**Gaucher disease** Gaucher disease is caused by deficiency of glucocerebrosidase leading to the accumulation of glucosylceramide within lysosomes. As with other LSDs, a broad spectrum of severity is seen in Gaucher disease. Severe mutations that inactivate the glucocerebrosidase enzyme completely are not compatible with life and result in hydrops fetalis. Where there is minimal residual enzyme activity, glucosylceramide accumulates in a wide range of cell types, including neurones, and affected infants suffer a rapidly progressive neurological deterioration, so-called type 2 Gaucher disease. In most patients, there is sufficient residual enzyme activity to fully degrade all glucosylceramide in most cell types, including neurones. Significant storage is only observed in macrophages, which are exposed to a much greater load of GSL than other cells because of their role in phagocytosing senescent erythrocytes. These patients therefore have visceral disease resulting from infiltration of the liver, spleen and bone marrow with lipid-laden macrophages, but they do not have neurological involvement. These patients have type 1 Gaucher disease.

Between these two extremes are a group of patients with often severe visceral disease that is accompanied by more slowly progressive neuropathic disease, traditionally termed type 3 Gaucher disease. These patients often present in childhood with a horizontal supranuclear gaze palsy. In more mildly affected patients this may be the only neurological manifestation, but a wide variety of other syndromes have been reported including myoclonic epilepsy, ataxia and dementia.

More recently, it has been shown that there is a strong association between parkinsonism and heterozygosity for mutations in the glucocerebrosidase gene. The nature of this association is not clear but it seems unlikely to relate to storage of glucosylceramide as the association seems to be stronger for heterozygotes than for homozygote patients who have Gaucher disease.

Gaucher disease was the first lysosomal storage disorder for which enzyme replacement therapy (ERT) became available. Enzyme replacement therapy involves the intravenous infusion of recombinant glucocerebrosidase. This is efficiently taken up by Gaucher macrophages and is a highly effective treatment for non-neuropathic Gaucher disease. However, because the recombinant molecule cannot cross the blood–brain barrier, enzyme replacement therapy has not been effective in treating neuropathic disease.

**Fabry disease** This is an X-linked disorder caused by a deficiency of the lysosomal enzyme  $\alpha$ -galactosidase A, the gene for which is localised at Xp22. This results in the accumulation of ceramide trihexoside (CTH) in many cell types. It is a multi-system disease affecting the heart, kidney and blood vessels. Stroke can be the first clinical manifestation. As in other X-linked diseases, men are generally, but not always, more severely affected than women.

Clinical symptoms usually develop in early adolescence with the initial manifestation often being the development of acroparaesthesiae with severe pain in the hands and feet, commonly triggered by hot weather or pyrexia. Angiokeratoma, hypohidrosis, irritable bowel syndrome, and corneal and lenticular abnormalities are other common features. Progressive renal, cardiac and cerebral involvement then develops. CNS involvement manifests as an increased risk of ischaemic stroke because of the involvement of the cerebral vessels

or secondary to cardiac disease. There is a predilection for the vertebro-basilar system with posterior circulation stroke manifesting as hemiparesis, vertigo, diplopia, nystagmus, dysarthria or ataxia.

Diagnosis in men depends on the demonstration of reduced  $\alpha$ -galactosidase A enzyme activity in plasma leukocytes or dried blood spots. This test is not useful in women, where genotyping is the investigation of choice. In some cases being investigated for renal impairment, kidney biopsy may show intralysosomal lipid deposition.

Classic Fabry disease has a poor prognosis, with most untreated males dying by the age of 40 years, generally from renal failure although cardiac and cerebrovascular disease can also cause fatal complications. With increased disease awareness, many patients with attenuated phenotypes are now being diagnosed who may not have severe end organ involvement. Life expectancy is reduced only slightly in heterozygous female patients.

**Management** Carbamazepine, gabapentin, pregabalin or even low doses of opiates are useful for the symptomatic treatment of the painful acroparaesthesiae. Progressive renal failure may require dialysis or transplantation. Angiokeratomata are generally asymptomatic but can be treated by laser coagulation of small and medium sized vessels. Conventional stroke protection with antiplatelet drugs or anticoagulation may have a role. Enzyme replacement therapy has been developed to treat the condition. Some symptoms may respond, but it is not as effective as enzyme replacement therapy for Gaucher in patients with established disease. It is hoped that if enzyme replacement therapy is started early enough, it may be able to prevent the long-term complications.

**GM<sub>2</sub> gangliosidosis** GM<sub>2</sub> gangliosidosis is caused by mutations in the genes encoding the subunits of  $\beta$ -hexosaminidase (an  $\alpha\beta$ -heterodimer). Mutations of the *HEXA* gene lead to Tay–Sachs disease and of the *HEXB* gene to Sandhoff disease.  $\beta$ -hexosaminidase cleaves the terminal galactose residue from GM<sub>2</sub> ganglioside. As GM<sub>2</sub> ganglioside is predominantly expressed in neurones, the GM<sub>2</sub> gangliosidoses are predominantly neurodegenerative disorders.

As with the other lysosomal storage disorders, there is a spectrum of disease severity. The classic infantile forms present within the first 6 months of life with seizures, blindness and developmental delay and are rapidly fatal. Although rare in the general population, certain ethnic groups have much higher incidences. In Ashkenazi Jewish populations, where the carrier frequency for Tay–Sachs disease is 1/30 (compared with 1/300 for the general population), carrier screening programmes have dramatically reduced the numbers of babies affected.

The late onset forms of GM<sub>2</sub> gangliosidosis can present in childhood or adulthood with gait problems, dystonia, cognitive decline and pronounced bulbar involvement. The disease is slowly progressive and patients eventually succumb to complications such as respiratory infections secondary to dysphagia.

The diagnosis is made by assaying the activity of  $\beta$ -hexosaminidase in peripheral blood leukocytes. Brain imaging shows striking cerebellar degeneration which is secondary to loss of Purkinje cells. Histologically there is neuraxonal dystrophy, characterised by the formation of axonal spheroids and meganeurites with ectopic dendritogenesis, which is also seen in other lysosomal storage disorders in which there is ganglioside storage within neurones.

**Management** Currently, therapy is supportive. Substrate reduction therapy with miglustat has been shown to prolong life in a knockout mouse model of Sandhoff disease but a clinical trial in patients with late onset Tay–Sachs disease showed no benefit.

## Adult onset inherited leukodystrophies

This complex set of inherited conditions have as their hallmark the progressive destruction or loss of myelin. The adult forms of disease can be an attenuated or frankly different phenotype from that reported in childhood. Reported prevalence varies from 40/million (X-linked adrenoleukodystrophy) to case reports (e.g. Nasu–Hakola disease), with perhaps a total of about 300/million. This is a rapidly evolving field, with easier access to MRI imaging and genetic testing likely to increase the reported incidence and prevalence over the coming years.

As an approach to investigation, we include here a summary of a recent review describing the most commonly presenting leukodystrophies in adults (age >16 years) with their major clinical and MRI features, a logical diagnostic approach and possible treatment options.

Table 19.24 lists the most frequent of the adult onset leukodystrophies, with non-classic leukodystrophies, mitochondrial disorders and CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) also included, as they commonly enter the differential diagnosis of these conditions.

Importantly, before embarking on investigating inherited causes of widespread MRI white matter involvement, there are a number of *acquired* conditions that need to be excluded: inflammatory, vascular, toxic, metabolic, autoimmune, infectious and neoplastic causes. The approaches are standard and similar to the differential diagnosis for example of multiple sclerosis (Chapter 11), and include lymphomatosis, functional B<sub>12</sub> deficiency, HIV infection and carbon monoxide poisoning. A very rapid onset and progression over months is much more likely to be acquired than genetic, though cerebral adrenoleukodystrophy (ALD) can present abruptly.

After eliminating acquired causes, a suggested structured approach would be to consider the following in turn:

- **Family history.** If a true dominant pattern can be established this is useful as it will reduce the current diagnostic possibilities significantly.
- **Ethnicity.** Some diagnoses are more common, though not exclusive, to certain populations: Ashkenazi Jewish (mucopolidosis, adult onset gangliosidosis and adult polyglucosan body disease); Asia-Indian or Turkish (megalencephalic leukodystrophy with cysts) and adult sialidosis (Finnish).
- **Clinical presentation.** Table 19.25 lists phenotypic features that can guide towards a particular leukodystrophy.
- **MRI pattern** (Table 19.26). This is illustrated schematically in Figure 19.28. There is overlap amongst the conditions and widespread atrophy can be seen in the late stage of many (Figures 19.29 and 19.30).

Initial specialist biochemical investigations include (fasting) very long chain fatty acid (VLCFA) levels, relevant white cell enzyme activities, cholestanol profile, urine bile alcohols and plasma amino acids. As ALD has a relatively high prevalence and potential options for treatment, it should be tested for early. Close liaison with the laboratory is important to optimise the handling of appropriate samples.

If no abnormalities are found on biochemical testing it can be appropriate to proceed to genetic testing, including whole exome sequencing. This is likely to be an area of rapid diagnostic advancement, with the development of DNA chip, exome and genome-based investigative technologies.

Brain biopsy can be considered if the patient is deteriorating and a potentially treatable condition is possible or when the result can have important implications for the management of the family. The yield for brain biopsy can be increased to near 80% by targeting a radiologically identified lesion (with contrast enhancement). The risk of complications including infection, seizures and haemorrhage, is approximately 10–20%, but no long-term neurological sequelae are reported.

There follows a brief description of the clinical and MRI features of some of the leading adult onset leukodystrophies (to be read in conjunction with Table 19.26 and Figures 19.29 and 19.30). The non-classical leukodystrophies, CADASIL and mitochondrial disorders, are described separately in Chapters 6 and 10.

### X-linked adrenoleukodystrophy

**Clinical presentation** The phenotypic expression is wide and varies between and within families. Recognised phenotypes include adrenal insufficiency alone, adult onset cerebral ALD, adult onset adrenomyeloneuropathy (AMN) without cerebral involvement, and AMN with cerebral involvement and/or adrenal insufficiency. Adult onset cerebral ALD usually presents with psychiatric features followed by ataxia, seizures, dementia and death. Adrenal insufficiency should be specifically tested for. The AMN phenotype consists of a slowly progressive spastic paraparesis, with sphincter dysfunction, erectile dysfunction and sensory involvement. At least 20% of heterozygous females also develop symptoms, commonly in their thirties, of an AMN-like phenotype.

**MRI features** Occipital regions are usually first to be involved, with the corpus callosum, splenium and internal capsule posterior limbs, which then progress anteriorly. In cerebral ALD, peripheral contrast enhancement is seen, and in AMN, cord atrophy. As transplant is now considered an option for very early adult cerebral ALD, annual MRI with contrast and neuropsychometric assessment is suggested.

### Krabbe disease

**Clinical presentation** The adult form (approximately 1 in 10 of all cases) classically presents with a paraparesis with cortical features of visual involvement, dementia and seizures. There can be slowing of peripheral nerve electrophysiology.

**MRI features** The signal change is posterior, with a pattern of radiating stripes of normal signal intensity. T2 high signal is seen in the posterior internal capsule, brainstem and corticospinal tracts. On CT, thalamic and basal ganglia hyperintensities are seen, which may represent calcification.

### Cerebrotendinous xanthomatosis

**Clinical presentation** Multisystem involvement is common, including cataracts, tendon xanthomata (Achilles tendon typically), osteoporosis, and liver, endocrine and chest involvement. Neurological features are spastic paraparesis, ataxia and a peripheral neuropathy followed by dementia.

**MRI features** Periventricular white matter change and atrophy, with sparing of the corpus callosum are seen. The T2-weighted signal intensity can be high in the cerebellar white matter and low in the dentate nucleus.

**Table 19.24** The most frequently described adult onset inherited leukodystrophies.

Disorder	Age of onset	Incidence	Ethnic predilection	Inheritance	Useful investigation(s)	Gene(s)
X linked adrenoleukodystrophy adrenomyeloneuropathy (ALD/AMN)	Juvenile to adulthood	Overall 1 in 27 000–40 000. >20% of affected men may have significant brain involvement		X-linked. Heterozygote women can develop spastic paraparesis	Very long chain fatty acid levels	<i>ABCD1</i>
Metachromatic leukodystrophy (MLD)	Up to 70 years	Overall 1 in 40 000. 20% adult onset		AR	Arylsulfatase A (ARSA) enzyme activity (leukocytes/fibroblasts)*	<i>ARSA</i>
Cerebrotendinous xanthomatosis (CTX)		Overall 1 in 50 000		AR	Sterol profile. Urine bile alcohols	<i>CYP27A1</i>
Globoid cell leukodystrophy (Krabbe disease)	Up to 60 years	Overall 1 in 100 000. 10% adult onset.		AR	Galactocerebrosidase (GALC) enzyme activity (leukocytes/fibroblasts)	<i>GALC</i> ; <i>PSAP</i>
Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL)	Migraine: mean 30 years (range: 6–48 years). Ischaemic events: mean 50 years (range: 20–70 years)	2–4/100 000 Finland. 1.98/100 000 west Scotland. 1.32/10 000 west England		AD and sporadic	Electron microscopy of skin biopsy	<i>NOTCH3</i>
Mitochondrial disorders (see also Chapter 10)				Maternal, AD, AR	Lactate (blood/CSF). Mitochondrial respiratory chain enzyme activity	Various
Hexosaminidase A deficiency (GM2 gangliosidosis, adult-onset Tay–Sachs disease)	20–40 years	64 cases	64% Jewish origin	AR	Beta-hexosaminidase A (HEX A) enzymatic activity (leukocytes)	<i>HEXA</i>
Diffuse leukoencephalopathy with neuroaxonal spheroids (HDLs)	Mean 40 years (range 15–78 years)	52 cases		AD and sporadic	Characteristic brain biopsy findings (now superceded by molecular genetic testing)	<i>CSFR1</i>
Adult polyglucosan body disease	40–60 years	47 cases	Ashkenazi Jewish	AR	Sural nerve biopsy. Glycogen branched enzyme (GBE) activity (fibroblasts)	<i>GBE1</i>
Alexander disease	12–62 years	36 cases		AD and sporadic	Characteristic brain biopsy findings (now superceded by molecular genetic testing)	<i>GFAP</i>

**Table 19.24** (continued)

Disorder	Age of onset	Incidence	Ethnic predilection	Inheritance	Useful investigation(s)	Gene(s)
Pelizaeus–Merzbacher disease (PMD)	Usually infant-childhood onset, case reports of adult onset up to age 45 years	Limited case reports		X-linked. Heterozygote women can develop spastic paraparesis		<i>PLP1</i>
Recessive hypomyelinating leukoencephalopathy (Pelizaeus–Merzbacher-like disease)	Case report of onset age 15 years	Case report		AR		<i>GJC2</i> ; <i>HSPD1</i> ; <i>AIMP1</i>
Leukoencephalopathy with brainstem and spinal cord involvement and lactate elevation (LBSL)	Usually childhood	Case report		AR	MRS: elevated lactate	<i>DARS2</i>
Polycystic lipomembranous osteodysplasia with sclerosing leukoencephalopathy (PLOS); Nasu–Hokola disease)	Mean 30 years (range 10–45 years)	33 cases in Japan	Most reported cases in Finland and Japan, but occurs worldwide	AR	Imaging of the hand	<i>TYROBP</i> ; <i>TREM2</i>
Cockayne syndrome	Usually infant/childhood	Overall 1.8–2.7 per million births. 4 cases reported with adult onset	Canada (aboriginal residents of Manitoba, Newfoundland), Japan, Middle Eastern and Western Asian countries (35)	AR		<i>ERCC6</i> ; <i>ERCC8</i>

\*ARSA enzyme activity in leukocytes that is 5–20% of normal controls may be caused by pseudodeficiency. Pseudodeficiency may be difficult to distinguish from true ARSA enzyme deficiency by biochemical testing alone. Therefore, the diagnosis of MLD is usually confirmed by molecular genetic testing of *ARSA*. Pseudodeficiency alleles are common polymorphisms that result in lower than average ARSA enzyme activity; however, these alleles are reported to still produce sufficient functional enzyme to avoid sulfatide accumulation and thus do not cause MLD in either the homozygous state or the compound heterozygous state with an MLD allele. For further information on mitochondrial disorders see Chapter 10.

**Table 19.25** Clinical features associated with specific adult-onset leukodystrophies.

Suggestive presenting features	Leukodystrophy
<b>Visual involvement</b>	
Optic atrophy	Metachromatic leukodystrophy, Krabbe disease, mitochondrial disorders, Pelizaeus–Merzbacher disease
Cortical blindness	Krabbe disease
Retinal degeneration	Krabbe disease, mitochondrial disorders, Cockayne syndrome
Cataracts	Cerebrotendinous xanthomatosis, mitochondrial respiratory chain disorders
Abnormal eye movements/ nystagmus	Pelizaeus–Merzbacher disease
<b>Neurological features</b>	
Peripheral neuropathy	Metachromatic leukodystrophy Cerebrotendinous xanthomatosis Krabbe disease Adult polyglucosan body disease (GSD IV)
Cerebellar ataxia	Cerebrotendinous xanthomatosis Alexander disease Adult polyglucosan body disease (GSD IV) Vanishing white matter disease
Psychiatric symptoms	Metachromatic leukodystrophy Vanishing white matter disease Cerebral adrenoleukodystrophy Hereditary diffuse leukoencephalopathy with axonal spheroids
Pyramidal weakness/spasticity	Adrenomyeloneuropathy/adrenoleukodystrophy Krabbe disease Cerebrotendinous xanthomatosis Vanishing white matter disease Adult polyglucosan body disease Hereditary diffuse leukoencephalopathy with axonal spheroids
Bulbar dysfunction and palatal myoclonus	Adult onset Alexander disease
Dystonic dyskinetic movement disorder	Glutaric acidemia type 1
Autonomic features	Adult onset autosomal dominant leukodystrophy
Migraine and stroke	CADASIL
<b>Other features</b>	
Primary/secondary amenorrhoea	Vanishing white matter disease
Fractures following minor trauma	Polycystic lipomembranous osteodysplasia with sclerosing leukoencephalopathy (PLOS); Nasu–Hokola disease)
Macrocephaly	Alexander disease, organic acidurias (Canavan disease, glutaric acidemia type 1, L-2-hydroxyglutaric aciduria), megalencephalic leukoencephalopathy with subcortical cysts
Tendon xanthomas	Cerebrotendinous xanthomatosis

### Metachromatic leukodystrophy

*Clinical presentation* The adult form accounts for approximately 20% of metachromatic leukodystrophy (MLD) presentations. The initial symptoms are often psychiatric, followed by motor involvement (spastic paraparesis), cerebellar ataxia and cognitive decline. Other neurological signs include dystonia, optic atrophy, a demyelinating peripheral neuropathy (though more often seen in children) and seizures.

*MRI features* These include widespread symmetrical confluent white matter change with a peri-ventricular frontal predominance, a tigroid pattern of radiating stripes in the affected white matter. The subcortical U fibres are typically spared and the corpus callosum is often involved early.

### Hereditary diffuse leukoencephalopathy with neuroaxonal spheroids

*Clinical presentation* Cognitive and personality change, particularly of executive function occur, usually progressing to death within 6 years. CSF1R (colony stimulating factor 1 receptor) is an important mediator of microglial function. Pathologically, loss of myelin, axonal destruction and spheroids and lipid-laden macrophages are seen.

*MRI features* The T2 signal change is bifrontal, extending to the subcortical regions, posterior limb of the internal capsule and pyramidal tracts of the brainstem. MRI changes can be asymmetrical at outset before becoming symmetrical.

### Alexander's disease

*Clinical presentation* In adults, bulbar and pyramidal tract involvement are well described, as well as sleep disturbance and cerebellar ataxia. This can be combined with autonomic and urinary dysfunction and palatal myoclonus. Cytoplasmic astrocyte inclusion bodies containing the intermediate glial filament acidic protein (GFAP) called Rosenthal fibres are seen.

*MRI features* Usually contrast enhancement can be seen if the patient is less than 40 years old. Atrophy of the medulla and upper spinal cord, as well as peri-ventricular white matter change is seen. The adult MRI appearances tend to be distinct from those seen in childhood which can include frontal change, peri-ventricular rim and thalamic and/or basal ganglia involvement.

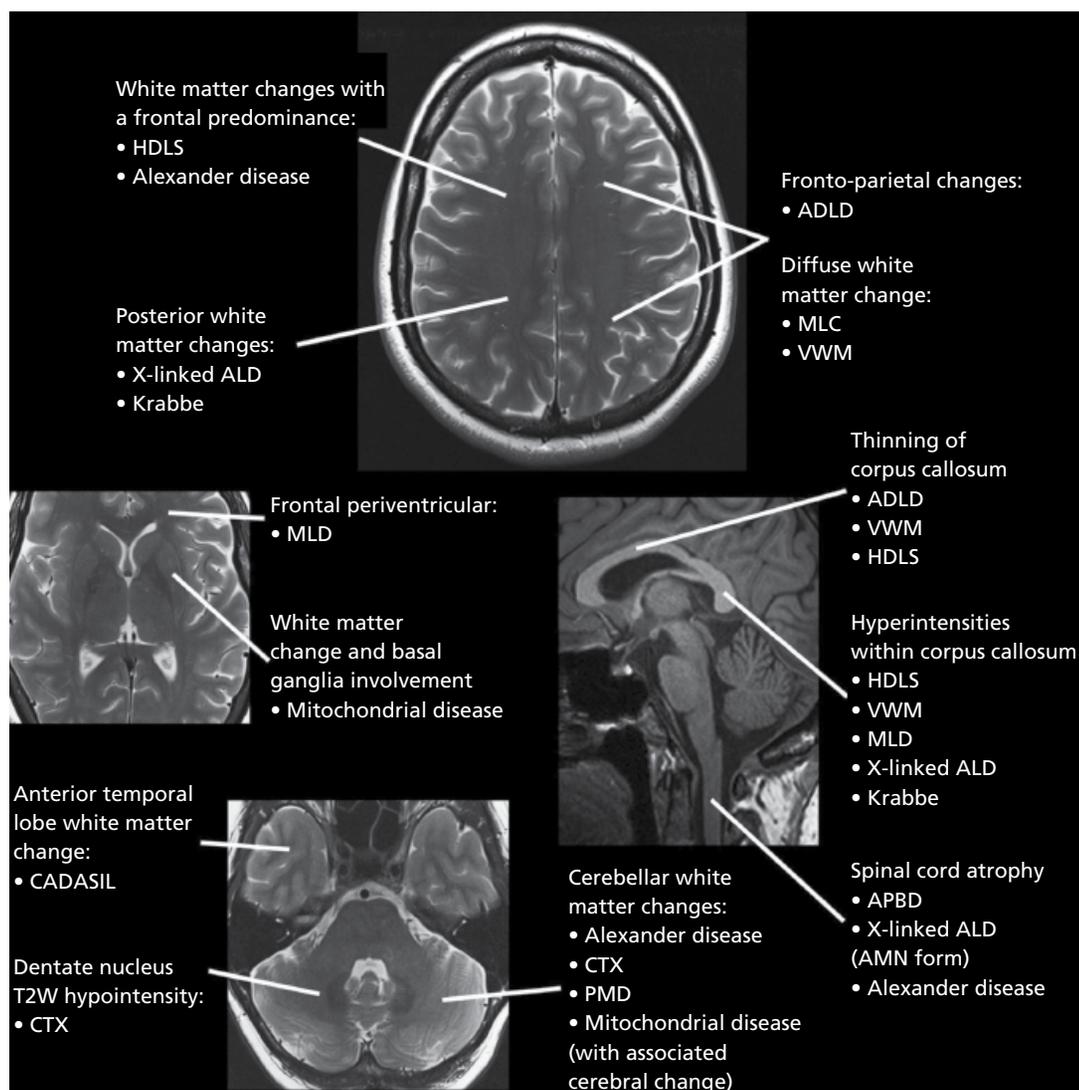

### Vanishing white matter disease

*Clinical presentation* Adult onset disease has been described in at least 25 cases in the literature, with cerebellar, spasticity, dementia, seizures and psychiatric symptoms (one-third) dominating. Ovarian failure is characteristic.

*MRI features* The signal change is diffuse hyper/hypo intensity on T2 weighting accompanied by cystic change and atrophy. Corpus callosal and cerebellar atrophy can be present. As the name suggests, ultimately, the hemispheric white matter can disappear.

### Pelizaeus–Merzbacher disease and Pelizaeus–Merzbacher-like disease

*Clinical features* Confined to limited case reports for the adult onset form with ataxia, dementia and tremor; though heterozygote females can present with a progressive cord syndrome. Pelizaeus–Merzbacher disease (PMD) is caused by mutations in the myelin

**Figure 19.28** Schematic illustration of brain MRI findings in specific leukodystrophies. ADLD, adult onset autosomal dominant leukodystrophy; ALD, adrenoleukodystrophy; AMN, adrenomyeloneuropathy; APBD, adult polyglucosan body disease; CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; CTX, cerebrotendinous xanthomatosis; HDLS, hereditary diffuse leukoencephalopathy with neuroaxonal spheroids; MLC, megalencephalic leukoencephalopathy with subcortical cysts; MLD, metachromatic leukodystrophy; PMD, Pelizaeus–Merzbacher disease; VWM, vanishing white matter disease. Source: Ahmed *et al.* 2014. Reproduced with permission of BMJ.

proteolipid protein (*PLP*) gene on the long arm of the X chromosome, and is allelic to hereditary spastic paraplegia (HSP) type 2 (Chapter 16). Pelizaeus–Merzbacher-like disease (PMLD) is clinically indistinct from PMD, but *PLP* mutation negative.

**MRI features** The MRI patterns tend to show diffuse white matter change (hyperintensity) cortically, sparing the U fibres.

**Management** Current treatment of adult onset leukodystrophies is largely supportive, though chenodeoxycholic acid has been used as therapy for cerebrotendinous xanthomatosis since 1975 (however, its effect in symptomatic adults may be limited). A number of clinical trials are currently underway using interventions such as haematopoietic stem cell transplant, intrathecal enzyme replacement therapy and autologous haematopoietic stem cell transplant

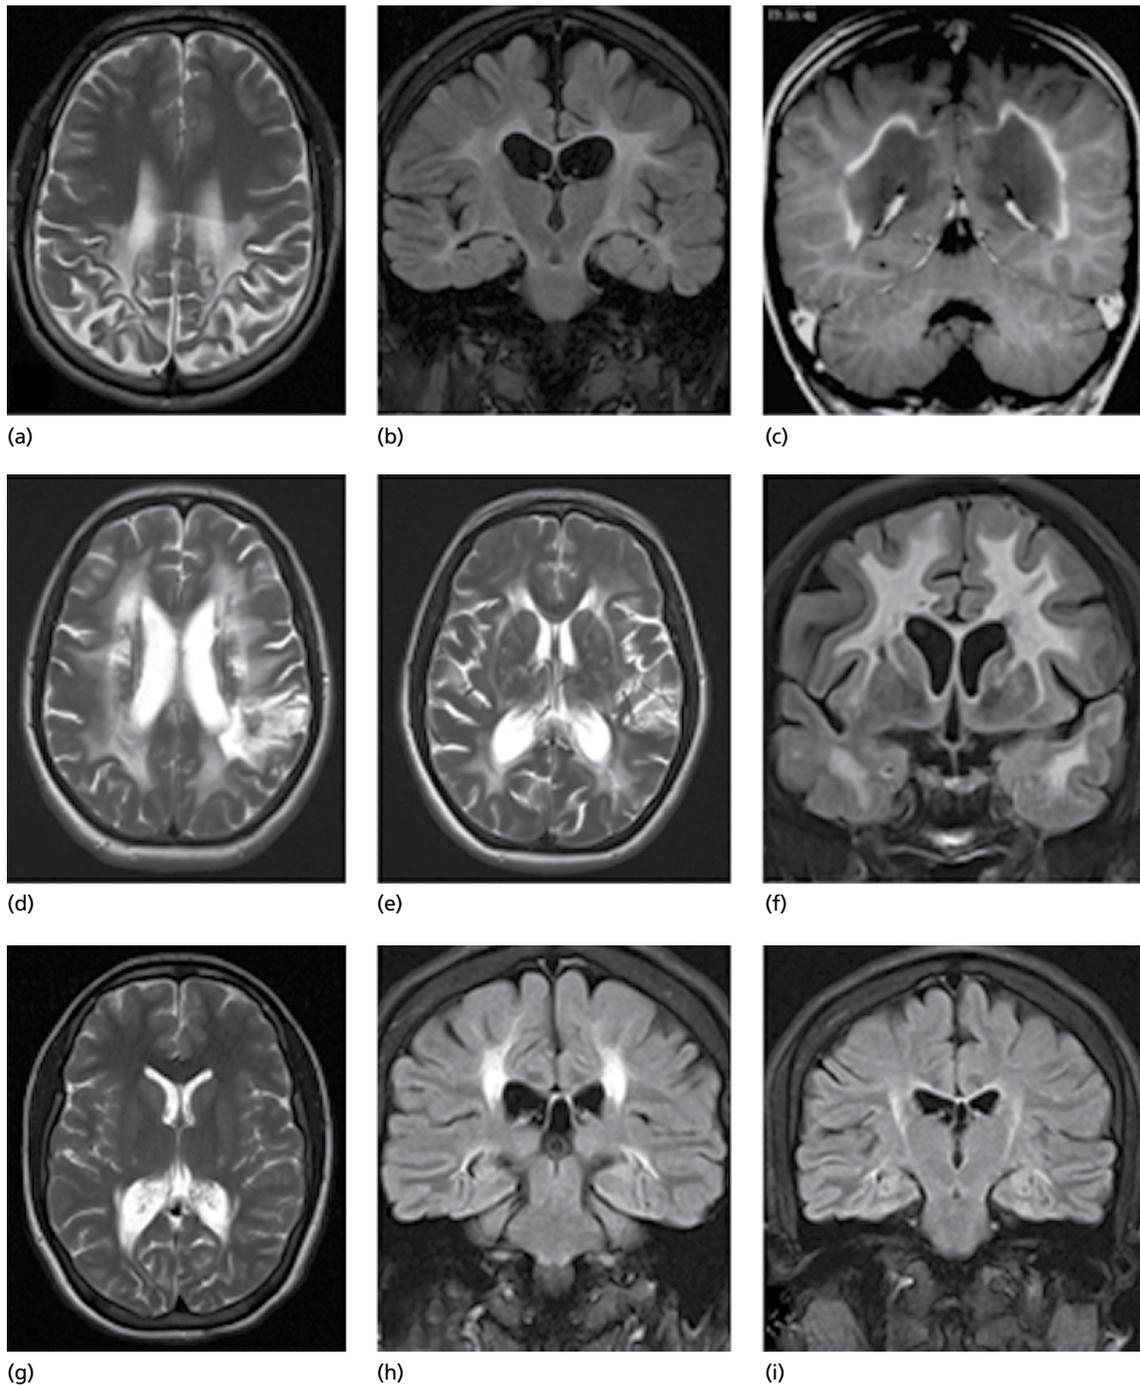

transduced with ABCD1 lentiviral vector (for ALD). Further details can be found on [www.clinicaltrials.gov](http://www.clinicaltrials.gov).

