particularly high mortality rate because of vasomotor disturbances such as hypertension, hypotension and circulatory collapse, autonomic dysfunction, dysphagia, dysphonia and respiratory failure. Polio may also cause an acute encephalitis. Recovery from the acute infection can be slow and prolonged periods of rehabilitation are necessary for recovery of limb function, severe permanent impairment is common.

The virus is commonly isolated from the nasopharynx or the stool. In the absence of a viral isolate, serological diagnosis can be established by neutralisation of sera against paired antigens of the three serotypes. PCR is now the technique of choice for serotypic identification of poliovirus and for differentiation of wild and vaccine-strain poliomyelitis.

### Differential diagnosis

Acute flaccid paralysis is associated with infection by other enteroviruses including coxsackie virus A7 and enterovirus 71, tick-borne encephalitis and by flaviviruses including Japanese encephalitis and, more recently, West Nile virus (Table 9.23). The differential diagnosis of asymmetric motor flaccid paralysis includes Guillain-Barré syndrome, acute intermittent porphyria, HIV neuropathy, diphtheria and *B. burgdorferi* (Lyme disease) infections.

### Prevention

Sabin trivalent oral live attenuated polio vaccine (OPV) is composed of live attenuated strains of polioviruses I, II and III grown in cell culture. The advantages over the older inactivated polio (IPV) (Salk) vaccine are that it can be administered orally, and causes an active attenuated infection of the oropharynx and intestinal endothelium, stimulating local secretory IgA in addition to serum antibody production. It is also cheap. Furthermore, the attenuated virus is excreted in the faeces leading to herd immunity. Complete immunisation with OPV has, conventionally, included four doses routinely given at 2, 4 and 6–18 months, with a booster at 4–6 years. Despite the success of the global eradication campaign difficulties remain and new outbreaks continue to occur. It is difficult to provide adequate heat-stable OPV, to ensure adequate sero-conversion in tropical populations and this has led to a suggestion that OPV should be abandoned in favour of IPV. OPV derived poliomyelitis is attenuated but can mutate and acquire properties similar to the wild type resulting in vaccine associated paralytic poliomyelitis. Vaccine derived poliomyelitis may occur in unimmunized direct contacts (particularly those changing the nappies of infants who have recently received OPV).

### Post-polio syndrome

Many patients with residual impairments following previous paralytic poliomyelitis develop new disabilities after a period of prolonged stability. These late changes include progressive muscular atrophy, weakness, pain and fatigue but most patients are aware of late functional deterioration giving rise to impairment of activities of daily living, mobility, upper limb function and respiratory capacity. The new wasting and weakness is probably caused by distal degeneration of post-poliomyelitis motor units associated with age, over-use or disuse. New impairments often occur as a consequence of prolonged stresses on skeletal deformity and previously weakened muscles. The extent of the original limb, trunk, respiratory and bulbar weakness is an important factor in predisposing to the development of late functional deterioration. Although there are no adequate longitudinal studies, experience suggests that post-polio functional deterioration is not necessarily an ongoing process. Fatigue and reduced mobility, often may progress slowly or stabilise. The prognosis also depends on the nature of any underlying cause for the functional deterioration.

### Subacute sclerosing panencephalitis

Subacute sclerosing panencephalitis (SSPE) is a progressive neurological condition associated with measles occurring at a young age (usually <2 years). The onset is usually in childhood at an average of 6–8 years, with a male : female ratio of 3 : 1. SSPE can also occur in adults and can be triggered during pregnancy. The clinical course is highly variable but the onset is usually with behavioural and intellectual change developing over weeks or months. There is frequently a decline in school performance with withdrawal, hyperactivity, aggressive behaviour and emotional lability. Motor signs progressively develop with dysarthria, incoordination and

tremor. There is usually a progressive decline with periodic stereotyped attacks of myoclonic jerks and seizures. Higher functions deteriorate with worsening apraxia, visuo-spatial abnormalities and progressive language impairment. Profound disability is associated with choreoathetosis, dystonia, persistent myoclonic jerking and autonomic instability with hyperpyrexia, tachycardia and an abnormal respiratory pattern. There may be an associated chorioidoretinitis pigmentosa and optic atrophy. The condition usually progresses to become fatal in 1–3 years. Ten per cent survive for up to 10 years. A more rapidly progressive course with death in 3 months occurs in about 10% of patients. The condition is associated with infection by measles virus at a young age. The virus is an enveloped RNA virus and can be recovered from the CSF and brain in most patients. The diagnosis is based on the clinical pattern and on EEG findings. There are characteristic bilateral synchronous and symmetrical periodic discharges occurring every 4–12 seconds. There is also associated slower background EEG activity which becomes disorganised. An elevated measles virus antibody is found in serum and CSF. MRI shows focal or generalised high white matter lesions in frontal, temporal and occipital regions. There is no effective treatment – inosiplex and intrathecal ribavirin have been used but evidence is lacking.

### Rabies

Rabies is a zoonosis of certain mammals endemic in all continents; it is caused by a lyssavirus which is inoculated into the tissue of a wound usually caused by a canine or bat bite. The virus may replicate locally in muscle cells or attach directly to nerve endings. It then enters the presynaptic nerve terminal and is carried in a retrograde direction. On reaching the CNS there is massive viral replication in neurones before transsynaptic transmission of the virus occurs from cell to cell. Viral proteins accumulate in the cytoplasm appearing as inclusions (Negri bodies).

### Clinical features

Clinical features develop 1–3 months after the bite although longer incubation periods are known. The onset is with a prodrome of fever, nausea, vomiting, chills, malaise, fatigue and insomnia together with the development of pain, pruritus, paraesthesiae and fasciculation close to the bite site. This is followed by the development of progressive encephalopathy. The disease is described as either furious rabies (80%) or paralytic rabies (20%).

Furious rabies is characterised by fluctuating episodes of excitement and hyper-excitability with periods of lucidity. Aggressive behaviour, confusion and hallucinations develop. Autonomic dysfunction is manifest as hypersalivation, sweating and pilo-erection. Patients develop severe muscle spasms of the throat, trunk and respiratory muscles triggered either by the sight or sound of water or attempts to drink (hydrophobia) or even by a draft of air (aerophobia). The spasms cause generalised extension, convulsions and opisthotonus with death usually occurring within a week of the onset of furious rabies as a consequence of cardiac arrhythmias, myocarditis and respiratory arrest.

Paralytic rabies is less common; it may occur following vampire bat transmission, in patients who have been infected by an attenuated virus or following post-exposure vaccination. It is associated with an ascending paralysis leading to constipation, urinary retention, respiratory failure and an inability to swallow. Flaccid muscle weakness develops early in the course of the disease. Hydrophobic spasms may also occur. Patients may go on to develop bulbar and respiratory muscle involvement but tend to survive longer than those with furious rabies.

The differential diagnosis includes:

- Viral encephalitis
- Tetanus
- Post-vaccinal encephalomyelitis
- Guillain–Barré syndrome.

### Diagnosis

The clinical features may be obvious. A CSF mononuclear pleocytosis develops, usually within the first week, but serum neutralising antibodies are not present until the tenth day of the illness. Viral isolation is occasionally possible from saliva, throat, trachea, CSF or brain biopsy and skin biopsy and immunofluorescent antibody techniques will demonstrate an antigen in the small nerves of the skin taken from the nape of the neck, often in a hair follicle. PCR detection of rabies virus RNA has also been demonstrated from the brain, saliva and CSF. Postmortem virus isolation and brain cultures should be taken if possible.

### Management

Management is supportive. Rabies is almost invariably fatal. Patients with rabies need heavy sedation and adequate analgesia to relieve terror or pain. Acute interventional care may be necessary to manage cardiac arrhythmias, cardiac and respiratory failure, raised intracranial pressure, convulsions and fluid and electrolyte disturbances. Only very occasional survival has been documented, usually in patients who had received rabies vaccine before the onset of symptoms. Immunisation before possible exposure is strongly recommended to travellers who plan to visit regions where rabies is endemic, as it provides protection after unrecognised exposure and may simplify treatment. Post-exposure treatment is summarised in Table 9.24.

**Table 9.24** Post-exposure treatment of rabies.

Post-exposure prophylaxis	<p>If there is any doubt about the possibility of rabies then post-exposure prophylaxis should begin immediately</p> <ul style="list-style-type: none"> <li>• <i>Local wound care</i> – washed thoroughly with soap and water, debridement as necessary and tetanus prophylaxis</li> <li>• <i>Active immunisation</i> – using either human diploid cell vaccine or alternatively purified chick embryo cell culture vaccine in five doses given over 28 days. If a bite occurs in a previously immunised individual only two booster doses are necessary</li> <li>• <i>Passive immunisation</i> – human rabies immunoglobulin should be given immediately before the vaccine. The wound should be infiltrated with the immunoglobulin and then a dose given intramuscularly</li> </ul>
Examination of the biting animal	<p>Ideally, the animal should be captured confined and observed for 10 days</p> <p>If there is any clinical suspicion of rabies, the animal should be killed and the brain examined for virus</p>
Antigen detection in animals	Using fluorescent antibody techniques or cell culture of mouse inoculation

Prevention is achieved with careful attempts to eradicate rabies from dogs by immunisation, careful border control and preventing contact of domestic pets with wild animals. Pre-exposure immunisation results in highly effective prevention and should be considered in individuals who are considered at high risk (e.g. vets, laboratory workers or those who handle imported animals) or those travelling to, living or working in endemic areas.

### HTLV-1

Human T-lymphotropic virus type 1 (HTLV-1) is a double-stranded RNA retrovirus that causes adult T-cell lymphoma/leukaemia and also neurological involvement manifest as tropical spastic paraparesis and, less commonly, myositis. Only a small proportion of seropositive people infected go on to develop neurological manifestations.

The virus is endemic in southern Japan, the Caribbean, South America and sub-Saharan Africa. Risk factors for transmission of HTLV-1 include sexual contact, exchange of blood products and vertical transmission from mother to child (see also Chapter 16).

### HTLV-1 associated myelopathy (tropical spastic paraparesis)

Tropical spastic paraparesis (TSP) is a progressive inflammatory myelopathy evolving over many decades. The incubation period may be many years. Females are more commonly affected than males. Onset tends to be in the fourth or fifth decades; symptoms develop insidiously with a slowly progressive paraparesis predominantly affecting proximal muscles with brisk reflexes and extensor plantar responses. Upper limb involvement develops as the condition progresses but the bulbar muscles are not involved. Bladder dysfunction becomes evident as urgency and incontinence; chronic retention and overflow may also occur leading to recurrent urinary tract infections; sexual dysfunction is common. There may be burning low back pain and painful dysaesthesia in the legs. The myelopathy is occasionally associated with cerebellar ataxia. Examination shows mild to moderate progressive spastic pyramidal weakness more marked proximally. In TSP the brunt of pathological change is seen within the thoracic cord. There is occasionally mild distal vibration sense impairment to the ankles.

The major differential diagnosis is:

- Primary progressive multiple sclerosis
- Hereditary spastic paraparesis (HSP)
- Primary lateral sclerosis.

The diagnosis may be suspected on clinical grounds. HTLV-1 antibodies can be detected in serum and CSF using Western blot techniques. CSF shows a mild lymphocytosis with elevated protein and local IgG synthesis. Oligoclonal bands are found that are specific for HTLV-1 core and envelope antigen. PCR is available in some centres. MRI may show atrophy of the cervical or thoracic cord and brain MRI often shows subcortical, periventricular white matter high signal.

Antiviral agents have been used in an attempt to inhibit replication of the HTLV-1 proviral load. Immunosuppression is now increasingly used to suppress the immune response to the virus. There is no clearly effective treatment although transient benefit may be gained from steroids. The condition is progressive, although the rate of evolution is variable and generally slow.

### Other neurological manifestations of HTLV-1 infection

Rarely, muscle inflammation is the only manifestation of HTLV-1 although muscle disease may accompany the myelopathy. Myalgia and progressive proximal muscle weakness develop over many months, occasionally associated with a dermatomyositis-like rash. The myositis is relentlessly progressive and does not respond to steroids. There have been no consistent reports of benefit from intravenous immunoglobulin (IVIG) or immunosuppression. Pathologically there is an inflammatory response with myofibre necrosis, regenerating fibres and mononuclear cell infiltrate.

HTLV-1 also causes both axonal and demyelinating neuropathies. Anterior and posterior uveitis have been described in association with HTLV-1. In these conditions the visual prognosis is good but there is a high relapse rate. A variety of other associations have been suggested, in particular between HTLV-1 and cognitive impairment or other autoallergic conditions, but these are unproven.

### HTLV-2

HTLV-2 is closely related to HTLV-1, sharing 70% genomic homology. It is found in intravenous drug abusers and Native Americans but has not been clearly linked to any disease. HTLV-III was previously the term used for HIV-1 and HTLV-IV for HIV-2, but these terms have fallen out of use. HTLV-III and HTLV-IV have recently been used to denote two newly characterised viruses of uncertain significance.

## Fungal infections

Fungi differ from bacteria by having a nucleus bounded by an organised membrane and a chitinous cell wall. They divide by mitosis, lack chlorophyll and are non-motile. Fungi exist in two forms: yeast and filamentous (hyphae and pseudohyphae). Yeasts are unicellular, multiply by budding and infections generally involve the CSF or meninges (Table 9.25). Filamentous fungi grow

by extension of their hyphae, liberate spores and usually lead to parenchymous cerebral involvement. Fungal infections have increased because of the increased numbers of patients who are immunocompromised as a result of HIV/AIDS, an immunodeficiency state or immunosuppression.

Fungi produce neurological disease by direct invasion, allergic phenomena and liberating toxins. Fungal meningitis generally develops insidiously over several days or weeks and is secondary to systemic mycosis elsewhere in the body. The CNS is seeded haematogenously either from a pulmonary or cardiac focus or secondary to direct spread from the sinuses or skull involving the subarachnoid space and leading to a basal meningitis. Fungal meningitis is characterised by meningism with subacute involvement of cranial nerves and an arteritis with thrombosis and cortical or subcortical infarction and micro-abscess formation.

Primary fungal pathogens include *Cryptococcus neoformans*, *Coccidioides immitis*, histoplasmosis, blastomycoses and *Paracoccidioides*. Secondary opportunistic pathogens are more common and occur with immune dysfunction, these include *Candida*, *Aspergillus* and mucormycosis. *Cryptococcus*, *Aspergillus*, *Candida* and *Mucor* occur worldwide but histoplasmosis and blastomycoses are generally confined to the Americas. *Cryptococcus*, histoplasmosis and *Coccidioides* are true yeasts, *Candida* mainly exists as pseudohyphae while *Aspergillus* and mucormycosis are filamentous.

### Risk factors

Cancer, chemotherapy and resulting neutropenia predispose particularly to *Candida* and *Aspergillus* meningitis and HIV to *Cryptococcus*, *Histoplasmosis* and *Coccidioides*. Fungal infection can also occur as a consequence of direct inoculation of fungi followed by penetrating trauma or neurosurgery. Other risk factors include:

- Pregnancy
- Lymphoreticular malignancy including leukaemia and lymphoma
- Diabetes

**Table 9.25** Main fungal infections of the nervous system.

	Geography	Risk factors	Clinical features	Treatment
<i>Cryptococcus neoformans</i>	Worldwide	HIV, cytotoxic drugs, RE malignancy	Granulomatous meningitis, hydrocephalus, raised intracranial pressure	Amphotericin B and flucytosine (induction) and fluconazole maintenance
Histoplasmosis	USA, Central America, Asia, Africa	HIV, steroids, organ transplant	Chronic basal meningitis or cerebritis Rarely, encephalitis or abscess	Amphotericin B then itraconazole maintenance
<i>Coccidioides</i>	USA, Central and South America	HIV, pregnancy, immunosuppression	Diffuse parenchymatous meningitis Meningoencephalitis Mass lesions	Amphotericin B or Fluconazole followed by prolonged Fluconazole maintenance
<i>Candida</i>	Worldwide	See text	Meningitis, vascular infiltration	Amphotericin B
<i>Aspergillus</i>	Worldwide	Neutropenia, immunosuppression	Cerebral abscess, diffuse granulomatous meningitis, ascular infiltration	Voriconazole or amphotericin B Debulking
Mucormycosis	Worldwide	DM, malignancy, steroids	Rhinocerebral invasion	Amphotericin B and surgical debridement. Posaconazole can be used as salvage

- Organ transplantation
- Severe burns
- Connective and vascular disease
- Malignancy.

There is an extensive differential diagnosis of fungal meningitis summarised in Tables 9.17 and 9.18. The most important differential diagnoses are:

- Tuberculous meningitis
- Granulomatous cerebral vasculitis (Churg–Strauss, Wegener’s granulomatosis)
- Viral meningoencephalitis
- Acute disseminated encephalomyelitis
- Sarcoidosis
- Lymphoma
- Carcinomatous meningitis
- Partially treated bacterial meningitis
- Other forms of chronic meningitis – lupus and idiopathic chronic meningitis.

The diagnosis of fungal meningitis is made on the basis of CSF examination which usually shows a mononuclear pleocytosis (20–500 cells/mm<sup>3</sup>) with occasional predominance of polymorphonuclear cells especially in aspergillosis. The cell count may be reduced if the patient is immunosuppressed. CSF India ink staining and agglutinin testing is important in the diagnosis of *Cryptococcus* infection. In culture, *Candida* is identified in 2–3 days but dimorphic fungi such as *Histoplasma* may take several weeks to grow. Serology is occasionally helpful.