### Peroxisomal disorders

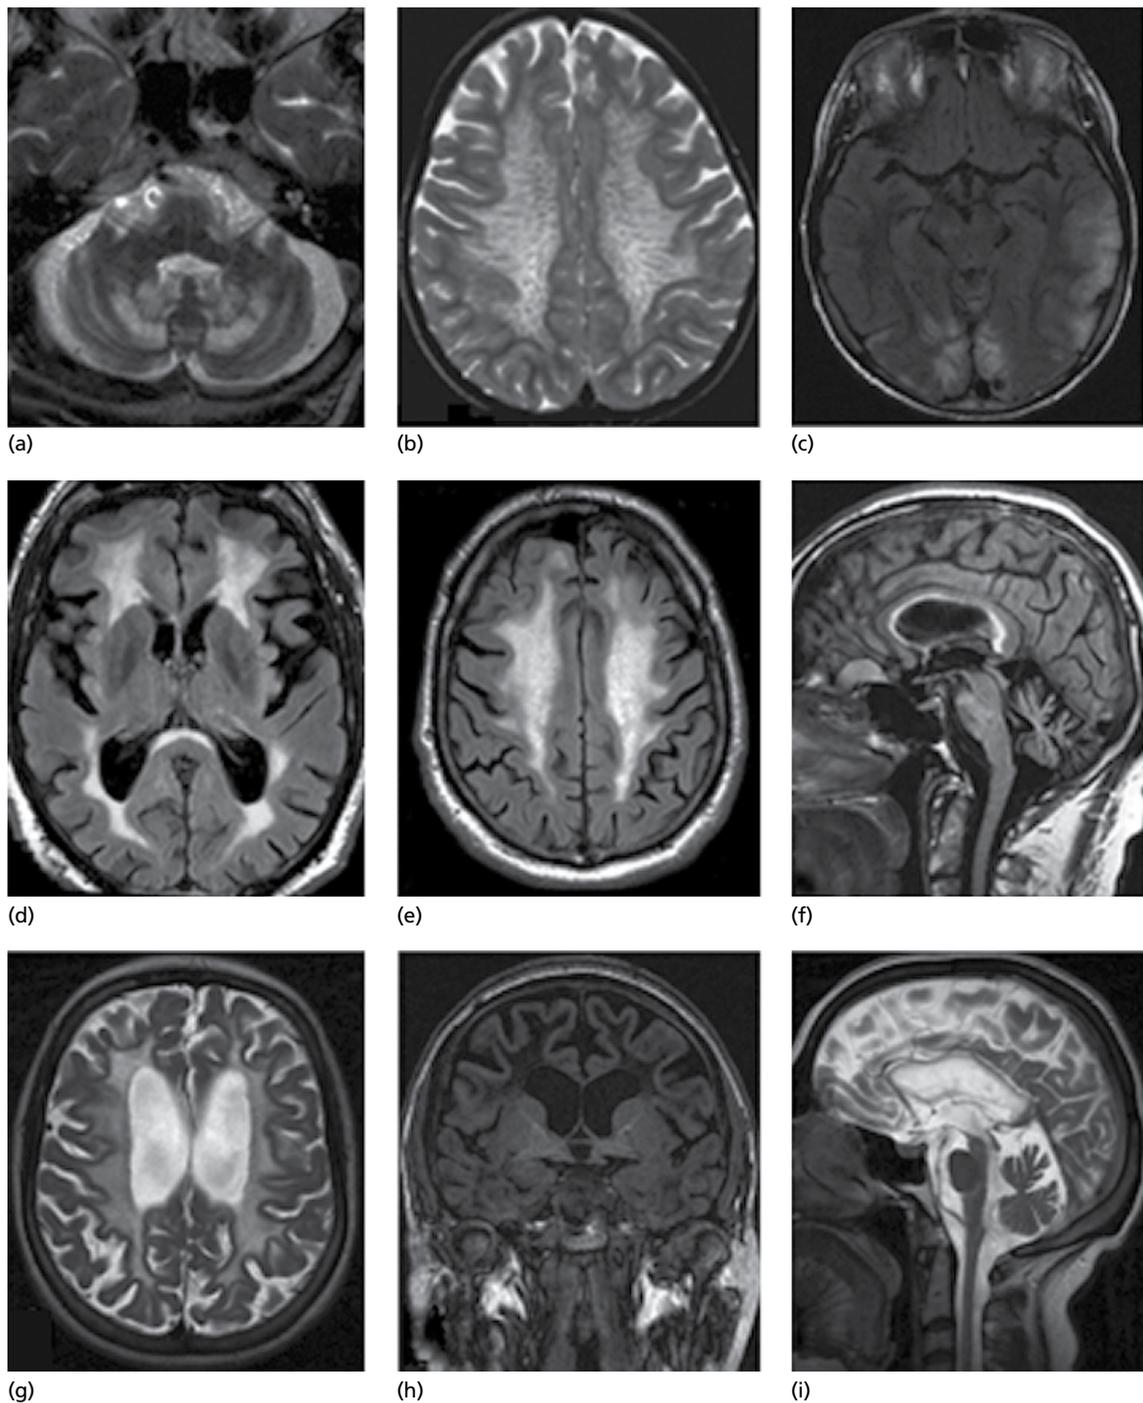

Peroxisomes are cellular organelles found in all human cells except erythrocytes. They have several functions including the synthesis of phospholipids, oxidation of VLCFA, oxidation of phytanic acid, catabolism of lysine and formation of bile acids.

Phenotypes vary considerably but the typical clinical presentation of a peroxisomal disorder is with dysmorphic features, neurological abnormalities, ocular signs, hepatic or gastrointestinal dysfunction.

Diagnosis is suggested by abnormal metabolites in plasma and/or erythrocytes and confirmed by specific fibroblast studies showing abnormalities of peroxisomal biogenesis or reduction in specific

**Figure 19.29** MRI brain acquisitions of: X-linked adrenoleukodystrophy on (a) axial T2-weighted, (b) coronal FLAIR and (c) coronal postgadolinium contrast sequences showing diffuse white matter signal T2-weighted hyperintensity and volume loss of the posterior frontal, posterior callosal and parieto-occipital regions, extending along the corticospinal tracts through the internal capsules and temporal peri-ventricular white matter. Peripheral enhancement of the parieto-occipital confluent symmetrical signal abnormality is demonstrated. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy on (d,e) axial T2-weighted and (f) coronal FLAIR sequences showing diffuse symmetrical white matter hyperintensity extending through the external capsules and temporal poles with multiple mature subcortical and a left superior parietal cortical infarcts. Krabbe disease (globoid cell leukodystrophy) on (g) axial T2-weighted and (h,i) coronal FLAIR sequences showing posterior peri-ventricular and deep white matter hyperintensity and volume loss involving the corticospinal tracts and splenium of the corpus callosum. Source: Ahmed *et al.* 2014. Reproduced with permission of BMJ.

**Figure 19.30** MRI brain acquisitions of: cerebrotendinous xanthomatosis on an axial T2-weighted sequence through the posterior fossa (a) demonstrating white matter signal hypointensity involving the dentate nuclei and surrounding hyperintensity. Note the diffuse volume loss of the cerebellum disproportionate to the visible temporal poles. Metachromatic leukodystrophy on an axial T2-weighted sequence through the centrum semiovale (b) demonstrating widespread symmetrical white matter signal hyperintensity sparing the subcortical U fibres and radiating transmedullary bands. Mitochondrial encephalopathy lactic acidosis and stroke-like episodes on an axial FLAIR sequence (c) demonstrating swelling and patchy hyperintensity of the cortical and subcortical matter of the occipital, right mesencephalic and left lateral temporal regions during an acute stroke-like episode. Adult polyglucosan body disease on an axial (d,e) and sagittal (f) FLAIR sequences demonstrating diffuse peri-ventricular and inferior callosal white matter hyperintensity and volume loss. There is similarly cerebellar and spinal cord volume loss. An incidental planum sphenoidal meningioma is present. Vanishing white matter disease on axial and sagittal T2-weighted (g,i) as well as coronal T1-weighted (h) sequences demonstrating diffuse white matter T2-weighted hyperintensity and volume loss. Atrophy of the corpus callosum and spinal cord is also present. Source: Ahmed et al 2014. Reproduced with permission of BMJ.

enzyme activities and/or genetic testing. The two most commonly encountered disorders of peroxisomal metabolism in adult practice are X-linked adrenoleukodystrophy/adrenomyeloneuropathy and Refsum disease.

### Refsum disease

Refsum disease is a rare inherited autosomal recessive condition caused by a deficiency in phytanoyl CoA-hydroxylase, resulting in the accumulation of phytanic acid. It is characterised by retinopathy, peripheral neuropathy and cerebellar ataxia. The onset of symptoms ranges from late childhood to the sixth decade and can be precipitated or exacerbated by intercurrent infections and pregnancy. Progressive visual failure, often presenting as night blindness, results from a 'salt and pepper' retinopathy and cataract formation. A demyelinating sensorimotor polyneuropathy is prominent, with symmetrical distal sensory impairment, and progressive mild to moderate distal weakness. Other

characteristic features include ichthyosis, cataracts, anosmia, sensorineural deafness and cardiomyopathy.

The diagnosis is established by finding elevated phytanic acid in the plasma (measured as part of a VLCFA profile) and reduced fibroblast phytanoyl CoA-hydroxylase activity.

*Management* Refsum disease is treated by restricting the dietary intake of phytanic acid. Although phytanic acid is present in fruit and vegetables, it is tightly bound to chlorophyll and humans do not absorb it efficiently so these foods are not restricted. Ruminants, however, do absorb phytanic acid and it is concentrated in their meat. Therefore beef, lamb, dairy products and fish need to be avoided. With a suitable diet, plasma phytanate levels can be brought into the normal range. If diet is not successful in doing this, plasma exchange can be considered. Unfortunately, even with normal phytanate levels, the disease remains slowly progressive and most patients will lose their sight and develop significant peripheral neuropathy.

**Table 19.27** Summary of potential inherited metabolic diseases potentially presenting as an neurological/psychiatric/encephalopathic emergency in adulthood.

Disorder	Emergency presentation	Laboratory tests	Treatment options
Glycogen storage disorders	Rhabdomyolysis Cardiomyopathy	Creatine kinase	Modified diet Exercise advice
Fatty acid oxidation disorders	Rhabdomyolysis Cardiomyopathy	Creatine kinase Acylcarnitine profile Urine organic acids Fibroblast FAO studies	Intervenous dextrose Modified diet Exercise advice Bezafibrate L-carnitine
Urea cycle defects	Encephalopathy Stroke-like episodes Psychiatric features	Ammonia Plasma amino acids Urine orotic acid	Intervenous dextrose Haemofiltration Arginine Sodium benzoate Sodium phenylbutyrate
Organic acidemias	Encephalopathy Cardiac disease Renal impairment	Blood gas Ammonia Acylcarnitine profile Urine organic acids	Intervenous dextrose Haemofiltration L-carnitine
Homocystinuria	Thrombosis Lens dislocation Psychiatric features	Plasma amino acids	Pyridoxine Folate B12 Betaine

	Stroke/stroke-like events	Fabry disease Mitochondrial disorders Homocystinuria Congenital disorders of glycosylation
Heart	Valve disease	Mucopolysaccharidoses Mucopolipidoses
	Cardiomyopathy	Fabry disease Some glycogen storage disorders Some fatty acid oxidation disorders Mucopolysaccharidoses Organic acidemias (methylmalonic and propionic)
	Dysrhythmia	Fabry disease Congenital disorders of glycosylation
Other features	Very early onset severe epilepsy	Pyridoxine, folinic acid, and pyridoxal-5'-phosphate dependent epilepsies Glycine encephalopathy
	Intermittent encephalopathy	Urea cycle disorders Organic acidemias
	Tendon xanthomas	Cerebrotendinous xanthomatosis
	Primary/early ovarian insufficiency	Galactosaemia

### Disorders of phospholipid and glycosphingolipid biosynthesis

Phospholipids are important components of cell membranes. Glycosphingolipids are also found in cell membranes, particularly in neurones. Recent advances in laboratory instrumentation and technology, and increased use of whole exome analysis, have allowed identification of an increasing number of disorders in this group. For the majority no specific treatment is available.

#### Disorders of phospholipid synthesis

Phosphatidate phosphatase 1 deficiency is caused by mutations in the *LIPN1* gene and characterised by episodes of recurrent myoglobinuria (precipitated by fever, anaesthesia or fasting) and muscle weakness.

Barth syndrome (cardiolipin remodelling enzyme deficiency) is an X-linked condition caused by mutations in the *TAZ* gene. Clinical presentation includes cardiomyopathy, skeletal muscle weakness, cyclical neutropenia and growth retardation.

Neurodegeneration with brain iron accumulation (NBIA) is characterised by static encephalopathy in childhood and neurodegeneration in adolescence or adulthood. It is caused by phospholipase A2 deficiency secondary to mutations in the *PLA2G6* gene. Other disorders such fatty acid 2-hydroxylase deficiency (*FA2H* mutations, a cause of SPG35) and pantothenate kinase-associated neurodegeneration (*PANK2* mutations) show overlapping clinical features.

#### Disorders of glycosphingolipid synthesis

Autosomal dominant serine palmitoyltransferase deficiency (*SPTLC1* or *SPTLC2* mutations) causes hereditary sensory autonomic neuropathy type 1. Mutilating ulcerative complications are a prominent sign.

#### Acute neurological emergencies caused by inherited metabolic disease

The majority of adults with a rare inherited disorder of metabolism who present to emergency services will have a known diagnosis,

usually made in childhood. They may bring with them specific information and guidelines for emergency management of their condition. In the United Kingdom, nationally agreed guidelines are accessible via the internet ([www.BIMDG.org.uk](http://www.BIMDG.org.uk)).

Other patients present for the first time in adulthood, and while, quite correctly, the emphasis in adulthood tends to be on acquired conditions such as infection or poisoning, the possibility of an late-presenting inherited disorder of metabolism should always be considered for adults with encephalopathy, atypical stroke, psychiatric features, rhabdomyolysis, and/or disturbances of acid–base balance – particularly if these episodes are recurrent and there is no other obvious underlying cause. Hypoglycaemia is an unusual initial presentation of inherited metabolic disease in adulthood. Because of compensatory mechanisms, adults can maintain their blood glucose levels despite significant metabolic disturbance so an adulthood presentation with hypoglycaemia often represents a late event secondary to severe decompensation (e.g. in fatty acid oxidation disorders or organic acidemias). Typically, acute episodes occur following metabolic ‘stress’ (e.g. fasting, intercurrent infection, major surgery, gastrointestinal illness, excessive alcohol or exercise), but a precise underlying precipitant is not always identified.

Table 19.27 summarises some of the more frequent acute presentations of adults with metabolic disease to emergency services, initial tests and potential treatments. A neurologist’s advice is likely to be sought for many of these presentations and so it is important for all physicians to be aware of these disorders as effective treatments are available for many, and, as the disorders are genetic, making the diagnosis has implications both for the affected patient and their relatives. Not all diagnostic tests are readily available in the emergency setting, or even outside specialist laboratories, so thought should be given to the storage of appropriate samples, including DNA, in the acute setting, particularly for patients in a critical condition. Table 19.28 summarises the prominent clinical features of some inborn errors of metabolism.

# Disorders of Consciousness, Intensive Care Neurology and Sleep

Robin Howard<sup>1</sup>, Sofia Eriksson<sup>1</sup>, Nicholas Hirsch<sup>1</sup>, Neil Kitchen<sup>1</sup>, Dimitri Kullmann<sup>2</sup>, Christopher Taylor<sup>1</sup> and Matthew Walker<sup>2</sup>

<sup>1</sup>National Hospital for Neurology & Neurosurgery

<sup>2</sup>UCL Institute of Neurology

## Consciousness

Consciousness is a state of awareness of self and environment that gives significance to stimuli from the internal and external environment. It depends on two critical components: arousal or alertness; and cognitive content of mental functions which allow expression of sensation, emotion and thought.

Arousal reflects the integrity of the ascending reticular activating system and the brainstem, predominantly bilateral tegmental regions of the upper pons and, to a lesser extent, the midbrain while cognitive function is subserved by the cerebral hemispheres. Coma can be caused either by bilateral hemispheric damage, or by a structural or metabolic lesion affecting the brainstem reticular activating system or its projections to the thalamus and cortex. Impairment of arousal leads to a reduced level of consciousness with secondary impairment of cognitive content, which may be temporary or permanent depending on the aetiology. Unilateral dysfunction or disease of the cerebral hemispheres does not, by itself, cause stupor or coma.

## States of impaired consciousness

The different patterns of arousal and awareness are complex and variable, but characteristic features do allow the description of a spectrum of states of conscious level. These range from full consciousness to coma. A number of terms have been applied to these intermediate states but overlap inevitably occurs (Table 20.1).

In the 'locked-in syndrome' consciousness and cognition are preserved. The condition is discussed here because it commonly presents diagnostic difficulties as the patient has lost motor function making movement and speech impossible. Horizontal eye movements are lost and the subject is usually only able to communicate by opening and voluntarily moving their eyes in the vertical plane.

## Causes of coma

Coma is caused by a large number of neurological and general medical disorders. In clinical practice a useful scheme depends on identifying the following findings in the initial assessment of the patient (Table 20.2):

- 1 Lateralising signs
- 2 Meningism
- 3 Pattern of brainstem reflexes.

## Initial assessment and management of coma

Acute initial management is summarised in Table 20.3. The clinical assessment of coma is summarised in Table 20.4.

## Medical assessment

It is essential to obtain as detailed and accurate a history as possible from all witnesses and to establish any history of a predisposing event (e.g. previous trauma), pyrexia, prodromal symptoms (e.g. headache, neck stiffness), ataxia, epilepsy or previous episodes as well as medication list and psychiatric history.

## Examination

An urgent and detailed general medical examination must be undertaken immediately after resuscitation. The breath may smell of alcohol, ketones, hepatic or renal fetor. Examination of the mucous membranes may show evidence of cyanosis, anaemia, jaundice or carbon monoxide intoxication. Bruising in the mastoid or orbital regions or blood in the external auditory meatus may suggest temporal, orbital or basal skull fractures. Endocarditis is suggested by splinter haemorrhages, and opiate intoxication by hypodermic needle marks. Other relevant skin lesions include a purpuric petechial rash suggesting meningococcal septicaemia or a coagulation disorder, maculopapular lesions indicating viral meningo-encephalitis, endocarditis or fungal infection, or bullous lesions suggesting barbiturate intoxication.

Pyrexia is usually caused by systemic sepsis but its absence does not exclude infection, particularly in elderly or immunocompromised patients. Hyperpyrexia occurs in thyrotoxic crisis, heat stroke, drug toxicity (e.g. Ecstasy) and malignant hyperthermia. Primary neurogenic hyperpyrexia is unusual but can be associated with hypothalamic lesions or subarachnoid haemorrhage (SAH). Rarely, severe hypothermia may be the primary cause of coma, but more commonly hypothermia occurs as a result of coma from environmental (accidental hypothermia) or metabolic causes, endocrine disorders (hypothyroidism, hypopituitarism or hypoadrenalism) or drugs (e.g. alcohol, barbiturates). Profuse sweating suggests cholinergic poisoning, neuroleptic malignant syndrome or serotonin syndrome.

Hypertensive crisis leads to disturbed consciousness, but hypertension is more commonly secondary to cerebral causes such as

**Table 20.1** Definitions and descriptions of states of altered consciousness.

Clouding of consciousness	Reduced alertness characterised by impaired attention and memory. Patients may be distractible, hyperexcitable and irritable, with slow thought processes
Acute confusional state	Impaired alertness state in which stimuli are intermittently misinterpreted. Patients are drowsy, bewildered and disorientated in time sometimes with day–night reversal. They have poor short-term memory and comprehension and difficulty undertaking complex tasks
Delirium	Rapid onset of a floridly abnormal mental state, with disturbed consciousness, disorientation, severe motor restlessness, fear, irritability, consistent misperception of sensory stimuli and visual hallucinations. There may be lucid periods with hyperactivity during which the patient is agitated, talkative and irritable. There may be hypoactive periods with hypersomnolence and sleep–wake inversion
Obtundation	Mental blunting with apathy and inactivity. The patient is drowsy with reduced alertness and a lessened interest in the environment
Stupor	Similar to deep sleep, from which the patient can be aroused only by vigorous and repeated stimuli. Even when aroused communication is by monosyllabic sounds and simple behaviours, and as soon as the stimulus ceases the stuporose subject lapses back into an unresponsive state
Akinetic mutism	Slowed or virtually absent bodily movements in the absence of paralysis or weakness. The patient is flaccid, does not respond to pain and lies immobile, mute and unresponsive to commands, questions and greetings. Wakefulness, alertness, sleep–wake cycles and self-awareness are preserved
Coma	A state of unrousable unresponsiveness in which the subject lies with eyes closed. There is no understandable response to external stimuli or inner need and the patient does not utter understandable responses nor accurately localises noxious stimuli. Thus, there is a total absence of awareness of self and environment even when the subject is externally stimulated. There is no spontaneous eye opening, response to voice, localisation to painful stimuli or verbal output

**Table 20.2** (a) Causes of coma with intact brainstem function, without meningism and without lateralising signs.

Alcohol	
Drugs	All sedatives, anaesthetics and many drugs (e.g. barbiturates, tranquillisers, opioids, psychotropics, salicylates, amphetamines)
Seizures, epilepsy	Convulsive status epilepticus, non-convulsive status epilepticus, post-ictal, non-epileptic status
Hypoxic–ischaemic encephalopathy	
Respiratory	Hypoxaemia, hypercarbia
Electrolyte disturbances	Hyponatraemia, hypernatraemia; hypocalcaemia, hypercalcaemia, hypermagnesaemia
Diabetes mellitus	Hypoglycaemia, ketoacidosis, lactic acidosis, hyperosmolar non-ketotic diabetic coma
Uraemia/dialysis	
Hepatic encephalopathy	
Endocrine	Panhypopituitarism, hypothyroidism, hyperthyroidism, hypoadrenalism, Hashimoto's encephalopathy
Core temperature change	Hypothermia, hyperpyrexia
Nutritional	Wernicke's encephalopathy
Inborn errors of metabolism	Hyperammoniacal states, aminoacidurias, organic acidurias
Toxins	Carbon monoxide, methanol, lead, cyanide, thallium, others
Extrapyramidal	Acute movement disorders (status dystonicus), neuroleptic malignant syndrome, serotonin syndrome
Autoimmune	Steroid responsive encephalopathy, autoimmune encephalitis
Others	e.g. porphyria, Reye's syndrome (hepatic), idiopathic recurrent stupor, mitochondrial disease, hypothalamic lesions, septic encephalopathy, malaria
States that mimic coma	Catatonia, conversion reaction, malingering, psychogenic unresponsiveness

SAH and raised intracranial pressure (ICP). Hypotension resulting in coma may be caused by hypovolaemia, myocardial infarction, septicæmia, diabetes mellitus or deliberate overdose with hypotensive medication.

The presence of meningism suggests infective or carcinomatous meningitis, SAH or herniation (either central, tentorial or cerebellar tonsillar). Meningism is rarely found in patients in deep coma and can be difficult to assess in those who have had tracheal intubation. The pattern of respiration is of some localising value (see Bulbar function), but is also affected by cerebral herniation

syndromes, metabolic and toxic conditions including drug overdose, acidosis, diabetes and liver disease.

Fundal examination can show retinopathy due to diabetes or hypertension. Papilloedema suggests raised ICP, hypertensive retinopathy or carbon dioxide retention and subhyaloid haemorrhage indicates aneurysmal SAH (Figure 20.1). Otoroscopic examination may reveal otorrhoea or haemotympanum from a basal skull fracture. Cerebrospinal fluid (CSF) rhinorrhoea can be confirmed by the presence of glucose in a watery nasal discharge but testing for 'beta-trace protein' is more specific.

**Table 20.2** (b) Typical causes of coma with meningism, with or without brainstem signs and with or without lateralising signs.

Infection	Meningitis, encephalitis, malaria, HIV-related
Vascular	Subarachnoid haemorrhage (spontaneous or traumatic)
Tumour	Malignant meningitis

**Table 20.2** (c) Typical causes of coma with intact brainstem function and asymmetrical lateralising signs with or without meningism.

<b>Cerebrovascular</b>
Infarction
Ischaemia
Embolic – cardiac, large vessel, fat
Hypoperfusion/hypotension
Haemorrhage
Extradural
Subdural
Subarachnoid
Intracerebral (primary or secondary)
Congophilic amyloid angiopathy
Intravascular lymphoma
Vasculitis
Venous thrombosis
Mitochondrial disease
Hypertensive encephalopathy
Eclampsia
Endocarditis
Bacterial, Libman–Sacks, marantic
<b>Traumatic brain injury</b>
<b>Cerebral oedema</b>
<b>Infection</b>
Brain abscess and tuberculoma, single or multiple
Subdural empyema
Creutzfeldt–Jakob disease
Malaria, HIV-related
Encephalitis
<b>Inflammatory</b>
Posterior reversible leukoencephalopathy
<b>Brain neoplasms</b>
<b>White matter diseases</b>
Multiple sclerosis
Leukoencephalopathy associated with chemotherapy and/or radiotherapy
Acute disseminated encephalomyelitis
Acute haemorrhagic leukoencephalitis
Posterior reversible leukoencephalopathy
Toxic leukoencephalopathy
Progressive multifocal leukoencephalopathy

**Table 20.2** (d) Causes of coma with intact brainstem function and symmetrical lateralising signs with or without meningism (and see Table 20.2c).

<b>Diffuse axonal (traumatic) brain injury</b>
<b>Hypoxic–ischaemic brain injury</b>
<b>Bilateral subdural haematoma/empyema</b>
<b>Cerebrovascular</b>
Subarachnoid haemorrhage
Multiple infarcts due to:
Fat emboli
Cholesterol emboli
Disseminated intravascular coagulation
Thrombotic thrombocytopenic purpura
Vasculitis
<b>Tumour</b>
Multiple metastases
Gliomatosis
Lymphoma
<b>Demyelination</b>
Acute disseminated encephalomyelitis
Acute haemorrhagic leukoencephalitis
<b>Infection</b>
Encephalitis

**Table 20.2** (e) Causes of coma with signs of focal brainstem dysfunction (with or without meningism, with or without lateralising signs).

<b>Herniation syndromes</b>
<b>Intrinsic brainstem disease</b>
<b>Advanced metabolic/toxic encephalopathy</b>
<b>Others</b>
Central pontine myelinolysis
Multiple sclerosis
Brainstem encephalitis
<b>Vascular</b>
Vertebrobasilar occlusion, dissection, haemorrhage, AVMs
Basilar artery and brainstem infarction
<b>Mass lesions affecting brainstem or cerebellum</b>
Posterior fossa tumours
Abscesses, tuberculomas
<b>Traumatic brain injury</b>
<b>Cerebellar</b>
Cerebellar infarct, haematoma, abscess, glioma

AVM, arteriovenous malformation.

### Level of consciousness

The level of consciousness should be assessed by the ability of the patient to respond to stimuli of varying intensity by speech, eye opening and motor movements. Because of the importance of correctly identifying locked-in patients, the eyelids should be held open and the patient asked to move their eyes in a horizontal and

vertical plane. Visual, auditory and painful stimuli of increasing intensity can then be systematically presented bilaterally in cranial nerve and limb territories.

### Glasgow Coma Scale

The Glasgow Coma Score (GCS) is the most widely used and reproducible scale to assess the level of consciousness. It is a standard scoring system used for the assessment of the unconscious patient based on their eye opening, motor and verbal responses to external stimuli (Table 20.5). It was designed as an easily used, objective, reproducible scale for patients with head trauma, to assess varying levels of consciousness facilitating the early recognition of deterioration resulting from raised ICP, usually from herniation. It has proved an extremely

**Table 20.5** Glasgow Coma Score (GCS).

Eye opening	Motor response	Verbal
4 Spontaneous	6 Obeys command	5 Orientated
3 To speech	5 Localises pain	4 Confused speech
2 To pain	4 Withdrawal	3 Inappropriate words
1 None	3 Flexion posturing	2 Incomprehensible sounds
	2 Extensor posturing	1 None
	1 None	

valuable and durable scale which can be used by medical, nursing and paramedical staff. It requires regular and serial observations.

However, there are several limitations to its use. The scale excludes assessment of many important neurological functions, requires regular and consecutive observations to be effective, and is limited to the best response in a single limb. It therefore cannot represent asymmetry and has poor diagnostic value. Its inter-rater reliability in non-experienced observers is limited because it is difficult to standardise the intensity of maximal auditory, visual and painful stimuli; full assessment cannot be undertaken in intubated patients or when soft tissue swelling prevents eye opening. Furthermore, the scale represents the addition of ordinal values that are not equal and are not independent of each other and it is relatively insensitive to changes in the level of consciousness at higher levels. Although the GCS score is helpful when assessing any change in the level of consciousness, particularly in the context of traumatic brain injury (TBI), it cannot replace detailed and careful neurological examination of the pattern of responsiveness.

Several new scores have been developed. The best is the Full Outline of UnResponsiveness (FOUR) introduced in 2005 to overcome many of the difficulties inherent in the GCS (Table 20.6). Instead of the verbal component, the FOUR score includes pupil reactions and respiratory pattern to reflect brainstem function, thus making it more applicable in the intubated patient. The score provides greater neurological detail than the GCS and it has good inter-observer reliability.

### Assessment of neurological function

**Eyelids** In coma the eyelids are usually closed. Opening by an examiner is followed by slow spontaneous re-closure while, in psychogenic coma, there is usually forceful resistance to eyelid opening and active closure. Rarely, the eyelids may be open in coma ('eyes open coma') because of a failure of inhibition of levator palpebrae associated with lesions in the ponto-mesencephalic region. In this situation, it is difficult to distinguish coma from the vegetative state.

**Pupillary responses** It is essential to ensure an adequate light source and, if necessary, to examine the pupils with a magnifying glass. Pre-existing ocular or neurological injury, or topical or systemic medication, may cause pupillary asymmetry or even a fixed dilated pupil (Chapter 14).

The pupillary response indicates the functional state of the afferent (II) and efferent (III) pathways and the midbrain tegmentum. The presence of equal, light-reactive pupils indicates that the reflex pathway is intact. A normal pupillary reaction to light in a comatose patient suggests a metabolic rather than structural cause of coma.

Unilateral or bilaterally small pupils with normal reactions to light may be caused by Horner's syndrome associated with lesions involving the descending sympathetic pathways in the hypothalamus, midbrain, pontine tegmentum, medulla (e.g. lateral medullary infarction), ventrolateral cervical spine or in the carotid sheath (e.g. carotid artery damage). The extent of constriction makes it difficult to observe responses to light and magnification may be required.

Mid position pupils, which do not respond to light but in which the accommodation reflex is spared, are associated with dorsal tectal, pretectal or tegmental lesions (Argyll Robertson pupils). The pupils may spontaneously and rhythmically fluctuate in size (hippus) and dilate to the ciliospinal reflex. This is a normal phenomenon.

In progressive compressive IIIrd nerve lesions, the initial sign is a sluggish pupillary response followed by the development of fixed dilatation (caused by involvement of the parasympathetic fibres with sparing of the sympathetic pathways). A unilateral IIIrd nerve lesion may also cause an efferent pupillary defect in which a light stimulus elicits a consensual but not a direct constriction response. This can be a sign of impending tentorial coning and is a medical emergency. Widely dilated pupils caused by anticholinergic agents do not reverse with pilocarpine. Irregular oval, unequal pupils follow brainstem transtentorial herniation which leads to midbrain infarction. Fixed and moderately dilated pupils are seen in brain death because of the loss of both sympathetic and parasympathetic influences.

**Oculomotor disorders** The preservation of normal eye movements means the brainstem is intact – from the oculomotor nucleus rostrally to the vestibular nuclei caudally, and their cerebellar connections (Chapter 14). In the primary ocular position, the eyes may be either dysconjugate, conjugate in the midline or deviated in a conjugate manner. Dysconjugate deviation of the eyes is common in patients with impaired consciousness and often reflects loss of descending voluntary control but may simply be caused by decompensation of a pre-existing strabismus or a cranial nerve palsy.

A complete IIIrd nerve palsy is manifest as pupillary dilatation, ptosis and deviation of the eye downward and laterally. Oculomotor nerve palsies may occur as a consequence of midbrain lesions from direct trauma or as a manifestation of transtentorial herniation but have many other causes (Chapter 14). Internuclear ophthalmoplegia (INO), caused by a lesion of the medial longitudinal fasciculus, causes isolated failure of ocular adduction with nystagmus of the abducting eye but normal vertical eye movements and pupils. Dysconjugate vertical gaze may be caused by IVth nerve palsy (which occurs commonly following trauma, metabolic encephalopathy or drug intoxication) or is caused by a skew deviation associated with otolithic, cerebellar or brainstem lesions. Inward deviation and failure of abduction indicates a VIth nerve palsy which is common and may be caused by trauma or raised ICP but is a poor guide to localisation.

Tonic horizontal conjugate ocular deviation is common in coma. The eyes usually deviate towards the side of a destructive hemispheric lesion (e.g. infarction, haemorrhage or tumour) and away from the hemiparesis. However, the eyes may deviate away from an irritative epileptic focus or from a thalamic lesion. Below the ponto-mesencephalic junction the eyes deviate away from the lesion side, and look towards the hemiparesis (pontine gaze palsy). In hemispheric lesions it is usually possible to drive the eyes across the midline with a vestibular stimulus but this is not true for brainstem gaze palsies. Seizure activity may cause intermittent aversive horizontal deviation although the eyes may deviate to the side of the focus in post-ictal gaze palsy. Tonic downward deviation of the eyes is

associated with tectal compression caused by thalamic or dorsal midbrain lesions (usually haemorrhagic) but can be seen in metabolic coma or rarely in pseudocoma. Prolonged tonic upward deviation occurs as a consequence of extensive hypoxic–ischaemic damage but may occur transiently in seizures or in oculogyric crises caused by encephalitis lethargica or neuroleptic medication.

Horizontal nystagmus occurring in comatose patients suggests an irritative or a supratentorial averse epileptic focus, usually associated with other motor manifestations of seizures including movements of the eyelids, face, jaw or tongue. Intermittent unilateral nystagmoid jerks in a horizontal or rotatory fashion indicate mid or lower pontine damage. Parinaud’s syndrome (dorsal midbrain

syndrome) is characterised by loss of upgaze, light-near dissociation of pupillary responses, convergence-retraction nystagmus and eyelid retraction (Collier's sign). There may also be accommodation or convergence spasm, associated oculomotor palsy (III, IV), skew deviation or internuclear ophthalmoplegia. It is associated with direct compressive lesions in the dorsal midbrain including pineal tumours, obstructive hydrocephalus, mesencephalic haemorrhage, arteriovenous malformation, trauma or multiple sclerosis (MS).

**Spontaneous eye movements** Spontaneous roving eye movements are intermittent slow random purposeless lateral movements, either conjugate or dysconjugate. Roving eye movements imply intact oculomotor brainstem pathways and indicates light coma, typically resulting from metabolic or toxic causes. Periodic alternating gaze disturbance is characterised by a slow cycle of horizontal gaze deviation in which the eyes are deviated for several minutes before moving to the opposite lateral gaze. This occurs in metabolic coma, particularly hepatic encephalopathy, but can also occur with bilateral hemispheric infarction or diffuse brain injury. Conjugate vertical eye movements are separated into different types according to the relative velocities of the downward and upward phases

(Table 20.7). Vertical nystagmus differs from ocular bobbing and dipping because there is no latency between the corrective saccade and the next slow deviation. In the primary position there is a slow downward drift followed by a rapid correcting saccade.

**Vestibulo-ocular reflexes** Vestibulo-ocular reflexes are the involuntary ocular movements that occur after stimulation of the vestibular apparatus, and can be tested either by mechanical rotation of the head (oculo-cephalic) or caloric irrigation (oculo-vestibular). The oculo-cephalic reflex is tested by sudden passive rotation of the head in either lateral direction, or flexion and extension of the neck, while observing the motion of the eyes (Table 20.8). The manoeuvre should not be performed on any patient in whom cervical instability is suspected. If supranuclear influences are absent the eyes will normally remain fixed in space (i.e. continue to look forward).

Incomplete abduction suggests a VIth nerve palsy while impaired adduction suggests a IIIrd nerve palsy or an INO. Reduced or absent oculo-vestibular reflexes indicate severe intrinsic brainstem impairment. They are tested by irrigation of the tympanic membrane with cold or warm water (30°C or 44°C, respectively). In the awake subject, cold water causes a slow conjugate deviation of the eyes towards

**Table 20.7** Involuntary vertical eye movements in coma.

Ocular bobbing	Initial vertical movement is downward Repetitive rapid downbeating saccades followed by a slow return to the mid position Paralysis of both reflex and spontaneous horizontal eye movements	Intrinsic pontine or cerebellar lesion Metabolic and toxic coma Extra-axial posterior fossa masses
Ocular dipping	Initial vertical movement is downward Slow initial downward phase is followed by a relatively rapid return to mid position	Hypoxic-ischaemic brain injury Following status epilepticus
Downbeat nystagmus	Rapid downward saccade followed by slow upward drift It may have a rotatory or circular component and moves with the same frequency as palatal myoclonus It is distinguished from ocular bobbing as there is no latency between the upward phase and the following downward jerk	Impairment of the lower brainstem in the region of the inferior olive and is particularly seen with the Arnold–Chiari malformation.
Reverse ocular bobbing	Initial vertical movement is upward Rapid conjugate upward jerk followed by slow downward drift that carries the eyes past the midposition. Then eyes slowly return to mid position	Non-localising Metabolic Viral encephalitis Pontine haemorrhage
Reverse ocular dipping	Initial vertical movement is upward Slow initial upward phase followed by rapid downward saccade returning the eyes to the mid position	Viral encephalitis Metabolic encephalopathy Pontine infarction
Upbeat Nystagmus	Slow downward drift followed by a rapid upward correcting saccade	Associated with disorders at the ponto-mesencephalic or ponto-medullary junction Cerebrovascular disease Multiple sclerosis Brainstem infarct Wernicke's encephalopathy
Opsoclonus	Intermittent bursts of large amplitude high-velocity multidirectional saccadic eye movements If the movements are entirely horizontal they are called ocular flutter	Paraneoplastic Viral encephalitis Metabolic encephalopathy Drug toxicity

**Table 20.8** Oculocephalic responses.

Passive head movement (by examiner)	Response	Cause
Horizontal movement	Eyes remain conjugate and maintain fixation (move in opposite direction to head)	Normal with reduced level of consciousness
	No movement in either eye	Low brainstem lesion Peripheral vestibular lesion Drugs, anaesthesia
	Eyes move appropriately in one direction but do not cross the midline in the other	Gaze palsy (unilateral lesion in pontine gaze centre) Pontine lesion
	One eye abducts but the other fails to adduct	IIIrd nerve palsy Internuclear ophthalmoplegia (lesion of the median longitudinal fasciculus)
	One eye adducts but the other fails to abduct	VIIth nerve palsy
Vertical movement	Eyes remain conjugate and maintain fixation (move in direction opposite head movement)	Normal with reduced level of consciousness
	No movement in either eye	Low brainstem lesion Peripheral vestibular lesion Drugs, anaesthesia
	Only one eye moves	IIIrd nerve palsy
	Loss of upward gaze	Pretectal or midbrain tegmental compression

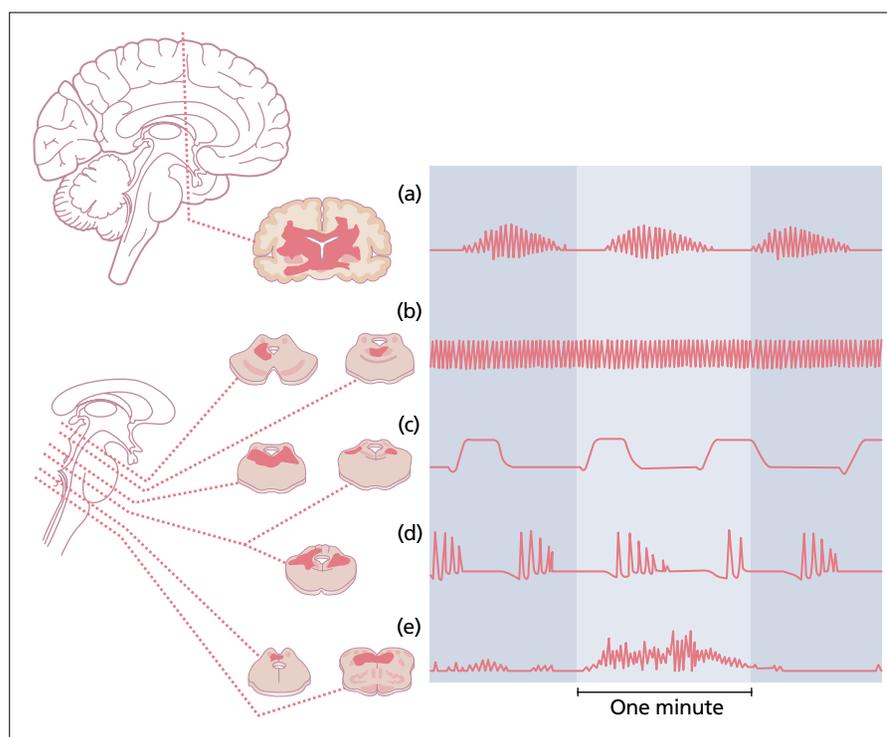

the stimulated ear followed by a corrective saccade towards the midline. Warm water irrigation causes conjugate eye deviation with a slow phase away from the stimulated ear followed by a corrective saccadic phase towards the ear. Simultaneous bilateral warm water application causes a slow upward deviation while simultaneous bilateral cold water application results in slow downward deviation. As with the oculo-cephalic manoeuvre, impaired abduction suggests a VIth nerve palsy while impaired adduction is compatible with a IIIrd nerve lesion or INO. Limited oculo-vestibular movements may be caused by metabolic and/or toxic coma or drug intoxication. Vertical movements are impaired by disorders of the midbrain particularly affecting regions responsible for maintaining consciousness, while pontine lesions lead to loss of horizontal saccadic movements.

**Other cranial nerves** The eyes are usually closed in coma. However, if the patient is in light coma and if both afferent and efferent limbs of the corneal reflex are intact and the eye is held open, a bilateral blink reflex can be elicited in response to corneal or eyelash stimulation. The blink reflex may be lost with a lesion at the level of the pons, interrupting the afferent pathway along the Vth cranial nerve. However, unilateral absence of blinking indicates a lesion of the VIIth nerve affecting the efferent pathway. In this situation the stimulus may induce deviation of the jaw to the opposite side (corneopterygoid reflex). The corneal reflex has a higher threshold in comatose patients and may be lost with deep sedation. The jaw jerk may be brisk in coma and the presence of clonus suggests involvement of the corticobulbar tract or metabolic encephalopathy but it is also seen during weaning from sedation or in the vegetative state. In coma the facial

grimace to painful stimuli reflects VIIth nerve function. Lesions at a pontine level may damage facial nerve nuclei and produce ipsilateral complete facial paralysis. Upper motor neurone lesions produce contralateral facial weakness, but tend to spare the forehead and orbicularis oculi muscles because of the bilateral cortical representation.

**Bulbar function** The clinical assessment of bulbar function in patients with an altered level of consciousness is difficult and unreliable. Airway protection may be impaired despite the presence of palatal movement and a pharyngeal and cough reflex. In an intubated patient the cough reflex may be tested indirectly by manipulating the tracheal tube or by administering tracheal suction. An impaired cough reflex is manifest as a poor or absent cough response, absence of distress and lack of lacrimation, and implies a central medullary lesion although the response may also be depressed by metabolic encephalopathy or by lesions of the afferent vagal pathway or efferent limb to the respiratory muscles. The pharyngeal (gag) reflex is also difficult to assess in comatose patients as it is suppressed by sedative drugs. However, impairment of palatal and uvula elevation upon pharyngeal and palatal stimulation implies low brainstem impairment.

Several characteristic patterns of respiratory irregularity have been described by Plum and Posner (Figure 20.2) but it is difficult to attribute precise respiratory function to discrete anatomical substrates because lesions are rarely localised and coexisting pulmonary, cardiovascular or autonomic influences may complicate the clinical picture. Furthermore, earlier recognition of respiratory insufficiency has led to rapid therapeutic intervention with controlled ventilation.

**Figure 20.2** Abnormal respiratory pattern associated with pathological lesions (shaded area) at various levels of the brain. tracings by chest-abdominal pneumograph, inspiration reads up. (a) Cheyne-Stokes respiration. (b) Central neurogenic hyperventilation. (c) Apneusis. (d) Cluster breathing. (e) Ataxic breathing. Source: Plum and Posner 1983. Reproduced with permission of Oxford University Press.

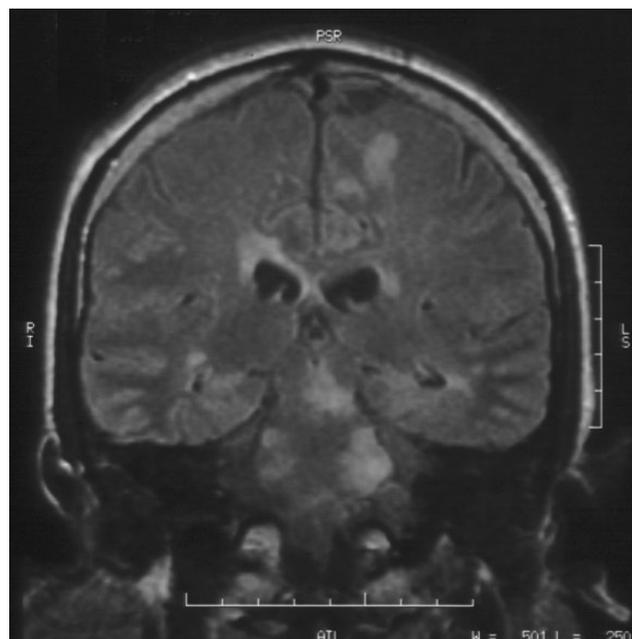

Primary central neurogenic hyperventilation is a rare condition characterised by rapid regular hyperventilation that persists in the face of alkalosis, elevated  $\text{PaO}_2$ , low  $\text{PaCO}_2$  and in the absence of any pulmonary or airway disorder. However, in the critically ill patient, an increased respiratory rate in coma is more commonly secondary to intrinsic lung involvement, especially aspiration pneumonia.

Apneustic breathing consists of sustained inspiratory cramps with prolonged pauses at full inspiration or alternating brief end-inspiratory and expiratory pauses. The pattern is associated with bilateral tegmental infarcts or demyelination in the pons (Figure 20.3).

In ataxic respiration there is a completely irregular respiratory cycle of variable frequency and tidal volume alternating with periods of apnoea; it is particularly associated with medullary impairment, either caused by brainstem stroke or compression and it is important to recognise as it may herald impending respiratory arrest.

Hiccups consist of brief bursts of intense inspiratory activity involving the diaphragm and inspiratory intercostal muscles. Intractable hiccups can be the result of structural or functional disturbances of the medulla or its afferent or efferent connections with the respiratory muscles. The presence of hiccups in this context can also presage the development of respiratory arrhythmia culminating in respiratory arrest.

Voluntary control of breathing can be impaired by bilateral lesions affecting the descending corticospinal or corticobulbar tracts, and is particularly seen in association with destructive vascular lesions of the basal pons or of the medullary pyramids which may result in the 'locked-in' syndrome. Selective interruption of the voluntary pathways leads to a strikingly regular and unvarying respiratory pattern, with loss of the ability to take a deep breath, hold the breath, cough voluntarily or initiate any kind of volitional respiratory movement although the respiratory pattern may vary with emotional stimuli. These patients can often be weaned from artificial ventilation.

**Figure 20.3** Extensive plaques of demyelination in the brainstem of a patient with ataxic breathing and progressive central apnoea requiring ventilatory support (MRI, coronal, FLAIR).

Cheyne-Stokes respiration (CSR) is characterised by a smooth waxing and waning of breath volume and frequency separated by periods of central apnoea. The respiratory oscillations are associated with phasic changes in cerebral blood flow (CBF), CSF pressure,

PaO<sub>2</sub> and alveolar oxygen and carbon dioxide, level of alertness and pupillary size; periodic heart block and ventricular arrhythmias are also common. Neurogenic CSR is associated with diffuse metabolic encephalopathy, cerebrovascular disease and raised ICP and may occur with supratentorial or, less commonly, infratentorial structural lesions.

**Motor responses** Examining the motor responses involves assessment of the:

- Resting posture of the limbs and head
- Involuntary movements
- Spontaneous movements (purposeful or non-purposeful)
- Response to external stimuli – the motor response to deep painful stimuli is extremely valuable in assessing diagnosis and prognosis of coma.

Two characteristic patterns of generalised responses are recognised:

- 1 Decorticate posturing refers to flexion at the elbows and wrists with shoulder adduction and internal rotation and extension of the lower extremities. It has a poor localising value and may result from lesions of the hemispheres or thalamus above the diencephalon.
- 2 Decerebrate posture is characterised by bilateral extension of the lower extremities, adduction and internal rotation of the shoulders and extension at the elbows. It is usually caused by brainstem lesions, particularly of the bilateral midbrain or pons, and carries a poor prognosis. Occasionally, decerebrate posturing occurs as a result of severe metabolic encephalopathy (e.g. caused by hypoglycaemia or liver failure) or bilateral supratentorial lesions involving the motor pathways.

In clinical practice the pattern of motor response to stimuli is often mixed within the same patient with localising, flexion or extension movements occurring in different limbs and varying with recovery.

**Tone** The pattern and asymmetry of muscle tone may be helpful in localising focal structural lesions, and may help in differentiating metabolic from structural coma. The presence of spasticity implies established lesions while acute structural damage affecting the spinal cord or metabolic encephalopathy usually leads to hypotonia and flaccidity. The presence of a unilateral grasp reflex indicates an ipsilateral frontal lobe disturbance. Plucking or clutching movements of the limbs indicate light coma and intact corticospinal pathways.

**Involuntary movements** Tonic-clonic or other stereotyped movements suggest generalised or focal seizures or *epilepsia partialis continua* (EPC). Myoclonic jerking (non-rhythmic jerking movements in single or multiple muscle groups) is seen with hypoxic-ischaemic encephalopathy or metabolic coma (e.g. hepatic encephalopathy). Rhythmic myoclonus must be distinguished from *epilepsia partialis continua*.

### Distinction of metabolic and toxic coma from structural coma

It is often possible to distinguish metabolic encephalopathy from structural causes on the basis of clinical examination although non-convulsive status epilepticus can resemble both causes. The preceding medical history may suggest a metabolic abnormality and the onset is more likely to be acute in the presence of a toxic or structural lesion. Metabolic or toxic lesions usually result in coma without lateralising or brainstem signs while structural lesions may be suggested by asymmetrical motor signs. Metabolic encephalopathy is

favoured by the presence of involuntary limb movements (tremor, myoclonus and asterixis), abnormalities of the respiratory pattern (hypoventilation or hyperventilation) and the presence of acid-base disturbances. The level of consciousness tends to fluctuate and be lighter in patients with metabolic disorders. However, these clinical features are merely indicators.

### Psychogenic unresponsiveness

This may be distinguished by history, examination and, if necessary, investigations. There are often atypical factors in the history and occasionally obvious psychiatric precipitating factors. Examination reveals inconsistent volitional responses, particularly on eyelid opening. When the patient's hand is held in front of their face and then loosened it may drop and slide next to the face rather than fall directly. Tickling the hair cells with a vibrating fork may cause the eyes to open. There may be forced upward or downward gaze which suddenly changes direction. Spontaneous saccadic eye movements are often present, and pupillary constriction will occur on eye opening. Oculo-vestibular stimulation with cold stimulus will show preservation of the fast phase away from the stimulated side and the electroencephalography (EEG) will show responsive alpha rhythms.

### Outcome from coma

Most patients who survive the initial insult emerge from coma within 2–4 weeks, although the pattern and extent of recovery is highly variable, ranging from vegetative state to full recovery. It is not possible to assess the prognosis of a patient in coma with accuracy but a number of clinical factors help in predicting the likely outcome. Most data are based on the assessment of patients with hypoxic-ischaemic brain injury (HIBI).

### Aetiology

Coma associated with drug and alcohol ingestion or metabolic disturbance generally carries a good prognosis for recovery providing there is no severe underlying disorder. The prognosis for a patient in traumatic coma is better than that for a patient at a similar level of coma from non-traumatic causes. Patients in coma caused by structural cerebral disease (e.g. cerebrovascular disease or SAH) and HIBI is poor.

### Depth of coma

The depth of coma, as determined by GCS and by the presence or absence of reflexes in the cranial nerve territory, is a sensitive guide to outcome.

### Duration of coma

Survival following cardiorespiratory arrest is closely correlated with the duration of coma. Only 12% of patients comatose more than 6 hours after cardiac arrest survive with a good outcome or moderate deficits and, if there is no eye opening, vocal response or motor function after 6 hours the patient has only a 6% chance of making a moderate or good recovery.

### Presence of seizures

The presence of focal or generalized seizures and convulsive and non-convulsive status epilepticus are all associated with a poorer outcome.

### Co-morbidity

Following cardiac arrest there is a clear correlation between outcome and age at cardiac arrest. The presence of coexisting general medical disorders are also associated with a poor outcome: ischaemic heart disease, structural cardiac disease, hypertension,

diabetes mellitus, impaired renal function and the presence of pneumonia or sepsis.

### Investigations

A poor prognosis is indicated by:

- Imaging showing either anteroseptal shift, extensive subcortical change (Figure 20.4), temporal lobe infarction and hydrocephalus implies a worse outlook.
- Raised ICP.
- An iso-electric EEG, burst-suppression or 'alpha coma' (8–12 Hz rhythm, which is not localised to the occipital lobe, and which does not suppress upon eye opening).
- Absent cortical somatosensory evoked potentials performed >12–24 hours after cardiorespiratory arrest.

Following TBI, the most important predictive features for survival of patients in coma >6 hours are:

- Depth of coma on GCS
- Age
- The extent of injury, presence of skull fracture, hemispheric damage or extracranial injury.

Following a cardiorespiratory arrest, the most accurate guides to a poor prognosis at 3 days are:

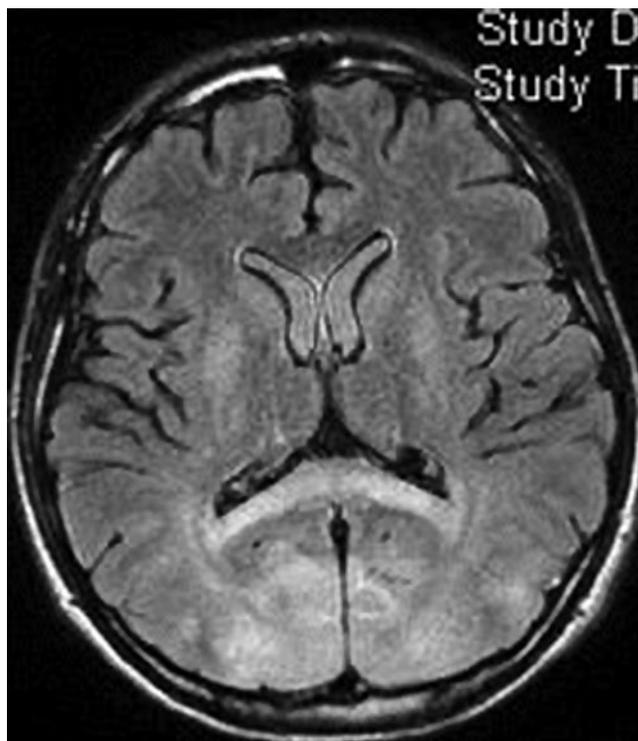

- Absence of pupillary light reflexes, corneal reflexes and motor responses (except extensor plantar responses)
- Absence of other brainstem reflexes
- Loss of cortical N20 response on short latency somatosensory evoked potential (SSEPs) at 1–3 days
- Elevated serum neurone-specific enolase
- EEG showing alpha coma, burst suppression or an isoelectric trace

These features provide some prognostic information to allow discussion with relatives about the patient's wishes and likely outcome. However, these indicators are by no means specific or reliable. A poor outcome may also occur even if the initial signs suggest recovery. It must be emphasised too that many of these statements relate to studies that were undertaken several years ago. With better techniques of intensive care, physiological measurement and cerebral protection these data should only be used as a general guide.

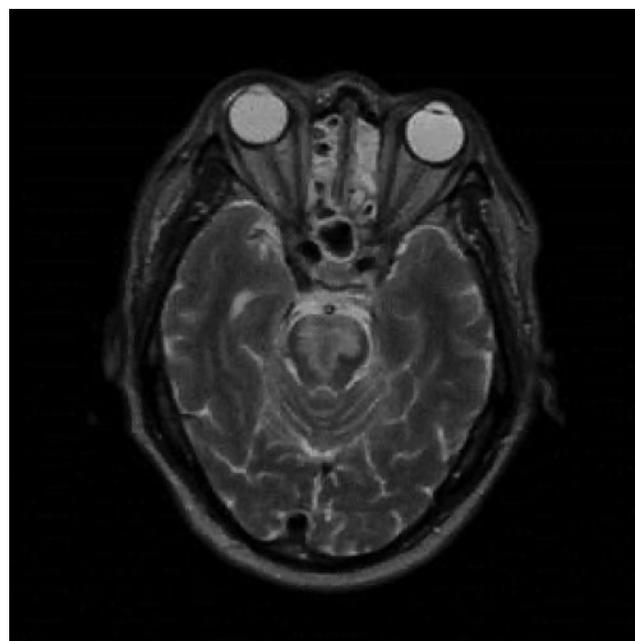

### Locked-in syndrome

The locked-in syndrome is characterised by preservation of consciousness with dissociation between automatic and volitional control of lower cranial nerve and limb function. Volitional respiratory, facial, bulbar and limb control is lost but there may be involuntary movements including ocular bobbing, facial grimacing, oral automatisms and trismus, palatal myoclonus and emotional responses including laughing and crying. There is preserved awareness of the environment and self, and patients can usually communicate through vertical eye movements, with synergistic elevation of the upper eyelids when looking upwards. These vertical eye movements are often slow and incomplete, but are the only way in which the patient can communicate because there is a horizontal gaze palsy, anarthria and tetraplegia. These patients are not in coma so it is essential to establish a consistent form of communication, however laborious for the patient and their carers.

The most frequent cause of locked-in syndrome is vertebro-basilar occlusion, usually in the rostral or middle segments (Figure 20.5). Pontine haemorrhage or embolism may also cause the condition. Other causes of the syndrome have been described in which the lesion was situated in the ventral pontine tegmentum, basis pontis or in the mesencephalic region at the level of the cerebral peduncles.

**Figure 20.4** Global ischaemic–hypoxic brain lesions (MRI, axial, FLAIR).

**Figure 20.5** Extensive pontine infarction caused by vertebrobasilar occlusion in a patient with locked-in syndrome (MRI, T2-weighted).

The aetiology of non-vascular cases include central pontine myelinolysis, trauma, encephalitis, tumour, pontine abscess, MS and heroin abuse. Peripheral lesions (i.e. severe neuropathy such as Guillain-Barré syndrome) may cause an apparent locked-in syndrome with severe limb, facial and bulbar paresis, although respiration is frequently affected because of respiratory muscle involvement. In addition, vertical eye movements are not selectively spared in the same way as with the classic syndrome.

Functional recovery is possible in both vascular and non-vascular groups of locked-in patients and therefore an aggressive rehabilitation programme should be instituted as early as possible to allow the patient to achieve the highest possible level of recovery as rapidly as possible. However, the prognosis for most patients in locked-in syndromes is poor, with severe residual disability. The mortality rate is high with most deaths occurring in the first 4 months, either from extension of the lesion or from respiratory complications (pneumonia, respiratory arrest or pulmonary embolus).

### Vegetative state

Patients in a vegetative state appear to be awake with their eyes open but show no evidence of awareness of self or environment, are unable to interact with others and have no evidence of sustained reproducible purposeful or voluntary behavioural responses to visual, auditory, tactile or noxious stimuli. There is no evidence of language comprehension or expression. Patients are able to breathe spontaneously and the papillary, ocular, gag, cough, sucking and swallowing reflexes are usually present. Sleep-wake cycles are preserved as are hypothalamic and brainstem autonomic responses. There is bladder and bowel incontinence. Inconsistent non-purposeful movements, facial grimacing, smiling and frowning, chewing, swallowing, bruxism, vocalisation, grasping and inconsistent auditory and oculomotor orientating reflexes to peripheral sounds or movement may occur. The diagnosis of vegetative state is not tenable if there is any degree of voluntary movement, sustained visual pursuit, consistent and reproducible visual fixation or response to threatening gestures.

The vegetative state usually develops after a variable period of coma; it may be partially or totally reversible or may become established. Persistent vegetative state is defined as a vegetative state that has continued for at least 1 month. This definition does not imply permanency or irreversibility. It has been recommended that the term “permanent vegetative state (PVS)” be used to describe patients who remain in a vegetative state for more than 3 months after a hypoxic brain injury or 12 months after cranial trauma as improvement after this time is highly unlikely. However, the term is best avoided because there is a high rate of misdiagnosis.

It has recently been shown by functional imaging techniques that exposure to personally meaningful information or verbal instructions activates the cerebral cortex in some patients in a vegetative state and in some exceptional instances patients in a vegetative state can retain a degree of awareness or even communication shown by reproducible changes on functional imaging in response to stimuli. These patients have generally sustained TBI and some emerge into a minimally conscious state. This finding emphasises the difficulty in establishing a diagnosis of permanent vegetative state. Functional imaging techniques may be used to supplement clinical observation of the unconscious patients but it is important to recognise that activation does not necessarily reveal conscious experience, memory or self-awareness. The clinical implication of these studies is that patients in a vegetative state cannot any more be considered to be totally lacking in awareness. This has led to the naming of the condition unresponsive wakefulness syndrome (UWS) rather than vegetative state.

### Minimally conscious state

Patients in a minimally conscious state (MCS) are no longer in coma nor in a vegetative state because they demonstrate low level behavioural responses consistent with severe neurological impairment and disability. MCS is much more common than vegetative state 6 months after brain injury. This condition includes a wide variety of responses. Patients who are minimally responsive may be able to show consistent evidence of awareness of themselves or their environments by making eye contact, or turning their heads to sound, following simple commands, gestural or verbal yes/no responses, intelligible speech or purposeful behaviour. They are not able to communicate consistently. These patients may remain in minimally responsive states or eventually recover some ability to communicate reliably or use objects functionally. Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) studies show that patients in MCS can have more extended cerebral processing in response to external stimuli or various modalities such as noxious or self-related auditory stimuli. The extent of activation in individual brain damage patients in response to complex stimuli sometimes correlates with clinical outcome and functional imaging may be helpful as a prognostic indicator.

### Determining brain death

Cardiac and respiratory function can be maintained artificially for prolonged periods after the brain has ceased to function. The diagnosis of brain death is necessary when withdrawal of artificial life support is considered and if the possibility of organ donation exists. These are both delicate issues.

Brain death is diagnosed in three stages.

- 1 It must be established that the patient has suffered an event of known aetiology resulting in irreversible brain damage with apnoeic coma (i.e. the patient is deeply unconscious, mechanically ventilated with no spontaneous respiratory movement)
- 2 Reversible causes of coma must be excluded, and
- 3 A set of bedside clinical tests of brainstem function are undertaken to confirm the diagnosis of brainstem death and to exclude any relevant metabolic derangement.

The procedure is as follows:

- 1 The cause of coma must be known to be irremediable brain damage of known aetiology. This may be obvious within hours of a primary intracranial event such as a severe head injury or spontaneous intracranial haemorrhage, but diagnosis may be more difficult following hypoxic brain injury or encephalitis.
- 2 There should be no evidence that coma could be caused by depressant drugs or neuromuscular blocking agents. Narcotics, hypnotics and tranquillisers may have prolonged action, particularly when hypothermia coexists or in the context of renal or hepatic failure. Determination of sedative drug levels and tests of neuromuscular function may be necessary.
- 3 Primary hypothermia (<35°C) as the cause of unconsciousness must have been excluded. It is important to recognise that the previously widespread adoption of therapeutic hypothermia can further complicate the determination of brain death.
- 4 Potentially reversible circulatory, metabolic and endocrine disturbances must have been excluded as the cause of the continuation of unconsciousness.
- 5 The patient is being maintained on the ventilator because spontaneous respiration has ceased.

- 6 All brainstem reflexes are absent:
- The pupils are fixed, dilated and do not respond to sharp changes in the intensity of light.
  - There is no corneal reflex (care should be taken to avoid damage to the cornea because this may be used for organ donation).
  - The vestibulo-ocular reflexes are absent. No eye movements are seen during or following the slow injection of at least 50 mL ice cold water over 1 minute into each external auditory meatus in turn. Wait several minutes before testing the other side. Clear access to the tympanic membrane must be established by direct inspection and the head should be flexed at 30°.
  - There is no gag reflex or reflex response to bronchial stimulation when a suction catheter is passed into the trachea.
  - No motor responses can be elicited following painful stimulation applied to an area within the cranial nerve distribution.
  - No respiratory movements occur when the patient is disconnected from the mechanical ventilator. During this test the PaCO<sub>2</sub> should reach 6.65 kPa. This should be ensured by arterial blood gas measurement. Hypoxaemia following disconnection from the ventilator should be prevented by pre-oxygenating the patient with 100% oxygen for 10 minutes while on the ventilator and then delivering oxygen at 6 L/minute through a catheter situated in the tracheal tube when mechanical ventilation is temporarily removed. This test examines the function of the respiratory centre.