CT and MRI may show meningeal enhancement and accompanying parenchymatous mass lesions, possibly with hydrocephalus. Meningeal biopsy is only occasionally of value.

## True yeasts

### *Cryptococcus neoformans*

*Cryptococcus neoformans* is an encapsulated yeast which is the most common pathogen causing fungal meningitis. It occurs in bird excreta and has a worldwide distribution. *Cryptococcus* characteristically occurs in patients with impaired cell-mediated immunity in HIV, or those who have received cytotoxic drugs or steroids and it is also associated with sarcoid and reticulo-endothelial malignancy. *Cryptococcus* occurs as a result of inhalation of small yeast forms into the respiratory tract. Infection may remain dormant for many years or lead to immediate local pulmonary or disseminated infection.

There is an acute or subacute granulomatous meningo-encephalitis with meningism, headache and pyrexia, culminating in the progressive development of raised intracranial pressure with or without hydrocephalus. There may be multiple cranial nerve palsies or focal neurological features including paraparesis, hemiparesis and ataxia. Visual impairment and cerebral infarction also occur. The onset may be subacute over many weeks with cognitive impairment and dementia. The diagnosis is based on culture, direct observation with India ink staining, CSF fungal culture or cryptococcal antigen (CrAg) testing which is both specific and sensitive. The CSF shows a variable lymphocytic pleocytosis.

The outcome of cryptococcal disease is variable. Untreated it can become disseminated and fatal within a few weeks but more often infection leads to persistently raised intracranial pressure with repeated lumbar puncture or a ventriculo-peritoneal shunt being necessary. It accounts for about 20% of all AIDS-related deaths.

*Cryptococcus* is treated with an induction phase of intravenous amphotericin B and flucytosine followed by fluconazole or

itraconazole for 8–10 weeks. Because of the high relapse rate in patients with AIDS, the third level of treatment using fluconazole 200 mg/day as a lifetime suppressive agent is recommended.

### Histoplasmosis

Histoplasmosis usually manifests as a respiratory illness that resembles miliary TB of the lung. It is associated with AIDS, steroids and organ transplantation. Histoplasmosis can also become disseminated; CNS involvement occurs in up to 20% of patients with a chronic basal meningitis or cerebritis. Less often there may be hydrocephalus, encephalitis, cerebral or spinal cord abscess. The diagnosis is made by CSF culture, which is positive in only about 30%; microscopy is usually negative. CSF antigen detection is also possible but there is a high incidence of false positives. Treatment is with amphotericin B but relapses are common and maintenance with itraconazole is indicated. Similar chronic basal meningitis occurs with blastomycosis and actinomycosis.

### Coccidiomycosis

Coccidiomycosis occurs particularly in the south-west United States, Mexico and South America and is caused by air-borne spores. The onset is usually with a self-limiting flu-like illness and pulmonary infiltrates but the *Coccidioides* may disseminate to cause a chronic diffuse parenchymatous basal meningitis or meningo-encephalitis. This causes lethargy, confusion and memory loss. Lytic skull and vertebral lesions occur and intracranial mass lesions may lead to communicating hydrocephalus.

The diagnosis is made by CSF culture and positivity to complement fixation tests. Treatment is with intravenous amphotericin B given over a prolonged period followed by prolonged or even lifelong treatment with fluconazole. Itraconazole and voriconazole are alternatives.

## Pseudohyphae

### *Candida* species

*Candida albicans* is a normal commensal but is the most common cause of fungal meningitis in neonates and young children.

### Risk factors

- Neutropenia
- Immunodeficiency (acquired in congenital shunt infection)
- Immunocompromised hosts
- HIV
- Organ transplants
- Diabetes
- Severe burns
- Total parenteral nutrition
- Malignancy
- Debility
- Steroids and broad-spectrum antibiotics
- Following neurosurgery.

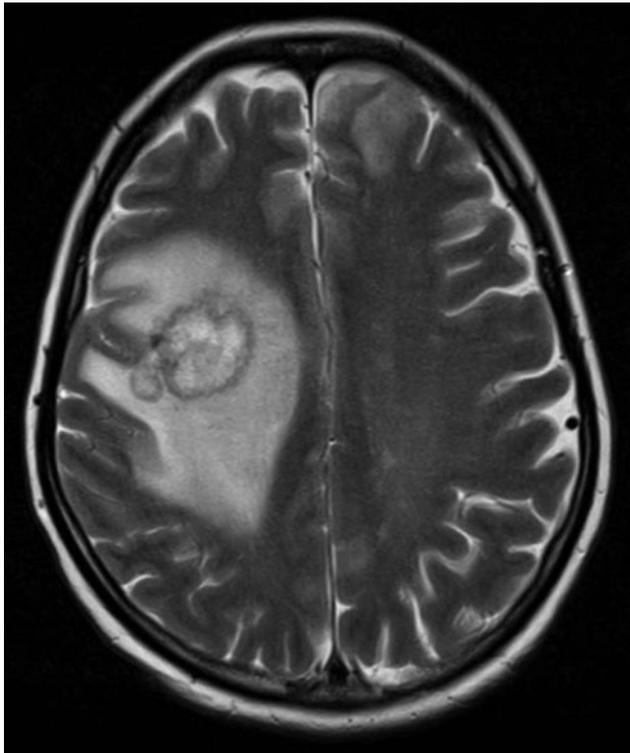

Candidiasis typically involves the lungs, heart, urogenital system, skin and mucous membranes. There can be an acute meningitis; diffuse infiltration occasionally leads to small vessel thrombosis with microinfarcts particularly in the middle cerebral artery territory. There may also be haemorrhage from rupture of mycotic aneurysms. Rarely, there is a subacute onset where invasion of the subarachnoid space occurs. Patients may have a ventriculoperitoneal shunt or ventriculostomy in place for other reasons and be receiving prophylactic antibiotics.

The diagnosis is made on the basis of clinical features together with the CSF showing a mild pleocytosis and low glucose. CSF staining has a low yield (<20%) but in nearly half of *Candida* cases the diagnosis can be confirmed by culture. While a very serious disease, mortality has been reduced by 10–20% by combined amphotericin B and flucytosine which act synergistically. Treatment should be continued for 6–8 weeks. Shunt replacement may be necessary. The mortality rate is still up to 30% in patients with HIV.

### True hyphae (moulds)

#### *Aspergillus fumigatus*

*Aspergillus fumigatus* accounts for about 5% of CNS fungal infections and carries a poor prognosis. It develops in association with prolonged neutropenia, immunosuppression and parenteral drug abuse. It can also occur as a complication of sinusitis, otitis or mastoiditis. Manifestations include cerebral abscess (Figure 9.10), diffuse and granulomatous meningitis. Direct hyphal invasion of the cerebral blood vessels causes thrombosis, necrosis and haemorrhage, particularly involving the posterior circulation. Intracranial mass lesions also occur which may be solitary or, less commonly, multiple. Progressive vascular infiltration may lead to multiple mycotic intracranial aneurysms clinically manifest as encephalopathy, seizures and focal neurological deficit. Haematogenous spread occurs. Diagnosis is difficult as cultures are rarely positive. Products of metabolism may show evidence of *Aspergillus*. Treatment is both medical and surgical involving debulking and amphotericin B (0.7–1.0 mg/kg/day) but higher doses may be used. Treatment is less effective than in cryptococcosis. In many centres voriconazole has replaced amphotericin B. The prognosis remains poor often because of the impaired status of the host.

**Figure 9.10** Aspergillosis: T2-weighted image showing a heterogeneous, irregular intraparenchymal aspergillus abscess with a hypointense rim.

### Mucormycosis

Mucormycosis is a rare fungal infection associated with diabetes, steroids, malignancy, pregnancy or drug addiction. There may be malignant infiltration of cerebral vessels with hyphae commencing in the nasal turbinates and paranasal sinuses and spreading along infected vessels to retro-orbital tissue. Cavernous sinus or internal carotid artery thrombosis and involvement of the adjacent brain contribute to haemorrhagic infarction. Ocular involvement is manifest as central retinal and ophthalmic artery occlusion or optic nerve compression. Treatment is with rapid correction of any hyperglycaemia and acidosis from diabetes, surgical debridement and amphotericin B but the prognosis is poor. Posaconazole can be used as salvage treatment.

### Parasitic disease of the nervous system

The parasitic causes of CNS lesions are summarised in Table 9.26, Table 9.27 and Table 9.28. Parasitic infection should be considered if the absolute number of eosinophils in blood is  $>0.4 \times 10^9$  cells/L or if any eosinophils are found in the CSF. These infections are rare in the United Kingdom with the exception of toxoplasmosis in the immunosuppressed patient and *Toxocara canis* in children.

#### Neurocysticercosis

Neurocysticercosis is caused by infection of the human CNS by the larval form of *Taenia solium*, the pork tapeworm. It is the most common cause of acquired epilepsy in most low income countries and of major importance worldwide.

Adult *T. solium* tapeworms reside only in the small intestine of humans, who are the definitive host. Humans only develop cysticercosis if they ingest viable *T. solium* ova which are the larval forms of the *T. solium* tapeworm. These eggs or ova are only shed in the faeces of humans who are infected by the tapeworm. Humans ingest tapeworm eggs from contaminated water, food or from food handlers or others who harbour the adult tapeworms in their small intestines. Human carriers of *T. solium* tapeworm are at very

Paragonimiasis

#### Protozoa

American trypanosomiasis (Chagas' disease)

African trypanosomiasis (sleeping sickness)

**Table 9.27** Nematodes (roundworms).

Angiostrongyloidiasis	Ingestion of raw or inadequately cooked shellfish or snails which are the intermediate host	Asymptomatic or associated with pruritus, abdominal pain Neurological involvement is rare – may be chronic meningitis with headache, progressive cranial neuropathy, spinal cord involvement or retinal detachment CSF eosinophilic pleocytosis and raised protein. Larvae may be found in biopsy or the CSF Imaging shows meningeal enhancement with oedema and high signal in the basal ganglia Treatment is supportive as the illness is self-limiting
Strongyloides	Human intestinal infection. Associated with poor sanitation Occurs on contact with the parasite in contaminated water or by direct penetration of the skin	Migrates via the venous circulation to the lungs and small intestine where it remains dormant for many years May subsequently reinfect the host and render them liable to secondary bacterial infection Affects the lungs and gastrointestinal tract but rarely may involve the CNS leading to encephalopathy, meningism and, rarely, vascular involvement including mycotic aneurysms, intracerebral haemorrhage or vasculitis Serum eosinophilia Larvae can be identified in stool, serum, CSF or peritoneal fluid Antibodies can be detected with immuno assay MRI scan shows atrophy and may show the presence of mycotic aneurysms or abscesses Treatment is with ivermectin (alternatives includes thiabendazole, albendazole or mebendazole)
<i>Toxocara canis</i>	Ingestion of parasites after contact with infected cats or dogs in whom the excreted eggs survive for many years	Endemic throughout the world The eggs hatch into larvae, which migrate to the liver and then to the viscera leading to an inflammatory response and granuloma formation Infection is usually mild and self-limiting but visceral larva migrans may migrate to the lungs, liver, kidney, heart muscle, brain or eyes and ocular involvement can cause optic ocular neuritis and blindness. Cognitive impairment occasionally occurs with CNS involvement The diagnosis is difficult because the eggs are not excreted in the faeces Serum and CSF eosinophilia. Antibody testing on CSF confirms the diagnosis Imaging may show subcortical and white matter disease suggesting a vasculitis Treatment is with diethylcarbamazine or alternatively mebendazole and albendazole

CSF, cerebrospinal fluid; MRI, magnetic resonance imaging.

high risk of auto-infection with cysticercosis through faeco-oral transmission and family members are at particular risk. Poor sanitation can cause contamination of food and water leading to widespread low level exposure. Pigs acquire infection through ingestion of food or water contaminated with human faeces containing ova. In the pig, the ova hatch and invade the intestinal wall. Larval cysts (oncospheres) are carried in the bloodstream throughout the body. Cysticercosis is not caused by eating raw or uncooked pork, which only causes adult tapeworm infestation (taeniasis) because infected pork contains the (oncospheres) which develop into adult worms in the human intestine but does not contain the eggs that cause cysticercosis.

Neurocysticercosis develops when ingested eggs (ova) hatch in the human intestine and the resulting embryos (oncospheres) become larvae that cross the intestinal wall and are carried by the

bloodstream to various organs, including the nervous system, where they lodge in small blood vessels and develop into viable cysts (cysticerci) after 2–3 months. Cysticerci are vesicles consisting of a wall and scolex. The main target organs of the cysticerci are the eye, skeletal muscle and the nervous system, where cysticerci form in the brain parenchyma often following blood flow or they become localised in the subarachnoid space, ventricular system or spinal cord.

Parenchymatous cysts are common in patients with heavy infections and are frequently located at the grey–white interface. They develop in the cerebral cortex or the basal ganglia because of the relatively high blood flow to these areas.

Other extraparenchymatous cysts affect the basal subarachnoid region or pass into the ventricles becoming lodged in the choroid plexus or 4th ventricle and lead to hydrocephalus. They may become massive and lodge within the cortical sulci or the basal CSF

**Table 9.28** Cestodes (tapeworms).

Echinococcus (Hydatid disease)	Humans and sheep are infected by ingesting eggs excreted by infected animals and the source is usually water or vegetables contaminated by canine faeces After ingestion the parasite rapidly disseminates to the liver, lungs and vertebrae	CNS involvement is characterised by cyst formation causing compression of the brain or intracerebral blood vessels which may manifest as raised intracranial pressure with headache, nausea, vomiting and seizures and is generally difficult to distinguish from cysticercosis. The cysts may also cause compressive spinal cord lesions <i>Investigations</i> Elevated ESR, serum eosinophilia and positive immunophoresis testing Imaging confirms the presence of cysts (often multiple) of various sizes <i>Management</i> Surgical intervention is necessary to remove enlarged cysts with mass effect. Medical treatment is with albendazole
Sparganosis	A form of the tapeworm – contracted from contaminated water or eating undercooked fish	Invasion of the CNS occurs occasionally and there may be focal neurological features including seizures and hemiparesis <i>Investigations</i> Peripheral eosinophilia Parasite may be demonstrated in human tissue specimens. Immunofluorescent antibody techniques are sensitive and specific. Imaging will show calcified lesions <i>Treatment</i> Praziquantel – only moderately successful and surgical excision of the parasite may be necessary

ESR, erythrocyte sedimentation rate.

cisterns and they may also involve the subdural space, the sellar and parasellar regions, the eye and the spinal cord.

Cysticerci elicit a mild inflammatory response when they enter the CNS. Cysts either remain viable for many years or enter a process of degeneration that ends with their death and calcification. Viable cysts are not associated with inflammation and remain static until they are eventually recognised by the host and undergo an intense inflammatory response which then leads to granuloma formation and degenerative change associated with varying amounts of enhancements on MRI and oedema. Eventually, the granuloma decreases in size and becomes nodular. Cysts can resolve entirely but most degenerating cysts hyalinise and calcify although intermittent flares of inflammation and oedema can still occur.

Following death, cysticerci undergo progressive involution in which the cyst becomes surrounded by a thick collagen capsule. Brain parenchyma develops astrocytic gliosis and diffuse oedema, progressing to granuloma formation and then calcification and astrocytic change as the oedema subsides. Cysticerci in the meninges induce an intense inflammatory response in the subarachnoid space with formation of a dense exudate leading to leptomeningeal thickening which may cause hydrocephalus or occlusion of the vessel lumen and cerebral infarction.

### Clinical features

CNS infection is often asymptomatic. Epilepsy is the most common presentation – the seizures are usually generalized tonic–clonic or simple partial but can be complex partial. Cognitive function may be impaired. Intracellular cysticerci present with visual field loss and endocrine disturbances from pituitary involvement while ocular cysticerci cause decreased visual acuity or visual field loss. Spinal

cord involvement is characterized by root pain or motor and sensory deficits that vary according to the level of the lesion. Massive infection of striated muscle may lead to generalised weakness with progressive muscle enlargement.

Extraparenchymal neurocysticercosis generally has a worse prognosis. It can be divided into ventricular and subarachnoid locations.

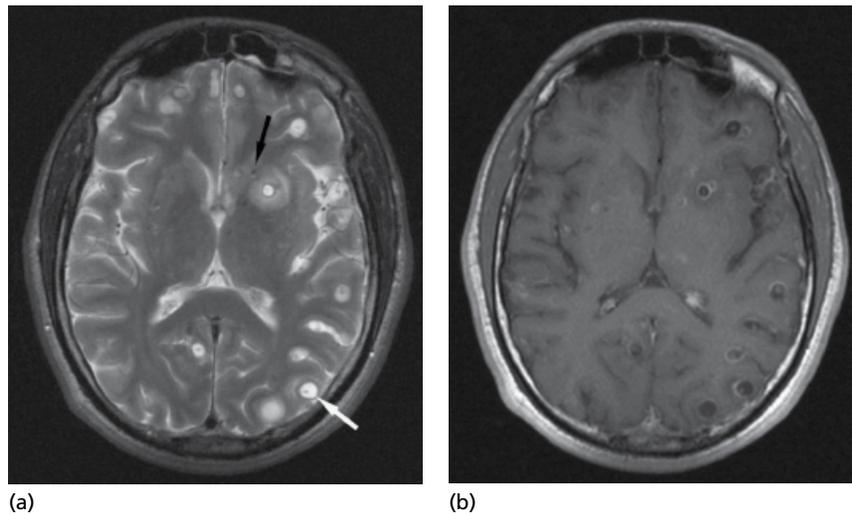

Cysts lodging in the ventricles (usually 4th but may involve a 3rd and lateral ventricles) may cause mechanical obstruction to CSF flow leading to hydrocephalus, often associated with headache, nausea, vomiting and vertigo. Focal signs may develop.