### Repetition of testing

In the United Kingdom, the diagnosis of death by brainstem testing should be made by at least two medical practitioners who have been registered for more than 5 years, have been trained in this field and are not members of the transplant team. The complete set of tests should always be performed on two separate occasions by the two practitioners working alone or together. The interval between tests has not been defined in adults, and usually the tests are repeated within a short period to avoid further distress to the patient's relatives. In legal terms, the time of death is taken as the time of the first failed brainstem test. Confirmatory ancillary tests (EEG, transcranial Doppler, CBF scanning or cerebral angiography) are not required in the United Kingdom, United States or most European countries.

It is essential that relatives, partners and carers be kept fully informed of the clinical condition of the patient and that explanation be given to them regarding the condition and prognosis. They should be given explanation of the investigations being undertaken and of their interpretation throughout the process of the determination of death of the brainstem in a sympathetic, timely and appropriate fashion by those concerned.

### Neurological intensive care

Dedicated neurological intensive care units (NICUs) are predominantly involved with the management of patients with primary encephalopathies, the control of raised ICP, the management of ventilatory, autonomic and bulbar insufficiency, and the consequences of profound neuromuscular weakness. The increasing availability of NICUs in Europe and the United States has allowed a focus on all critical needs of the neurological patient as well as the management of peri-operative instability of patients with neurosurgical or interventional neuroradiology. In general, critical

illness resulting from primary neurological diseases such as myasthenia gravis, Guillain-Barré syndrome, CNS infections, status epilepticus and stroke have a better outcome than those patients with neurological disease secondary to general medical disorders seen on general ICUs. However, such patients can remain dependent on ICU support for very much longer periods of time. This results in significant psychological demands on the patients, their carers, nurses, physicians and other health care professionals. There is sound evidence that patients with critical neurological disease have better outcomes when cared for in dedicated NICUs.

### Indications for intensive care management of neurological patients

The major indications for considering admission to NICU include the management of coma, bulbar or generalised weakness, autonomic failure, raised ICP and/or status epilepticus.

The aim of neurological intensive care is monitoring, early detection and management of impending neurological or systemic deterioration, as well as the minimisation of such risk that will potentially lead to deterioration or poor outcome. There are general principles of intensive care management including meticulous nursing and medical care, monitoring of a range of physiological variables and early and aggressive physiotherapy, including frequent alterations of limb positioning, passive limb movements and appropriate splinting which helps to maintain joint mobility and prevents limb contractures and pain while awaiting neurological improvement. Other aspects of general ICU care include the management of agitation and pain, maintenance of an adequate airway and ventilation, cardiovascular stability, nutrition and prophylaxis against thromboembolism.

Many patients with impaired consciousness or severe neuromuscular weakness are not able to communicate adequately. It is essential that satisfactory means of communication are established as soon as possible. Furthermore, when communication is difficult, the family often represents the patient's interests and they must therefore have comprehensive access to medical and nursing staff throughout so that they understand the immediate clinical situation, management and outlook.

### Ventilatory failure associated with neurological disease

The central and peripheral causes of ventilatory insufficiency or failure that may require admission to the NICU are listed in Tables 20.9 and 20.10. It is essential to anticipate the development of respiratory failure before the emergence of hypoxia and/or hypercapnia. Thus, the threshold for tracheal intubation is lower in the context of rapidly progressive neuromuscular weakness. Patients with acute neurological disorders require tracheal intubation and ventilation because of the development of acute respiratory insufficiency or because they are unable to protect their upper airway from obstruction as a consequence of impaired consciousness or bulbar weakness. The latter predisposes to pulmonary aspiration of saliva and food that cannot be cleared by the patient because of an inadequate cough secondary to poor diaphragmatic and anterior abdominal wall musculature. Bronchopneumonia often results.

The most useful and reproducible bedside test of ventilatory function is the measurement of the forced vital capacity (FVC). The normal value is approximately 10–15 mL/kg. Serial measurements often indicate whether respiratory muscle function is stable or deteriorating and are especially important in fluctuating diseases such as myasthenia gravis. By the time arterial blood gas

tensions have become abnormal respiratory muscle function is often severely compromised.

### Neurological indications for tracheal intubation and mechanical ventilation

The nature of neurological respiratory failure can dictate a prolonged period of mechanical ventilation. When this is the case, the orotracheal tube should be replaced by a tracheostomy as soon as possible. Tracheostomy allows greater patient comfort, easier nursing management (including suction) and the possibility of oral nutrition and speech, as well as aiding weaning from mechanical ventilation by reducing respiratory dead space. Indications for tracheal intubation are shown in Table 20.11.

### Mechanical ventilation

Mechanical ventilation of the lungs may be provided by intermittent negative pressure ventilation or intermittent positive pressure ventilation. The former is delivered using devices such as tank ventilators (iron lungs) and cuirass ventilators; apart from in a few specialised units, these devices are rarely used nowadays. Modes of ventilation are summarised in Table 20.12.

### Weaning

Weaning of patients from mechanical ventilation may start as soon as respiratory muscle function returns; the patient needs to be able to maintain adequate oxygenation, a normal respiratory rate and appropriate spontaneous tidal volumes with minimal mechanical support. In addition, the patient needs to maintain a patent airway, to initiate cough and gag reflexes and to clear secretions independently. Sophisticated ventilatory modes (Table 20.12) aid weaning, but many units prefer to wean by allowing patients to breathe spontaneously off the ventilator for increasing periods solely with continuous positive airway pressure (CPAP).

### Conditions requiring neurointensive care support

#### Raised intracranial pressure

ICP is the pressure exerted by the CSF in the frontal horns of the lateral ventricles of the brain. It is normally 7–17 mmHg (1–2 kPa) when supine. Because the skull, in an adult, is a rigid box and its contents are incompressible, the ICP depends on the volume of intracranial contents, normally approximately 100 mL blood (5–7%), 50–120 mL CSF (5–12%) and 1.4 L brain tissue (80–85%). The Monro–Kellie doctrine states that because the total intracranial volume remains constant, an increase in the volume of one of the components of the intracranial cavity (e.g. brain) requires a compensatory reduction in another (e.g. CSF) to maintain a constant pressure. Because brain tissue is essentially incompressible, any additional volume results in movement of CSF into the spinal subarachnoid space, reduction of CSF volume by increased absorption in the arachnoid villi and removal of blood from the cerebrovascular bed. As mass effect worsens, compensatory mechanisms are pushed to exhaustion and a relatively small increase in volume will precipitate a large rise in ICP.

ICP has a key role in determining cerebral perfusion pressure (CPP) and CBF. As the ICP rises, CPP and CBF decrease, particularly when cerebral autoregulation is impaired. This may lead to obstruction of venous blood vessels, brain swelling, regional ischaemia, structural distortion and the development of brainstem compression. Recent studies show that ICP elevation itself (in the presence of well-controlled CPP <60) was independently associated with neurological deterioration; so even if CPP is maintained, an elevated ICP state can still aggravate neurological injury.

Raised ICP can be caused by:

- Mass effect (e.g. tumour, infarction with oedema, contusion, intracerebral haemorrhage, haematoma – extradural or subdural).
- Generalised cerebral oedema (e.g. hypertensive encephalopathy, following hypoxic ischaemic brain injury and status epilepticus, liver failure or hypercapnia).
- Increase in venous pressure (e.g. venous sinus thrombosis, superior vena cava obstruction).
- Obstruction to CSF flow and/or absorption (e.g. obstructive hydrocephalus, extensive meningeal infiltration, SAH).
- Increased CSF production (e.g. choroid plexus tumour, meningitis, SAH).

Raised ICP in the conscious patient is characterised by headache, which may be exacerbated by coughing, sneezing or straining. It is often worse on waking and associated with nausea and vomiting. The diurnal variation in headache is caused by raised ICP when recumbent and associated raised PaCO<sub>2</sub> and reduced CSF absorption during sleep.

**Table 20.11** Indications for tracheal intubation.

A decreasing forced vital capacity in the presence of bulbar dysfunction
Impending neuromuscular respiratory failure (forced vital capacity <15 mL/kg, tachypnoea, poor cough, dyspnoea at rest, use of accessory muscles, staccato speech)
Respiratory failure ( $\text{PaO}_2 < 8 \text{ kPa}$ (60 mmHg) breathing room air) with or without hypercarbia
Inability to protect airway
Failure of central regulation of respiration (apnoea, ataxic or cluster breathing)
Brain swelling with depressed level of consciousness (Glasgow Coma Score <9)
To provide control of $\text{PaCO}_2$ in patients with raised intracranial pressure
Bulbar failure (in order to protect the airway from pulmonary aspiration)
Encephalopathy/coma
Cardiovascular instability (e.g. hypotension)

Reduced level of consciousness is an almost universal finding in patients who have significant acute herniation syndromes; with or without ICP elevation. In severely raised ICP this is accompanied by Cushing's triad (bradycardia, hypertension and respiratory irregularity). It is important to note that raised ICP is not always observed in herniation.

Raised ICP may be unvarying, particularly following head injury when the level reflects the severity of the insult (severe >20 mmHg). However, the presence of fluctuations and, in particular, A and B waves, indicates rapid deterioration because of vasogenic change and suggests that intracranial hypertension leading to herniation will develop unless urgent intervention is undertaken (Figure 20.6).

#### Measurement of intracranial pressure

A variety of different techniques are available for the measurement of ICP. Intraventricular fluid filled catheter transducer systems require an external pressure transducer connected to a catheter placed in the lateral ventricle to allow direct pressure management. The system is the most accurate technique for ICP measurement as it can be recalibrated as required and allows drainage of CSF. It is not limited by intercompartment pressure gradients provided all

**Table 20.12** Modes of ventilatory support.

Controlled mechanical ventilation (CMV)	Preset tidal volume at a preset respiratory rate, independent of the patient's respiratory effort Patient is completely dependent on the ventilator Used for patients who are unable to breathe or who have received neuromuscular blocking agents
Intermittent mandatory ventilation (IMV)	A mandatory minute volume is preset and delivered by the ventilator, but the patient is allowed to breathe spontaneously from a gas source between ventilator breaths
Synchronised intermittent mandatory ventilation (SIMV)	As for IMV but with coordination of the positive pressure ventilation by the ventilator so that it coincides with a spontaneous breath
Inspiratory pressure support	The patient's spontaneous breath is augmented with supplementary gas flow
Inspiratory volume support	Ventilator automatically monitors the lung properties and modifies the inspiratory pressure support in order to deliver a predetermined tidal volume
Positive end expiratory pressure (PEEP)	An adjunct to intermittent positive pressure ventilation (IPPV) and maintains a positive pressure during expiration. Helps minimise alveolar collapse and improves lung compliance
Continuous positive airway pressure (CPAP)	The application of positive airway pressure throughout all phases of spontaneous ventilation. Helps prevent airway and alveolar collapse

the ventricles are in communication. However, these catheters are associated with a risk of infection, blockage, haematoma formation and seizures and are difficult to place in small ventricles which are a common problem if raised ICP is caused by brain swelling.

More commonly, a catheter tip transducer system is used to record from the ventricle, subdural or subarachnoid space or parenchyma. This is usually undertaken with a catheter tip transducer inserted via an airtight support bolt (e.g. Codman® or Camino®). These systems are slightly less reliable, require pre-insertion calibration and may fail after several days, but the ease of placement has led to their widespread use in patients with cerebral trauma.

#### Indications for intracranial pressure monitoring

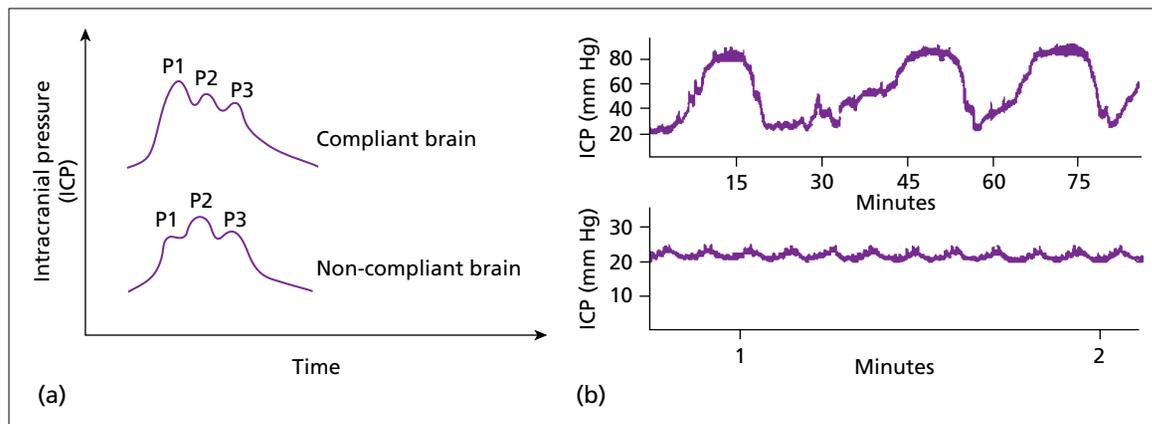

ICP monitoring is undertaken as a guide to treatment or, less commonly, as a diagnostic investigation. Clinical and radiological evidence is not always a reliable guide to raised ICP and monitoring is necessary if there is an unstable haemodynamic state or a mass lesion indicating the possibility of incipient herniation.

Evidence supports the routine use of ICP monitoring in patients with severe head injury (GCS 3–8) and an abnormal CT scan, significant focal motor signs or hypotension. ICP monitoring may be helpful following SAH, intracerebral haemorrhage, venous sinus thrombosis or following hypoxic brain injury, encephalitis or hepatic encephalopathy. It may also be of diagnostic value in patients with normal pressure hydrocephalus, idiopathic intracranial hypertension or decompensated hydrocephalus.

#### Management

The management of raised ICP following TBI is summarised in (Figure 20.7). Urgent treatment of raised ICP may be necessary to avoid development and progression of herniation and subsequent brain ischaemia, infarction and death. If ICP exceeds 20 mmHg treatment is mandatory.

The first line of management of raised ICP is to ensure a secure airway and maintain oxygenation and systemic mean arterial blood

**Figure 20.6** (a) The ICP waveform is essentially a modified arterial pressure trace and has characteristic elements. In the normal brain, the first peak (P1, the percussive wave) is a result of arterial pressure transmitted from the choroid plexus. P2 is the 'tidal' wave and reflects brain compliance. P3 is caused by closure of the aortic valve (i.e. the dicrotic notch). In the non-compliant brain, the amplitude of P2 typically exceeds P1. (b) More useful information is gained by recording ICP waveforms over time and certain patterns may be seen. Lundberg A (plateau) waves consist of rapid rises in ICP lasting 5–10 minutes (upper trace). They are always pathological and represent severe intracranial hypertension. Lundberg B waves are oscillations in ICP of 0.5–2 waves/min and represent unstable ICP, possibly related to cerebral vasospasm. Intracranial pressure (ICP) trace for a patient with a plateau of high ICP (lower trace).

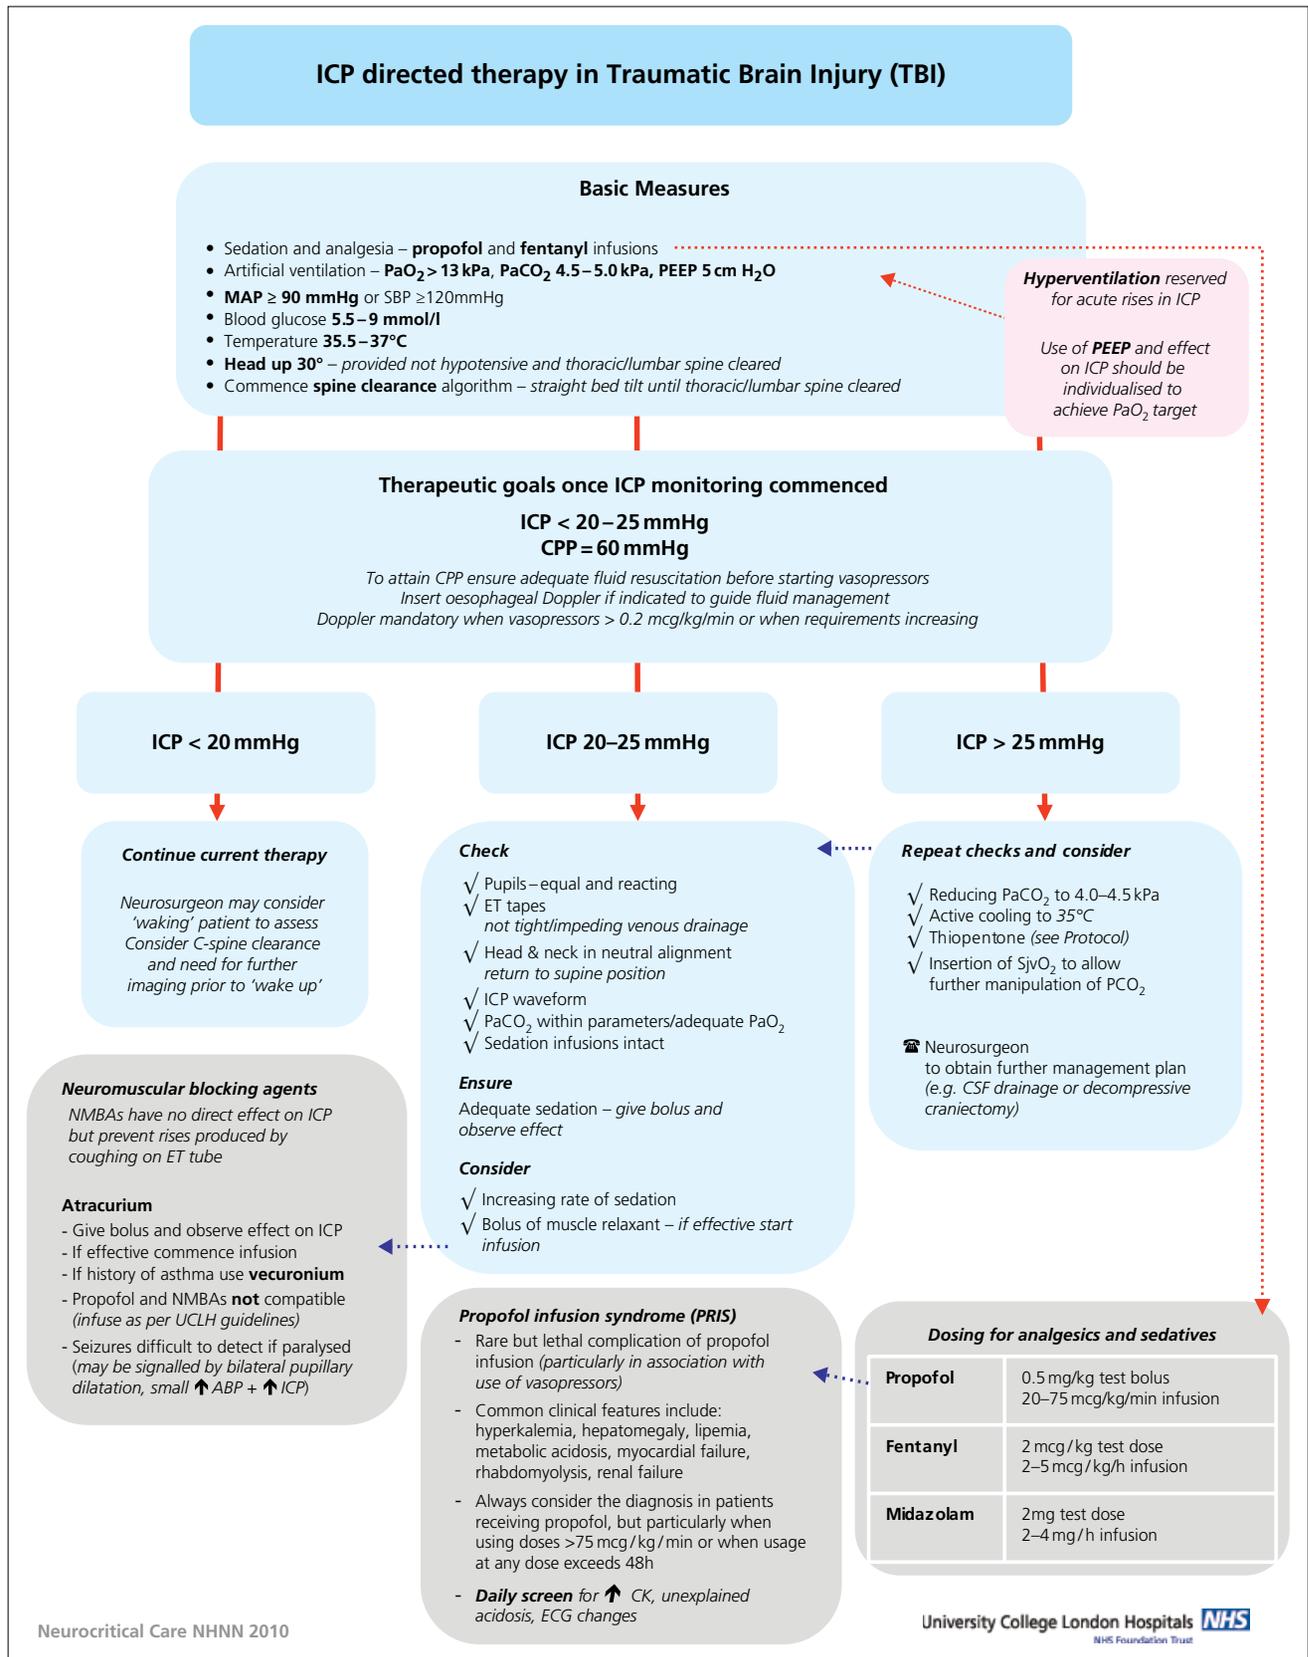

Figure 20.7 National Hospital protocol for the management of patients with raised intracranial pressure following traumatic brain injury (TBI).

pressure (MAP >80 mmHg should be targeted). Treatment of the underlying cause, where possible, should be undertaken urgently and aggressive control of metabolic derangements, seizures and pyrexia is essential. CPP must be maintained at 50–70 mmHg by ensuring optimal arterial blood pressure with avoidance of hypotension; this requires careful intravenous fluid management and the use of inotropic agents. Neuromuscular blockade, sedation and analgesia are needed to help avoid surges in ICP from suctioning, coughing or other interventions such as physiotherapy.

**Head positioning** The head should be elevated to 30° to facilitate venous drainage. Any constriction around the neck (e.g. tracheal tube ties) must be avoided as this may obstruct cerebral venous drainage.

**Controlled hyperventilation** Hyperventilation lowers PaCO<sub>2</sub> and induces cerebral vasoconstriction reducing cerebral blood volume. This is a rapid, effective way of reducing elevated ICP but is limited by a contingent reduction in CBF to any area of critical perfusion. Patients are therefore ventilated to a PaCO<sub>2</sub> of 4 kPa. Beneficial effects of hyperventilation are often transient and it should only be used for 10–20 hours and then weaned slowly.

**Osmotic agents** Mannitol is a hyperosmolar diuretic that lowers ICP and increases CBF by drawing free water out of the brain tissue and into the circulation thus reducing interstitial water content and dehydrating brain parenchyma. This effect is achieved by establishing an osmotic gradient between blood and brain parenchyma. However, with prolonged therapy, mannitol may diffuse into damaged brain cells and exacerbate tissue oedema. It is also associated with a hyperosmotic state and leads to a profound diuresis with consequent fluid management difficulties. Mannitol 20% is given as a bolus 1 g/kg. Repeat doses are given at 0.25–0.5 g/kg as needed every 6–8 hours. Furosemide and thiazide diuretics may also be used to increase osmolarity in the vascular compartment and maintain the intravascular volume.

**Inotropic support** Augmentation of MAP may help delivery of oxygen and glucose to the brain averting the progression to cytotoxic oedema and reducing ICP.

**CSF drainage via an intraventricular catheter** This may be undertaken intermittently in response to elevations in ICP. However, ventriculostomy is associated with a risk of peri-operative haemorrhage and secondary infection thereafter.

**Hypothermia** Hypothermia can lower ICP by decreasing cerebral metabolism. Moderate hypothermia (35°C) decreases raised ICP but lower body temperatures cause cardiac arrhythmias and coagulation disturbances. Raised body temperature is deleterious as it increases ICP and must therefore be treated aggressively. Hypothermia is now widely used in combination with other therapies for lowering raised ICP; however, there remains considerable uncertainty about the long-term benefits.

**Fever control** Temperature elevation causes more harm, by vasodilatation, an increase in intracranial mass and thus more neuronal injury. Adequate control of pyrexia is essential.

**Decompressive surgery** This has been increasingly used following extensive TBI and middle cerebral artery occlusion, intracranial haemorrhage, SAH or severe encephalitis. Some reports suggest

good recovery but there is a high incidence of severe residual morbidity.

**Other interventions** Barbiturate-induced coma reduces cerebral metabolic activity and causes cerebral vasoconstriction which leads to a reduction in CBF, cerebral blood volume and consequently ICP but may be accompanied by a high incidence of side effects, particularly hypotension.

### Cerebral herniation

Cerebral herniation is an important mechanism of coma and permanent neurological impairment. It occurs when raised ICP leads to torsion and compression of the brainstem against the tentorium, falx and bony structures.

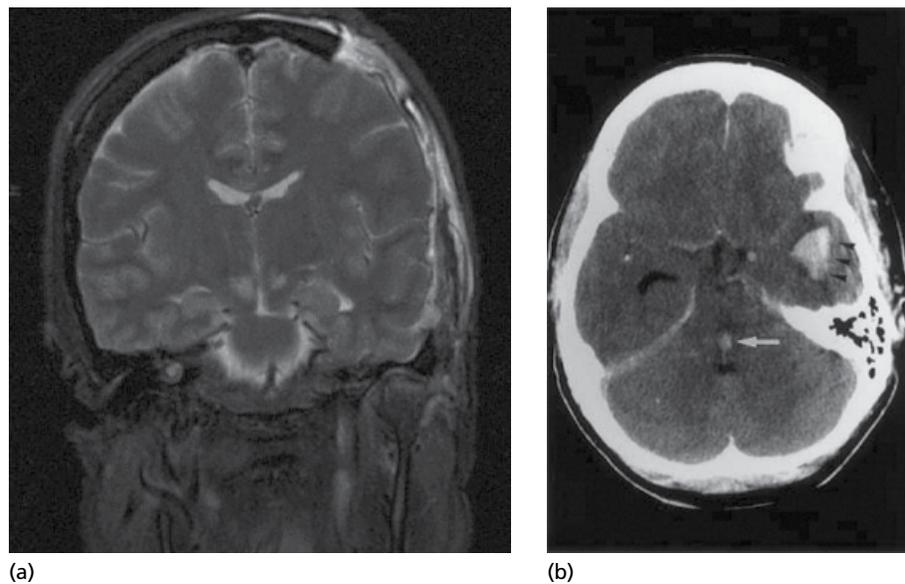

#### Herniation of the temporal lobe through the tentorium (uncal herniation)

This is caused by asymmetrical mass effect causing the temporal lobe, uncus and hippocampus to shift towards the midline leading to compression of the midbrain against the tentorial edge (Figure 20.8). The initial manifestation of incipient uncal herniation is involvement of the IIIrd nerve ipsilateral to the mass lesion, causing a sluggish reaction to light which is followed by fixed pupillary dilatation. This occurs because the parasympathetic fibres lie outermost and are therefore involved at an early stage. Alteration of consciousness occurs because of involvement of the anterior reticular activating system (RAS). Following this there may be compression of the ipsilateral posterior cerebral artery against the tentorial edge which may lead to occlusion and haemorrhagic infarction of the occipital lobe. The herniated uncus causes the midbrain to be shifted and compressed against the rigid dura on the contralateral side causing damage to the cerebral peduncles, particularly affecting fibres that project to the leg leading to a hemiparesis ipsilateral to the lesion and a worsening IIIrd nerve palsy. The rigid tentorium carves out a notch on the lateral aspect of the midbrain (Kernohan's notch). Tearing of the paramedian perforating vessels is caused by torsion, anteroposterior elongation and downward displacement of the midbrain and leads to consequent brainstem infarction and haemorrhage. The dilated pupil may become a little smaller as the sympathetic pathway in the brainstem is damaged, while with further brainstem compression the other pupil becomes midsized and unresponsive. Established oculomotor paresis appears, first in the eye originally involved and shortly afterwards in the other eye.

Survivors of tentorial herniation may be left in a locked-in or vegetative state or may demonstrate other signs of residual brainstem damage including oculomotor nerve dysfunction, INO, vertical gaze paresis, homonymous hemianopia or blindness, pyramidal limb weakness, parkinsonism or other extrapyramidal syndromes. Tentorial herniation may occasionally be arrested and reversed without residual deficit. Imaging may show the presence of small intrinsic brainstem haemorrhages (Duret haemorrhages) (Figure 20.8).

#### Central herniation of the brainstem

This occurs as a result of diffuse symmetrical raised ICP often because of cerebral oedema or obstructive hydrocephalus. Downward displacement of the hemispheres leads to compression of the diencephalon and midbrain and descent through the tentorial notch. Characteristic patterns of brainstem descent were described by Plum and Posner, but these are now rarely observed in practice because of early therapeutic intervention. They outlined that initially compression of the midbrain leads to impairment of

**Figure 20.8** (a) Uncal herniation (MRI, T2-weighted coronal); (b) Duret haemorrhage (arrow) (CT scan). Source: Parizel 2002. Reproduced with permission of Springer Science + Business Media.

concentration and alertness leading to progressive somnolence and reduced levels of consciousness. The pupils remain reactive but constricted, because of involvement of sympathetic pathways, and roving eye movements are gradually lost with progressive compression. With increasing supratentorial pressure there is a further downward shift leading to compression and torsion of the pons with rupture of the paramedian perforating arteries. With progressive descent of the brainstem the patient becomes deeply unconscious with abnormal patterns of respiration and temperature control. The pupils are unequal, unreactive, midsized and irregular. Vestibulo-ocular reflexes may elicit restricted vertical gaze, but then a progressive total ophthalmoplegia develops. Eventually there may be decerebrate posturing to painful stimuli prior to the development of hypotension, apnoea, cardiac arrhythmia and death.

#### Subfalcine herniation

This occurs when the cingulate gyrus is displaced across the midline and under the falx. It is usually caused by a structural lesion in the frontal lobe but may follow a traumatic injury. There may be compression of the ipsilateral anterior cerebral artery with secondary frontal infarction and oedema.

#### Upward transtentorial herniation

Upward transtentorial herniation of the brainstem may rarely occur as a result of lesions that compress the upper brainstem including tumour or haemorrhage in the pons, cerebellum or region of the 4th ventricle, particularly if any resulting hydrocephalus is drained. The tectum of the midbrain and the anterior cerebellar lobules are forced upwards through the tentorium leading to signs of brainstem dysfunction: small, asymmetrical and fixed pupils, vertical ophthalmoplegia and abnormal respiratory patterns leading to decerebrate posturing and coma.

#### Tonsillar herniation

Tonsillar herniation occurs if there is downward displacement of inferior medial cerebellar tonsils into the foramen magnum. This may be caused by an Arnold–Chiari malformation or a posterior

fossa mass lesion. There may be progressive medullary compression and ischaemia characterised by a sudden respiratory arrest with quadriplegia or the development of a stiff neck, vomiting, skew deviation of the eyes, respiratory irregularity, coma and death.

#### Traumatic brain injury

Head injury causes acceleration and deceleration of the skull which results in rotational forces on the supratentorial brain exerting shearing forces on the grey and white matter tracts and vessels, and traction on the midbrain and hypothalamic reticular neurones. Damage to the brain following trauma includes the immediate, or primary, injury caused at the moment of impact, and the secondary injury that develops in the first few hours or days after the impact which may result from extracranial or intracranial causes.

The consequences of severe TBI are summarised below:

##### 1 Primary brain injury

- Disruption of brain vessels
- Haemorrhagic contusion
- Diffuse axonal injury

##### 2 Secondary brain injury

Intracranial causes:

- Lobar contusion
- Intracranial haemorrhage (extradural, subdural or intracerebral) causing raised ICP or herniation
- Raised ICP caused by brain swelling around a contusion or diffusely within the brain.

Extracranial causes:

- Systemic hypotension (systolic BP <90 mmHg)
- Hypoxaemia ( $\text{PaO}_2 < 60$  mmHg)
- Hypercarbia (high blood  $\text{CO}_2$ )
- Disturbances of blood coagulation.

Early management should follow Advanced Trauma Life Support guidelines:

- Stabilisation of the airway, breathing and circulation
- Attention to cervical spine trauma
- Neurological assessment.

At present, no neuroprotective agent has been shown to reduce primary brain injury. However, secondary insults, which further exacerbate neuronal injury and lead to a worse outcome, are often preventable with prompt intervention. Over one-third of all patients with severe TBI develop hypoxia and/or hypotension during the acute post-injury period. These secondary insults are correlated with a large increase in morbidity and mortality.

### Skull fractures

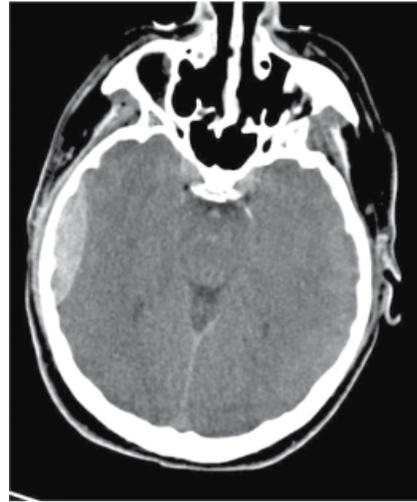

Skull fractures occur three times more commonly in the vault than the base of the skull and are associated with a high incidence of intracranial haematomas. If the fracture is open (involves the basal air sinuses) or depressed, then surgical intervention is required. Clinical indicators of a base of skull fracture include periorbital bruising (panda or racoon eyes), retro-auricular bruising over the mastoid process (Battle sign), blood in the tympanic membrane (haemotympanum) and an associated CSF leak from the nose (rhinorrhoea) or the ears (otorrhoea). Eighty per cent of CSF leaks close spontaneously but bacterial meningitis may complicate some cases. There is no evidence to support the use of routine antibiotic prophylaxis for skull fractures.

### Extradural haematoma

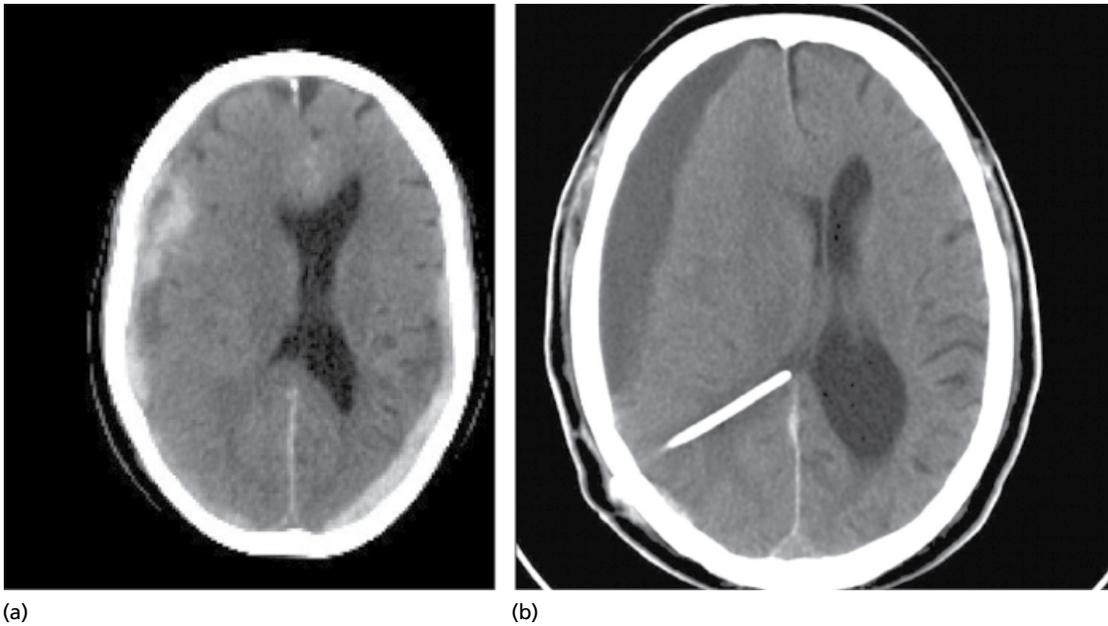

An extradural haematoma (Figure 20.9) is an accumulation of blood in the extradural space between the inner side of the skull and the dura mater. Most (>90%) are associated with skull fracture and are caused by injury of the middle meningeal artery, therefore affecting the parietal and temporo-parietal areas. Rarely, a fracture may be associated with tearing of large veins at the vertex of the skull or of the venous sinuses. Associated brain contusion is less common than with subdural haematoma (SDH). There is typically a lucid interval after the injury in which the patient temporarily regains consciousness. The outcome depends on the level of consciousness at the time of surgery, with mortality approaching 20% if the patient is unconscious prior to surgery.

### Subdural haematoma

A subdural haematoma (SDH) is an accumulation of blood between the inner side of the dura and the arachnoid layer (Figure 20.10). It is either due to tearing of cortical veins when the haematoma is usually frontal, or small arteries, when it is more often temporo-parietal. Most patients with acute SDH have an accompanying brain injury and their prognosis is worse than those with extradural haematoma. The patient is usually unconscious or there is impaired alertness, cognition with focal signs – continued deterioration is usual. Acute SDH can present with seizures. A poor outcome is more likely if the trauma is severe with underlying brain contusion, the SDHs are bilateral, accumulated rapidly, or if there was >4 hours delay in surgical management. CT imaging allows assessment of skull fracture, contusion and haemorrhage

**Figure 20.9** CT scan showing acute extradural haematoma.

**Figure 20.10** CT scan showing: (a) extensive fresh bilateral acute subdural haematoma with midline shift; and (b) large chronic subdural haematoma following insertion of intraventricular shunt.

but SDH can become isodense 1–3 weeks after onset or in the presence of anaemia; therefore, in the subacute or chronic state MRI is preferable to CT.

Chronic SDH can develop many weeks or even months after head injury. The injury may be minor and the patient may not remember a particular event. Predisposing factors include increasing age, alcoholism, coagulopathy, epilepsy and the presence of ventricular drains. The most common symptom is headache, which worsens progressively and is associated with a fluctuating level of consciousness, focal signs, seizures and raised ICP. The treatment of choice is evacuation of the subdural collection and irrigation with isotonic saline at body temperature. Many small SDHs are treated conservatively.

### Traumatic subarachnoid haemorrhage

Traumatic SAH is seen in 30–40% of patients following severe TBI but must be quantified on early CT scan because later scans underestimate its incidence and severity. Its presence indicates a poor outcome following TBI (Figure 20.11). It is important to ensure that the SAH was not the primary event leading to a fall and secondary head trauma by excluding the presence of an aneurysm.

### Haemorrhagic contusions and lacerations

Haemorrhagic contusions and lacerations are superficial areas of haemorrhage usually affecting the frontal and temporal lobes although they may involve deeper structures (Figure 20.12). They are usually caused by venous injury sustained as the brain hits the bony protruberances of the skull at the site of impact and then the opposite side during deceleration (contrecoup injury). The term contusion is used when the pia mater has not been breached, and laceration when the pia mater is torn. Local areas of contusion with no or minimal blood flow are common after severe TBI and the

centre of the contusion is often irreversibly damaged. However, areas around the contusion (known as penumbra) are associated with localised cerebral oedema and have survival potential if the oxygen supply to this region is maintained. Focal contusions can be associated with cerebral oedema and raised ICP leading to delayed neurological deterioration and surgical evacuation may be necessary.

### Intracerebral haematoma

Intracerebral haematoma usually occurs as a result of direct trauma to intracranial vessels and affects the frontal and temporal lobes or basal ganglia. It is a cause of delayed neurological deterioration in <20% of patients with severe TBI particularly if there is a coagulopathy.

### Diffuse axonal injury

Diffuse axonal injury (DAI) occurs in 50–60% of patients with severe head injury and is the most common cause of coma, vegetative state and subsequent disability (Figure 20.13). Severe DAI has three neuropathological components:

- 1 A focal lesion in the corpus callosum, often associated with traumatic intraventricular haemorrhage
- 2 Focal lesions in the brainstem, and
- 3 Widespread microscopic damage to axons, often associated with scattered small haemorrhages, mainly located along or near the grey–white matter interface.

### Cerebral ischaemia

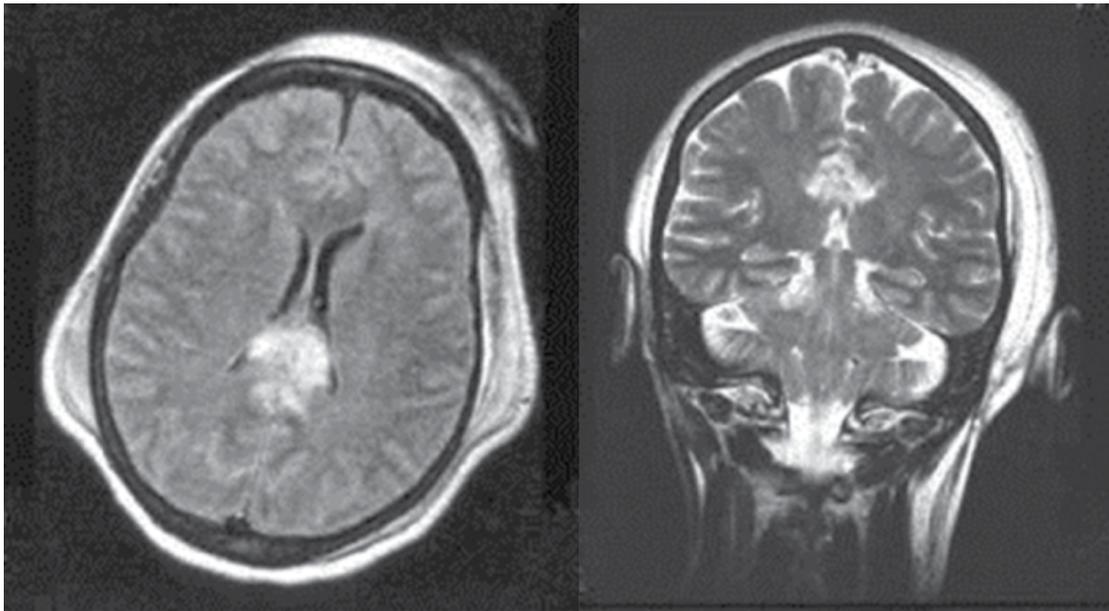

Cerebral ischaemia, whether brought about by hypoxia, hypotension or intracranial hypertension, dominates severe TBI and is the single most important factor in determining outcome, with ischaemic lesions being found in 90% of patients at postmortem. Areas of

**Figure 20.11** CT scan showing traumatic subarachnoid haemorrhage (arrow).

**Figure 20.12** CT scan of patient with traumatic brain injury (TBI) showing extensive left temporal contusion (arrow) and laceration with contrecoup injury in right temporal region.

**Figure 20.13** Diffuse axonal injury showing extensive haemorrhagic change in the region of the splenium (MRI T1-weighted axial and T2-weighted coronal).

focal ischaemia occur in <50% of patients with SDH or DAI but are rare in patients with extradural haematoma or normal imaging. Blood flow in and around areas of brain tissue damaged by trauma may be abnormal because of vasomotor paralysis with loss of autoregulation leading to impaired blood pressure control and reduced reactivity to carbon dioxide. CBF becomes pressure-dependent, rendering this area of brain more susceptible to ischaemia at lower blood pressures and more likely to sustain injury at higher pressures.

#### Intensive care management of TBI

The aim of intensive care management of the head-injured patient is to prevent and treat secondary physiological insults.

**Monitoring** Monitoring of ECG, direct arterial blood pressure, central venous pressure and pulse oximetry is mandatory in all patients. An oesophageal Doppler monitor or pulmonary artery catheter may assist in directing therapy in those patients with haemodynamic instability. Regular arterial blood gas analysis, measurement of blood glucose and sodium and core temperature monitoring are also required to optimise treatment strategies. Cerebral monitoring allows measurement of CPP, estimation of CBF and assessment of the adequacy of oxygen delivery to the brain. This allows therapy to be targeted to specific changes in brain function and to ensure a balance between cerebral metabolic supply and demand. Monitoring may include measurement of ICP, transcranial Doppler ultrasonography (TCD) of blood flow velocity in the middle cerebral artery and jugular venous bulb oximetry to assess the balance between cerebral oxygen supply and demand after head injury.

**Paroxysmal sympathetic hyperactivity** Episodes of paroxysmal sympathetic hyperactivity (autonomic storms) occur in patients with severe TBI particularly with diffuse axonal injury, following HIBI, SAH, intracerebral haemorrhage and hydrocephalus. Manifestations typically include fluctuation in temperature, blood

pressure, heart rate, respiratory rate, sweating and muscle tone. Pupillary dilatation, intense flushing and severe dystonia may also be present. The episodes recur regularly and last for between 1 and 10 hours. They tend to reduce in frequency with time. It is suggested that the episodes are caused by activity of the diencephalic or brain-stem sympathoexcitatory regions as a result of direct activation or inhibition secondary to loss of cortical and subcortical control. The episodes may be induced by stimulation or may occur spontaneously. They may be confused with seizures or other paroxysmal syndromes including malignant hyperthermia, neurologic malignant syndrome, sepsis or the response to raised ICP. The management includes ensuring adequate hydration, exclusion of mimicking conditions (infection, pulmonary embolism, hydrocephalus, epilepsy), effective analgesia and avoidance of triggers. The most useful pharmacological agents are non-selective beta-blockers (e.g. propranolol), opiates and clonidine.

**ICP after TBI** ICP monitoring is indicated for all patients with head injury with any abnormality on CT scan who do not obey commands. Conventional approaches to the management of patients with head injury have concentrated on a reduction in ICP to prevent secondary ischaemic insults. ICP >20 mmHg and CPP <60 mmHg are powerful predictors of outcome together with age, admission GCS and pupillary signs. Aggressive management, based on ICP monitoring, significantly reduces the overall mortality rate without causing a disproportionate number of severely disabled or vegetative patients.

**Decompressive craniectomy** Decompressive craniectomy is based on the concept of reducing the pressure buildup within the intracranial bony compartment resulting from brain swelling (compartment syndrome) by removal of skull bone (at least 12 cm flap) and opening the dural membranes. This allows improved compliance, reduced ICP and improved blood supply to the brain. Craniectomy decreases the mean ICP and the duration of both

**Table 20.13** Indications for decompressive surgery.

Intracranial mass lesions with midline shift or basal cistern compression on CT scan
A surgically significant EDH or acute SDH needs evacuation within 2–4 hours of injury to achieve optimal chance of recovery
For small haemorrhagic contusions or other small intracerebral lesions a conservative approach is generally adopted but operation should be considered urgent for a large ICH (>20–30 mL) based on position, clinical condition and ICP
Skull fractures that are depressed > skull thickness and compound fractures with torn dura require surgery

CT, computed tomography; EDH, extradural haematoma; ICH, intracerebral haematoma; ICP, intracranial pressure; SDH, subdural haematoma.

ventilatory support and ICU stay but is associated with a significantly worse outcome at 6 months so the role of decompressive surgery remains uncertain. The indications for decompressive surgery are summarised in Table 20.13.

### Hydrocephalus and shunts

Hydrocephalus may be defined as excessive CSF. It can be caused by excess production, altered flow through the ventricular system and/or impaired reabsorption into the venous system circulation via the arachnoid granulations. Such is the importance of CSF that Harvey Cushing, one of the founders of neurosurgery, called it the 'fourth circulation'.

Clinically, hydrocephalus can be divided into communicating and non-communicating. Communicating (non-obstructive) hydrocephalus denotes an enlarged ventricular system but normal communication and flow between the ventricles and the extracerebral CSF. The aetiology is impaired absorption while non-communicating (obstructive) hydrocephalus results from obstruction to the normal CSF pathways.

Sometimes both categories of hydrocephalus are distinct (e.g. communicating hydrocephalus secondary to SAH and non-communicating hydrocephalus secondary to a colloid cyst of the 3rd ventricle). However, they may coexist (e.g. an intraventricular or skull base tumour causing some obstruction but also producing a highly proteinaceous CSF or chronic meningitis leading to impaired reabsorption of CSF). It is also important to differentiate between acute hydrocephalus (which has more rapid and devastating consequences including herniation and death) and chronic hydrocephalus.

Arrested hydrocephalus applies to those adult patients who have some developmental hydrocephalus and abnormality of the brain development resulting in large ventricles and often large heads but who are well. Occasionally, these patients decompensate later in life and can present with headaches and/or ataxia or more acutely following what would otherwise be a minor head injury. Hydrocephalus *ex vacuo* describes apparent enlargement secondary to cerebral volume loss for any reason. Normal pressure hydrocephalus (NPH) describes a mild degree of hydrocephalus where the CSF pressure is intermittently raised. Clearly, this condition of NPH and hydrocephalus *ex vacuo* would need to be distinguished in the elderly population where the rare triad of cognitive failure, urinary incontinence and gait apraxia associated with NPH may be incomplete.

The presenting features of hydrocephalus depend on its aetiology and rate of development and the presence of raised ICP. For example, a sudden collapse into coma and even sudden death can occur

in rare instances of colloid cysts obstructing the 3rd ventricle outflow, whereas the gradual development of non-communicating hydrocephalus will result in headache and papilloedema progressing to a gait disturbance before more obvious symptoms and signs of raised ICP develop.

### Investigations

Imaging (CT or MRI) will define ventricular size and therefore show enlargement. Imaging also gives an indirect indication of raised ICP (e.g. periventricular lucency, ventricular to sulcal effacement and differential size of the different parts of the ventricular system). It is important to reflect on both the ventricular volume and the presumptive pressure before deciding on a management plan. Investigation of patients with suspected NPH is controversial. Walking tests following lumbar puncture, lumbar infusion and concomitant ICP measurements as well as isotope cisternography have been used to determine the pressure–volume relationship.

### Management

Frequently, conservative management is appropriate, particularly in those cases of arrested hydrocephalus. The mainstay of active treatment involves either a shunt or third ventriculostomy. With a shunt procedure CSF is channelled via a hollow silicon tube between the ventricular system and the peritoneum. Other sites can be used such as the right atrium and occasionally the pleura. Shunts have the advantage of being simple and relatively reliable. However, they do have a failure rate that accumulates over time secondary to blockage and they can also become infected despite the numerous proprietary attempts to either impregnate them with antibiotics and/or the use of non-touch techniques by surgeons and perioperative antibiotics. The shunts themselves range from the very simple to those with anti-siphon devices and programmable options where the flow may be altered to suit the response of the patient. These may be particularly appropriate in those patients with relatively low raised pressure, typically NPH, where over-drainage would be a serious complication.

Endoscopic third ventriculostomy is an increasingly used technique in which a hole is fashioned in the thinned floor of the 3rd ventricle such that the ventricular CSF communicates directly with the basal cisterns. This is particularly useful in cases of aqueduct stenosis or tumours in the posterior fossa and midbrain and thus this technique is far more commonly used in paediatric than in adult patients. In the acute clinical situation, such as hydrocephalus secondary to meningitis or SAH, particularly where the protein level is very high and/or when intrathecal antibiotics are to be administered, then a temporary shunt or external ventricular drain is inserted, which may be converted to a shunt at a later date. Finally, lumboperitoneal shunts are used on occasion, particularly when there is a technical issue in cannulating the ventricular system, usually when the ventricles are small and the pressures are high and very typically in idiopathic intracranial hypertension.

### Stroke (Chapter 5)

The principles of assessment and resuscitation from acute stroke are similar regardless of the underlying cause and include the following:

- Airway management – tracheal intubation is indicated when there is:
  - impaired level of consciousness (GCS <9)
  - progressive respiratory impairment or respiratory failure

- impaired cough and airway clearance
- pulmonary oedema/aspiration
- seizure activity
- a need for diagnostic or therapeutic procedures such as MRI or thrombolysis
- Maintenance of adequate arterial blood pressure–cerebral perfusion pressure
- Intravenous fluid management
- Temperature control
- Control of seizures
- Institution of enteral nutrition
- ICP management
- Medical treatment of complications (e.g. sepsis)
- Other management related to the underlying cause (e.g. anticoagulation, thrombolysis, evacuation of haematoma, clipping and coiling of intracerebral aneurysms)
- Decompressive hemicraniectomy (Figure 20.14).

Late deterioration following stroke occurs for a number of reasons.

### Middle cerebral artery occlusion

Late clinical deterioration following middle cerebral artery (MCA) occlusion is common and depends on the severity, localisation and pathology. It is associated with cerebral oedema, which usually develops after 2–7 days and causes a mass effect leading to horizontal and vertical distortion and shift of the brainstem. This change in dynamics may not be reflected by ICP monitors. Other causes of deterioration include haemorrhagic conversion of the infarct, which may produce diencephalic brain herniation, the development of seizures and systemic factors including congestive cardiac failure, pulmonary oedema, cardiac arrhythmias or pulmonary emboli.

**Figure 20.14** Malignant middle cerebral artery (MCA) syndrome. Axial CT demonstrating a large left MCA infarct with a decompressive frontal craniectomy and herniation of swollen brain through the defect.

### Acute basilar occlusion

Following acute basilar occlusion, late deterioration occurs in up to one-third of patients because of extension of the thrombus causing successive occlusion of the perforating arteries or because of emboli arising from the occluded vessel.

### Artery of Percheron

This is a rare vascular variant in which a single dominant thalamoperforating artery arises from one posterior cerebral artery and supplies both paramedian thalami. Occlusion of this vessel results in bilateral paramedian thalamic infarction with or without mesencephalic infarction. This is an uncommon but important cause of altered consciousness or coma.

### Cerebellar infarcts

These are associated with progression of infarction leading to brainstem involvement and herniation, late brainstem compression arising from cerebral oedema around the infarct, the development of hydrocephalus from obstruction of 3rd and 4th ventricles, aqueduct or outflow and systemic complications. Occasionally, decompressive surgery is necessary.

### Subarachnoid haemorrhage

The acute management of SAH is summarised in Table 20.14. Sudden death may occur following SAH in up to 10% because of early rebleeding, intraventricular extension of the haemorrhage or complications including pulmonary aspiration, cardiac arrhythmias and neurogenic pulmonary oedema. Clinical deterioration may also develop because of delayed cerebral ischaemia from progressive vasospasm, enlargement of intracerebral haematoma or the development of hydrocephalus.

### Supratentorial intracerebral haemorrhage (basal ganglia or lobar)

This is associated with enlargement of the haematoma, development of surrounding oedema, obstructive hydrocephalus or systemic complications including aspiration pneumonia, sepsis or cardiac arrhythmias.

### Infratentorial intracranial haemorrhage (cerebellar or brainstem)

Following infratentorial intracranial haemorrhage (cerebellar or brainstem), clinical deterioration is commonly caused by direct brainstem compression accompanied by cerebellar herniation rather than obstructive hydrocephalus. Rebleeding is a neurosurgical emergency and the high mortality often justifies surgical evacuation. The management of intracerebral haemorrhage is summarised in Table 20.15.

### Cerebral venous thrombosis

Late complications of cerebral venous thrombosis include extension of the thrombosis, development of haemorrhagic infarction, raised ICP secondary to cerebral oedema, seizures, the development of systemic complications including aspiration pneumonia, pulmonary emboli and sepsis and complications of a hypercoagulable state (Figure 20.15). Deep cerebral venous thrombosis due to involvement of the deep cerebral veins causes venous infarction and oedema of the thalamus which can be markedly asymmetric and can also involve the basal ganglia. There may be severe impairment of consciousness or coma, particularly if there is bilateral thalamic swelling causing 3rd ventricular compression and hydrocephalus.

### Seizures (Chapter 7)

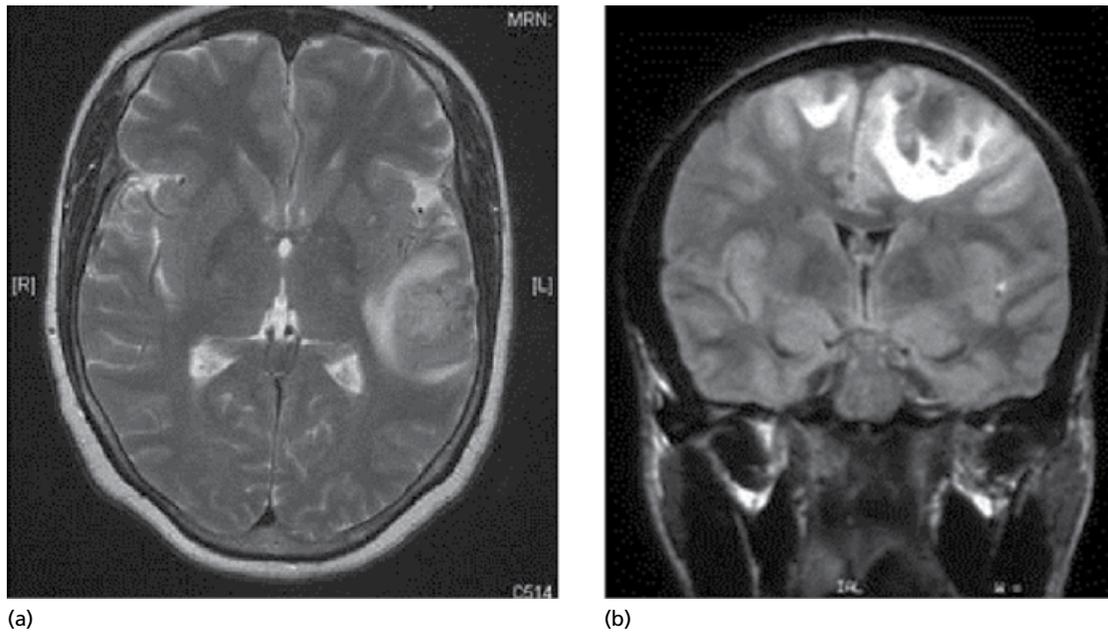

Seizures on the ICU are usually focal or generalised motor convulsions, although all seizure types occur. Common precipitants are hypoxia-ischaemia, drug toxicity, narcotic withdrawal and metabolic abnormalities (Table 20.16). It is essential to diagnose the seizure type and cause to ensure early appropriate treatment and

CPP, cerebral perfusion pressure; ICP, intracranial pressure; MAP, mean arterial blood pressure.

differentiation from metabolic myoclonus and extrapyramidal movement disorders. Non-convulsive status epilepticus (NCSE) is common and a poorly recognised cause of coma. Classic ictal signs may be absent and diagnosis may depend on the observation of subtle movements of fingers, eyes or lips. NCSE should be considered where there is abrupt deterioration in conscious level without explanation, often following a recognised seizure or after anoxic ischaemic insult with preserved brainstem reflexes. Convulsive status is less common. EEG monitoring can be helpful.

**Figure 20.15** Extensive haemorrhagic venous infarction. (a) T2 axial MRI; (b) FLAIR coronal MRI.

**Table 20.16** Causes of partial or generalised status epilepticus in an ITU setting.

Acute	Chronic
Head injury	Pre-existing epilepsy
CNS infection (encephalitis, meningitis)	Poor antiepilepsy drug compliance
Cerebrovascular accident	Dosage alteration
Renal failure	Chronic alcoholism/alcohol withdrawal
Sepsis syndrome	Cerebral space-occupying lesion
Drug toxicity	
Electrolyte imbalance	
Hypoglycaemia	
Hypoxic – ischaemic brain injury	
Pseudostatus	
Benzodiazepine or other suppressant withdrawal	

Myoclonic status and Lance-Adams syndrome are discussed later.

### Status epilepticus (SE)

Following adequate resuscitation, the treatment of status epilepticus (Chapter 7) in the NICU has four simultaneous aims:

- termination of seizures;
- prevention of seizure recurrence once status is controlled;
- management of the precipitating causes;
- management of the complications.

Monitoring respiratory and cardiac function and continuous EEG (cEEG) recording is necessary in prolonged and refractory status. The appropriate titration of anaesthetic agents during status epilepticus may be based on the appearance of burst or,

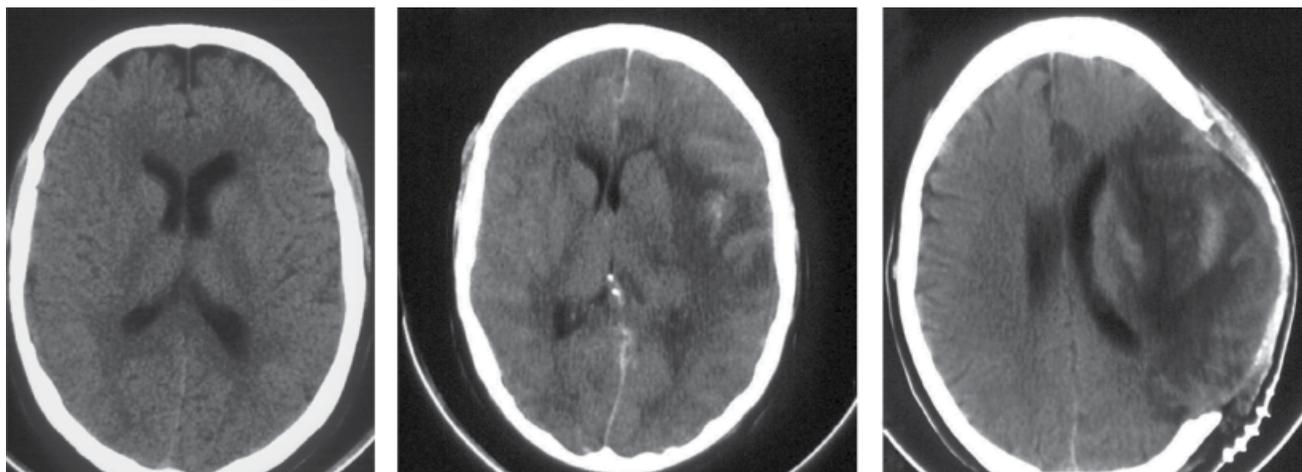

preferably, total suppression on the EEG. cEEG recording will give an indication of worsening or recurrent status epilepticus regardless of the presence or absence of sedating drugs or paralyzing agents.

The underlying cause of SE can require urgent treatment. Causes include acute bacterial meningitis or viral encephalitis, cerebral vascular disease due to emboli, arterial occlusion or venous sinus thrombosis, withdrawal of anti-epilepsy drugs or alcohol. Autoimmune limbic or brainstem encephalitides (e.g. *N*-methyl-D-aspartate [NMDA] and VGKCAb) can cause SE and can require immunomodulatory treatment.

The complications of status epilepticus relate either to the cerebral and metabolic consequences of prolonged seizures or to the effects of medical treatment. Cardiopulmonary problems include the development of aspiration pneumonia, adult respiratory distress syndrome, deep vein thrombosis, pulmonary emboli, myocardial ischaemia and cardiac arrhythmia. Hyperthermia is common and rhabdomyolysis may develop. Prolonged hypoxia may cause cerebral damage whilst electrolyte disturbance, and metabolic acidosis may contribute to the development of multi-organ failure. Many drug treatments used in status epilepticus cause sedation, respiratory depression and hypotension. Artificial ventilation is required if general anaesthesia is indicated or if the seizures remain difficult to control. It is also necessary to maintain systemic blood pressure at normal or supranormal levels to ensure adequate cerebral perfusion. Fluid resuscitation and/or inotropic support should be guided by appropriate cardiovascular monitoring.

### Acute bacterial meningitis

The mortality and morbidity of acute meningitis in adults remain substantial, particularly if there is a delay in initiating treatment and monitoring complications (Chapter 9). Patients with meningitis are usually admitted to an ICU when in coma, with complications such as seizures, cerebral oedema and tentorial herniation, or because they have developed systemic problems including septicaemia, pulmonary aspiration or cardiopulmonary compromise. Late deterioration

**Figure 20.16** Sequence of CT scans in a patient with herpes simplex encephalitis showing progressive hemispheric swelling and decompression.

following acute bacterial meningitis may be caused by antibiotic resistance or by the development of cerebral oedema, subdural effusion or empyema, superior sagittal sinus thrombosis, hydrocephalus, vasculitis, or systemic complications including pericardial effusion and polyarteritis.