Subarachnoid cysts may affect the brain convexity causing surface compression and leading to epilepsy or the effects of a space occupying lesion. Involvement of the Sylvian fissure by multiple cysts or a single giant cyst may result in a mass effect or calcification and infarction of the middle cerebral artery. Basal subarachnoid neurocysticercosis often causes an extensive inflammatory response affecting the arachnoid space, meninges, foramina and brain tissue leading to arachnoiditis, pachymeningitis and mass effect. Spread may occur throughout the subarachnoid space and in the spinal cord and may lead to arachnoiditis or cord compression.

### Diagnosis

Plain films may show small <1 cm cigar-shaped soft tissue calcification in brain or cysticerci in the anterior chamber of the eye and in muscles. In countries where neurocysticercosis is prevalent, small <1 cm brain lesions are often regarded as neurocysticercosis cysts unless proved otherwise, and are common incidental findings.

Imaging appearances depend on the stage of the cysticercus. On MRI, the initial vesicular stage appears as a CSF-like cyst with the scolex as a dot at its centre. Oedema and rim-enhancement develop

**Figure 9.11** Cysticercosis: (a) T2-weighted and (b) T1-weighted post contrast images showing multiple lesions in varying states of maturity. The scolex can be seen as a central hypointense dot in several of the vesicular lesions (white arrow). Old calcified lesions are visible as punctate hypointense foci (black arrow).

as the scolex degenerates, eventually contracting to a small calcified nodule. CT shows the viable cystercerci as hypodense lesions, occasionally with a central hyperdense scolex, and is particularly sensitive for detection of the mature calcified nodular stage (Figure 9.11). Degenerating cysts appear as contrast enhancing rings on FLAIR MRI sequences. There may be hydrocephalus. Cystercerci should be distinguished from lesions of tuberculosis which tend to be larger and to have mass effect. The differential diagnosis also includes tumours, particularly glioma.

Serological tests – enzyme-linked immunoelectro-transfer blot with purified glycoprotein antigens (Western blot) – can be undertaken on serum or CSF but may be negative. Cystercerci may be noted on muscle biopsy. Stool examination may reveal *T. solium* ova in those who carry gut tapeworms, which typically cause no symptoms.

### Management

Acute treatment includes in immediate measures to manage raised intracranial pressure or mass effect (mannitol or high dose steroids). Surgical procedures are necessary to remove the cyst or to relieve the blockages or hydrocephalus. Antiepileptic drugs are used to control seizures. Corticosteroids reduce the acute inflammatory response and antihelminthic medication will kill the cysts.

There remains uncertainty about the value of medication in neurocysticercosis because many clinical manifestations are caused by calcified cysts rather than active lesions. In most patients a single enhancing lesion will disappear spontaneously. There is evidence to support the use of antihelminthic medication, usually accompanied by corticosteroids, to treat patients with viable cysts. The purpose is to kill the parasites and to alleviate symptoms.

There is debate about treatment of the patient with a single enhancing lesion. The two most used antihelminthic drugs are albendazole and praziquantel. Both are cysticidal and result in either cyst degeneration followed by clearance and eventual calcification of the cyst. However, many patients develop treatment-related exacerbations of disease.

The treatment of patients with cystic disease decreases generalised and partial seizures but the efficacy for single enhancing lesions

remains unproven. Uncomplicated parenchymal disease is commonly treated with 15 mg/kg albendazole in two divided doses for 8 days to 2 weeks. Praziquantel at 50 mg/kg/day is taken for 1–2 weeks with cimetidine to prevent metabolism of the active drug in the liver. The commonly used antihelminthic treatment regimens provide relatively low cure rates and repeated courses of treatment are often necessary. Combined therapy is increasingly used. In patients with numerous or large areas of cysts there may be an extensive inflammatory response and this can be exacerbated by treatment. These patients require corticosteroids. A single course of albendazole or praziquantel kills 60–85% of viable brain cysts leading to rapid radiological resolution of the cysts. Corticosteroids are indicated in the presence of encephalitis angiitis or chronic meningitis causing progressive entrapment of cranial nerves. Antiepileptic medication may need to be life-long. Ventricular shunting to resolve hydrocephalus may be necessary but is associated with a high level of shunt malfunction.

Antihelminthic treatment is not indicated in patients with calcified neurocysticercosis because calcified lesions are non-viable and consist only of encapsulated cyst remnants.

### Trematodes

Paragonimus is the only mammalian lung fluke that can infect humans. CNS involvement is extremely rare although chronic meningo-encephalitis, focal lesions including transverse myelitis, myelopathy and seizures may occur. There is often a marked serum and CSF eosinophilia. The eggs may be demonstrated in the CSF or on brain biopsy material. Serum antibody tests are positive and imaging showing multiple clusters of calcified density in the right frontal and temporal region. Treatment is with praziquantel and steroids.

### Schistosomiasis (bilharzia)

Schistosomiasis occurs in up to 200 million people worldwide. There are five forms but CNS involvement occurs particularly with *Schistosoma mansoni*, *S. haematobium* and *S. japonicum*. Infection is acquired in areas where the water supply or sanitation is poor. The larva invades the skin and migrates into the venous system.

Subsequent spread depends on the species involved. Schistosomiasis commonly causes hepatointestinal and urinary tract disease. The eggs of *S. japonicum* cause 60% of all schistosomal brain infections while *S. mansoni* tends to be confined to the spinal cord. *S. haematobium* can involve brain or cord. Eggs enter the CNS and cause a granulomatous response which walls off the invading parasite. The granulomas expand, become exudative and necrotic, involving vascular walls as well as local tissue.

The onset is with an acute pyrexia, urticarial swelling, myalgia, bloody diarrhea and eosinophilia. Neurological involvement occurs in <5% of patients and develops after weeks or months when the eggs migrate through the vascular system to the brain or spinal cord. Mass lesions may be produced by expanding granulomas leading to raised intracranial pressure or erosion of vessel walls culminating in intracranial haemorrhage. Spinal cord involvement may be caused by granuloma formation and transverse myelitis (usually below T6) is the most common manifestation although cauda equina and conus syndromes are also characteristic.

There is usually a CSF eosinophilia. Diagnosis is made by detection of the eggs in stool, urine or tissue biopsy. Antibody detection, using ELISA, is possible but this is not reliable as seroconversion takes 4–12 weeks. CT scan shows single or multiple small, hyperdense enhancing lesions caused by granuloma formation, which is inflammatory and surrounded by oedema with variable contrast enhancement. They are usually seen in the frontal, parietal and occipital lobes and the brainstem. The diagnosis depends on a high level of suspicion in those exposed to fresh water in endemic areas.

**Treatment** Treatment is conventionally with praziquantel, which is effective against all schistosome species and curative for >90% of patients. If patients continue to excrete the eggs then it is necessary to have a further course of treatment. Alternative treatments include niridazole or artemether, which kills immature migrating larvae and is synergistic with praziquantel. Steroids are used for lesions if there is extensive surrounding oedema and large granulomas may need to be excised surgically. Most patients make a full recovery if diagnosis and treatment are prompt.

## Protozoa

### American trypanosomiasis (Chagas disease)

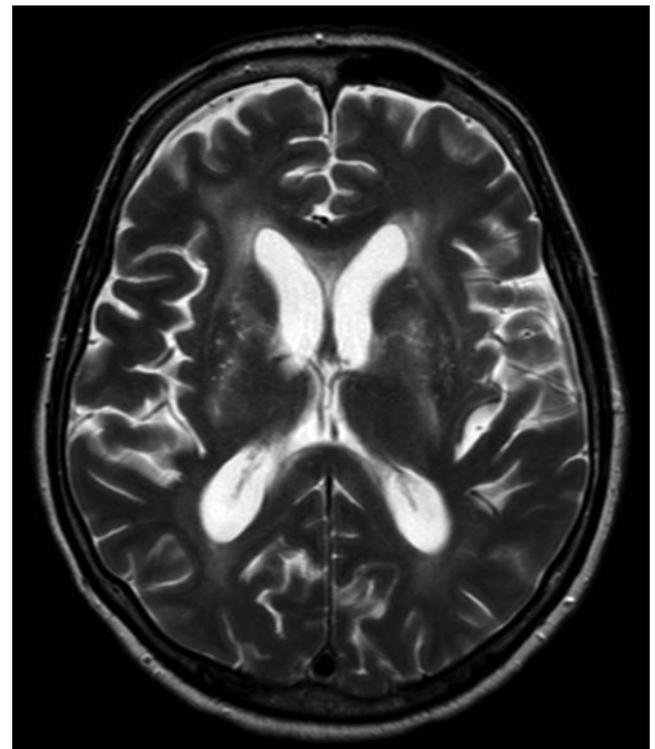

American trypanosomiasis (Chagas disease) is caused by *Trypanosoma cruzi*, which is endemic in South and Central America. Infection occurs secondary to contact with reduviid bug, ingesting guinea pig excreta, blood transfusion or organ transplantation. Larval eggs are taken through the site of pruritic skin lesions. The larvae then mature and are transported by the bloodstream to distant sites. They divide intracellularly before rupture of the cell releases the infectious parasite and inflammatory substances.

Chagas disease has an onset with malaise, myalgia, headache and anorexia. There is unilateral or bilateral periorbital oedema (Roman's sign). Cardiac failure and intestinal involvements are common. Meningo-encephalitis may occur in a minority of patients depending on the severity of infection and extent of host immune response. The diagnosis is made by CSF demonstration of trypanosomes. Serum antibody detection tests are sensitive and specific for acute and chronic forms. MRI scanning may show one or more ring enhancing lesions involving the grey and white matter. Acute Chagas disease can be eradicated by benznidazole or nifurtimox but chronic infection remains symptomatic and is difficult to clear.

### African trypanosomiasis (sleeping sickness)

African trypanosomiasis (sleeping sickness) occurs in humans in two forms: *Trypanosoma brucei gambiense* (West African) and *Trypanosoma brucei rhodensiense* (East African). The condition is widespread throughout sub-Saharan Africa. The vector of both species is the tsetse fly which feeds from infected animals. A superficial chancre forms at the site of the bite and the parasite larvae migrate, via the bloodstream, to the lymphatic vessels before maturing and reproducing. There is then a secondary spread of mature forms to the lymph nodes, spleen, liver, heart, endocrine system, eye and CNS leading to a host immune response and meningo-encephalitis.

West African trypanosomiasis is slow or indolent in onset and characterised by rash, intermittent fever and lymphadenopathy. The symptoms are episodic. The East African form is more aggressive with behavioural disturbance, psychiatric manifestations including anxiety and agitation with manic and uncontrolled behaviours. Sleep disruption occurs with day–night reversal and uncontrolled urges to sleep. The condition progresses to motor disturbances including ataxia, rigidity, akinesia and progressive pyramidal signs but meningism is rare. Visual involvement includes optic neuritis, optic atrophy and papilloedema. Death occurs as a result of coma, secondary infection or cardiac involvement but chronic forms occur. The diagnosis of trypanosomiasis can be made by direct observation in wet preparations of stained blood, CSF or biopsy. However, antibody and PCR tests are unreliable. MRI may demonstrate abnormal signal within the deep white matter and basal ganglia (Figure 9.12). The treatment is with suramin and pentamidine but this is not suitable if there is CNS involvement when melarsoprol or eflornithine are recommended. Some of the

**Figure 9.12** African trypanosomiasis: T2-weighted axial image showing abnormal signal within the basal ganglia, internal and external capsules and peri-ventricular white matter.

agents are toxic and should be used at specialist centres with experience of the condition and its management.

### ***Toxoplasma gondii***

*Toxoplasma gondii* is an intracellular protozoan which is widely distributed. Invasion occurs as a result of ingestion of uncooked meat and exposure to cat faeces. *Toxoplasma* may invade multiple organs but in immunocompetent individuals infection is generally asymptomatic or associated with a mild mononucleosis-like illness with lymphadenopathy and a non-specific systemic illness. However, severe disease may occur in the immunocompromised patient, particularly in association with HIV, and this is discussed below.

### **Malaria**

Malaria is the most important parasitic disease of humans and it is estimated that >5% of the world population has been infected. Each year >500 million new cases of malaria occur worldwide, 90% of these are in Africa or South-East Asia. The condition accounts for 200 million deaths per year.

Malaria is caused by five parasitic protozoa of the genus *Plasmodium*: *P. vivax*, *P. falciparum*, *P. ovale*, *P. malariae* and *P. knowlesi*. It is predominantly *P. falciparum* that can cause severe generalised disease and in particular cerebral malaria. The protozoa is transmitted by the female *Anopheles* mosquito which feeds at night-time although, rarely, transmission may also be transplacental or from contaminated needles. Infection is initiated by sporozoites injected in the bite of the mosquito. The protozoa undergoes a complex life cycle in the human host in which the sporozoites multiply within hepatocytes, producing thousands of multinucleated merozoites which enter the red blood cells and become mature forms (trophozoites and schizonts) before rupturing and releasing further merozoites. In *falciparum* malaria the red blood cells become distorted and excessively adherent binding to endothelial cells and causing sequestration, clumping and eventually vascular obstruction within the cerebral vessels. There is also an associated suppression of haemopoiesis leading to anaemia, thrombocytopenia and hepatosplenomegaly. *P. vivax*, *P. ovale* and *P. malariae* are either asymptomatic or cause recurrent episodic fever of varying severity. *P. knowlesi* is a primate malaria which causes non-relapsing disease that can also rarely lead to a rapidly severe and generalised malaria in parts of South-East Asia. In *P. falciparum* malaria, clinical manifestations depend on the load of parasite and the immune state of the host. Onset is with a flu-like illness, headache, fever and muscle aches. There are often paroxysms of rigor and shivering in between the pyrexia with extensive diaphoresis and hypothermia. Cerebral malaria is manifest by the onset of coma often heralded by focal or generalised seizures. Raised intracranial pressure develops rapidly, leading to possible brainstem herniation; in addition, vascular engorgement leads to the development of cerebral arterial occlusion, aneurysms or intracranial haemorrhage. A subacute syndrome or diffuse symmetrical encephalopathy may also occur associated with brainstem signs, eye movement abnormalities, pyramidal signs or extrapyramidal movements including choreo-athetosis and myoclonus. Retinal haemorrhages are characteristic. Severe malaria is an acute form of the condition, generally but not exclusively due to *P. falciparum* (90%), and associated with organ dysfunction and a high level of paraesthesia (>5%). In endemic areas children, pregnant women and travellers with no previous exposure are at particular risk of severe infection. Severe malaria may be associated with respiratory distress syndrome, pulmonary oedema, acidosis, circulatory collapse, pulmonary oedema, renal

failure with haemoglobinuria (Blackwater fever), jaundice, disseminated intravascular coagulation, anaemia and hypoglycaemia. Neurological involvement is manifest as seizures and altered consciousness culminating in coma.

### **Diagnosis**

The diagnosis of cerebral malaria is made on thick blood films and light microscopy ensuring that large amounts of blood are available and a minimum of 100 fields are observed. Thin film assessment allows species recognition. Newer antigen tests are now available based on recognition of the HRP-2 antigen of *falciparum*. PCR techniques are specific and sensitive to *Plasmodium*, but do not give an estimate of the parasite load.

Coma occurring in patients with cerebral malaria carries a fatality rate of up to 20% when appropriately treated and is invariably fatal if untreated. Complications include cerebral or dural venous thrombosis and cortical infarction. The management of acute malaria depends on the infecting species, the severity of parasitaemia, the pattern of clinical involvement and potential drug resistance.

### **Acute management**

Acute management of cerebral malaria involves supportive care with appropriate attention to ventilation, fluid balance, renal function and seizures. *P. malariae*, *P. ovale*, *P. vivax* and *P. knowlesi* should be treated with a standard course of chloroquine over 48 hours. In severe cases it may be necessary to treat with an intravenous infusion of chloroquine. Primaquine may be added to eradicate the exerythrocytic forms and prevent relapses (Table 9.29).

Because chloroquine resistant *P. falciparum* is widespread, treatment of mild infections is with oral quinine sulfate followed by doxycycline or clindamycin to eradicate remaining asexual forms. Alternatives include mefloquine or co-artemether.

The management of acute malaria requires the provision of intensive care with ventilatory and haemodynamic support as well as treatment of hypoglycaemia, fluids, pyrexia, anaemia, sepsis and thrombotic risk.

**Table 9.29** Antimicrobial treatment for malaria.

<i>Plasmodium</i>	Chloroquine and primaquine
<i>P. malariae</i>	
<i>P. ovale</i>	
<i>P. vivax</i>	
<i>P. knowlesi</i>	
Chloroquine sensitive	
<i>P. falciparum</i>	
Chloroquine resistant	
<i>P. falciparum</i>	Quinine sulfate and tetracycline (alternative to tetracycline is sulfadoxine and pyrimethamine or amiodaquine or doxycycline)
Multi-drug resistant	
<i>P. falciparum</i>	Mefloquine or artesunate or sulfadoxine and pyrimethamine or proguanil and atovaquone
Severe complex multi-drug resistant <i>P. falciparum</i> (particularly if mefloquine resistant)	Quinine dihydrochloride or artesunate

There are two major classes of drugs available for parental treatment of severe malaria: the cinchona alkaloids (quinine and quinidine) and the artemisinin derivatives (artesunate, artemether, artemotil). Artesunate, administered intravenously, is the preferred therapy for acute severe falciparum in children and adults. It is given as a high doses of 2.4 mg/kg over 3 days. However, the emergence of artemisinin resistance in South-East Asia is an important concern and monotherapy is now strongly discouraged. An important contribution to the recent success in malaria control has been the widespread use of highly effective artemisinin-based combination therapy. Intravenous quinine or quinidine remains the treatment of choice that areas where artesunate is an available or unreliable. Quinine can also be given by intramuscular injection.

In rural environments, if intravenous treatment cannot be commenced immediately, the patient should be treated with intramuscular quinine or artesunate or rectal artesunate.

The total duration of therapy with quinine/quinidine of the severe malaria is 7 days and for artemisinin-based therapy is 3 days.

### Prevention

Although the complete genome of the *Anopheles* mosquito and *P. falciparum* has been sequenced, this has not yet led to new therapy and therefore traditional prophylaxis is still mandatory. Recommendations concerning appropriate prophylaxis vary depending on the characteristics of malaria and drug resistance in particular areas. There is considerable variation in the advice given when travellers are to visit a malarial zone. Meticulous attention to physical prevention with appropriate clothing, mosquito-repellants and nets at night are the most important.

### Neurological disorders resulting from HIV

It is now more than 30 years since the onset of the HIV/AIDS pandemic. Although it was soon apparent that the CNS was frequently involved with opportunistic infections and tumours, it was subsequently recognised that patients developed complications from HIV itself such as dementia, myelopathy, neuropathy and myopathy. With the introduction of HAART (highly active anti-retroviral therapy) in 1997, the incidence of opportunistic infections and tumours, as well as HIV-related complications, have drastically reduced, with a fall in the incidence of opportunistic infections from 13.1 per 1000 in 1996 to 1.0 per 1000 in 2006. This group of patients now present with problems resulting from drug side effects such as neuropathy and a metabolic syndrome that may predispose to cerebrovascular and cardiovascular disease. Newer clinical syndromes now encountered include the phenomena of immune reconstitution inflammatory syndrome (IRIS) and CNS compartmentalisation (with a viraemia in the blood but independent replication of the virus in the CSF which acts as a sanctuary site). There is also concern regarding effective CSF penetration of antiretroviral drugs, CNS drug neurotoxicity and much current research is focused on patients who may continue to decline cognitively despite adequate HIV treatment. In addition, because of greater longevity, patients with HIV are now prone to the same disorders associated with ageing found in the non-infected population.

HIV-1 is a retrovirus (lentivirus) which is single-stranded with a positive sense RNA. It contains reverse transcriptase, which transcribes viral RNA into DNA that is integrated into the host genome. It targets CD4 receptors and infects CD4+ lymphocytes as well as

monocytes and macrophages. HIV is neuroinvasive (with invasion occurring early in the course of the infection), neurovirulent (causing a neuropathy, myopathy, myelopathy and encephalopathy) but not particularly neurotropic (capable of infecting nerve cells). The virus is rarely isolated from the neurones of the peripheral or central nervous systems and productive infection is usually found within the associated inflammatory infiltrate, predominantly in macrophages and microglia.

HIV infection can be divided into the following stages:

- Primary acute HIV infection
- Seroconversion
- Chronic latent infection (often associated with generalised lymphadenopathy)
- Early symptomatic HIV infection
- AIDS (CD4 count below 200/mm<sup>3</sup>)
- Advanced AIDS infection (CD4 cell count below 50/mm<sup>3</sup>).

HIV infection is generally acquired through sexual intercourse, exposure to contaminated blood or perinatal transmission.

Primary acute HIV infection is usually associated with fever, lymphadenopathy, rash, myalgia, arthralgia, headache and mucocutaneous ulceration. In the absence of treatment with HAART, disease progression is highly variable and the mean time to the development of AIDS is 10–11 years with the mean survival after the development of AIDS of 1.3–3.7 years. Up to 25% of patients with symptomatic primary acute HIV infection may develop symptoms or signs of aseptic meningitis or a self-limiting encephalopathy. Acute encephalitis due to HIV-1 and HIV-2 has rarely been reported in seronegative patients as a form of primary infection.

Most patients seroconvert to positive HIV serology 4–10 weeks after exposure but 95% have converted by 6 months. At seroconversion, a glandular fever-like illness occurs in 70% of cases. Seroconversion may be associated with neurological symptoms and signs in 10% – syndromes described include aseptic meningo-encephalitis, acute disseminated encephalomyelitis (ADEM), transverse myelitis, polymyositis, brachial neuritis or a cauda equina syndrome. Guillain-Barré syndrome has also been described at seroconversion and during the asymptomatic phase of HIV infection although the CSF shows a significant pleocytosis in contrast to the findings in HIV-negative patients where CSF examination is usually acellular with a high protein.

During the asymptomatic phase of HIV infection, when there is no evidence of immunosuppression clinically and the CD4 count is above at least 350 cells/mm<sup>3</sup>, there are no neurological symptoms or signs. This has been ascertained by a number of large cohort serial studies using clinical, neurophysiological, neuroradiological and neuropsychological methods of assessment. During the clinically latent phase the only abnormal finding may be a persistent generalised lymphadenopathy.

Early symptomatic HIV infection (AIDS related complex, ARC) is associated with a variety of systemic manifestations that are not AIDS defining but occur more frequently and severely in association with HIV infection: thrush, leukoplakia, herpes zoster, peripheral neuropathy, cervical dysplasia, persistent pyrexia and diarrhoea.

Neurological conditions defining AIDS generally occur when the CD4 count falls below 200/mm<sup>3</sup> and include:

- HIV-associated dementia (HAD)
- Opportunistic infection (toxoplasmosis, *Cryptococcus*, CMV or mycobacterium)
- HIV-associated wasting
- Cerebral lymphoma
- Progressive multifocal leukoencephalopathy (PML).

Other AIDS defining conditions include pneumocystitis pneumonia, oesophageal candidiasis, cervical carcinoma, Kaposi's sarcoma, mycobacterial infection, CMV, toxoplasmosis, histoplasmosis and lymphoma. Advanced AIDS is considered to be present if the CD4 count falls below 50/mm<sup>3</sup>.

Some patients exhibit remarkable clinical stability and remain asymptomatic over many years without antiretroviral therapy (long-term non-progressors). Elite controllers are HIV seropositive individuals who have no evidence of viraemia and maintain a high CD4 count.

Prior to the introduction of HAART, in up to 5% of cases HAD was the AIDS defining diagnosis. HIV infection should therefore be considered in the differential diagnosis in any young patient presenting with cognitive impairment. HIV-associated psychosis develops suddenly without a prodrome. There may be delusions, hallucinations and mood swings. When psychosis occurs in patients with HAD, it is characterised by prominent agitation, irritability and delusions (AIDS mania). HIV infection may be associated with a vasculitis or a thrombophilic state with anticardiolipin antibody and lupus anticoagulant and therefore enters the differential diagnosis of young stroke.

The timing of initiating HAART may be critical to the management of opportunistic infection for which no effective treatment is available (e.g. PML). HAART carries a significant risk of complications including drug intolerance, toxic effects and immune reconstitution inflammatory syndrome. Failure of HAART may be because of viral resistance, drug toxicity or poor compliance (which may be a result of cognitive impairment).

### Basic principles of neuroAIDS

- As a result of immunosuppression, the clinical presentations may be atypical. For example, only one-third of patients with cryptococcal meningitis develop classic features of meningism. A low threshold for investigation with CT and/or MRI and lumbar puncture is necessary.
- Each area of the neuro-axis in an HIV infected individual may be affected by multiple different aetiological agents. For example, a patient may have a mass lesion in the brain resulting from toxoplasmosis, a concurrent HIV-related myelopathy and a drug-induced neuropathy.
- Dual infections are relatively common and this possibility must be borne in mind when assessing a treatment response. For example, patients may have meningitis resulting from *C. neoformans* and *M. tuberculosis*.
- CSF examination may be abnormal as a consequence of HIV infection alone even in the asymptomatic immunocompetent stages. These include a mild lymphocytic pleocytosis, an elevated CSF protein and oligoclonal bands. Conversely, as a result of HIV-induced immunosuppression, patients with meningitis or encephalitis may have normal CSF indices. The diagnosis of neurological disorders therefore relies on specific tests on the CSF such as the detection of cryptococcal antigen (by latex agglutination – CRAG), culture or using PCR techniques.
- Serological studies (e.g. in toxoplasmosis) are unhelpful in making a diagnosis as used in immunocompetent cases as there is no diagnostic fourfold rise in IgM and IgG titres.
- In patients who have not received HAART, the CD4 count is a useful guide in attempting to determine the specific aetiologies of opportunistic infections and tumours:
  - CD4 >500 cells/mm<sup>3</sup> – seroconversion manifestations include Guillain-Barré syndrome, myopathy and aseptic meningitis

- CD4 <350 cells/mm<sup>3</sup> – complications resulting from *M. tuberculosis*
- CD4 <200 cells/mm<sup>3</sup> – opportunistic infections (toxoplasmosis, cryptococcal meningitis, HSV and *Mycobacterium*) PML, peripheral neuropathy, vacuolar myopathy, cerebral lymphoma and HAD
- CD4 <50 cells/mm<sup>3</sup> – disseminated CMV retinitis, encephalitis and polyradiculopathy and cerebral lymphoma.

In HAART exposed patients, these guidelines are less robust because even if there is a rise in the CD4 count, these lymphocytes may not be fully competent as some antigen-specific clones will have been lost.

The major neurological complications of HIV-1 infection are summarised in Table 9.30.

**Table 9.30** Major neurological complications in HIV-1 infection.

Opportunistic infections	<i>Toxoplasma gondii</i> – abscesses, encephalitis <i>Cryptococcus neoformans</i> – meningitis, cryptococcoma <i>Mycobacterium tuberculosis</i> – meningitis, abscesses, tuberculoma, myeloradiculopathy <i>Mycobacterium avium</i> , <i>M. kansasii</i> CMV – encephalitis, retinitis, lumbosacral polyradiculopathy, vasculitic neuropathy JC virus – PML <i>Varicella zoster virus</i> – encephalitis, CNS vasculitis, myelitis <i>Herpes simplex virus</i> – encephalitis, myelitis
Tumours	Primary CNS lymphoma (EBV-related) Metastatic systemic lymphoma
Caused by HIV	Peripheral neuropathy Distal sensory peripheral neuropathy Inflammatory demyelinating neuropathy (GBS and CIDP) Vasculitic neuropathy Diffuse inflammatory lymphocytosis syndrome HIV associated dementia Vacuolar myelopathy HIV polymyositis
Cerebrovascular disease	HIV associated thrombophilia Cardioembolic – endocarditis, infectious and marantic Vasculitis – HIV associated, infectious (varicella zoster)
Drug-related complications	Peripheral neuropathy Drugs (ddC, ddl, d4T) Other drugs (thalidomide, isoniazid, dapsone) Myopathy (AZT)
Immune reconstitution	Immune reconstitution inflammatory syndrome – related to JC virus (PML), MTb, cryptococcus, CMV, HIV

CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; CMV, cytomegalovirus; EBV, Epstein-Barr virus; GBS, Guillain-Barré syndrome; JC, Japanese encephalitis; MTb, *Mycobacterium tuberculosis*; PML, progressive multifocal leukoencephalopathy.

## Opportunistic infections in HIV

### *Toxoplasma gondii*

Toxoplasmosis is the most common opportunistic infection but there has been a decline in the incidence. It occurs as a consequence of reactivation of the disease after prior infection. Human infection occurs as a result of ingestion of oocysts in cat faeces and the ingestion of tissue cysts in undercooked meat. Variations in dietary habits explain the differing seroprevalence rates worldwide – 90% in French adults compared with 50% in the United Kingdom. Symptomatic toxoplasmosis is usually caused by reactivation of latent infection which persists in the brain and muscle in immunosuppressed individuals. The risk of an HIV-infected patient who is seropositive for IgG *T. gondii* antibody developing toxoplasmosis is around 25%.

Toxoplasmosis is the most common cause of mass lesions in the CNS of HIV patients even in developing countries where tuberculosis is rife. Reactivation occurs when the CD4 count drops to 100–200 cells/mm<sup>3</sup> and the CD4 T cells are unable to suppress the latent infection. The clinical presentation is with headache, fever, confusion and/or seizures in association with hemiplegia, dysphasia and visual field defects. Other clinical features include a variety of movement disorders (choreoathetosis, dystonia and hemiparkinsonism); psychiatric illness such as depression and personality change resulting from frontal lobe pathology; brainstem syndromes and, rarely, a rapidly progressive diffuse encephalitis. Rarely, the spinal cord may be involved with a myelitis or a cauda equina syndrome.

On imaging studies, preferably MRI, *Toxoplasma* lesions have a predilection for the grey–white interface of the frontal or parietal lobes and the basal ganglia and thalamus (Figure 9.13). There is normally mass effect with surrounding oedema with patchy ring enhancement. A single lesion or peri-ventricular lesions are more likely to be caused by primary CNS lymphoma, the main differential diagnosis that occurs with a similar clinical presentation and at similar low CD4 counts.

Although negative blood serology makes the diagnosis less likely, this may still occur in up to 17% of cases. These cases are a result of impaired antibody synthesis with increasing immunosuppression and only occasionally caused by primary infection. It is useful therefore to document *Toxoplasma* serology at the time of HIV

diagnosis. IgG antibodies to *T. gondii* may be present in the serum and PCR can be undertaken on the CSF although the sensitivity is only 50%. A definitive diagnosis of *Toxoplasma* encephalitis can only be made by brain biopsy. With increasing experience and pragmatism, it is now standard practice to treat any HIV-infected individual with a low CD4 count and mass lesions on imaging with anti-*Toxoplasma* therapy. A response, clinically and radiologically, confirms the diagnosis.

The treatment is with combined pyrimethamine, folinic acid and sulfadiazine or co-trimoxazole for 6 weeks' induction and then maintenance treatment until the CD4 count is above 200 for at least 6 months (Table 9.31).

Response to treatment is seen in 90% of patients by the second week of treatment. It is important to re-image even if there is clinical improvement because it is not rare for some lesions to improve and others, such as those due to *M. tuberculosis*, to enlarge making it necessary to consider biopsy. The radiological improvement generally lags behind the clinical improvement.

Patients who are HIV infected and who are seropositive for IgG against *T. gondii* should be offered primary prophylaxis with 980 mg co-trimoxazole (trimethoprim and sulfamethoxazole) when the CD4 count drops below 200 cells/mm<sup>3</sup>. This also offers protection against *Pneumocystis jirovecii*.

**Table 9.31** Treatment of toxoplasmosis in HIV positive patients.

#### Acute phase (for 6 weeks)

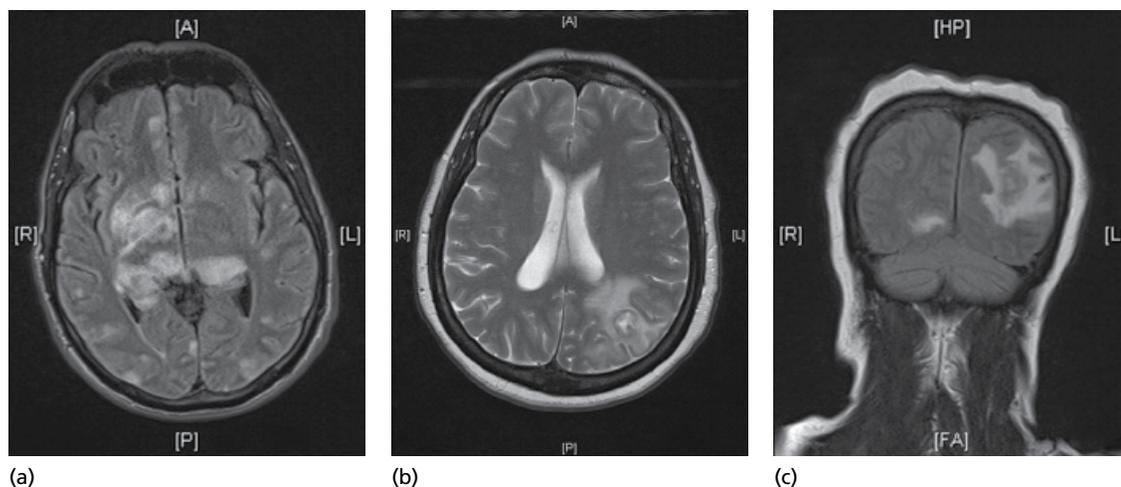

##### First line therapy

Pyrimethamine (100 mg po for 3 days, then 75 mg/day) and sulfadiazine 6–8 g/day po/IV (or clindamycin 600–900 mg/day po/IV) and folinic acid 15 mg/day

(Side effects: pyrimethamine – marrow suppression; sulfadiazine – rash, nephrotoxicity, marrow suppression; clindamycin – rash, diarrhoea)

##### Maintenance treatment

Pyrimethamine 25–50 mg/day and sulfadiazine 2– g/day or clindamycin 600 mg/day and folinic acid 10 mg/day

**Figure 9.13** Cerebral toxoplasmosis in HIV: (a) FLAIR axial, (b) T2 axial and (c) FLAIR coronal MRI.

### Tuberculous meningitis and brain abscess

The issues relating to tuberculous infection of the CNS in AIDS are a similar to those in that non-AIDS patients considered earlier in the chapter. The WHO estimate that one-third of the world population has latent *M. tuberculosis* and co-infection with HIV increases the risk of dissemination and tuberculous meningitis.