#### Herpes simplex encephalitis

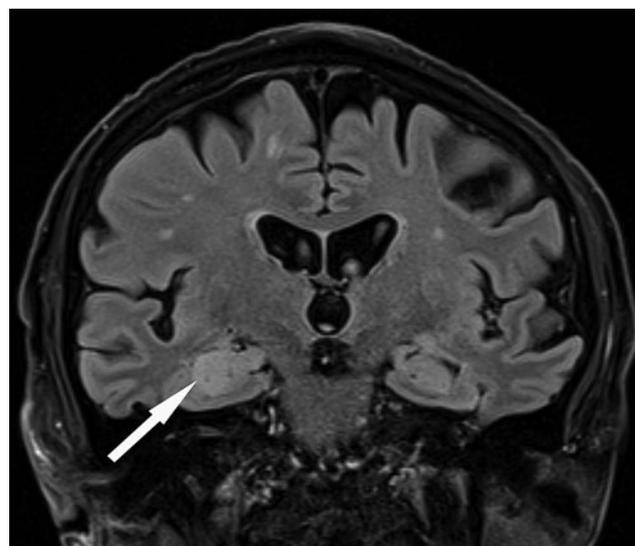

Clinical deterioration in this condition is usually the result of severe cerebral oedema with diencephalic herniation or systemic complications, including generalised sepsis and aspiration (Chapter 9). Furthermore, progressive worsening of focal seizures may lead to status epilepticus. Aggressive treatment including tracheal intubation and mechanical ventilation with appropriate sedation should be instituted and seizures treated. Prolonged sedation or general anaesthesia may be necessary. Decompressive craniotomy may be successful in cases where there is rapid swelling of a non-dominant temporal lobe (Figure 20.16).

#### Autoimmune encephalopathy

Antibodies directed against cell-surface neuronal antigens are associated with central nervous system disorders which present with encephalopathy or seizures requiring intensive care. They often respond to immunotherapies.

#### Limbic encephalitis associated with neuronal surface antigens

Limbic encephalitis (LE) typically present with acute to subacute onset of memory loss, confusion and seizures. There may be psychiatric/behavioural disturbances. Patients with VGKC-complex-antibodies (generally LGI1Ab) may present to intensive care because of worsening encephalopathy with hyponatraemia due to inappropriate antidiuretic hormone (ADH) secretion or because of seizures. MRI typically shows evidence of hippocampal swelling, inflammation and high signal in the medial temporal lobes (Figure 20.17). The EEG is abnormal with diffuse slowing and occasional temporal epileptogenic foci and CSF may be normal or show a mild lymphocytosis with unmatched oligoclonal bands. Encephalopathy due to VGKC-complex antibodies may be amenable to immunotherapy and some patients respond well to high-dose oral corticosteroids, pulsed methyl prednisolone, plasma exchange

**Figure 20.17** Limbic encephalitis. FLAIR coronal image showing swelling and abnormally high signal within the right hippocampal formation (arrow).

and/or immunoglobulin. The seizures often cease and hyponatraemia resolves but patients may be left with prolonged encephalopathy and late-onset hippocampal sclerosis. LE may also be associated with AMPA receptor and GABA<sub>B</sub> antibodies, there is often a tendency for these forms to relapse and require longer term immunosuppression.

#### Morvan's syndrome

Morvan's syndrome is characterised by muscle fasciculation and cramp. However, the presence of autonomic disturbance and CNS involvement manifests as sleep disturbance, particularly insomnia, and hallucinations may require admission to intensive care. Patients with antibodies to the VGKC-complex-protein CASPR2 commonly have neuromyotonia and there is a significant incidence of underlying tumour (often thymoma).

### Encephalitis due to NMDA receptor antibodies

This condition is distinct from LE with much more extensive involvement of brain function. The onset is generally with psychiatric or behavioural disturbances. Seizures develop and worsen over 2 to 3 weeks before evolving into severe and, occasionally life-threatening, dyskinesia (orofacial grimacing, dystonic posturing and choreoathetoid movements). There is often autonomic instability and reduced consciousness which may require prolonged ventilatory support. The CSF may show pleocytosis, intrathecal synthesis of oligoclonal bands and positive antibodies. MRI is generally normal but may show mild abnormalities in the cerebral cortex, meninges or basal ganglia. The condition is often associated with ovarian tumour (usually teratoma) in women, or other tumours in men and women (e.g. lymphoma) but this is not invariable and there is a separate autoimmune form of the condition. The syndrome often responds to removal of the tumour and immunotherapy but recovery may be prolonged and in some cases the outcome is very poor with a significant mortality amongst patients who require prolonged intensive care. Treatment is with immunomodulation with steroids, plasma exchange or IVIg but long-term immunosuppression with cyclophosphamide or rituximab is often necessary and relapses can occur in up to 25% of non-paraneoplastic patients.

### Steroid responsive encephalopathy

This condition is often associated with raised thyroid antibodies and was previously called Hashimoto's encephalopathy. There is a slow impairment of consciousness with episodic confusion often associated with agitation, hallucinations, tremor, recurrent stroke-like episodes and cognitive impairment. There may be raised microsomal, peroxidase or anti-thyroglobulin thyroid antibodies at variable titres. The condition may be prolonged but responds well to steroids and is likely to be autoimmune mediated although the thyroid antibodies are unlikely to be pathogenic.

### Other antibody-mediated encephalomyelopathies

Stiff person syndrome and PERM (progressive encephalomyelopathy with rigidity and myoclonus) are discussed in Movement disorder emergencies.

### Metabolic encephalopathy

Acute metabolic encephalopathy can be considered as an acute condition of global cerebral dysfunction in the absence of primary structural brain disease. The diagnosis includes delirium and acute confusional states. The pathophysiology of metabolic encephalopathy varies according to the cause but all forms interfere with the function of the ascending reticular activating system and its cortical projections leading to impairment of arousal and awareness. All causes of metabolic encephalopathy are characterised by impaired and fluctuating attention and cognition from mild memory loss to severe delirium or coma. Marked variation in the mental status over times is characteristic. While metabolic encephalopathy is often treatable, the clinical course can be protracted, with neurological recovery often lagging behind recovery of the underlying condition.

If prolonged sedation has been excluded, the most common cause of depressed consciousness is a metabolic encephalopathy which may be a result of one or more causes. The diagnosis can be difficult in an unconscious patient and careful assessment of medication, sepsis, metabolic status and fluid balance is essential.

Metabolic encephalopathy presents as an acute confusional state, decreased level of arousal, delirium (characterised by a fluctuating level of attentiveness) or coma. It is associated with a variety of conditions including hepatic and renal failure, sepsis, electrolyte imbalance, endocrine dysfunction or HIBI. There may be a lack of fixed focal deficit, tremor, asterixis, multifocal myoclonus and relative sparing of the cranial nerves.

### Septic encephalopathy

Septic encephalopathy is the most common form of encephalopathy encountered in intensive care medicine and is present in 50–70% of septic patients. It is characterised by disorientation, delirium, impaired consciousness or coma. There may be rigidity, tremors and seizures. Usually, an extracranial site of infection can be identified and appropriate treatment commenced, but in less than <50% of cases is an organism isolated from blood cultures. EEG is a sensitive diagnostic investigation for septic encephalopathy; the findings lack specificity but correlate well with the severity of encephalopathy and mortality.

### Uraemic encephalopathy

Uraemic encephalopathy, dialysis disequilibrium and dialysis dementia are distinct conditions. Uraemic encephalopathy can occur as a consequence of renal failure particularly if the onset is acute or if there is coexisting hepatic failure. Clinical features of uraemic encephalopathy are non-specific with fatigue, insomnia, pruritus and progressive cognitive impairment culminating in asterixis, tetany, myoclonus, confusion, seizures, stupor and coma. Progression mirrors the severity of uraemia although coexisting metabolic and endocrine factors may also be present (e.g. hypocalcaemia, hyperphosphataemia, hypokalaemia and metabolic acidosis). Uraemic encephalopathy is easily reversible with dialysis or transplantation.

Dialysis disequilibrium syndrome generally follows the initiation of treatment with haemodialysis and is probably caused by the development of cerebral oedema resulting from a urea gradient in which brain urea concentration exceeds that in the blood. It may be associated with milder manifestations including disorientation, tremor or more severe features such as seizures and coma. Dialysis dementia is now extremely rare. It was thought to be related to aluminium toxicity incurred through dialysis. This led to progressive and permanent memory loss, dysarthria, facial grimacing, myoclonus and psychiatric sequelae.

### Hepatic encephalopathy

Hepatic encephalopathy presents with lethargy, somnolence and disorientation leading to coma associated with slurred speech, a flapping tremor (asterixis) and foetor culminating in coma. Cerebral oedema is caused by ammonia-induced vasodilation and leads to impaired autoregulation. Features of raised ICP and seizures may occur before the development of deep coma. There are no specific diagnostic liver function test abnormalities although elevated blood ammonia levels and an abnormal EEG (bilateral synchronous delta waves and triphasic waves) indicate hepatic encephalopathy and portal–systemic shunting. The management of chronic hepatic encephalopathy requires avoidance of precipitating factors, and the use of lactulose and antibiotics, particularly neomycin.

Severe acute hepatic encephalopathy caused by fulminant hepatic failure is an ICU emergency involving the management of cerebral oedema, acute elevated ICP and seizures. It requires monitoring, ventilation and osmotherapy with mannitol. Hypothermia and

hyperbaric oxygen have also been used. The only proven therapy to improve outcome is orthotopic liver transplantation.

### Hyperpyrexia and hyperthermia

Hyperpyrexia is most commonly caused by sepsis but may be brought about by inflammation, drug reaction (e.g. Ecstasy), malignant hyperpyrexia, heatstroke or injury (e.g. stroke), SAH and TBI. It leads to tachycardia, elevated cardiac output, hypotension, an increase in tissue oxygen demand associated with an increase in metabolic rate. Neurological involvement includes altered consciousness and seizures associated with the development of multiorgan dysfunction (rhabdomyolysis, disorders of clotting, renal and liver failure).

Management involves:

- Minimise heat gain – controlled temperature, avoid ambient environmental warming
- Reduce shivering – magnesium, meperidine, benzodiazepines or propofol
- Treat underlying cause – antibiotics, drain sepsis
- Drug treatment of pyrexia – antipyretics, muscle relaxation
- Cooling – external, extracorporeal, intravascular.

### Hypernatraemia

Hypernatraemia may be caused by unreplaced water loss (e.g. insensible sweat loss), gastrointestinal loss, cranial or nephrogenic diabetes insipidus, osmotic diuresis (e.g. glucose in uncontrolled diabetes mellitus or mannitol). It may also be caused by sodium overload (intake of hypertonic sodium solution). Slowly developing hypernatraemia is not a concern because brain cells maintain volume but patients with serum osmolality >350 mOsm/kg or with serum sodium >160 mEq/L may develop lethargy, confusion, decreased mental status and occasionally seizures. Severe hypernatraemia causes of water movement out of the brain resulting in a decrease in brain volume which may cause new focal intracerebral, and SAH and venous sinus thrombosis. The rate of correction should be slow.

### Hyponatraemia

Hyponatraemia is a common problem on NICU and is defined as serum sodium level <135 mmol/L. The causes of hyponatraemia are classified according to the extracellular fluid osmolality, intravascular volume and pressure status. Normal serum osmolality ( $2[\text{Na}^+] + \text{urea} + \text{glucose}$  [mmol/L]) is in the range of 285–295 mOsm/kg. Encephalopathy resulting from hyponatraemia depends on the rate of development and the absolute sodium levels. Rapidly evolving hyponatraemia results in confusion, seizures (generalised tonic-clonic seizures), muscle cramps, generalised weakness and coma. Hypertonic hyponatraemia is caused by the presence of osmotically active solutes other than sodium (e.g. glucose and mannitol), which lead to shifts of free water from the intracellular to the extracellular component. Normotonic hyponatraemia is usually caused by retention of large volumes of isotonic solutes that dilute sodium (e.g. hyperlipidaemia). Hypotonic hyponatraemia (serum osmolality <260 mOsm/kg) is by far the most common abnormality seen in neurological patients. It occurs when there is excessive water retention in relation to sodium ions and may be classified according to the intravascular volume state of the patient. Hypervolaemic hypotonic hyponatraemia is associated with excessive body fluid load as may be seen with cirrhosis, ascites, congestive cardiac failure, nephrotic syndrome and severe hypoproteinaemia. Hypovolaemic hypotonic hyponatraemia is caused by excessive extrarenal loss (e.g.

diarrhoea, vomiting, sweating, pancreatitis, burns) or renal loss (e.g. use of diuretics or as occurs in renal failure) or centrally mediated cerebral salt wasting.

In normovolaemic hypotonic hyponatraemia (inappropriate secretion of ADH SIADH) there is excessive water retention by the kidneys leading to dilutional hyponatraemia with mild expansion of the extracellular fluid. This occurs because appropriate secretion of ADH is not appropriately suppressed by low plasma osmolality. This leads to further reabsorption of free water in the distal renal tubules; however, in SIADH sodium handling remains unaffected so that there is a paradoxical increase in sodium excretion attempting to return the intravascular volume to normal levels. Therefore, increased urinary sodium excretion continues despite the increase in free water.

The features of SIADH are summarised in Table 20.17. Inappropriate ADH secretion is associated with a variety of neurological and systemic causes summarised in Table 20.18.

**Table 20.17** Criteria for the diagnosis of syndrome of inappropriate antidiuretic hormone (ADH) secretion.

Hyponatraemia (serum sodium <135 mOsm/L)
Plasma hypotonicity (plasma osmolality <280 mmol/kg)
Inappropriately concentrated urine (osmolality >100 mOsm/kg)
Continued sodium excretion (urinary sodium >20 mOsm/L)
The patient is clinically normovolaemic
Exclusion of cardiac, renal or endocrine disease

Inappropriate ADH secretion is associated with a variety of neurological and systemic causes summarised in Table 20.18.

**Table 20.18** Causes of syndrome of inappropriate ADH secretion.

Neurological disorders
Head injury, trauma
Cerebrovascular – infarction, ICH, SAH
Tumours
Abscess, meningitis, encephalitis
Guillain-Barré syndrome, acute intermittent porphyria
Pulmonary disorders – pneumonia, TB, COPD, asthma
Malignancy – bronchus, lymphoma, prostate, pancreas
Endocrine – hypothyroidism, Addison's disease
Drugs
Analgesics – NSAIDs, opiates
Antiepileptics – carbamazepine
Antidepressants – SSRIs, tricyclics, monoamine oxidase inhibitors
Chemotherapy agents – vincristine, vinblastine, cyclophosphamide
Antipsychotics – haloperidol, thioridazine
Hypoglycaemic agents – chlorpropamide, tolbutamide
Postoperative

COPD, chronic obstructive pulmonary disease; ICH, intracerebral haematoma; NSAID, non-steroidal anti-inflammatory drug; SAH, subarachnoid haemorrhage; SSRI, selective serotonin re-uptake inhibitor; TB, tuberculosis.

### Cerebral salt wasting

Hypovolaemic hyponatraemia may also occur in association with the condition of cerebral salt wasting (CSW). In this condition a centrally mediated process leads to increased sodium and water excretion and hypovolaemia, in contrast to SIADH which is characterised by excessive sodium loss with water retention by the kidneys. In clinical practice the only reliable way of distinguishing SIADH from CSW is assessment of the volume status. Hypovolaemia, as seen in CSW, is associated with orthostatic hypotension, tachycardia, dry mucous membranes, poor skin turgor and reduced central venous pressure but none of these signs is entirely reliable.

The distinction between SIADH and CSW is essential because the management of SIADH involves reduction in the intake of electrolyte-free water to reduce the expansion of intracellular volume. The administration of saline would simply increase the extracellular fluid as sodium continues to be lost as a consequence of ongoing ADH secretion and the shift of sodium from the extracellular fluid to the intracellular fluid would cause progressive cerebral oedema. Conversely, in CSW, where there is a hypovolaemic state, treatment is the administration of both salt and water with isotonic or hypertonic saline to counteract the primary abnormality of renal salt wasting. In this situation, fluid restriction actually worsens the hypovolaemia and hyponatraemia as the salt wasting continues and would cause cerebral infarction. The situation is particularly complex in SAH where there appear to be features of both SIADH and CSW. However, the hypovolaemic state exacerbates vascular spasm and therefore it is now widely accepted that hypervolaemic therapy is appropriate to prevent further vascular spasm.

In general clinical practice, acute symptomatic hyponatraemia is often brought about by hypervolaemic states such that occur in congestive cardiac failure or nephrotic syndrome and treatment is therefore with loop diuretics to promote renal loss of water in excess

of sodium. Treatment of asymptomatic hyponatraemia should be cautious with mild free water restriction if the patient is isovolaemic or hypovolaemic.

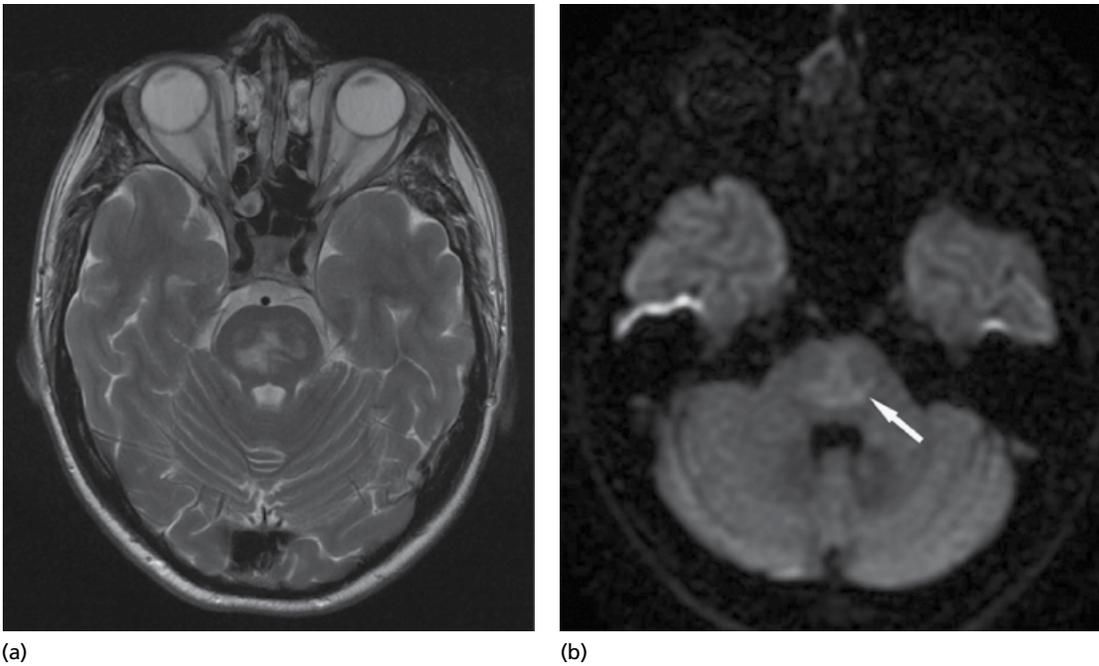

### Central pontine myelinolysis

Central pontine myelinolysis is a demyelinating syndrome, initially described in alcohol or malnourished patients. The condition is associated with rapid correction of hyponatraemia which leads to shift of fluid from the intracellular to the extracellular compartments causing dehydration of the brain resulting in non-inflammatory damage to the myelin sheath and the oligodendrocytes with relative sparing of neurones and axons.

The condition may present with a severe and unexplained encephalopathy or seizures occurring secondary to hyponatraemia but it may progress to flaccid quadriplegia, pseudobulbar palsy manifest as dysarthria, dysphagia with pupillary and oculomotor abnormalities and occasionally patients may present with a locked-in syndrome. The presence of extrapontine myelinolysis leads to a more diffuse neurological pattern with movement disorders including parkinsonism, choreoathetosis, dystonia and spasmodic dysphonia.

Demyelination is most frequently seen in the central pons, but may extend into the midbrain; however, extrapontine myelinolysis is often symmetrical and may occur in the cerebral cortex, external capsule, limbic system or basal ganglia. MRI confirms the presence of hyperintense, 'bat-wing' lesions on T2-weighted images, which do not enhance and are seen primarily in the central pons (Figure 20.18). Diffusion-weighted imaging is a more sensitive technique to show these abnormalities.

The outcome is variable and the prognosis depends on the severity and extent of demyelination in the pons. Some patients may recover from the condition despite extensive radiological or clinical involvement.

**Figure 20.18** Central Pontine myelinolysis. T2-weighted (a) and diffusion weighted (b) axial images demonstrating abnormally high signal and restricted diffusion (white arrow) within the central pons in a typical trident pattern.

### Posterior reversible encephalopathy syndrome

Posterior reversible encephalopathy syndrome (PRES) occurs as a result of acute hypertensive encephalopathy, eclampsia or immunosuppression. The onset is with headache, vomiting and a progressive encephalopathy characterised by confusion and disorientation. There may be seizures and visual disturbance, in particular cortical blindness. The condition is associated with immunosuppressive therapy particularly after transplantation using ciclosporin, cisplatinum, 5-fluouracil, amphotericin B, methotrexate, tacrolimus or interferon- $\alpha$ . Reversible posterior leukoencephalopathy seems to arise from a mechanical disruption of the blood–brain barrier, either by overwhelming hydrostatic factors (e.g. hypertension) or dysfunction of the endothelial cells of the barrier because of toxins. The MRI shows characteristic high intensity white matter abnormalities on T2-weighted sequences in the parieto-occipital white matter. Fluid attenuated inversion recovery (FLAIR) sequences show a similar predominantly white matter pattern of hyperintensity consistent with vasogenic oedema (Figure 20.19). In general, changes are confined to the posterior circulation territory. It is suggested this is because the vascular blood in this area has lower pressure and less sympathetic innervation compared with the anterior circulation and is therefore more easily affected by systemic hypertension. However, there are increasing reports of anterior territory or asymmetrical changes occurring. Management is with antihypertensive agents, withdrawal of immunosuppression and supportive care. This condition is reversible with treatment and the MRI scan may normalise but there may be residual focal cerebral haemorrhage or permanent injury.

### Hypoxic–ischaemic brain injury

HIBI usually follows cardiac arrest and carries a very poor prognosis. The history of the event and the presence of pre-arrest morbidity are important prognostic factors but detailed examination of the patient remains the mainstay of assessment. The assessment of HIBI remains primarily clinical and is made more difficult by the use of ever more sophisticated techniques of sedation, ventilation,

hypothermia, neuromuscular blockade and haemodynamic management (Figure 20.20).

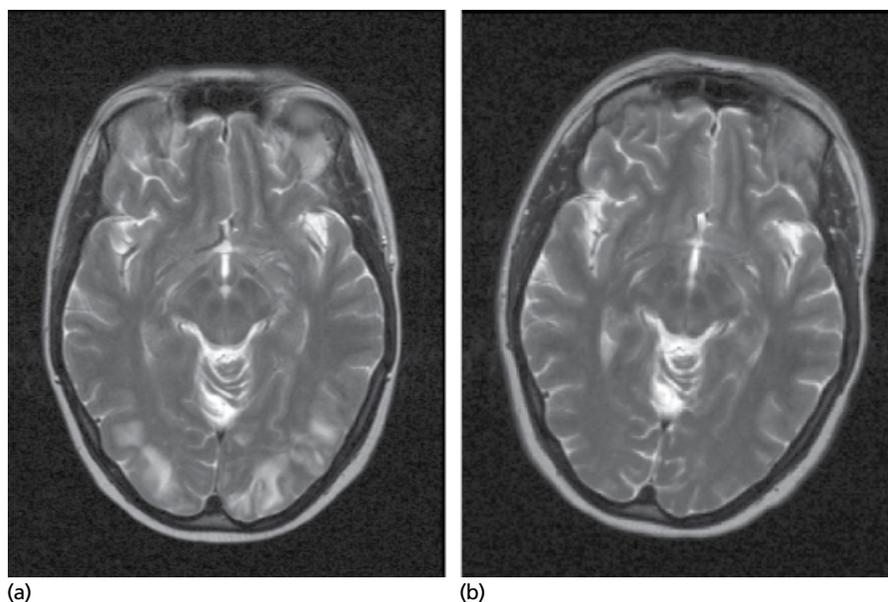

Hypoxia and ischaemia should be considered as pathologically and clinically distinct patterns of brain injury although they usually coexist. Ischaemia describes a reduction in blood supply leading to decreased oxygen delivery and limited or no removal of damaging cellular metabolites which therefore accumulate (e.g. lactate,  $H^+$ , glutamate) leading to severe brain injury. Hypoxia refers to a reduction of either oxygen supply or utilisation. It can develop as a direct consequence of reduced oxygen supply, reduced ambient oxygen  $pO_2$ , low haemoglobin or impaired tissue utilisation following poisoning of the mitochondrial cytochrome enzymes (e.g. due to cyanide). The pathophysiology of carbon monoxide poisoning is complex with components of both anaemic and histotoxic hypoxia and occasionally global ischaemia caused by cardiac failure. Following isolated hypoxia there is an increase in CBF which allows continuing delivery of glucose to the brain and clearance of toxic metabolites from the brain. Therefore, hypoxia that occurs in isolation, even if prolonged, rarely causes severe brain injury, provided the systemic circulation is preserved.

### Prognostic factors following cardiac arrest

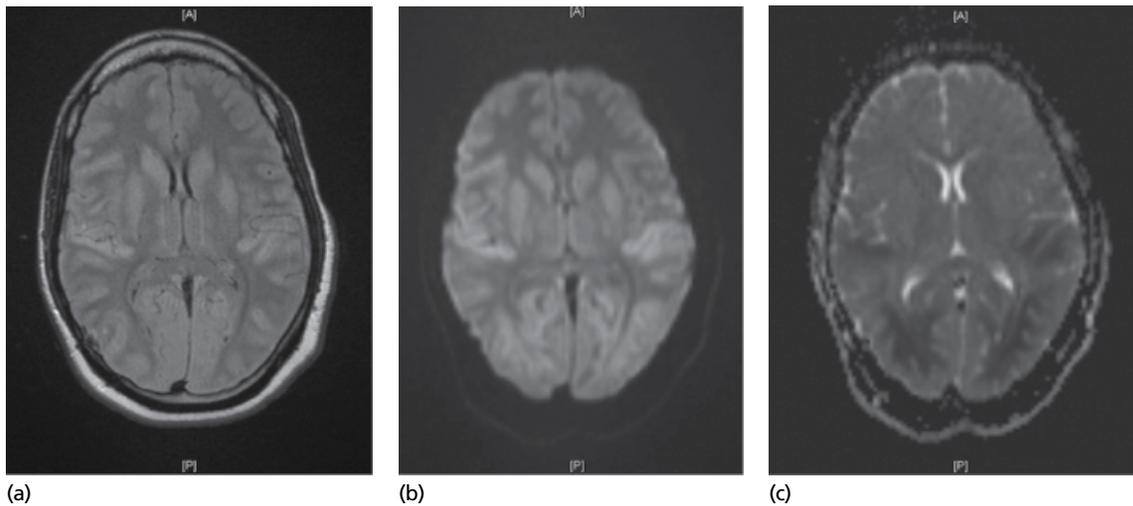

The long-term outcome is critically dependent on the cause of arrest and the peri-arrest management. The outcome is best for patients with ventricular tachycardia or fibrillation in whom resuscitation is commenced rapidly. The likelihood of successful resuscitation in asystole or pulseless electrical activity is much lower. In primary hypoxic arrest immediate restoration of oxygenation is of overwhelming importance to outcome.

The most important prognostic factors following out-of-hospital cardiac arrests are:

- Age
- Co-morbidity
- Circumstances of arrest
- Witness/immediate bystander resuscitation

**Figure 20.19** Posterior reversible leukoencephalopathy in a patient who was hypertensive following the administration of intrathecal methotrexate. MRI T2-weighted: (a) following intrathecal methotrexate; and (b) 3 months later showing complete resolution. Courtesy of Dr Paul Holmes, St Thomas' Hospital.

**Figure 20.20** After hypoxic-ischaemic brain injury, MRI changes include high signal in the caudate and putamen, less so in the thalami (a) T1 (b) DWI sagittal with restricted diffusion on ADC (c) in the occipital regions and peri-rolandic cortex.

- Effective CPR
- Early attendance of paramedics
- Cardiac rhythm
- Resuscitation
- Fever within first 48 hours
- Duration of cardiac arrest
- Advanced directive.

It is well recognised that a good outcome may result after prolonged cardiac arrest occurring in hypothermic conditions. This led to the use of induced controlled hypothermia following cardiac arrest associated with ventricular fibrillation. However, induced controlled hypothermia can be difficult to apply and uncomfortable, patients require sedation and a neuromuscular blocking agent (vecuronium or pancuronium) to prevent shivering. Recent studies have suggested that induced controlled hypothermia has no effect on outcome and the treatment is now being abandoned in both TBI and following HIBI.

The outcome of HIBI worsens if:

- The patient has been in coma (i.e. unresponsive) for >6 hours.
- Lack of spontaneous limb movements or failure to localise painful stimuli in the initial stages.
- Prolonged loss of pupillary responses (if atropine has not been administered).
- Sustained conjugate eye deviation (upgaze or downgaze).
- Specific forms of abnormal eye movements (including upbeat and downbeat nystagmus, ping pong gaze or period alternating nystagmus).
- Myoclonic seizures.
- Involvement of lower cranial nerve function.

However, these signs are variable and dependent on medication used during resuscitation.

### Seizures

Focal or generalised convulsive tonic-clonic seizures are relatively unusual in the initial stages following HIBI but may evolve during the recovery period. Status epilepticus occurring after HIBI responds poorly to conventional antiepileptic drugs including phenytoin.

Post-hypoxic myoclonic status may develop immediately after resuscitation when it typically causes bilateral synchronous local or

generalised multifocal jerking of the face, limbs, trunk or diaphragm. The EEG shows limited background activity with a burst suppression pattern and intermittent generalised periodic complexes with no cortical focus. It responds poorly to medication and carries a uniformly bad prognosis.

Another form of myoclonus (Lance–Adams syndrome) comes on after a latent period of 24–48 hours after resuscitation. It often follows a primary respiratory arrest or anaesthetic event and usually occurs in a younger age group. Consciousness is usually less deeply impaired, and focal myoclonus is often action or startle sensitive. The prognosis of the Lance–Adams form of post-hypoxic myoclonus is generally favourable and these patients continue to improve over time although cerebellar signs including ataxia, dysarthria and intention tremor may persist. The EEG shows a focal cortical origin with responsive cortical rhythms which progressively regain normal patterns. The condition responds reasonably well to antiepileptic drugs including valproate, piracetam, levetiracetam and clonazepam.

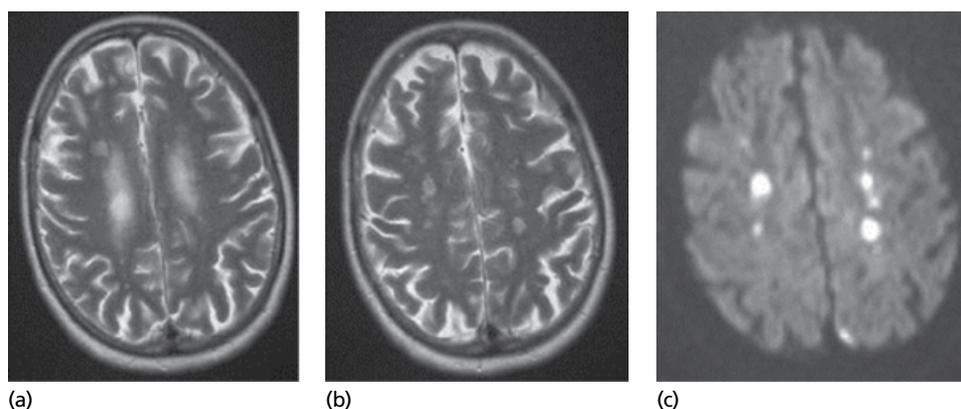

The EEG has been widely used over many years to assess the level of consciousness and to guide prognosis after HIBI. A number of patterns suggest a poor prognosis:

- Generalised electrical suppression
- Generalised burst suppression
- Unresponsive alpha, theta or delta rhythms
- Periodic patterns
  - periodic lateralised epileptiform discharges (PLEDS)
  - bilateral independent or synchronous PLEDS (BiPLEDS).