Clinical presentation of TBM is with fever, change in mental state, headache, seizures, cranial nerve or focal limb deficit. The CT may show hydrocephalus, tuberculomas, abscess or haemorrhage and in approximately 50% there is basilar enhancement. MRI may confirm the presence of a mass lesion and define exudates and vasculitis (with or without infarction) particularly affecting infratentorial regions and the basal ganglia. There may be infarcts secondary to vasculitis. The CSF shows a lymphocytosis with elevated protein levels and reduced glucose. AFB may be seen and *M. tuberculosis* may be cultured. The CSF TB PCR increases total sensitivity to 80% but as a stand alone test is less sensitive than culture. It is important to ensure that large volumes of CSF (at least 10 mL) are taken at repeated lumbar puncture.

The diagnosis may be difficult because the sensitivity of standard detection of AFB, culture and even PCR is only approximately 50% although it may be higher in HIV because of the higher infective load and incomplete immune response. Other investigations including tuberculin skin test and interferon gamma release assays (e.g. Quantiferon, TB Gold) may increase sensitivity although they do not discriminate between latent and active infection. Occasionally, it may be necessary to resort to a brain biopsy to confirm the diagnosis.

The treatment is as previously described but the mortality rate is >50% which is double the rate occurring in non-HIV patients. Multi-resistant TB is seen in approximately 3% of cases worldwide and this may include resistance to isoniazid, rifampicin and fluoroquinolones.

*Mycobacterium avium complex* refers to infections caused by non-tuberculous *Mycobacterium* species. They may cause localised lymphadenopathy or disseminated infection involving the respiratory or gastrointestinal tract and occasionally cause localised abscess.

### Cryptococcal meningitis

*C. neoformans* is ubiquitous in the environment and is commonly found in the soil and in the excreta of pigeons. Exposure occurs by inhalation of spores leading to primary pulmonary infection followed by secondary dissemination following reactivation of latent infection in an immune-compromised host with haematogenous spread to the meninges.

In patients infected with HIV, meningitis caused by *C. neoformans* occurs in 10% of patients with advanced HIV disease, usually when the CD4 count falls below 50 cells/mm<sup>3</sup>. The incidence has fallen significantly since the introduction of HAART.

The clinical presentation is usually with headache which initially may be mild, fever and drowsiness. Only 30% of individuals present with features of meningism: photophobia, neck stiffness and a positive Kernig's sign. There may be communicating hydrocephalus in 15% because of impaired resorption of CSF by arachnoid villi leading to headache, vomiting, visual impairment and VIth nerve palsy. Multiple cranial nerve palsies may occur secondary to basal meningitis.

In 20% of cases there may be extraneurological involvement with diffuse pulmonary infiltrates, lobar consolidation or cavitating lesions on chest X-ray, skin lesions (small papules which resemble molluscum contagiosum) and infection of the urinary tract.

**Table 9.32** Treatment of cryptococcal infection in HIV positive patient.

**Acute phase therapy** for 4–6 weeks or until CSF culture negative

Amphotericin B 0.7–1.0 mg/kg/day (via central line) and flucytosine 100–150 mg/kg/day p.o.

*In milder cases*

Fluconazole 400 mg IV/p.o. for 8 weeks

**Maintenance treatment**

Fluconazole 200–400 mg/day p.o.

(Side effects: amphotericin B – nephrotoxicity, anaemia, hepatitis; flucytosine – marrow suppression; fluconazole – rash, hepatitis).

Liposomal amphotericin B is associated with a lower risk of renal toxic effects but is more expensive

Brain imaging may be normal or may reveal hydrocephalus, cryptococcomas which are dilated Virchow–Robin spaces filled with the fungal organisms, and basal meningeal enhancement. Measurement of the serum cryptococcal antigen is a useful screening test in those with mild symptoms and, if positive, necessitates imaging and CSF examination. At lumbar puncture, CSF pressure is frequently elevated. In most cases there is a moderate mononuclear pleocytosis, elevated protein and a low glucose; however, in 25%, the CSF may be normal. The diagnosis is established by the identification of India ink positive hypae in 75% and the detection of cryptococcal antigen in 95% of cases. A number of poor prognostic markers have been identified:

- CSF opening pressure >25 cm CSF
- Altered mental status
- CSF cryptococcal antigen titre >1 : 1024
- CSF white cell count <20 cells/mm<sup>3</sup>
- Hyponatraemia.

Amphotericin B with or without flucytosine is the treatment of choice, but in patients with mild disease without any of the poor prognostic markers fluconazole may be considered (as long as *C. gattii* has been excluded). Acute treatment should be continued until the CSF culture is sterile which may take 4–6 weeks, following this, secondary prophylaxis should continue with fluconazole (Table 9.32). HAART should be commenced on complete recovery if the patient was not already receiving this. However, if HAART is started too soon there is a risk of developing IRIS.

Raised intracranial pressure, unrelated to hydrocephalus, should be managed aggressively, as it may result in visual loss, by repeated lumbar puncture with high volume CSF removal and, if required, by the placement of a lumbar or ventricular drain. Acetazolamide may also be used as an adjunct.

### Cytomegalovirus infection

CMV infections of the nervous system occur when the CD4 counts are very low (usually below 50 cells/mm<sup>3</sup>). It is due to reactivation and is usually associated with CMV disease elsewhere in the body.

- CMV encephalitis presents with a rapidly evolving encephalopathy with headache, fever, seizures, change in mental state or cranial neuropathy. There may be hyponatraemia due to adrenal involvement and a brainstem syndrome (retinitis often coexists). Imaging studies have shown a range of abnormalities including a periventriculitis with progressive ventricular enlargement, periventricular enhancement and increased peri-ventricular signal or widely distributed multi-focal, non-enhancing hypodense lesions

**Table 9.33** Treatment of CNS CMV infection in HIV.

<b>Acute phase therapy</b>
Ganciclovir 5 mg/kg every 12 hours for 14–21 days or Foscarnet 60 mg/kg 8-hourly for 14–21 days
<b>Maintenance treatment*</b>
Ganciclovir 5 mg/kg every 24 hours or Foscarnet 90–120 mg/kg/day
(Side effects: ganciclovir – anaemia, leukopenia, thrombocytopenia; foscarnet – renal failure, leukopenia)

\* Consider stopping maintenance treatment if after HAART is started the CD4 remains >200 cells/mm<sup>3</sup> for >6 months.

in the cortex, brainstem and basal ganglia, resembling PML and, rarely, single or multiple ring-enhancing mass lesions with oedema and mass effect.

- CMV retinitis presents with floaters, loss of peripheral vision and central scotoma leading to haemorrhagic infarction, vascular sheathing and retinal opacification. Visual loss is a result of retinal necrosis which may be associated with macular oedema or retinal detachment. Prior to HAART, CMV retinitis was the most common cause of blindness in this group of patients. Typically, patients present with painless visual loss. Fundoscopy shows extensive haemorrhage and necrosis described as a 'ketchup and cheese' appearance.
- CMV lumbosacral polyradiculopathy presents subacutely with back pain and progressive weakness of the legs with sphincter involvement. Radiculomyelitis affecting the lumbosacral area can present with rapidly progressive cauda equina syndrome. The differential diagnosis includes Guillain-Barré syndrome. Imaging studies may be normal or show thickened nerve roots. CSF examination, which is essential to exclude other causes of a polyradiculopathy such as syphilis and lymphomatous infiltration, shows a polymorphonuclear pleocytosis which is unusual in a viral infection, an elevated protein and low glucose. CMV DNA can be isolated from the CSF by PCR. CMV has also been associated with a mononeuritis multiplex, usually in the context of CMV elsewhere such as a retinitis. The diagnosis is confirmed by sural or superficial peroneal nerve biopsy.
- The preferred treatment for CMV is either ganciclovir (or oral valganciclovir, the prodrug) or foscarnet. Cidofovir has also been used (Table 9.33).

### Herpes simplex virus

Herpes simplex virus type 1 (HSV-1) is generally acquired in early life and remains latent in sensory ganglia while HSV type 2 is acquired via contact with infected mucosal surfaces. HSV-1 causes necrotising encephalitis which is usually acute but may evolve over weeks. Onset is with fever, headache, vomiting and seizures. There may be disorientation, memory loss, confusion and personality change. Herpes simplex type 2 (HSV-2) is associated with a diffuse meningo-encephalitis often affecting the brainstem and rarely causes a rapidly progressive myelitis in those presenting with back pain, progressive leg weakness and sphincter disturbance.

CSF PCR is both sensitive and specific for viral DNA but may be negative in the first 72 hours. MRI shows high signal change on T2W imaging in the inferior temporal lobe but this may spread to

involve the parenchyma, cerebellum and diencephalon. In HSV-2 myelitis, MRI shows an oedematous cord.

Treatment is with aciclovir 10 mg/kg three times daily IV over 21 days. If there is a failure to respond or aciclovir resistance ganciclovir or foscarnet are alternatives.

### Varicella-zoster virus

Although dermatomal zoster (shingles) is common in the HIV population, occasionally patients may progress to a severe myelodisculopathy. Following zoster involving the trigeminal nerves, VZV involvement of the small cerebral vessels can cause granulomatous angiitis. The clinical presentation is with headache, progressive focal neurological deficits and seizures. MRI shows multiple abnormalities on T2W images. The CSF is diagnostic with the identification of viral DNA by PCR. Treatment is with high-dose aciclovir and corticosteroids.

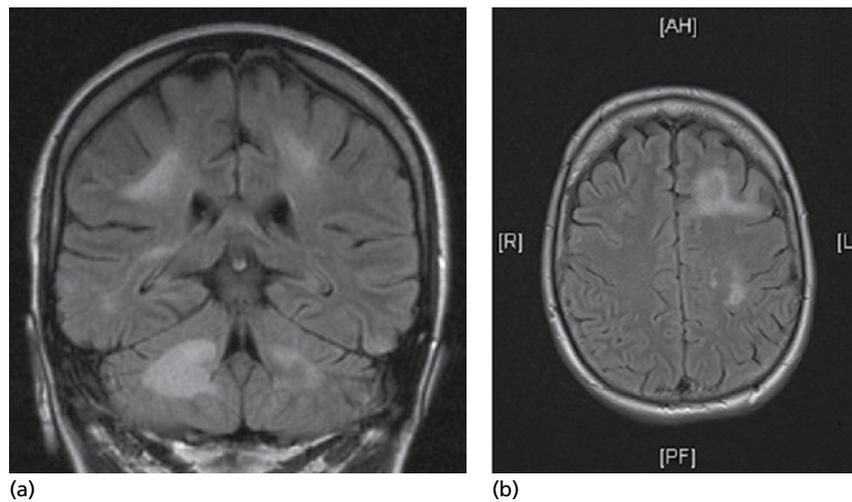

### Progressive multifocal leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is caused by the reactivation of the JC virus (JC; the initials of the patient from whom the virus was first isolated), a common polyoma DNA virus, which infects 75% of the general population. As the virus is frequently excreted in the urine of healthy individuals, primary infection is postulated to occur via the urine-oral route. Primary JC virus infection is asymptomatic and the virus remains permanently in the kidneys, bone marrow and lymphoid tissue.

Because impaired cell-mediated immunity is the major predisposing factor for the development of PML, prior to the AIDS epidemic, the condition was occasionally encountered in patients with lymphoproliferative disorders, sarcoidosis and those treated with immunosuppressive drugs (e.g. after transplant operations and systemic lupus erythematosus, SLE). A marked increase in the incidence of PML is reported in patients treated with monoclonal antibodies (natalizumab, rituximab, efalizumab, alemtuzumab). HIV-induced immunosuppression currently accounts for 85% of cases of PML. Prior to HAART, 5% of AIDS patients developed PML with CD4 counts usually below 100/mm<sup>3</sup>. However, after the introduction of HAART, PML has remained more prevalent than expected and this may be related to increased activation of JC virus by the HIV proteins. The underlying pathology results from replication of the virus within the oligodendrocytes and astrocytes causing lysis and demyelination. It is unclear whether PML results from reactivation of the virus in the CNS following immunosuppression or if it is a result of invasion of the CNS by infected lymphocytes from the peripheral circulation (30% shed the virus in the urine).

The clinical presentation is with a progressive subacute focal deficit which includes hemiparesis, hemianopia or ataxia. Cognitive dysfunction is usually associated with focal neurological signs. Lesions adjacent to the cortex may occasionally result in dysphasia and seizures. Optic nerve involvement occurs rarely but spinal cord involvement does not seem to occur. In contrast to other more common causes of focal lesions found in HIV infected patients such as toxoplasmosis, there are usually no symptoms or signs of systemic infection or raised intracranial pressure. A cerebellar syndrome with isolated cerebellar atrophy on MRI scans may occur, pathological studies show JC virus infection of the granular cells (JC virus granule cell neuronopathy).

Cranial CT shows low attenuation lesions. MRI shows large single or multiple lesions involving white matter, with scalloping at the grey-white interface; the parieto-occipital and frontal lobes are most commonly affected. The affected areas are low signal on

**Figure 9.14** Progressive multifocal leukoencephalopathy: FLAIR coronal and axial images demonstrating multiple regions of white matter hyperintensity both supratentorially and within the posterior fossa.

T1-weighted images and hyperintense on T2-weighted sequences. This may help distinguish PML from HIV dementia. There is no mass effect but contrast enhancement may be seen and has been identified as a good prognostic marker (Figure 9.14).

Early in the AIDS epidemic the diagnosis was only possible by brain biopsy showing the histological demonstration of demyelination, enlarged oligodendrocyte nuclei with JC virus inclusion particles and bizarre enlarged astrocytes. Prior to the HAART era, JC virus DNA could be isolated from the CSF by PCR with a sensitivity of 75% and a specificity of 99%. Since HAART, the sensitivity seems to have dropped to 58% perhaps because of decreased viral replication. The yield can be increased to 85% with repeated CSF examination in PCR negative cases but stereotactic brain biopsy may be necessary.

The treatment of PML in patients with HIV is two-pronged: reversing the underlying immunosuppression with HAART and specific anti-JC virus therapy. Institution of the former has resulted in fourfold improvement in survival, with some patients' neurological status stabilising or improving. A number of drugs such as cytosine arabinoside (araC) given intravenously or intrathecally, alpha interferon and cidofovir have anti-JC virus activity but have not been shown to be of clear benefit. Anecdotal reports have suggested benefit with mirtazapine and mefloquine but more data are required.

### Primary CNS lymphoma

Primary CNS lymphoma (PCNSL) is the second most common cause of mass lesions in adults and the most common in children with AIDS although the incidence has fallen with the introduction of HAART. The incidence of PCNSL in HIV-infected patients is approximately 5%, compared to 1% of the general population, and it accounts for approximately 15% of all non-Hodgkin lymphoma (NHL). Histologically, PCNSL is a high grade, NHL diffuse, large B-cell lymphoma (Chapter 21), less commonly Burkitt's lymphoma may occur and also, rarely, T-cell lymphoma is seen. The Epstein-Barr virus is causally linked to PCNSL, with the identification of the viral DNA incorporated into that of the neoplastic cells. It usually occurs in patients with more advanced HIV infection and a CD4 count usually  $<100/\text{mm}^3$  and a high viral load with plasma HIV RNA levels  $>100\,000$  copies/mL.

The common presenting symptoms are non-specific with headache, focal neurological deficits, cognitive change, altered level of consciousness and seizures. PCNSL remains confined to the central nervous system, but within this space leptomeningeal spread to all compartments including the spinal cord and the anterior chamber of the eye may occur.

Imaging shows single or multifocal enhancing mass lesions, with surrounding oedema, which are predominantly supratentorial and may spread into the white-matter tracts (Figure 9.15). It characteristically involves the corpus callosum, periventricular and peripendymal areas. PCNSL is more likely to present with a single lesion than toxoplasmosis and is also more likely to invade the ventricular walls and exert mass effect. Whole body imaging is indicated to exclude systemic lymphoma. Studies using thallium-201 single photon emission computed tomography (SPECT) suggest that it may be possible to differentiate between an abscess and a tumour with the former having little uptake compared with high uptake of the mitotically active lymphoma. CSF analysis is usually not performed because of raised intracranial pressure but when possible the identification of EBV by PCR is useful diagnostically with a sensitivity of 50–100% and a specificity of 94%.

The diagnosis often depends on the exclusion of other causes of mass lesions (toxoplasmosis, PML, other infective lesions or tumours). There is no effective therapy for PCNSL and most patients succumb within 2–3 months. Radiotherapy may increase survival times by a few months. However, recent data suggest that treatment with HAART can also improve survival times.

A scheme for the diagnosis and management of HIV presenting with focal neurology and  $\text{CD4} < 200$  cells/ $\text{mm}^3$  is presented in Figure 9.16.

### Neurological complications resulting directly from HIV

HIV enters the CNS early in the course of infection. The evidence for this includes the neurological seroconversion illness, the presence of CSF abnormalities in asymptomatic immunocompetent individuals and the presence of HIV DNA in brain pathological studies of asymptomatic HIV-infected patients who died from other causes. In one case of iatrogenic HIV transmission caused by a blood product given intravenously, the patient died 15 days after

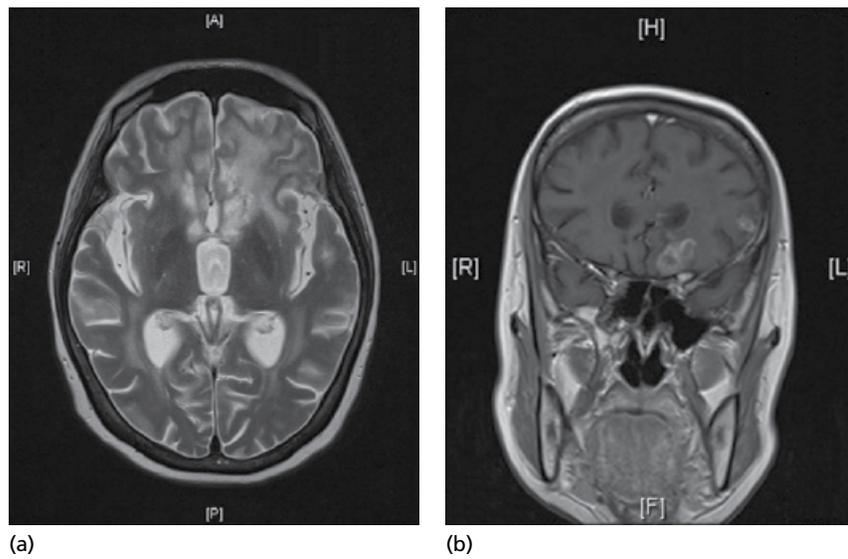

Figure 9.15 High grade primary CNS lymphoma in a patient with HIV: (a) T2 axial; (b) T1 enhanced coronal MRI.

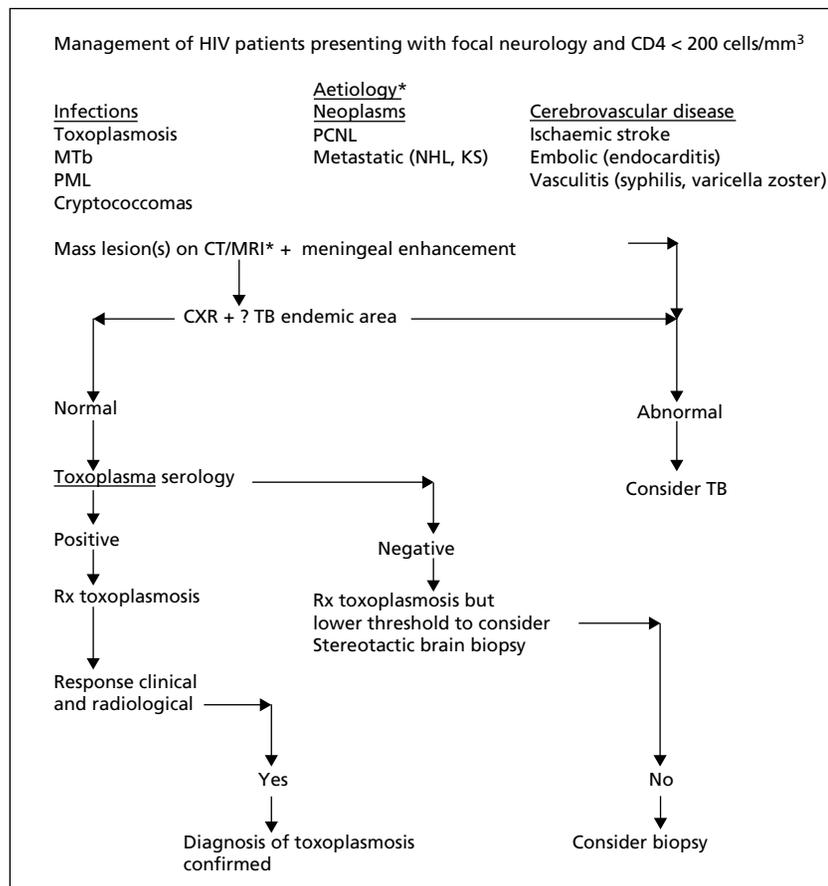

Figure 9.16 Management of HIV patients presenting with focal neurology and CD4 <200 cells/mm<sup>3</sup>. CT, computed tomography; CXR, chest X-ray; KS, Kaposi's sarcoma; MRI, magnetic resonance imaging; MTb, *Mycobacterium tuberculosis*; NHL, non-Hodgkin's lymphoma; PCNL, primary CNS lymphoma; PML, progressive multifocal leukoencephalopathy.

the accident from an unrelated cause. HIV DNA was identified in the brain on day 14.

The mechanism of viral entry into the CNS remains controversial because the blood–brain barrier is an effective physical and metabolic barrier. The most accepted current theory is the Trojan horse mechanism, which proposes that HIV viral entry through the blood–brain barrier occurs via infected macrophages from the peripheral circulation. The choroid plexus, which resides outside the blood–brain barrier, is another potential site of viral entry because the choroid capillary endothelial cells are freely permeable with the stromal cells containing monocytes and macrophages.

Within the brain, neurones and oligodendrocytes are resistant to direct invasion by HIV and infection is localised primarily within the microglial cells and macrophages which are derived from peripheral blood monocytes. HIV does not infect neuronal cells even though neuronal cell death is an important aspect of the neuropathology of HIV dementia. There is some evidence suggesting a low level of astrocyte infection; this may be important because the astrocytic foot processes are an integral part of the blood–brain barrier and a low level of infection may be enough to disrupt functioning of the tight junctions between the endothelial cells. Neuronal damage is usually caused by viral proteins or as a result of chronic inflammation. Although demyelination is also a feature of HIV brain disease, infection of the oligodendrocytes has rarely been reported.

The neurovirulence of HIV occurs later in the course of the disease when immunosuppression develops and HIV acts like an opportunistic infection. It remains uncertain if this is a result of activation of the virus seeded in the nervous system early in the course of disease or trafficking of new HIV viral species from the peripheral circulation, or both. There is no doubt that since the introduction of HAART the incidence of HIV dementia has reduced, suggesting that suppression of HIV in the peripheral circulation has a crucial role.

### HIV-associated neurocognitive disorders

HIV infection is associated with a hierarchy of progressively more severe cognitive dysfunction (HAND). It may be classified as:

- Asymptomatic neurocognitive impairment (ANI)
- HIV-1 associated mild neurocognitive disorder (MND)
- HAD, also called AIDS dementia complex (ADC) or HIV encephalopathy (HIVE).

Because neuronal cells are rarely infected, HAND probably results from the release of inflammatory cytokines such as tumour necrosis factor, quinolinic acid and platelet-activating factor by activated macrophages and microglia as well as toxic viral proteins such as Gp41 and Tat. These neurotoxins affect developing and mature nervous tissue leading to degeneration of synaptic function and contributing to neuronal cell death.

The pathological feature HIVE usually occurs at the grey–white interface, suggesting haematogenous dissemination. The hallmark for HIVE is the presence of microglial nodules which are a fusion of HIV infected and non-infected macrophages. Most infection is demonstrated in the basal ganglia, the brainstem and the deep white matter areas. Other pathological features include a leukoencephalopathy and areas of neuronal cell loss, especially in the hippocampal areas and the frontal and temporal lobes.

In the early stages the clinical features of HAND may be mild, with symptoms of poor concentration, mental slowing and apathy, which may mimic a depressive disorder. Later, as the syndrome progresses, more specific cognitive changes with memory loss and personality change develop. These occur in association with motor

changes such as impaired dexterity and gait problems which result from the associated vacuolar myelopathy and peripheral neuropathy. Examination may show impaired pursuit and saccadic eye movements, generalised hyperreflexia, cerebellar and frontal release signs. HIV-associated psychosis develops suddenly without a prodrome. There may be delusions, hallucinations and mood swings. When psychosis occurs in patients with HAD, it is characterised by prominent agitation, irritability and delusions (AIDS mania).

HAD is a subcortical dementia which occurred in 15% of AIDS patients prior to the introduction of HAART but the incidence has now been reduced by 50%, although the incidence of ANI and MND are probably unchanged or may have increased slightly. Risk factors for the development of HAD include:

- Nadir CD4 count
- Increasing age
- Systemic symptoms, anaemia, low body mass index
- Substance abuse
- Co-infection with other viruses (e.g. hepatitis C)
- Host genetic factors (e.g. E4 isoform of apolipoprotein E, polymorphisms in the TNF alpha promoter and CCR2 genes)
- Viral clade subtypes.

Investigations are indicated to exclude other causes – MRI typically shows evidence of atrophy with diffuse white matter changes on T2-weighted images. The CSF shows non-specific cytochemical abnormalities but must be examined to exclude conditions such as neurosyphilis, CMV and PML. The CSF viral load correlates with severity of dementia but is not sensitive enough for diagnostic purposes. Formal neuropsychological assessments typically reveal abnormalities in the following cognitive domains: psychomotor speed, attention, frontal lobe function and verbal and non-verbal memory.

In patients with cognitive impairment, especially if progressive, it is prudent to first optimise the antiretroviral therapy to render the blood aviraemic. In patients who have an undetectable viral load in the blood, a CSF viral load should be checked in case of the compartmentalisation syndrome and changes made to the antiretroviral treatment using more CSF penetrating drugs.

Pre-HAART, the mean survival rate for patients with HAD was 12 months. With the introduction of HAART, some patients may improve implying some degree of reversibility, some remain static (perhaps because of burnt out brain damage) and some with virological failure may continue to deteriorate. A minority of patients with evidence of viral suppression in the peripheral circulation may continue to deteriorate as a result of ‘compartmentalisation’ with a high viral load in the CSF which will necessitate a change in HAART regimen. There is concern regarding the ability of the currently available antiretroviral drugs to penetrate the blood–brain barrier. The CNS penetration effectiveness (CPE) score has been proposed as a numeric tool to evaluate CNS penetration. The system is arbitrary in that scoring is based upon publications incorporating available pharmacokinetic data, results of clinical studies and drug properties. Although the CPE has been criticised it nevertheless represents an attempt at rationalisation of drug regimens in patients with HAND.

### HIV-related vacuolar myelopathy

Clinically significant vacuolar myelopathy affects up to 10% of patients with AIDS, usually in patients who also have HAD. The condition is characterised by a slowly progressive spastic paraparesis, sphincter disturbance and a sensory ataxia resulting from posterior column involvement. There is no sensory level. Pathological specimens demonstrate a vacuolar degeneration of the white matter

within the thoracic spinal cord similar to that seen in subacute degeneration of the cord resulting from vitamin B<sub>12</sub> deficiency. Although B<sub>12</sub> levels are usually normal, it is possible that a methylation defect is responsible because S-adenosylmethionine is reduced in the CSF of patients with vacuolar myelopathy. This degeneration is not specific to AIDS and has been described in other immunodeficient states and malignancy. As with the other complications of HIV, significant productive HIV infection is not found. However, there is evidence of macrophage activation and increased levels of cytokines. MRI shows increased signal in the white matter tracts on T2 images or may be normal. CSF examination is necessary to exclude viral myelitis resulting from herpes zoster, herpes simplex and CMV although these myelitides tend to be much more acute. Co-infection with HTLV-1, which has a similar mode of transmission to HIV, merits consideration. There is no specific treatment apart from HAART. A small study using 3 g methionine showed some limited benefit but results of larger studies are awaited.

### HIV-related neuropathy

The most common peripheral nerve disorder encountered in association with HIV is distal sensory peripheral neuropathy (DSPN) (Table 9.34). The prevalence rate pre-HAART was estimated at 35% and at necropsy 95% of patients had sural nerve pathological abnormalities. The underlying pathology in DSPN is one of a dying back axonopathy with secondary demyelination. Increased numbers of macrophages are found in the dorsal root ganglia and within the peripheral nerves. HIV RNA is rarely detected in the peripheral nerves and the pathophysiological mechanisms for the development of DSPN are the same as those for HAD (i.e. neurotoxicity of viral proteins such as Gp 120 and tat) as well as a bystander effect of neurotoxic cytokines released by activated macrophages.

Risk factors for the development of DSPN include age, higher viral load and lower CD4 counts. Patients with other risk factors for neuropathy such as diabetes, excess alcohol intake and genetic

neuropathies are more vulnerable. The presentation is with 'painful, burning, numb feet'. Patients also complain of paraesthesiae, dysaesthesiae and allodynia but the upper limbs are rarely involved. Examination may reveal limited weakness, often confined to the intrinsic foot muscles. The reflexes may be normal, depressed or absent. There is characteristically impaired sensation to pain and temperature but subsequently other modalities are involved. Nerve conduction tests (NCTs) may be normal or show mild axonal abnormalities. Thermal thresholds are abnormal indicating small fibre involvement. Punch skin biopsies with the assessment of epidermal nerve fibre densities are increasingly being utilised in diagnosis and treatment trials of DSPN. In atypical cases where, for example, there is more extensive weakness with foot drop or significant upper limb involvement clinically or on NCTs, CSF examination and nerve biopsy should be considered to exclude vasculitis, demyelinating neuropathies and lymphomatous infiltration.

The treatment of DSPN is symptomatic – only lamotrigine and recombinant human nerve growth factor have been shown to be effective in relieving the pain of DSPN in randomised placebo controlled trials. Gabapentin, although often used, has only been shown to be effective in small trials. Amitriptyline, although not proven to be effective in placebo controlled trials, has a role in individual patients starting at low doses. Mexiletine, acupuncture and topical capsaicin have not shown benefit.

A form of mononeuritis multiplex may occur either as an early and mild self-limiting condition with CD4 > 200 cells/mm<sup>3</sup> or in association with severe immunosuppression and CMV infection. There may be multifocal cranial nerve or limb involvement. Neurophysiology studies confirm a patchy axonal neuropathy and nerve biopsy shows an endoneurial or epineurial perivascular inflammatory infiltrate with axonal degeneration. The neuropathy may respond to treatment with corticosteroids.

### Diffuse inflammatory lymphocytosis syndrome

Some patients respond to HIV infection by developing diffuse inflammatory lymphocytosis syndrome (DILS), a syndrome characterised by a persistent circulating CD8 lymphocytosis with visceral lymphocytic infiltration particularly affecting the salivary glands. This multisystem disorder resembles Sjögren's syndrome, although anti-Ro/SS-A and anti-La/SS-B antibodies are absent. Patients present with salivary gland enlargement, xerostomia, keratoconjunctivitis sicca, uveitis and lymphocytic pulmonary, gastrointestinal and renal involvement. An uncommon form of HIV-associated neuropathy is seen in DILS which is eminently treatable with antiretroviral drugs and corticosteroids. The peripheral nerve complications present with a painful sensorimotor neuropathy which may be symmetrical or asymmetrical. Neurophysiological studies show an axonal neuropathy although rare cases of demyelination are reported. The CD4 counts are variable but the CD8 counts are consistently high, resulting in a low CD4 : CD8 ratio. The diagnosis is confirmed at nerve biopsy which shows angiocentric CD8 T-cell infiltration in endoneurium and epineurium.

### Toxic neuropathy for antiretroviral drugs

The nucleoside reverse transcriptase inhibitors (NRTIs) didanosine (ddI), zalcitabine (ddC) and stavudine (d4T) have all been shown to cause a dose-dependent peripheral neuropathy but an association with lamivudine (3TC) is not well documented. Although their use in industrialised countries is now infrequent, in view of their low cost they are increasingly used in resource-poor settings. Mitochondrial toxicity from inhibition of the DNA polymerase

**Table 9.34** Peripheral nerve complications in HIV infection.

HIV related	Axonal neuropathy (DSPN) Demyelinating neuropathy (GBS and CIDP) Vasculitic neuropathy Diffuse inflammatory lymphocytic syndrome Mononeuritis multiplex Lower motor neurone syndrome (resembling MND)

Drugs	Antiretroviral drugs (ddl, ddC, D4T) Isoniazid (treatment of TB) Thalidomide (treatment of mouth ulcers) Dapsone (treatment and prophylaxis of toxoplasmosis and <i>Pneumocystis jirovecii</i> ) Vincristine and vinblastine (treatment of KS and lymphoma) Paclitaxel (Taxol) (treatment of KS)
Others	Syphilis (polyradiculopathy) Metastatic NHL Dorsal root ganglionitis Autonomic neuropathy

CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; DSPN, distal sensory peripheral neuropathy; GBS, Guillain-Barré syndrome; KS, Kaposi's sarcoma; MND, motor neurone disease; NHL, non-Hodgkin's lymphoma; TB, tuberculosis.

enzyme may be the underlying mechanism for the neuropathy and the same mechanism may also account for the other side effects of this class of drug – pancreatitis, fulminant hepatic failure, lactic acidosis and lipodystrophy. The clinical presentation of toxic neuropathy for antiretroviral drugs (TNA) is similar to that seen with DSPN. The drug-related neuropathies are, however, more likely to be painful, have an abrupt onset and progress rapidly. After stopping the appropriate drug, there may be a paradoxical worsening of neuropathic symptoms over a period of 4–8 weeks (coasting). An improvement of symptoms may occur in some patients but a number may be left with underlying DSPN which has been unmasked by the TNA.