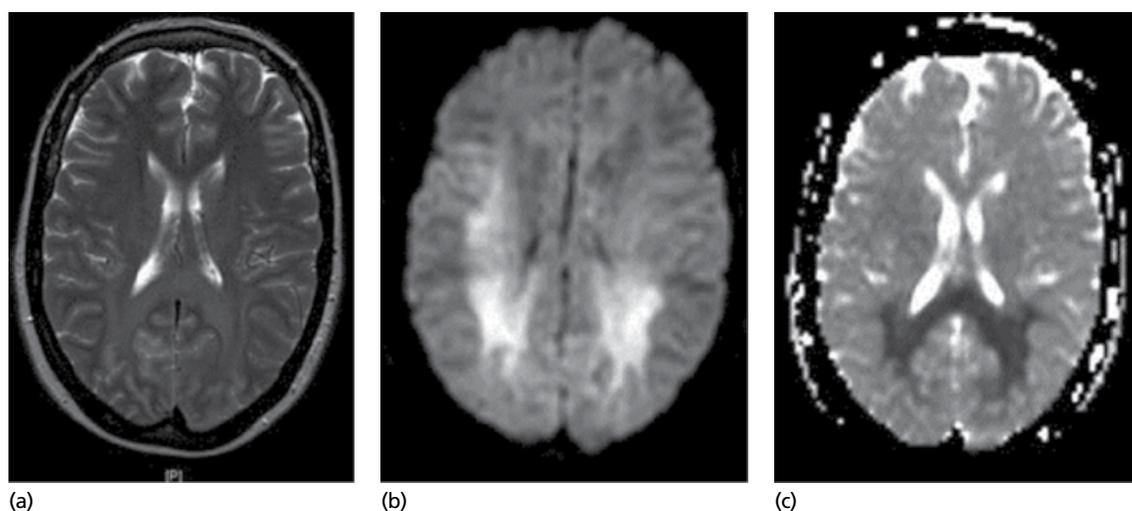

SSEPs are valuable in assessing the prognosis following HIBI. Bilateral absence of the cortical N20 response represents widespread cortical injury after cardiac arrest with a high specificity for poor outcome.

In the first 2 days after HIBI, CT scans may show diffuse swelling with effacement of the basal cisterns, ventricles and sulci, attenuation of the grey–white matter interface and hypodensity of the cortical grey matter and basal ganglia (caudate, lenticular nucleus, thalamus and putamen) resulting from cytotoxic oedema. Focal areas of infarction may develop in the basal ganglia or cortical watershed territories.

MRI is undertaken less commonly following HIBI because patients often require sedation, ventilation and airway protection. In

**Figure 20.21** After severe circulatory compromise, for example following problematic cardiac surgery, a pattern of border-zone ischaemia may occur. MRI shows high signal on T2 (a) and FLAIR (b) in the deep border-zone regions, as well as high signal on diffusion weighted imaging (c).

**Figure 20.22** Diffuse white matter high signal following hypoxic–ischaemic brain injury (HIBI). T2 (a), DWI (b), ADC map (c).

the acute stages (first few days) after severe HIBI, diffusion-weighted and FLAIR images show widespread hyperintensity initially involving the basal ganglia, caudate, striatum and thalamus followed by the cortex and subcortical white matter, cerebellum and hippocampus. Conventional T1 and T2 weighted scans are normal. Diffusely abnormal findings on diffusion-weighted images and fluid attenuated inversion recovery correlate with a poor outcome (Figures 20.21 and 20.22).

#### Longer-term complications of HIBI

Following resuscitation after a severe HIBI the patient generally remains in coma for several days although, rarely, this may persist for longer. The level of consciousness may improve but many patients remain in a vegetative or minimally aware state for prolonged periods. Recovery is often associated with a variable level of residual cognitive impairment.

**Movement disorders** A variety of movement disorders may develop after HIBI because the basal ganglia are particularly vulnerable to injury. In younger patients with predominantly hypoxic brain injury later onset dystonia develops after several weeks, while in

older patients with predominantly ischaemic insults an akinetic rigid syndrome may occur.

**Border-zone infarction** Border-zone infarction is associated with HIBI resulting from cardiac arrest, it is also seen after prolonged cardiac bypass associated with hypotension but can also be caused by multiple emboli particularly following aortic procedures with prolonged bypass time. The vulnerable border-zone regions lie between the territories of brain supplied by the three major cerebral arteries (Figure 20.21). Unilateral border-zone infarction may develop with severe stenosis or occlusion of an internal carotid artery. The syndromes of border-zone infarction are summarised in Table 20.19.

**Delayed post-hypoxic encephalopathy** Delayed post-hypoxic encephalopathy is a rare condition that follows primarily hypoxic injury such as carbon monoxide poisoning, drowning, hanging, strangulation, drug overdose and respiratory depression. Patients seem to have made a complete recovery from hypoxic coma with normal cognitive function for 1–4 weeks before a relapse occurs with cognitive deterioration, frontal lobe (urinary incontinence and gait disturbance) and

**Table 20.19** Syndromes of border-zone infarction.

Border zone	Clinical syndrome
Anterior and middle cerebral arteries	<p>Bi-brachial weakness and sensory loss. Initially, this involves the whole limb but later becomes confined to the hands and forearms ('man in a barrel')</p> <p>Mild spasticity and brisk reflexes, particularly the finger jerks</p> <p>Superficial sensation is retained but there is cortical sensory loss in the fingers</p> <p>Disturbance of volitional eye movement caused by lesions in both frontal eye fields</p> <p>Rarely, fluctuating cortical ischaemic over the frontal parasagittal border-zone may lead to non-epileptic myoclonic limb jerking, during which the EEG shows diffuse slow waves with no focal or ictal features</p>
Middle and posterior cerebral arteries	<p>Initial period of cortical blindness that rapidly improves although visual acuity may be reduced for some weeks</p> <p>Dyslexia, dysgraphia and dyscalculia and often a memory deficit for both verbal and non-verbal material</p>
Common border zone of the three vessels	<p>Lower altitudinal field defect</p> <p>Difficulty in visual judgement of size, distance and movement and a disorder of smooth oculomotor pursuit</p> <p>Restriction of visual attention and an absence of blink reaction to visual threat</p> <p>Difficulty with movements performed under visual guidance (optic ataxia)</p>
Cerebellum	<p>Unusual because of the extensive anastomosis on the cerebellar cortex</p> <p>Border-zone between the territories of supply of the superior cerebellar and posterior inferior cerebellar arteries</p> <p>May present as dizziness, vertigo and ataxia</p>
Spinal cord	<p>Longitudinal and horizontal border-zone</p> <p>Anterior spinal artery has a highly variable segmental supply and discontinuity between cervical, thoracic and lumbar levels</p> <p>Infarction in the thoracic cord may occur at the border-zone territories between the cervical and thoracic supply (T3/T4) or between the mid thoracic and lumbar enlargement at approximately T9. However, the entire mid thoracic region (T4–T9) is vulnerable</p> <p>Anterior spinal artery syndrome or border zone infarction restricted to deep grey matter causing amyotrophy</p>

extrapyramidal signs from basal ganglia involvement (short stooping gait, parkinsonian faces and rigidity). MRI shows extensive white matter change and involvement of the basal ganglia (globus pallidus and occasionally putamen, caudate nucleus, thalamus and hippocampus). The outcome is variable. Up to 50% are said to make a

good recovery but residual cognitive and extrapyramidal deficits are also common and delayed post-hypoxic encephalopathy may culminate in an unresponsive vegetative state.

### Movement disorder emergencies

Movement disorder emergencies are characterised by inadequate voluntary movements (hypokinetic) or the presence of abnormal involuntary movements (hyperkinetic). Occasionally, movement disorders may become severe and prolonged enough to threaten respiratory function or risk aspiration, and severe exhaustion with metabolic derangements (status dystonicus).

Acute parkinsonism is most commonly caused by dopamine blocking drugs. Toxic causes are usually associated with severe encephalopathy often leading to akinesia which is poorly responsive to levodopa. Acute illnesses worsen parkinsonism and require correction of the underlying medical condition, while maintaining Parkinson's disease medication. Abrupt discontinuation of treatment may also result in disastrous and even fatal consequences and can be prevented by the administration of Parkinson's disease medication orally or parentally. The use of transdermal delivery of dopamine agonists allows more flexibility for the delivery of Parkinson's disease medication on the ICU. The parkinsonism-hyperpyrexia syndrome is usually indistinguishable from neuroleptic malignant syndrome and is probably caused by a central dopamine deficiency.

Hyperkinetic movement disorders are typically categorised by the predominant type of abnormal involuntary movement:

- Tremor
- Dystonia
- Myoclonus
- Chorea
- Athetosis
- Ballism
- Tardive dyskinesia

Hyperkinetic emergencies, because of fulminant muscle activity, carry a risk of hyperthermia and rhabdomyolysis. Close monitoring of serum creatine kinase (CK), electrolyte and renal function is essential for the early detection of rhabdomyolysis and intravenous hydration is critical in preventing acute renal failure. Severe pain may be a feature and adequate analgesia is necessary.

Symptomatic treatment is often necessary:

- Sedation – benzodiazepines.
- Anaesthesia – propofol is an ideal choice because of the short half-life.
- Neuromuscular blockade – required if sedation fails to control hypokinetic movement adequately. Non-depolarising paralytic agents (e.g. atracurium) are preferable to depolarising agents (succinylcholine) because the latter may induce or worsen rhabdomyolysis.

Lethal catatonia is a rare condition with features of neuroleptic malignant syndrome but no exposure to dopamine blocking drugs. Clinically there is agitation, stereotypes, psychosis and autonomic disturbance leading to the development of catatonia in which patient adopt fixed abnormal postures in association with major behavioural disturbances. Rigidity and mutism occur with periods of intense agitation and bizarre repetitive movements. The condition is usually associated with major psychiatric disturbances, especially schizophrenia, but may occur following stroke, meningitis, head trauma and metabolic disturbance. Treatment is with electroconvulsive therapy (ECT) which is tolerated even by severely debilitated patients.

### Stiff person syndromes and progressive encephalopathy with rigidity and myoclonus

Stiff person syndrome is associated with severe pain and spasms in the lumbar paraspinal muscles and lower limbs with an exaggerated lumbar lordosis. Muscle spasms can occur spontaneously or be provoked by noise or movement but may be so forceful as to produce femoral fractures or joint subluxation and are associated with life-threatening autonomic dysfunction. It is particularly associated with anti-GAD antibodies, and is amenable to immunomodulatory treatment with plasma exchange or immunoglobulin (IVIg). A more aggressive variant is PERM (progressive encephalopathy with rigidity and myoclonus) which is associated with muscle rigidity, stimulus sensitive spasms and brainstem dysfunction. There may also be hyperekplexia and cerebellar ataxia with autonomic dysfunction. Breathing and swallowing difficulties may contribute to the development of respiratory failure. The condition is associated with antiglycine receptor antibodies. Treatment is with immunomodulation using corticosteroids, IVIg, plasma exchange or cyclophosphamide. Intrathecal baclofen has also been used.

### Acute dystonia

Acute dystonia is usually precipitated by neuroleptics or other dopamine blocking drugs such as antiemetics. It may be life-threatening if the airway or breathing are compromised. It includes conditions such as oculogyric crisis, laryngeal dystonia, blepharospasm, torticollis, trismus, dysarthria and dystonia. Dystonia is usually short-lived and easily reversed by procyclidine but it may recur. Acute dystonia may evolve into status dystonicus in which there is a life-threatening disorder of unremitting severe generalised dystonic spasms (dystonic storms). Drug treatment is very difficult but involves the use of dopamine blockers and dopamine depletors including benzhexol, tetrabenzine and pimozide. Treatment also often involves introducing sedation, paralysis and ventilation. Intrathecal baclofen has been used. Functional surgery is often recommended (e.g. bilateral ventral lateral thalamotomy, unilateral pallidotomy, bilateral pallidal stimulation).

### Stridor

The development of stridor in MSA can be the presenting feature. It results from failure of the vocal cords to abduct normally. The incidence of sudden death is high because of respiratory obstruction possibly associated with autonomic failure and central apnoea. Treatment has included nasal CPAP and botulinum toxin injection into the laryngeal adductors but tracheostomy is treatment of choice. Acute laryngeal dystonia can also present with nocturnal; stridor that interferes with the normal breathing pattern.

### Cervical cord disorders (Chapter 16)

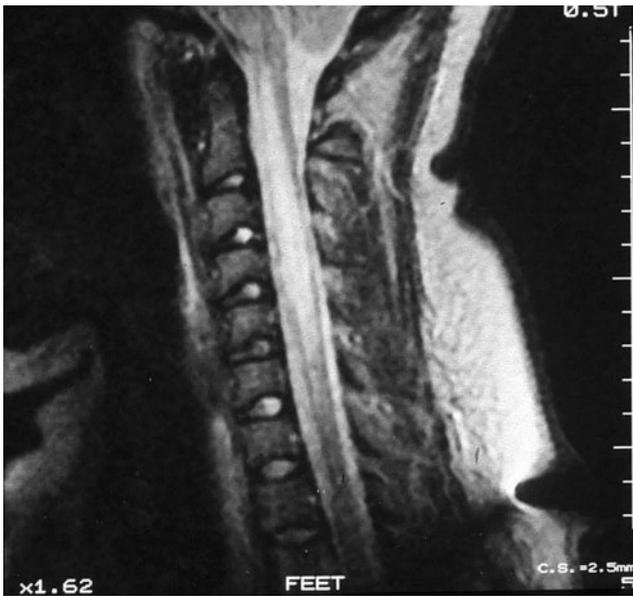

Traumatic, demyelinating or vascular lesions of the spinal cord, particularly at high cervical levels, may cause acute flaccid tetraplegia, selectively affecting respiratory control. Patients with previously unsuspected Arnold–Chiari malformation with cerebellar ectopia may present with acute ventilatory failure and tetraparesis following a cervical spine hyperextension injury. Cervical myelitis or structural lesions of the cord may selectively affect respiratory control, in particular the automatic generation of the respiratory rhythm leading to central apnoea. Examples of conditions that may lead to impaired respiratory control as a consequence of lesions of the cervical cord are shown in Figures 20.23, 20.24 and 20.25.

**Figure 20.23** Subacute combined degeneration (MRI, T2-weighted sagittal).

**Figure 20.24** Spinal cord infarction (MRI, T2-weighted sagittal).

**Figure 20.25** Neuromyelitis optica (MRI, T2-weighted sagittal).

### Anterior horn cell disease

Patients with motor neurone disease can present with acute respiratory weakness, or develop this early in the course of their disease – often associated with infection. These patients may be intubated and ventilated before the diagnosis has been made. The progressive nature of the condition means that weaning to non-invasive ventilatory support may be impossible. Patients with late post-polio functional deterioration may also present with progressive nocturnal hypoventilation or acute respiratory failure and acute flaccid paralysis may be caused by poliomyelitis and West Nile virus, or occur as a paraneoplastic syndrome.

### Neuromuscular disease

Patients with neuromuscular disease (Chapter 10) require NICU care when they develop acute or acute on chronic respiratory failure or acute bulbar or limb weakness. They may develop severe and unexpected deterioration of respiratory, bulbar and limb function as a consequence of intercurrent events including systemic infection, disease exacerbation and increased pulmonary load (e.g. pregnancy or obesity).

### Neuropathies (Chapter 10)

Patients can be admitted because of a severe, primary neuropathy which recovers slowly (e.g. acute inflammatory demyelinating neuropathy), or develop neuropathy related to therapeutic agents (e.g. acute intermittent porphyria) or nutritional deficiencies. The intensive care patient is at particular risk of developing critical illness polyneuropathy.

**Acute inflammatory demyelinating polyneuropathy** About one-third of patients with Guillain–Barré syndrome require admission to ICU because of respiratory insufficiency requiring mechanical ventilation, severe bulbar weakness threatening pulmonary aspiration or autonomic instability, causing cardiac arrhythmias or fluctuations in blood pressure (Chapter 10); often there is a combination of factors. Ventilatory failure is primarily caused by inspiratory muscle weakness, although weakness of the abdominal and accessory muscles of

respiration, retained airway secretions leading to pulmonary aspiration and atelectasis are all contributory factors. The associated bulbar weakness and autonomic instability reinforce the need for control of the airway and ventilation. Patients with acute motor and sensory axonal neuropathy (the axonal form of Guillain–Barré syndrome) usually present with a rapidly developing paralysis developing over hours leading to respiratory failure requiring tracheal intubation and ventilation. There may be total paralysis of all voluntary muscles of the body, including the cranial musculature, the ocular muscles and the pupils. Prolonged paralysis and incomplete recovery are more likely and prolonged ventilatory support may be necessary.

The diagnosis of neuropathy may be difficult to recognise because of the presence of multi-organ impairment or other general medical factors. Occasionally, some patients may actually develop acute demyelinating polyneuropathy during the course of a critical illness; not surprisingly, when this occurs the rapid development of inexplicable weakness and its cause may not be recognised.

**Miller Fisher syndrome** Ataxia, areflexia and ophthalmoplegia are the classic features. Diplopia is the most common initial complaint (in about one-third), while ataxia is evident in about one-fifth of patients at onset. Facial weakness, bulbar impairments with dysphagia and dysarthria, along with facial or limb paraesthesias, may also occur and mild proximal limb weakness is found in approximately one-third of patients.

**Bickerstaff's brainstem encephalitis** Bickerstaff's brainstem encephalitis is a closely related condition in which progressive ophthalmoplegia and ataxia, maximal at less than 4 weeks, are associated with drowsiness and coma, and upper motor neurone signs. MRI shows high intensity abnormalities in the posterior fossa, white matter or thalami in 30% of patients. The course is monophasic with complete recovery at 6 months in 66%.

**Acute intermittent porphyria (Chapter 19)** Acute intermittent porphyria is an uncommon autosomal dominant disease, characterised by recurrent episodes of abdominal pain, psychiatric disturbances, seizures and acute, predominantly motor axonal, neuropathy with autonomic features, which may mimic the Guillain–Barré syndrome causing bulbar and ventilatory failure with patchy sensory involvement. Attacks can be precipitated by heavy alcohol consumption and by numerous medications, many of which are commonly administered in the ICU, such as diazepam, theophylline and barbiturates.

**Phrenic nerve neuropathies** Phrenic nerve neuropathies may lead to ventilatory failure and admission to ICU (Table 20.20).

**Critical illness polyneuropathy** Critical illness polyneuropathy (CIP) is an acute sensorimotor axonal neuropathy that develops in the setting of systemic inflammatory response syndrome (SIRS) and/or multi-organ failure, particularly in the presence of hypoalbuminaemia, hyperglycaemia and insulin deficiency with or without corticosteroids and neuromuscular blocking agents. Up to 70% of patients with sepsis and multi-organ failure develop abnormalities on nerve conduction studies. CIP is characterised by delayed weaning, severe flaccid wasting and weakness; areflexia and sensory impairment may be seen in patients who are able to cooperate with the examination. However, the signs are variable and difficult to

elicit because of sedation or coexistent septic encephalopathy. CIP is self-limiting but the overall prognosis is influenced by the severity of the underlying condition and this accounts for most of the mortality. The outcome is also related to the severity of the sepsis and other factors including the extent and severity of the neuropathy, the time on ICU and the presence of hyperglycaemia, hyperosmolality or hypoalbuminaemia. When the neuropathy is mild or moderate, recovery is relatively rapid and complete. In those with more severe polyneuropathy, recovery is limited; persisting weakness and sensory deficits are common in long-term survivors of protracted critical illness, even up to 4 years after discharge.

The differential diagnosis of CIP includes other neuropathies, neuromuscular transmission defects and myopathies, of which the most important one is critical illness myopathy. The diagnosis of neuromuscular blockade can be established by repetitive nerve stimulation studies. Differentiating CIP from critical illness myopathy is more difficult and sometimes these two diseases can occur simultaneously.

**Table 20.20** Causes of phrenic nerve neuropathy.

Brachial neuritis
Brachial plexopathy
Following thoracotomy, cardiac surgery
Trauma
Heavy metal intoxication – lead, thallium, arsenic
Metabolic – hypophosphataemia, renal failure
Infections – Borrelia, HIV
Neuropathies:
Chronic inflammatory demyelinating neuropathy
Multi-focal motor neuropathy
Hereditary neuropathy with liability to pressure palsy
Hereditary sensorimotor neuropathy
Diabetes

### Neuromuscular junction disease

Disruption of neuromuscular transmission is an important cause for weakness and failure to wean in critically ill patients.

**Prolonged neuromuscular blockade** Prolonged neuromuscular blockade after either short- or long-term blockade with non-depolarising neuromuscular blocking agents (NMBAs; Table 20.21) may occur in association with metabolic acidosis, hepatic or renal insufficiency and elevated levels of magnesium. Weakness should not persist beyond 2 weeks after stopping the blocking agent and typically lasts for only a few days. Prolonged blockade should be considered in any patient who remains weak after discontinuation of NMBAs. The condition occurs in the context of cumulative doses of NMBAs often given with corticosteroids, aminoglycosides or other anaesthetic agents. Repetitive nerve stimulation is abnormal with a decremental response in the compound muscle potential amplitude but the CK levels are normal. Recovery usually occurs within several days of discontinuation of the NMBA.

Neuromuscular disorders resulting from the disruption of neuromuscular transmission should be considered as a cause for neuromuscular weakness and failure to wean in critically ill patients. Patients with myasthenia gravis or the Lambert–Eaton myasthenic syndrome have an extremely high sensitivity to even low doses of NMBAs and other agents such as aminoglycoside antibiotics and antiarrhythmic agents (Table 20.21).

**Myasthenia gravis** In myasthenia gravis admission to the NICU is indicated by the development of incipient ventilatory failure, progressive bulbar weakness leading to failure of airway protection or severe limb and truncal weakness causing extensive paralysis (Chapter 10). Admission should be determined by the rate of progression, the presence of bulbar weakness and the clinical state of the patient rather than an absolute level of FVC alone. Respiratory failure often results from a myasthenic crisis (usually precipitated by infection, surgery or inadequate treatment), but may also more rarely be precipitated by a cholinergic crisis. The associated bulbar weakness predisposes to pulmonary aspiration and acute respiratory failure necessitating urgent tracheal intubation and ventilation. Patients with recent onset generalised myasthenia gravis started on

**Table 20.21** Drugs that may affect the neuromuscular junction.

Neuromuscular blocking agents (non-depolarising)	Aminosteroidal (pancuronium, vecuronium, pipecuronium, rocuronium) Benzylisoquinolinium (D-tubocurarine, atracurium, cisatracurium, doxacurium, mivacurium)
Antibiotics	Aminoglycosides, clindamycin, tetracycline, quinolones, polymyxin, erythromycin
Local anaesthetics	Lidocaine
Antiarrhythmics	Quinidine, procainamide
Beta-blocking agents	Propranolol, atenolol, acebutolol, bisoprolol, labetalol, metoprolol, oxprenolol, pindolol, sotalol, timolol
Calcium channel blockers	Verapamil, diltiazem
Immunosuppressive agents	Cyclophosphamide, ciclosporin
Diuretics	
Corticosteroids	
Statins	
Antiretrovirals	Zidovudine, lamivudine
Others	D-penicillamine, phenytoin, dantrolene, lithium carbonate, interferon $\alpha$

a high-dose daily corticosteroid regimen are particularly at risk for acute paradoxical deterioration during the first 48–96 hours of treatment. Thymectomy should be coordinated by an NICU with experience of the procedure and the postoperative care of patients with myasthenia.

**Botulism** This is caused by toxins produced by *Clostridium botulinum*, an anaerobic Gram-positive organism. These act at the presynaptic region of the neuromuscular junction causing failure of release of acetylcholine from the terminal. The classic form occurs after ingestion of food that contains toxin, but increasing numbers of patients are being seen who have developed botulism as a consequence of using contaminated opiates or unclean needles to inject drugs of abuse into infected skin lesions (skin popping).

Patients develop cranial nerve deficits, including blurred vision, diplopia, ptosis, dysarthria and dysphagia. The weakness often affects the arms before progressing to the legs. Autonomic symptoms, including dry mouth, unreactive pupils and ileus, are frequent. The condition may be suspected by prominent and early ocular signs (dilated sluggishly reactive pupils and ophthalmoplegia) and dysphagia. Management is described in Chapter 9.

Other neuromuscular transmission disorders that may cause confusion in ICU include organophosphate poisoning, tick paralysis, black widow spider and certain types of snake envenomation.

### Muscle disease

Myopathies occur much more frequently during critical illness than previously recognised. Three main types have been identified:

- 1 Diffuse non-necrotising cachectic myopathy
- 2 Myopathy with selective loss of thick (myosin) filaments ('critical illness myopathy')
- 3 Acute necrotising myopathy of intensive care.

**Diffuse non-necrotising cachectic myopathy** This is common and presents as muscle wasting with associated weakness. However, the CK levels and electromyograms (EMG) are normal or show only mild changes. It is associated with prolonged ICU admission, sedation or paralysis causing muscle disuse, and poor nutrition with protein catabolism during critical illness. There is proximal or general weakness. Biopsy shows type 2 fibre atrophy and neurogenic atrophy. The outcome depends on the underlying critical illness.

**Critical illness myopathy (myopathy with selective loss of thick [myosin] filaments)** This is a distinct form of myopathy that occurs in patients with critical illness on ICU. It is under-recognised and is one of the most common forms of generalised weakness on the ICU, being considerably more frequent than critical illness polyneuropathy. It is sometimes associated with prolonged exposure to high doses of corticosteroids and non-depolarising muscle blocking agents (e.g. pancuronium, vecuronium or atracurium) used to treat acute pulmonary disorders, such as asthma. However, it can occur in other situations including SIRS, major organ transplantation – particularly liver – and it does not seem to correlate with the duration of intensive care. Other factors that may contribute include nutritional deficiencies, concurrent drug administration with aminoglycosides or ciclosporin, hyperglycaemia, renal and hepatic dysfunction, fever, severe metabolic and electrolyte disorders.

The problem tends to be recognised as the acute illness resolves, when it becomes apparent that the patient cannot wean from

ventilatory support because of limb and respiratory muscle weakness. The limb weakness may be mild or severe and is predominantly proximal although it may be generalised. There may be facial and neck weakness but the extraocular movements are often spared, reflexes are reduced and sensation is not affected.

Blood CK levels are elevated in <50%. Needle EMG may show myopathic features but is often unhelpful in distinguishing between myopathy and polyneuropathy because insufficient motor units are obtained. Muscle biopsy is necessary to establish the diagnosis. Histological changes include abnormal variation of muscle fibre size, fibre atrophy, angulated fibres, internalised nuclei, rimmed vacuoles, fatty degeneration of muscle fibres, fibrosis and single fibre necrosis. Inflammatory changes are absent (Figure 20.26). There is selective loss of thick (myosin) myofilaments and preservation of thin (actin) myofilaments and Z discs (Figure 20.27).

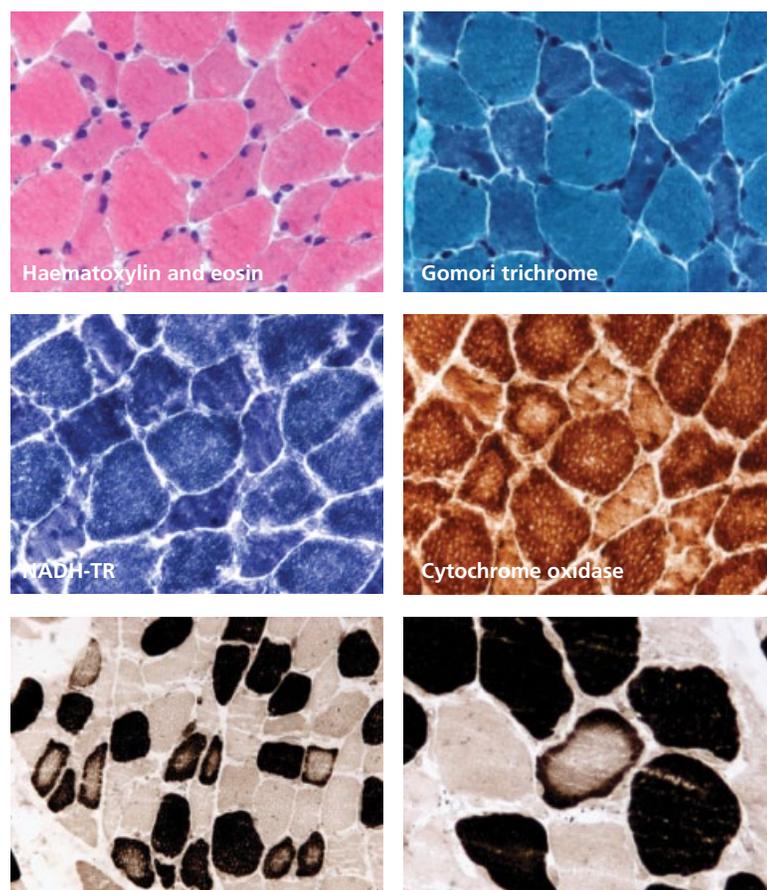

The outcome from critical illness myopathy is generally better than after critical illness polyneuropathy and most patients make a full recovery unless there has been severe and prolonged paralysis.

**Acute necrotising myopathy of intensive care** This is a rare condition which may be a form of rhabdomyolysis. It develops after exposure to neuromuscular blocking agents with or without steroid therapy but may be associated with other infective or metabolic insults. The serum CK is markedly elevated, there is usually associated myoglobinuria. EMG confirms a severe myopathy and biopsy shows patchy or widespread necrosis with occasionally vasculitis or infarction within the muscle. The prognosis for recovery of weakness is poor.

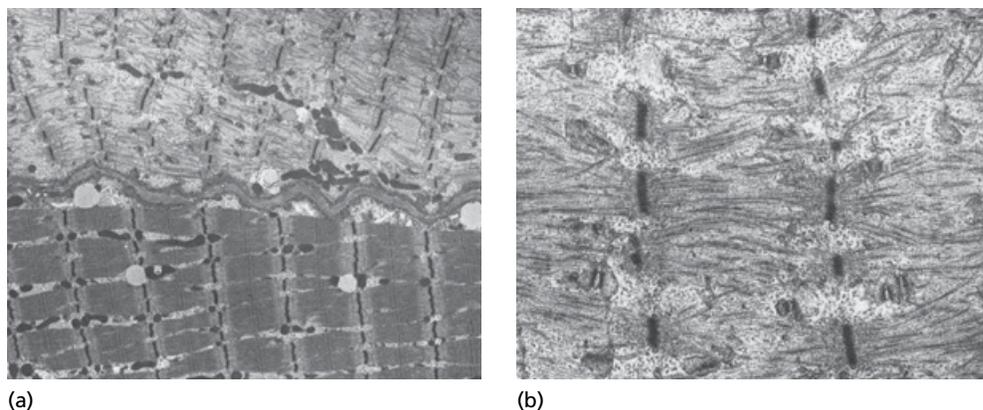

**Other myopathies** Almost any form of myopathy may be responsible for prolonged respiratory failure in critical care units. Patients with weakness and asthma and others who have been exposed to corticosteroids alone may have acute steroid myopathy. This is a slowly evolving mild to moderate proximal weakness with mild elevation of CK and type 2 fibre atrophy. Occasionally, direct sepsis may affect the muscle causing pyomyositis resulting from septic micrometastases.

Inflammatory myopathies may cause respiratory muscle weakness. Patients with dermatomyositis may have a characteristic skin rash. The EMG may be misleading, showing numerous fibrillation potentials and positive sharp waves that are more characteristic of denervation from neuropathy. The CK is elevated and muscle biopsy of an involved muscle is necessary to make the diagnosis. Other inflammatory myopathies include viral myositis, acute alcoholic rhabdomyolysis and myopathy secondary to hypophosphataemia. Trichinosis caused by the ingestion of raw contaminated pork may cause an acute and severe myopathy with diaphragm and intercostal muscle involvement.