As with DSPN, the management of this group of patients can be difficult. The development of this painful sensory neuropathy is a significant cause of morbidity and poor drug compliance. If the patient is on a neurotoxic drug, the issue of stopping it needs to be discussed with their HIV physician. In practice, this maybe a difficult decision if there has been a good virological response and the CD4 count has risen significantly as lowering the drug dosage risks the possibility of viral drug resistance. Treatment is otherwise symptomatic. One small study has shown acetylcarnitine improves neuropathic pain scores and epidermal skin nerve fibre densities.

### HIV-associated myopathy

An immunologically mediated polymyositis may occur at seroconversion or during the asymptomatic phases of the disease. As with non-HIV patients, the subacute illness manifests with proximal weakness, myalgia, and myopathic changes on EMG studies but the patients tend to be younger and the CK levels are lower. The disorder is usually steroid responsive. The inflammatory infiltrates found on muscle biopsy are similar to HIV – negative polymyositis with endomysial infiltrates of cytotoxic CD8+ T cells and MHC-I expression but there is a reduction of CD4-positive T cells. Zidovudine (AZT), an NRTI introduced in 1986, causes a mitochondrial myopathy. Muscle biopsies show ragged red fibres and muscle mitochondrial DNA levels are significantly depleted. Patients improve when the drug is stopped. This complication is now rare since the drug doses have been reduced from 1000–1500 to 600 mg/day.

### Motor neurone disease

Anecdotal case series have described an association between motor neurone disease (MND) and HIV infection. Motor neurone loss is caused by viral proteins or by immune activation but the relationship to HIV remains uncertain. The clinical pattern may be similar to non-HIV MND but some patients have a more indolent course and an exclusively lower motor neurone pattern of disease often in a segmental distribution (e.g. flail upper limbs). The incidence and progression are not related to the CD4 counts or viral load and the response to HAART is often poor.

### Immune reconstitution inflammatory syndrome

IRIS is a paradoxical worsening of pre-existing infectious processes following the initiation of HAART in HIV-infected individuals. It has been defined as the paradoxical deterioration of clinical or laboratory parameters including imaging studies, despite a favourable response of the HIV surrogate markers (i.e. viral load and CD4 count) to HAART. Some 10–25% of patients on HAART may develop IRIS, which usually occurs within the first 2 months although more chronic forms of IRIS with a long duration between the initiation of antiretroviral therapy and the development of the first symptoms may occur. IRIS develops in the setting of treatment of HIV with immune restoration leading to the recovery of CD4 T lymphocytes and memory T cells. After initiation of HAART, plasma HIV RNA levels fall to less

than 10% of pre-therapy levels within 2 weeks. In parallel a biphasic increase in CD4 T lymphocyte count occurs. When this process of immune reconstitution develops in the presence of an antigenic stimulus (either a foreign or self-antigen), the immune reaction to the antigen may be excessive and pathological leading to IRIS. Risk factors in the development of CNS – IRIS include:

- Low CD4 nadir (<50 cells/mm<sup>3</sup>)
- Rapid fall in viral load following initiation of HAART
- Underlying opportunistic infection
- Genetic factors.

In the presence of an existing opportunistic infection IRIS may either occur because the underlying opportunistic infection becomes ‘unmasked’ after immune restoration or because immune restoration leads to a devastating T-cell mediated encephalitis with infiltration of the brain by activated T cells in an attempt to control the underlying CNS infection. The inflammatory cell infiltrate is composed predominantly of CD3 and CD8 T cells with scattered CD68 macrophages. No CD20 B cells are seen. CD3 and CD8 T cells are also seen in increased numbers in the white matter, away from the blood vessels. Both forms of IRIS are associated with enhancing MRI lesions due to breakdown of the blood–brain barrier.

Several different pathogens have been associated with the development of IRIS, the most serious being *Mycobacterium*, *Cryptococcus*, *Pneumocystis* or viruses (HSV, VZV, CMV, EBV, hepatitis B and C and JC virus).

In neurological IRIS with co-existing *M. tuberculosis* there may be meningitis and abscesses in addition to systemic manifestations. IRIS resulting from reactivation of *M. avium* may cause paravertebral and brain abscesses. Following previous cryptococcus infection, IRIS may cause a recurrence of meningo-encephalitis or cavitating lung lesions leading to respiratory failure. IRIS due to prior cytomegalovirus infection leads to the development of vitritis, uveitis and cystoid macular oedema with visual loss. Unmasked PML IRIS resulting from pre-existing infection with JC virus is the most devastating form of the disease as no antiviral agent is available to treat JC virus. It is associated with CD4 counts <200/mm<sup>3</sup>. IRIS-induced cases of PML demonstrate gadolinium enhancement on MRI and biopsy shows extensive inflammatory infiltrates and demyelination. Occasionally, IRIS occurs without a clear pathogen; it may then be associated with sarcoid-like granulomatous lesions in the lungs or an autoimmune diathesis with patients developing disorders such as thyroiditis, SLE, polymyositis and rheumatoid arthritis.

Systemic IRIS is usually mild and self-limiting with the majority of cases occurring within 3 months after the initiation of HAART. Neurological presentation of IRIS is much less common than systemic IRIS, with an estimated incidence of <1%.

The management of neurological IRIS consists of treating any identified opportunistic infection and corticosteroids for the inflammatory component. HAART should be initiated early in the course of AIDS, despite the risk of IRIS, because it reduces mortality and it should also be initiated within 2 weeks of commencing therapy for opportunistic infections. If IRIS develops after commencing HAART the question of whether to stop or continue treatment is controversial. In most cases it is reasonable to continue HAART providing the IRIS is not serious or there is little risk of permanent sequelae. However, if there is a life-threatening complication such as a mass lesion within the brain, HAART should be discontinued for a period of time. Corticosteroids (prednisolone 1 mg/kg/day; maximum dose 60–80 mg) or other non-steroidal anti-inflammatory agents may decrease the inflammatory response. Prevention of IRIS may be possible by identifying potential opportunistic infections 1 or 2 months prior to commencing HAART.

## Conclusions

Since the onset of the AIDS epidemic, tremendous strides have been made in unravelling the immunobiology of HIV; the development of the antiretroviral drugs which have made HIV a chronic medical disorder rather than an inexorably fatal one; identifying and treating the opportunistic complications with better diagnostic and therapeutic options. However, these benefits have not to date reached the areas of the world most affected by the epidemic. From the neurology point of view, toxic neuropathy continues to pose problems although less so since the use of d-drugs has declined at least in resource-rich settings. Although the incidence of HAD has declined, as a result of increased longevity, the prevalence has increased. There is concern regarding effective CSF penetration of drugs, which is currently being addressed as is the issue of ongoing cognitive decline despite undetectable virus in the blood. This could be a result of drug neurotoxicity, a low grade inflammation that is triggered when immunosuppression supervenes (HAND legacy) and continues despite adequate antiviral treatment or to a persistent low grade IRIS phenomenon. Neurological IRIS mainly associated with PML and HIV itself has also proved difficult to diagnose and manage.

<sup>1</sup>National Hospital for Neurology & Neurosurgery

<sup>2</sup>UCL Institute of Neurology

Neuromuscular diseases have traditionally been overlooked, underdiagnosed and poorly treated when compared with neurological diseases with greater visibility (e.g. Parkinson's disease or epilepsy), social impact (such as the dementias) or which pose a threat for survival (e.g. brain tumours or meningitis). However, neuromuscular disorders are diverse and extremely common, possibly accounting for up to 40% of neurological diagnoses. They may lead to significant disability or death. The accurate and early diagnosis of a cause may lead to effective treatment, reduction in disability and improved quality of life.

This chapter provides a comprehensive summary of disorders of peripheral nerve, neuromuscular junction, muscle and the anterior horn cell.

### Peripheral nerve disorders

An understanding of the many peripheral nerve disorders relies upon a comprehension of the complexities of the macro- and micro-anatomy of peripheral nerves, their molecular biology, immunology and pathophysiology. Much of this is beyond the scope of this chapter but a short synopsis is provided here.

#### Macro-anatomy of the peripheral nerve

Peripheral nerves are bundles of axons, Schwann cells, elaborated myelin and the supporting cellular tissues whose primary purpose is to communicate neural information between the central nervous system (CNS) and peripheral sensory or effector structures (e.g. muscles, sweat glands, blood vessels). In very simplified terms, the peripheral nervous system (PNS) functions via a series of reflex arc circuits with efferent and afferent arms controlled from above by the CNS (Figure 10.1).

The anatomy of the major nerve trunks and their connections has been known for more than 500 years, even if there was little understanding of their function (Figure 10.2). The PNS consists of 10 of the 12 cranial nerves and the spinal roots, becoming the peripheral nerves, exiting from the spinal cord. Knowledge of basic peripheral neuroanatomy, physiology and immunology is the key to understanding the pathophysiology of diseases affecting peripheral nerves.

### Upper limbs

The brachial plexus is formed from the anterior rami of the spinal roots from C5 to T1 (Figure 10.3). Within the course of the brachial plexus, axons originating from these cervical roots are rearranged and exit in major and minor nerve branches to supply sensory, motor and autonomic inputs and outputs to the upper limb and shoulder girdle (Table 10.1a; Figure 10.4). Many find the localisation of processes affecting the brachial plexus or cervical roots difficult but it is simplified by an understanding of the anatomy. The identification of affected muscle groups and sensory territories assist.

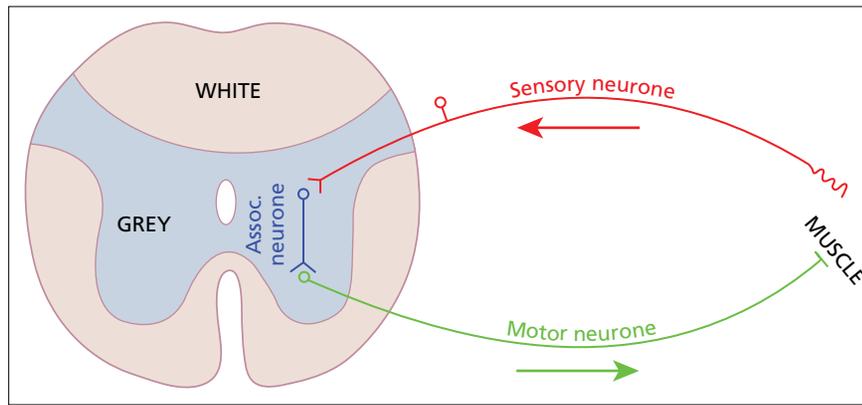

The major nerves leaving the brachial plexus are the musculocutaneous, median, ulnar and radial nerves (Figure 10.4). Each nerve has its innervated muscles, although there are occasional anatomical variations.

### Lower limbs

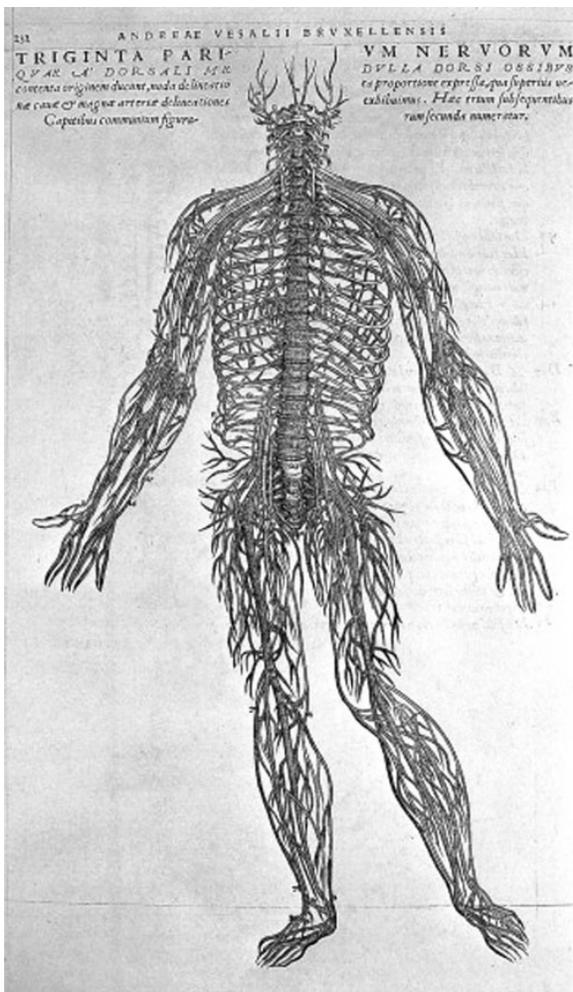

The lumbosacral plexus is formed from the ventral rami of L1–S4 nerve roots (Figure 10.5). The upper (or lumbar) part of the plexus gives rise to the obturator and femoral nerves. The lower part of the plexus gives rise to the sciatic nerve, which is regionally organised in its cross-section, and this later divides into the tibial and common peroneal nerves at the knee. As with the brachial plexus, some smaller nerves exit the plexus directly (e.g. the genitofemoral and lateral cutaneous nerve of the thigh). The major nerves of the lumbosacral plexus innervate individual muscles as indicated in Figure 10.5 (see also Table 10.1b). An ability to identify which muscles or areas of skin innervation are affected on clinical and neurophysiological examination and to correlate this to the anatomical innervation is central to being able to make successful peripheral nerve diagnoses (Figures 10.6 and 10.7).

#### Micro-anatomy of the peripheral nerve

Each peripheral nerve comprises a collection of neurones and their bundles of axonal processes, supporting cells, blood vessels, connective tissue and other elements including cells of the immune system (e.g. macrophages and mast cells). An axon and its supporting cells (an axon–Schwann cell unit) are often referred to as nerve fibre. A fascicle is a group of nerve fibres with associated endoneurial elements enclosed in ensheathing perineurium. A nerve is a collection

**Figure 10.1** The reflex arc is the foundation of peripheral nerve function. Although highly stylised, peripheral stimuli enter the arc along the afferent limb and exit to effector organs along the efferent limb. Responses may be modified by synaptic connections along this pathway.

**Figure 10.2** Vesalius, 1543. Source: Wellcome Library, London. Reproduced under the terms of the Creative Commons CC-BY-4.0 licence.

of fascicles surrounded by supportive and protective epineurium. Apart from post-ganglionic neurones of the autonomic nervous system, all PNS axons have a CNS extension or origin where the axonal and support matrix characteristics are different.

### Peripheral nerve compartments

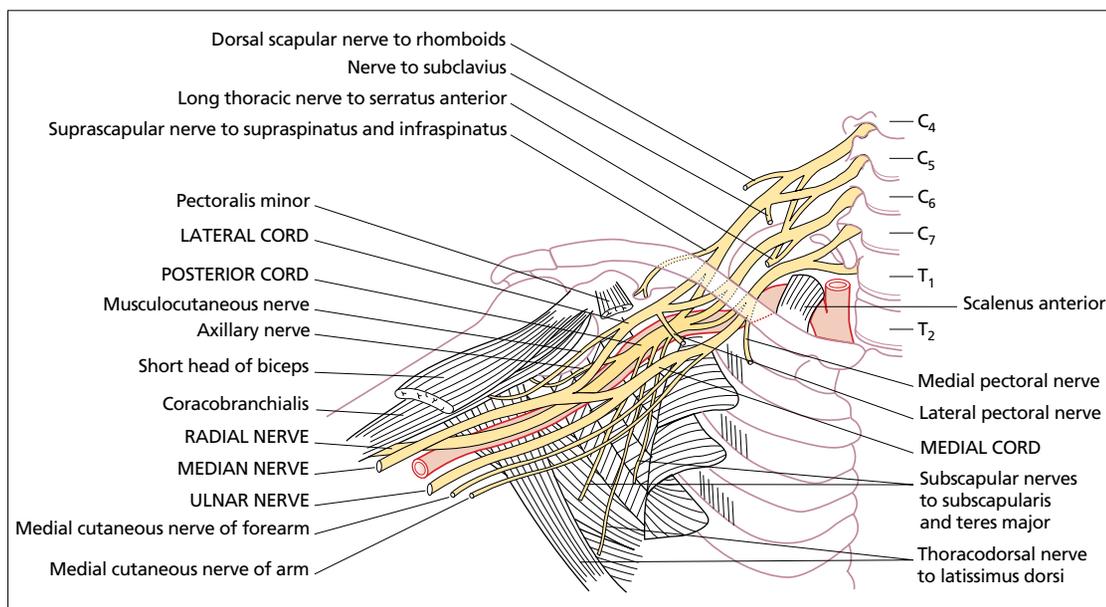

The peripheral nerve is divided into distinct compartments easily visible when cross-sectioned nerves are examined under the light microscope (Figure 10.8). The compartmentalisation of the peripheral nerve provides several layers of protection able to resist physical and immunological attack. Axons are protected from most immune reactions that might otherwise interfere with effective electrical impulse transmission.

The outer layer of epineurium is composed of loosely packed collagenous connective tissue containing adipocytes, fibroblasts, collagen and mast cells and serves to provide tensile strength and resist impact and trauma. The perineurium is a tight sleeve of flattened cells separated by collagen within the epineurium, and surrounds each individual nerve fascicle. The specialised flattened fibroblasts, connected by occlusive tight junctions, form an effective barrier to diffusion of macromolecules between the epineurium and endoneurium.

The endoneurium is a tissue space containing connective tissue, axon–Schwann cell units, pericytes, fibroblasts, macrophages and mast cells. The blood vessels in the endoneurium have a specialised endothelium which forms tight junctions and is also impermeable to macromolecules. There is no endoneurial lymphatic drainage. The endoneurial space is bathed in endoneurial fluid, the composition of which betrays the specialised protection afforded to this space. The electrolyte composition is that of extracellular fluid to enable electrical nerve conduction but the protein and immunoglobulin content is some 250 times less than that found extracellularly. The fluid is under positive pressure. This unique set of characteristics is possible because the perineurium and the specialised endoneurial endothelium form a blood–nerve barrier (BNB) that is relatively impenetrable to cells and macromolecules under normal conditions. Any active transcellular traffic of essential substances through the perineurium and into the endoneurium probably occurs in pinocytotic vesicles.

### Immunology

The peripheral nerves are isolated behind the BNB which provides relative protection from circulating immune factors and perturbations of homeostasis. Not only is the endoneurium physically protected from outside attack, but it is also relatively deficient in the immunological machinery with which to make an internal immunological response. A few macrophages constitutively displaying major histocompatibility complex (MHC) Class II are found within

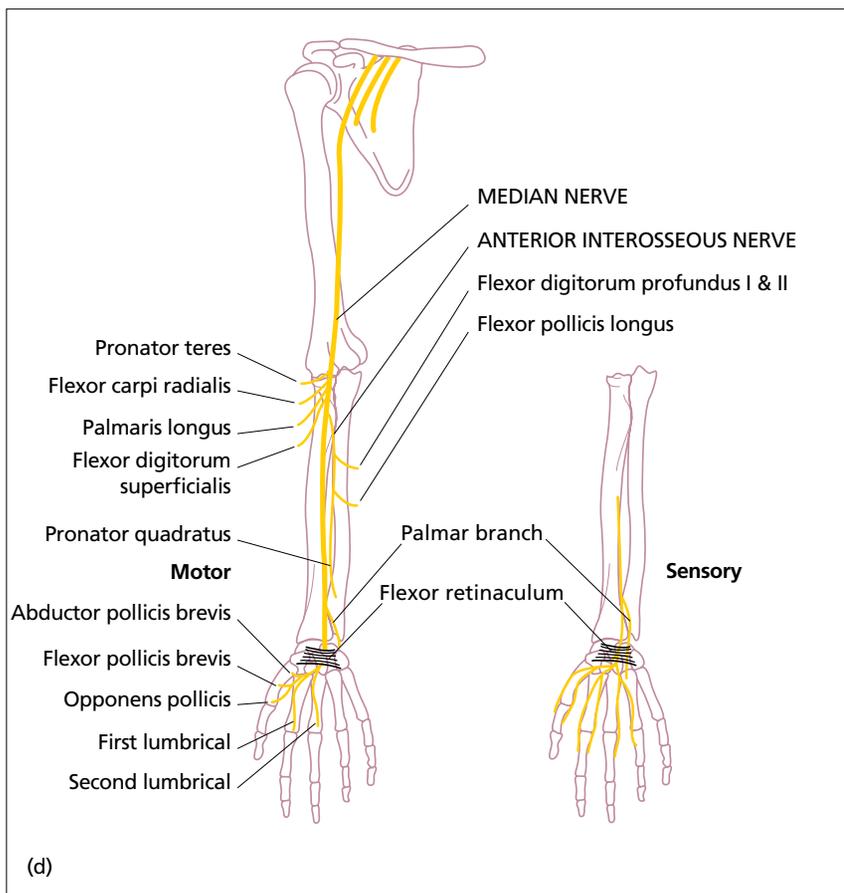

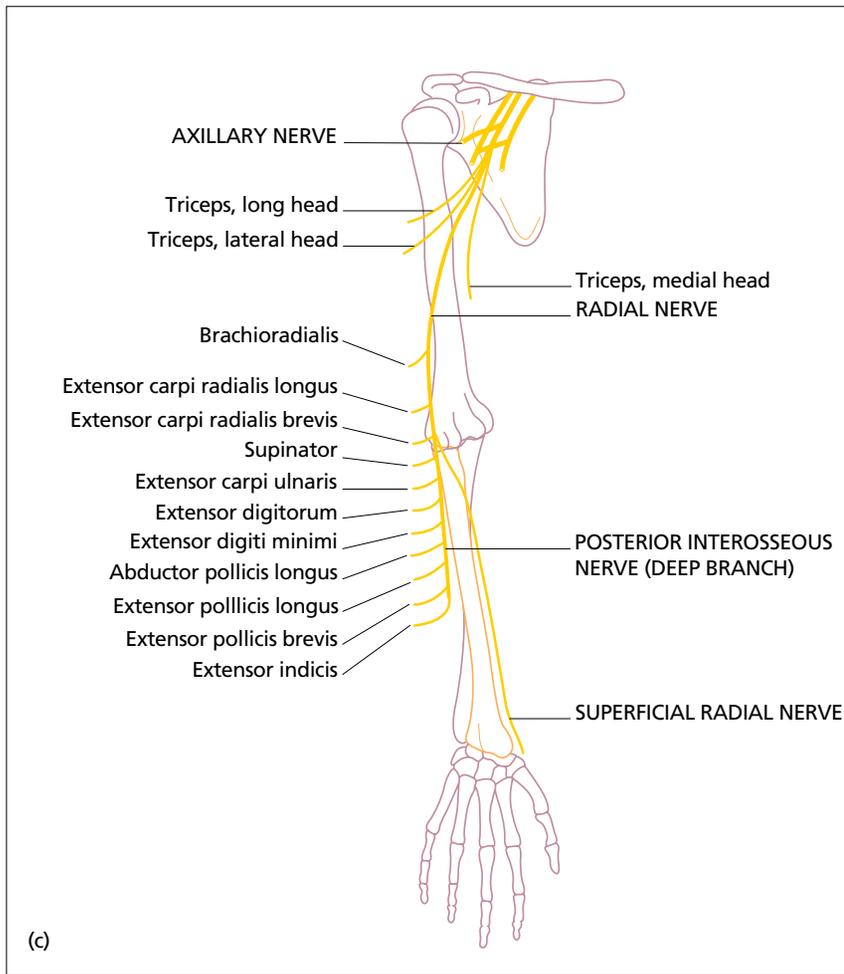

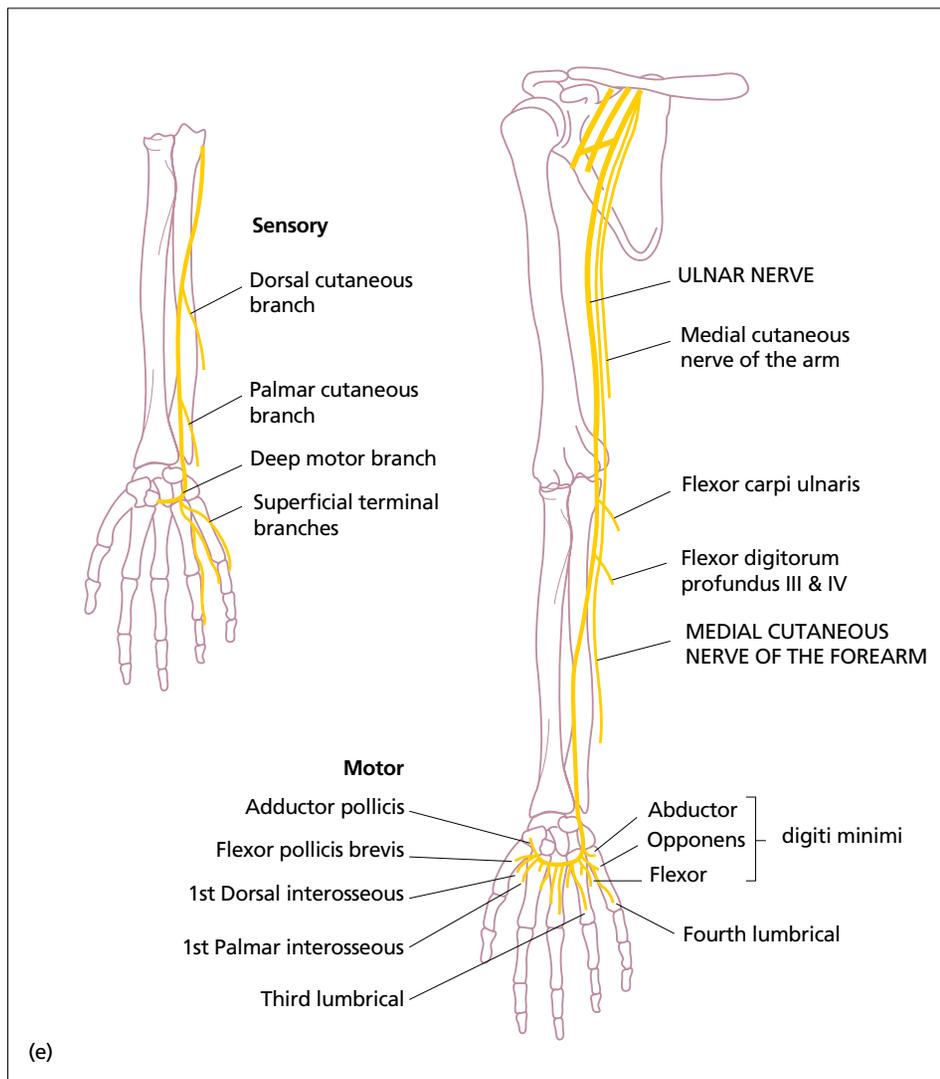

Figure 10.4 (continued)

**Figure 10.4** (continued)

the endoneurium and Schwann cells do not usually express MHC markers. Only very limited T-cell traffic occurs into and out of the endoneurium under normal conditions. Restricted access and egress of cells and molecules, raised endoneurial pressure, low constitutive MHC expression and limited patrol by cells of the immune system all contribute to antigen sequestration in the PNS and the relative BNB.

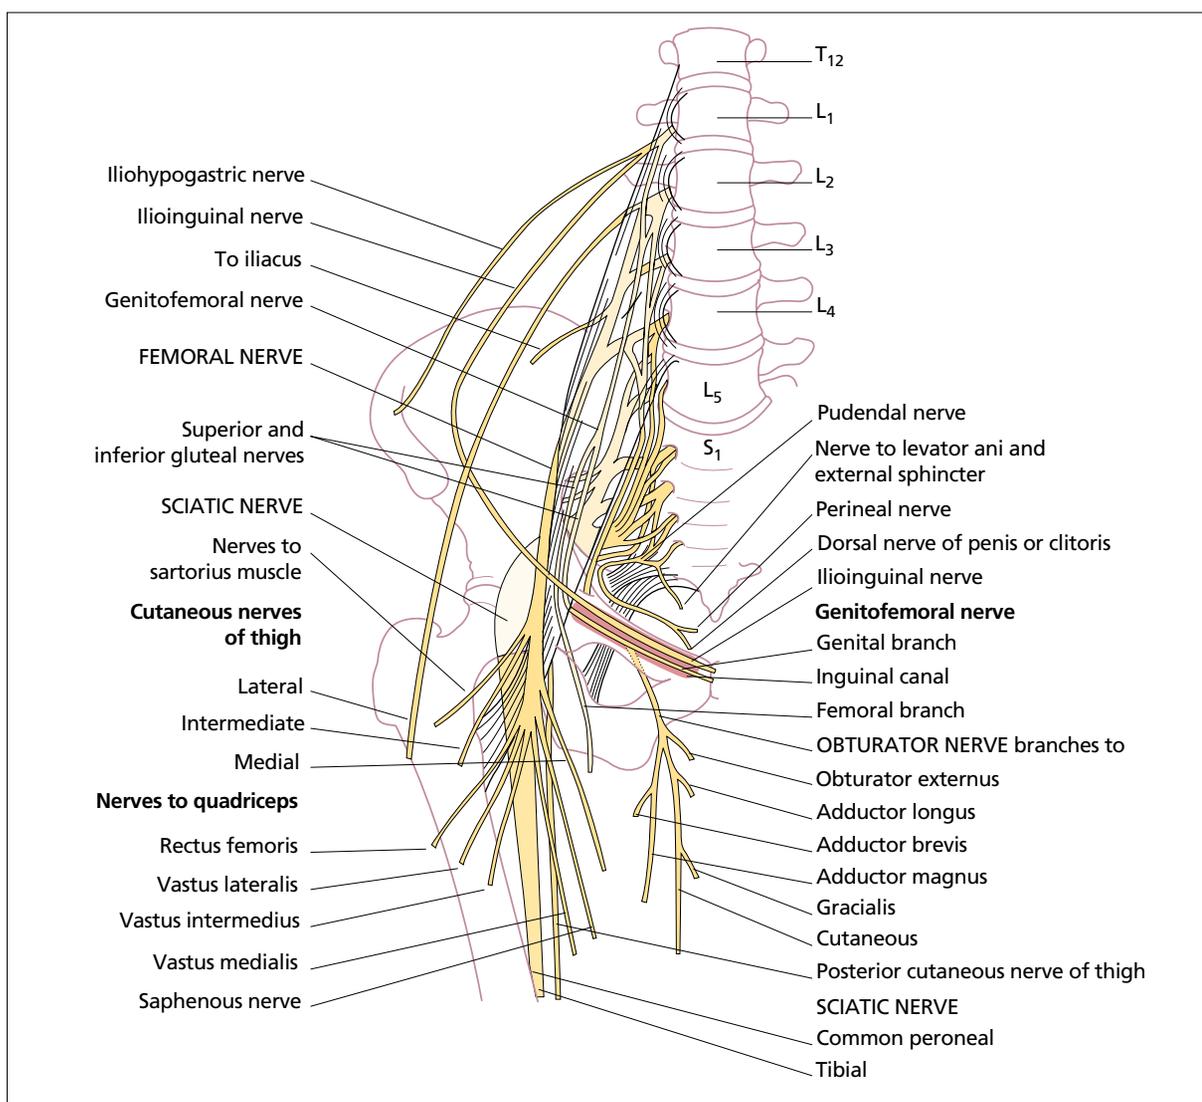

The physical characteristics of the BNB are not the same throughout the PNS. The barrier is relatively deficient at the trigeminal and dorsal root ganglia (DRG), the motor nerve terminals and the sensory endings. MHC Class II expression is up-regulated at the DRG as a result of continuous immune stimulation because of the physical deficiency and the need to patrol more effectively for invading pathogens. In some neuropathies these are the preferred sites for immune attack and development of pathology.

### Pathophysiology of the peripheral nerve

All PNS axons are ensheathed by Schwann cells and the Schwann cells are, in turn, invested by a continuous layer of basal lamina. Schwann cells surrounding smaller axons (0.5–1.5  $\mu\text{m}$ ) do not

elaborate myelin and one Schwann cell may surround several unmyelinated fibres (a Remak bundle). Those surrounding axons of larger calibre (1–20  $\mu\text{m}$ ) wrap a single axon only and form a tightly compacted multi-lamellar myelin sheath. Myelin is a lipid-rich specialised extension of the Schwann cell membrane in the PNS (and of oligodendrocytes in the CNS). Although broadly similar in structure, PNS differs from CNS myelin in its molecular composition (Chapter 2).

The pathophysiological mechanisms that result in peripheral neuropathies are almost as diverse as the number of peripheral nerve diagnoses. However, the patterns of damage at a microscopic level are few. Axonal degeneration occurs distal to a site of nerve transection (which may be physical, inflammatory or vascular; and focal, multi-focal or diffuse). Axonal degeneration can also occur as a distal dying back phenomenon especially in toxic, metabolic and hereditary neuropathies. The primary pathology in the most common hereditary neuropathies is demyelination which classically is uniform. In many inflammatory neuropathies segmental demyelination occurs which may result in conduction failure but not necessarily subsequent axonal degeneration. Remyelination

**Figure 10.5** Diagram of the lumbosacral plexus, its branches and the muscles that they supply. Source: O'Brien 2000. Reproduced with permission of The Guarantors of Brain.

(with thin myelin, short internodes and onion bulbs) may occur, restoring adequate clinical nerve function. Axonal regeneration occurs less consistently and over distances of centimetres only.

## Diseases of the peripheral nerve

Diseases of the peripheral nerve can be genetic or acquired. The acquired neuropathies may be primary or secondary to other conditions. The initial clinical approach is similar in all peripheral nerve disorders.

### General approach to peripheral nerve disease

#### History

Patients with peripheral nerve disease complain of sensory disturbances, muscle weakness or wasting, sometimes fasciculation and cramping and/or symptoms referable to the autonomic nervous system.