Patients with muscular dystrophy may present with ventilatory failure or develop respiratory insufficiency either as an early manifestation or as an inevitable feature of disease progression. Myotonic dystrophy is occasionally identified for the first time in the ICU. In adults, acid maltase deficiency may present with proximal weakness, scoliosis and diaphragmatic paralysis. The apparently abrupt respiratory insufficiency probably occurs on the background of long-standing unrecognised disease. Progressive respiratory impairment occurs in all patients with Duchenne muscular dystrophy, and acute deterioration may occur because of intercurrent events such as aspiration pneumonia.

**Figure 20.26** Muscle biopsy in critical illness myopathy showing abnormal variation in fibre size with dark atrophic fibres. Courtesy of Prof Janice Holton, Professor of Neuropathology, Institute of Neurology, Queen Square.

**Figure 20.27** Electron microscope of muscle biopsy: (a) in normal; (b) in critical illness myopathy showing loss of myosin thick filaments. Courtesy of Prof Janice Holton, Professor of Neuropathology, Institute of Neurology, Queen Square.

Rhabdomyolysis may be precipitated by trauma, compartment syndrome, ischaemic arterial occlusion or drugs and is associated with high serum CK levels, myoglobinuria and general weakness. There are reports of respiratory decompensation associated with mitochondrial myopathies, limb girdle muscular dystrophy, HIV-related myopathy and sarcoid myopathy involving the diaphragm.

### Tetanus (Chapter 9)

Most patients with established tetanus will be admitted to an NICU because of increased muscle tone and spasms that typically begin in the masseter muscles, resulting in the classic finding of trismus. Respiratory compromise is caused by spasm of respiratory muscles or laryngospasm. Autonomic dysfunction occurs in severe cases and results in heart rate and blood pressure lability, arrhythmias,

fever, profuse sweating, peripheral vasoconstriction and ileus. Muscle rupture and rhabdomyolysis can complicate extreme cases.

Supportive care consists of treatment in a quiet ICU setting to allow cardiorespiratory monitoring with minimal stimulation. Intubation may be required owing to hypoventilation caused by muscular rigidity or laryngospasm and should be performed in a controlled elective manner if possible. Therapeutic paralysis with neuromuscular blocking agents may be necessary in severe cases. Treatment in the ICU has resulted in a pronounced improvement in prognosis for patients with tetanus. Modern mortality is approximately 10%.

### Rabies (Chapter 9)

Paralytic rabies, produces neuromuscular weakness that can be difficult to differentiate from other causes of weakness such as Guillain–Barré syndrome. Rabies may begin with local wound pain and paraesthesias followed by fasciculations near the site of inoculation.

## General medical care on the NICU

The role of an ICU is to maintain normal physiological homeostasis while actively treating the underlying cause of any physiological derangement. The following general medical complications may arise during the care of patients on an NICU (Table 20.22).

### Nosocomial infection and infection surveillance

Sepsis (and the systemic inflammatory response to sepsis) remains the major cause of organ failure and death in the ICU, being either directly or indirectly responsible for 75% of all deaths. Common sites of infection include the urinary tract, respiratory tract (especially ventilator-associated pneumonia) and catheter-related sepsis. Placement of intravenous catheters requires meticulous aseptic technique and regular changing of lines. It is important to ensure that the tips of catheters that have been removed are sent for culture. Catheter-related infections are usually caused by coagulase-negative staphylococci (*Staphylococcus epidermidis* or *S. aureus*) and treatment should be directed by sensitivities determined by culture. The importance of infection control in the NICU cannot be overstated. This involves the isolation of the infected patient whenever possible, meticulous staff hygiene (e.g. hand-washing before and after each patient contact, aseptic techniques for invasive procedures), early identification and treatment of infection by routine blood, urine, sputum culture, use of disposable equipment and, most importantly, joint ward rounds between microbiologists and the ICU team (Table 20.23).

### Anticoagulation

Prophylaxis against venous thrombosis is essential and all patients should wear graduated compression stockings and have regular active or passive leg exercises. Unless contraindicated, low molecular weight heparin should be routinely administered.

### Delirium

Delirium is characterised by alteration in the level of consciousness ranging from paradoxical agitation to sedation and stupor. Impairment of attention may be manifest as distractibility or difficulty shifting the focus of attention (perseveration), distorted thinking and memory impairment. Symptoms fluctuate and are worse at night with sleep wake reversal, often associated with the development of hallucinations, visual illusions, disorientation and

perceptual distortion. Delirium is common in ICU patients and is associated with increased mortality and poor cognitive outcome. Risk factors for the development of delirium are summarised in Table 20.24.

Primary prevention of delirium may need to be balanced against the requirements for sedation, analgesia and general ITU management. Prevention is multi-factorial and the principles are summarised in Table 20.25.

### Patient comfort

Agitation is common in the NICU and is distinct from delirium. It has a variety of causes (Table 20.26). It may manifest as discomfort, pulling at intravenous and bladder catheters, tracheal and nasogastric tubes, shouting, aggressive behaviour, extreme restlessness and confusion. Pain is particularly common and often unrecognised because of confusion and the difficulties with communication in the aphonic or paralysed patient.

Many patients require sedation but there is a natural reluctance to sedate patients with an evolving CNS disorder. The first line of management is to reassure and calm the patient in a quiet environment and to ensure a normal diurnal cycle. There should be careful nursing and treatment of the underlying causes, including positioning, splinting, bed cages, catheterisation and physical treatments. Nonetheless, sedative and analgesic drugs are often necessary to reduce distress, anxiety and pain and to aid toleration of tracheal tubes, intermittent positive pressure ventilation (IPPV), tracheal suction and physiotherapy.

### Pain

Pain is a prominent feature of many neurological conditions seen in the NICU and needs to be recognised and treated effectively, particularly in patients with a reduced level of consciousness or who are mechanically ventilated and unable to communicate. Combinations of opioid and non-opioid drug treatment, including agents directed towards neuropathic pain (e.g. amitriptyline, gabapentin), may be required. These provide effective analgesia, induce euphoria and aid toleration of IPPV. Side effects of opiates include hypotension, respiratory depression, nausea and vomiting, and decreased gut motility; the fear of addiction is vastly exaggerated. Intravenous administration is more easily controlled and predictable. Commonly used drugs include morphine and fentanyl but short-acting drugs such as remifentanyl may be valuable.

### Communication

Speech is often possible even in patients who are mechanically ventilated via a tracheostomy. It requires speaking valves and, more importantly, the expertise of an experienced speech and language therapist. Where speech is impossible, other communication aids should be used.

### Sleep

Sleep deprivation almost invariably occurs in patients nursed in an ICU setting. Factors include disruption of day–night cycles, environmental factors such as noise and patient fear. The disruption is associated with agitation, confusion and the development of ICU psychosis. Furthermore, sleep deprivation has a direct effect on respiratory muscle function, catabolism and the immune response. It is essential to re-establish a normal pattern of sleep by the use of hypnotic drugs (e.g. benzodiazepines, sedative tricyclic antidepressants, zopiclone). The use of melatonin has proved useful in resistant insomnia.

**Table 20.22** General medical complications of the neurological intensive care unit (NICU).

Pulmonary complications	<p>Acute hypoxaemic respiratory failure caused by ventilation–perfusion mismatch from infection (often secondary to aspiration), atelectasis, pulmonary oedema or pulmonary embolus</p> <p>Nosocomial or aspiration pneumonia</p> <p>Ventilator-associated pneumonia caused by gastro-oesophageal reflux and cross-colonisation from other patients, hospital personnel or equipment</p> <p>Acute lung injury and acute respiratory distress syndrome are associated with sepsis, trauma, aspiration pneumonitis and fat embolism</p> <p>Neurogenic pulmonary oedema</p> <p>Pulmonary emboli</p>
Cardiovascular system	<p>The principal function of monitoring the cardiovascular system in NICU is the maintenance of arterial blood pressure and blood volume to ensure adequate organ perfusion</p> <p>Hypotension may be the result of an inadequate circulating blood volume, poor myocardial contractility, a decreased SVR or a combination of these factors</p> <p>Hypovolaemia</p> <p>Decreased myocardial contractility may be the result of many factors including ischaemic heart disease, sepsis, hypoxaemia, hypercarbia, acidosis, cardiac disease, electrolyte disturbance and drugs</p> <p>Hypertension is a common consequence of acute neurological events</p> <p>Cardiac arrhythmias are associated with aneurysmal SAH, head injury, acute ischaemic or haemorrhagic stroke, status epilepticus, Guillain–Barré syndrome and impending or established brain death</p> <p>Sinus bradycardia is due to sympathetic blockade and/or increased vagal tone and occurs in Guillain–Barré syndrome</p> <p>Sinus tachycardia is extremely common in acute neurological illness and may be associated with hypoxaemia, hypercapnia and neuromuscular blockade or as a compensatory mechanism in anaemia, hypovolaemia and pulmonary emboli</p> <p>Atrial fibrillation with a rapid ventricular response is common, as either a cause or a consequence, in acute stroke</p> <p>Atrial flutter may compromise ventricular filling and increase the risk of ischaemia</p> <p>Heart block</p> <p>Ventricular tachycardia is common in SAH and may predispose to the development of torsade de pointes, ventricular flutter and ventricular fibrillation</p>

**Table 20.22** (continued)

Alimentary system	<p>Protein catabolism is almost invariable in patients nursed on the ICU and is often caused by an inadequate supply of calories and an increased energy and oxygen consumption associated with the stress response to injury and sepsis</p> <p>Enteral feeding via a nasogastric tube should be started as soon as possible as this decreases catabolism, provides protection against peptic ulceration and maintains intestinal integrity, thus decreasing the occurrence of bacterial translocation (see nosocomial infection)</p> <ul style="list-style-type: none"> <li>• Adynamic ileus</li> <li>• Gastrointestinal bleeding</li> <li>• Constipation occurs as a result of opioid drug administration, immobility and a lack of fibre in some enteral feeds</li> <li>• Diarrhoea has many causes but infection (including that by <i>Clostridium difficile</i>), malabsorption and diarrhoea associated with enteral feeds are the most important</li> </ul>
-------------------	--

SAH, subarachnoid haemorrhage; SVR, systemic vascular resistance.

**Table 20.23** Risk factors for nosocomial infections.

Age over 70 years
Widespread use of broad-spectrum antibacterial drugs
Mechanical ventilation and endotracheal tube
Presence of foreign bodies (e.g. intravascular cannulae, bladder catheter, pacemaker)
Immunodeficiency states and immunosuppressant medication
Colonisation of the oropharynx
Use of H <sub>2</sub> receptor antagonists
Underlying chronic lung disease and reintubation

**Table 20.24** Delirium.

<p>The development of delirium is related to:</p> <ul style="list-style-type: none"> <li>• The degree of sedative exposure (especially benzodiazepines)</li> <li>• Pain caused by suboptimal analgesia</li> <li>• Sleep disruption</li> <li>• Age</li> <li>• Pre-existing cognitive dysfunction</li> <li>• Sensory impairment</li> <li>• Poor nutrition – multiple surgical procedures, malnutrition, dehydration, alcohol</li> <li>• Systemic infection</li> <li>• Surgery</li> </ul>
--

### Communication with the family

Communication with family and friends on the ICU presents great challenges for medical and nursing staff. It is essential that staff should be consistent in their assessment and honest in the appraisal of the uncertainties in management and prognosis. It is preferable if only one or two clinicians act as the primary source of information.

It is important to recognise that the family may experience acute stress reactions which may be manifest as anger, frustration, bitterness and guilt. There must be adequate and patient discussion, often on a daily basis.

### End of life issues on intensive care

In the final stages of severe illness when treatment fails, or no longer provides a net benefit to patients, the primary goal of medicine – to restore a person's health – cannot be achieved. This is a common situation on ICU where many patients are unable to communicate their wishes to family or doctors.

There must always be a heavy presumption in favour of administering life-prolonging treatments when they are considered of potential benefit (e.g. cardiopulmonary resuscitation, mechanical ventilation, renal support, artificial nutrition and hydration, drug infusions, blood products and antibiotics). However, the decision to withdraw such treatment is difficult and depends on the assessment of best interest given the possibility of meaningful recovery,

the sanctity of life and the right of each individual to be treated with dignity, compassion and respect. Withdrawal of life prolonging treatment is entirely distinct from euthanasia and physician assisted suicide; rather it switches attention to palliation and allows the already dying patient to achieve a peaceful, natural and dignified death.

When patients are competent to make decisions themselves the overriding principle of autonomy to determine their wishes must be respected. If the patient is not competent to make a decision on his or her own behalf then that decision rests with the medical carers made in the best interest of the patient. The responsible doctors must not transpose their own beliefs, values or priorities on to the patient and must make a concerted effort to ascertain the wishes of the patient from the family or caregivers.

The ethical issues of withholding and withdrawing life-prolonging medical treatment are complex and demanding. When treatment is futile and modern technology is simply prolonging the dying process, it is often in the best interest of the patient to withdraw life-prolonging medical treatment and to allow the illness to run its natural course. However, such decisions require meticulous and sensitive communication and a deep understanding of the emotional turmoil experienced by the family or caregivers. Ultimately, the clinician's primary duty is always to the patient and his or her best interests. These issues continue to be extensively debated. While patients are insentient as a consequence of the disease or its treatment, the family are their advocate. Frequently, families are involved in end-of-life decisions for patients in coma or vegetative state in whom there is no hope of recovery. It is essential to establish, if possible, the patient's own preference for management through living wills, advanced directives or simply by having voiced a clear preference to family or the surrogate decision-makers. The autonomy of the patient must be maintained by respecting these preferences, although a consensus agreement of family members must always be sought by careful explanation and education.

**Table 20.25** Management of delirium.

<b>Non-pharmacological</b>
Treat hypoxia, infection and pain
Provide support and orientation (natural daylight, news, TV)
Allow clear day-night cycles
Maintain afferent sensory input (glasses, hearing aids)
<b>Pharmacological</b>
Avoid medication particularly antimuscarinic agents, phenothiazides, amitriptyline, hyoscine, prednisolone, ranitidine, dopaminergic (levodopa), GABAergic (benzodiazepines) and drugs that suppress REM sleep (e.g. opioids, benzodiazepines, tricyclic antidepressants)
<b>Hyperactive/mixed delirium</b>
Haloperidol – but risk of extrapyramidal side effects and QT <sub>c</sub> prolongation
Atypical antipsychotics (preferred) – olanzapine, risperidone, quetiapine
α-2 agonists – particularly clonidine in hyperactive delirium
Propofol
Benzodiazepines – should be avoided because they may exacerbate the delirium but short acting midazolam is useful in the management of alcohol withdrawal

**Table 20.26** Causes of agitation and restlessness on the neurological intensive care unit (NICU).

Pain
Anxiety
Confusion
Sleep deprivation
Sepsis
Drugs and withdrawal
Metabolic – hypoglycaemia, hyperglycaemia, hyponatraemia, uraemia, hepatic
Respiratory – infection, hypoxaemia, hypercarbia
Cardiac – low output state, hypotension

## Neurology of general critical care

The majority of neurologists work in district general or teaching hospitals with large general ICUs. In this setting, ICUs require an increasing input from neurologists, especially with regard to the assessment of hypoxic brain damage and the neurological complications of organ failure, critical illness and sepsis.

Neurological complications on the ICU are usually caused by metabolic encephalopathy, seizures, hypoxic-ischaemic encephalopathy, stroke or neuromuscular disorders but multiple complications are common.

### Failure to awaken/depressed conscious state

Sudden or gradual deterioration in consciousness may occur during an ICU stay or reflect failure to awaken after general anaesthesia for several reasons (Table 20.27). Sedation and analgesia are

**Table 20.27** Causes of failure to awaken on ICU after sedation or anaesthetic.

Drugs – sedation, analgesia, neuromuscular paralysis
Hypoxic – ischaemic injury
Sepsis
Metabolic encephalopathy – renal, hepatic, electrolyte, endocrine
Stroke
Primary CNS inflammation
Multi-factorial – most common

**Table 20.28** Causes of persistent weakness on the ICU.**Disorders of the cortex and brainstem**

Epilepsy – status epilepticus (convulsive & non-convulsive)  
 Vascular – brainstem infarction or haemorrhage, subarachnoid haemorrhage, intracerebral haemorrhage  
 Infection – brainstem encephalitis, herpes simplex encephalitis, poliomyelitis  
 Inflammatory – Multiple sclerosis (MS), acute disseminated encephalomyelitis (ADEM), acute haemorrhagic leukoencephalopathy (AHL)  
 Metabolic – central pontine myelinolysis  
 Hypoxic–ischaemic encephalopathy  
 White matter disease – posterior reversible leukoencephalopathy, toxic leukoencephalopathy  
 Autoimmune encephalitis – paraneoplastic, Morvan's, Hashimoto's

**Disorders of the spinal cord**

Arnold–Chiari malformation, cerebellar ectopic  
 Trauma  
 • Acute epidural compression due to neoplasm, infection, haematoma  
 • Acute transverse myelitis (demyelination, infective)  
 • Cord infarction

**Anterior horn cell**

Motor neurone disease  
 Poliomyelitis and post polio syndrome  
 Spinal muscular atrophy

**Multiple radiculopathies**

Carcinomatous meningitis  
 AIDS polyradiculitis

**Acute polyneuropathy**

Acute inflammatory demyelinating polyneuropathy (AIDP)  
 Acute motor and sensory axonal neuropathy (AMSAN)  
 Acute motor axonal neuropathy (AMAN)  
 Phrenic neuropathies  
 Critical illness polyneuropathy (CIP)  
 Others – toxic neuropathies, vasculitis, diphtheria, porphyria

**Chronic polyneuropathies**

Chronic inflammatory demyelinating polyneuropathy (CIDP)  
 Diabetic polyneuropathy

**Neuromuscular transmission defects**

Myasthenia gravis  
 Lambert–Eaton myasthenic syndrome  
 Congenital myasthenic syndromes  
 Neuromuscular blocking agents  
 Other: botulism, snake bites, fish toxins, organophosphates, hypermagnesaemia, poisoning

**Table 20.28** (continued)**Myopathy**

*Congenital*  
 Myotonic dystrophy  
 Acid maltase deficiency  
 Mitochondrial  
 Periodic paralysis  
*Acquired*  
 Inflammatory myopathies – polymyositis, dermatomyositis  
 Critical illness myopathy  
 • Associated with neuromuscular blocking agents and steroids  
 • Associated with sepsis  
 Non-necrotic cachectic myopathy  
 Rhabdomyolysis  
 Others: HIV-related, sarcoid, hypokalaemia, hypophosphataemia

confounding factors in those with depressed consciousness. These drugs are used to reduce agitation and pain, with the goals of diminishing discomfort, oxygen demand, ventilator asynchrony and self-removal of catheters and other devices. They also induce amnesia and reduce the risk of a post-traumatic stress disorder. Withdrawal of sedation before review is essential for reliable neurological assessment and it is important to realise that the effects of sedative drugs may take several days to clear; any of them may accumulate if there is multi-organ failure, and even with apparently normal metabolic function their half-life may be abnormally long in patients who have been critically ill. Deep sedation leads to prolonged recovery time, difficulty weaning, ileus and a confusional state. Other drugs used for sedation or analgesia may also contribute to apparent neuromuscular weakness; opioids (particularly morphine, fentanyl, alfentanil), benzodiazepines and other anxiolytic and hypnotic agents.

**Weakness and failure to wean from mechanical ventilation**

Weakness on the ICU often presents as difficulty in weaning from ventilation but there may also be reduced movements in an obtunded patient, or generalised or focal weakness in an alert patient. This must be distinguished from the non-specific weakness of fatigue secondary to systemic illness (Table 20.28).

Weakness may be central or peripheral. In the comatose patient, a central cause should be suspected if there are upper motor neurone signs, if the distribution of the weakness is pyramidal or if there is a hemiparesis. Paraparesis is often caused by nerve or muscle disorders, and less often spinal disorders (infarction secondary to a hypotensive or embolic episode). Monoparesis may occasionally be a manifestation of a stroke but more often a consequence of pressure or positioning palsy (femoral or common peroneal nerve palsies).

Neuromuscular disease may occur in the ICU patient as:

- A complication of a non-neurological illness (e.g. critical illness polyneuropathy associated with SIRS)
- A primary neurological disorder (e.g. Guillain–Barré syndrome)
- An acute exacerbation of an underlying neuromuscular condition (e.g. myasthenia gravis)

- Progression of a previously diagnosed neuromuscular disease (e.g. Duchenne muscular dystrophy, motor neurone disease, acid maltase deficiency), or
- A complication of treatment (e.g. acute quadriplegic myopathy).

## Sleep and its disorders

### Structure of normal sleep

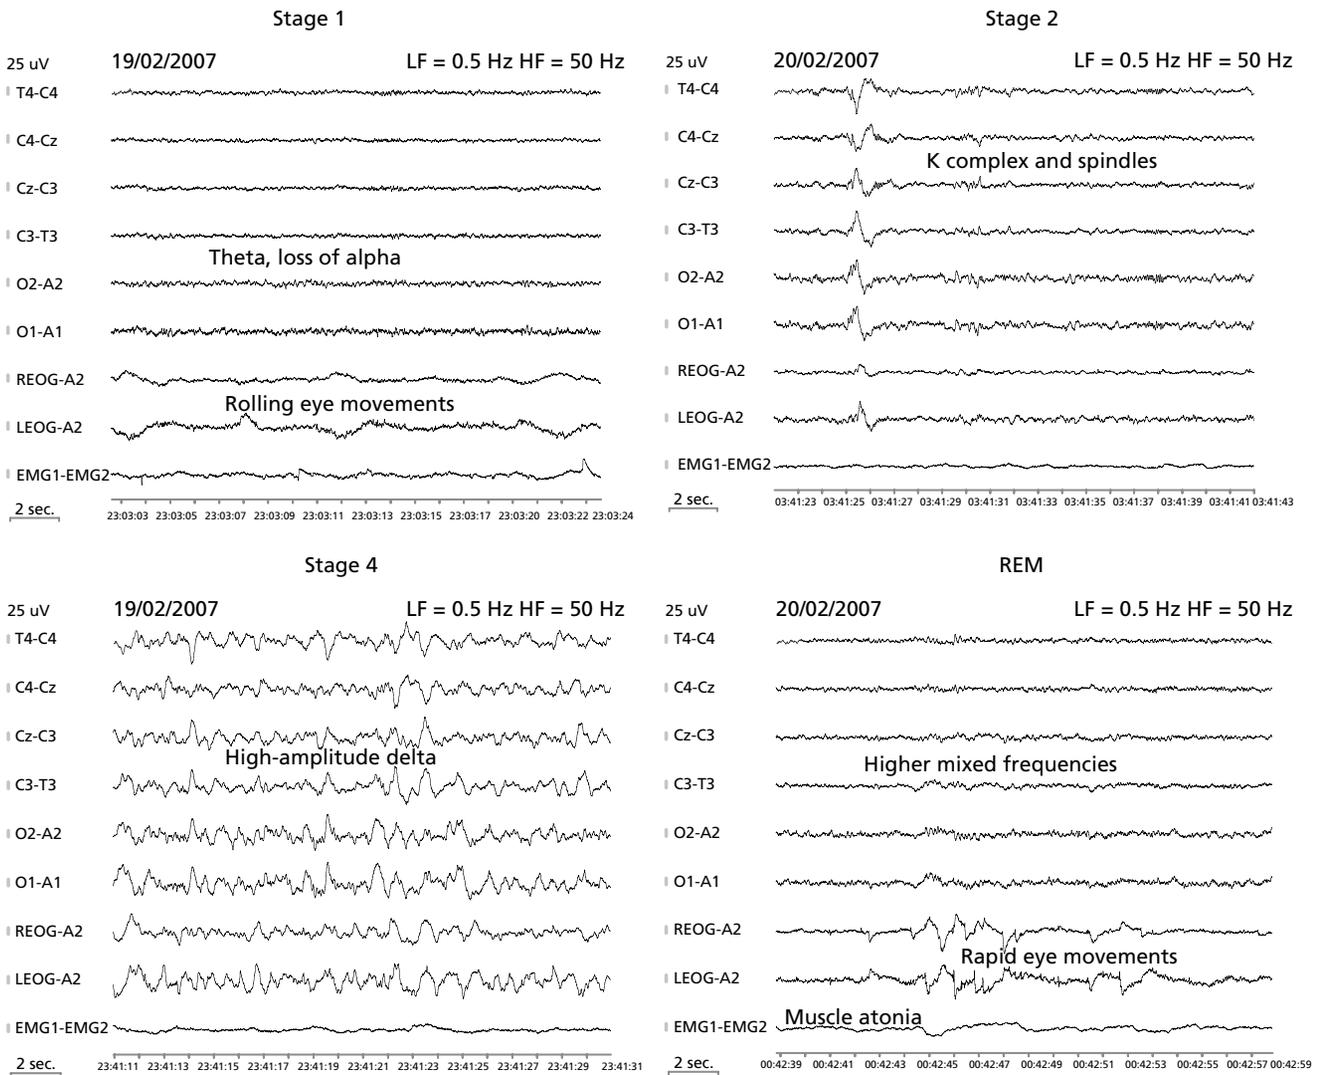

Sleep is a highly organised and regular process which is divided into stages defined by changes in EEG, electro-oculogram (EOG) and muscle tone (EMG). Four principal states of consciousness – wakefulness, light sleep, slow wave sleep (SWS) and rapid eye movement (REM) sleep – can be distinguished (Figure 20.28).

The onset of sleep is characterised by a brief transitional phase (stage 1) in which the alert and wakeful alpha rhythm (8–13 Hz) begins to slow, and slow theta (4–7 Hz) waves appear. EOG usually demonstrates rolling eye movements. EMG activity may be reduced from that during wakefulness but is still present. Stage 2 sleep is characterised by the appearance on the EEG of episodic bursts of central, 14–16 Hz rhythms (sleep spindles) and 0.5–1 second

high-amplitude central sharp waves (K complexes). EMG activity is similar to that in stage 1. In stages 3 and 4 sleep (SWS) the EEG is dominated by high-amplitude delta activity (>4 Hz). SWS is associated with slowing of cardiac and respiratory rate, lowered blood pressure, marked muscular relaxation and a reduction in metabolic rate by approximately 70% of normal levels. Normal values for sleep parameters in an adult are summarised in Table 20.29.

**Table 20.29** Approximate normal values for sleep parameters in an adult.

Sleep efficiency	>90%
Stage 1	10%
Stage 2	50%
Stage 3/4	20%
REM sleep	20%
Sleep onset	>10 minutes
REM sleep onset	90 minutes

**Figure 20.28** EEG recordings showing sleep stages.

### REM sleep

REM sleep is characterised by desynchronisation of the EEG with the appearances of faster frequency rhythms. There are bursts of saccadic eye movements and profound relaxation of muscle tone in most major muscle groups of the limbs, neck and trunk including the diaphragm. Functional imaging during REM sleep shows that limbic regions, associated with emotional behavioural and experience, are activated during REM sleep, while regions of the frontal cortex are less active. Descending neuromuscular inhibition leads to profound muscular relaxation (atonia) of REM sleep. This may be important in preventing dream enactment.

### Patterns of sleep

As a subject falls asleep there is descent through four stages of deepening non-REM sleep during the first hour which is accompanied by a gradual slowing of the EEG rhythms. This is followed by ascent through the same stages culminating in REM sleep. The process is then repeated several times during the night. The first episode of REM sleep generally occurs as the sleep stages ascend through light sleep after about 60–90 minutes following sleep onset and it is often relatively short. As rhythmic cycling continues, the length of time spent in REM sleep tends to increase throughout the night while the time spent in SWS progressively decreases.

### Regulation of wakefulness and sleep

The regulation of wakefulness and sleep depends on complex neuronal and biochemical interactions involving the cortex (basal forebrain), diencephalon (thalamus and hypothalamus) and brainstem. A number of neurochemicals are involved in the regulation of sleep including those that are wake promoting (e.g. noradrenaline, acetylcholine, histamine, and dopamine); sleep promoting (e.g. melatonin and GABA); and both sleep and wake promoting (e.g. serotonin). More recently, the hypocretin (orexin) system has been shown to have a critical role in sleep regulation. The occurrence of REM sleep depends on the interaction between REM-inhibiting nuclei (raphe nucleus secreting serotonin, locus coeruleus secreting noradrenaline) and REM-promoting nuclei (laterodorsal and pedunculo-pontine tegmental nuclei secreting acetylcholine).

Regulation of the timing of the sleep cycles involves two mechanisms:

- 1 Central rhythm generation which is determined by a circadian oscillator located in the suprachiasmatic nucleus of the hypothalamus. This is influenced by light detected in the retina and melatonin. The oscillations are mediated by the cyclical transcription and translation of specific genes, so-called clock genes. The circadian rhythm affects not only sleep, but also other functions via the diurnal secretion of hormones from the pituitary and pineal gland.
- 2 Independent homeostatic mechanisms which are controlled by the time spent awake. It is suggested that the 'sleep debt' which builds up during long periods of wakefulness depends on the accumulation of 'somnogens', possibly adenosine, in the brain.

### Functions of sleep

The functions of sleep remain unclear. The traditional role of sleep has been thought to be restorative but there is evidence to suggest a more complex mechanism in information processing such as memory consolidation. Even minor degrees of sleep deprivation have significant effects on cognition, memory and behaviour.

### Sleep and breathing

SWS sleep leads to an increase in parasympathetic tone and decrease in sympathetic tone leading to a reduction in heart rate, blood pressure and respiratory rate. REM sleep is associated with autonomic instability causing fluctuations in heart rate and blood pressure. The muscles of the upper airway relax during all stages of sleep (especially in REM sleep) causing snoring and predisposing to the significant airway obstruction that underlies sleep apnoea or hypopnoea syndrome. Respiratory failure resulting from neuromuscular weakness is also exacerbated during REM sleep because of the muscular relaxation involving upper airway, intercostal muscles and the diaphragm.

### Classification of sleep disorders

Sleep medicine is an evolving field with wide variability in knowledge of each individual sleep disorder. Table 20.30 lists the most recent classification that is based on common complaints (e.g. insomnia or hypersomnias) as well as presumed aetiological basis (e.g. circadian rhythm disorders) or organ system from which problems arise (e.g. sleep-related breathing disorders). The classification system is currently under review.

### Insomnia

Insomnia is the complaint of 'poor sleep'; the duration or subjective quality of sleep is inadequate and non-restorative. Insomnia is extremely common and is said to merit treatment in 8–14% of the normal population. It is often associated with daytime fatigue but rarely daytime sleepiness. Although insomnia can be idiopathic, in many instances there is an underlying cause.

Several factors may contribute to insomnia: psychological difficulties, a variety of prescribed medications (particularly beta-blockers) and non-prescribed drugs including caffeine, alcohol and substances of abuse, particularly cocaine and amphetamine. Sleep is also disrupted by depression, anxiety, stress, pain, cognitive impairment, pregnancy, nocturia and other medical disorders (especially respiratory and cardiac disorders). Insomnia may occur as a consequence of other sleep disorders (e.g. restless legs syndrome) causing interrupted sleep architecture. Neurological conditions that cause insomnia include those in which sleep is disrupted because of pain or discomfort (e.g. MS); those in which there is interference with sleep onset or maintenance; and those in which a structural lesion may interfere with sleep generation. In addition to the economic and social effects, chronic unremitting insomnia predisposes to

**Table 20.30** Classification of sleep disorders.

psychiatric disorders including depression, anxiety and substance abuse.

Insomnia can, exceptionally, result from prion disease. Fatal familial insomnia is a very rare hereditary prion disease caused by a mutation in codon 178 of the prion protein gene. It is characterised by insomnia, loss of slow wave sleep, oneiric episodes (daytime dream episodes and enactment) and progressive neurological decline.

### Management

A critical aspect of management is to treat the underlying cause (e.g. anxiety, depression). In addition, the first line is to teach, establish and maintain good sleep hygiene with a regular bedtime, the avoidance of nocturnal stimulants, stressful activity or exercise close to bedtime and daytime napping and establishing comfortable and regular sleep arrangements. Regular exercise not close to bedtime can increase and consolidate deep sleep. Cognitive-behavioural therapy (CBT) has been shown to be the most effective treatment for chronic insomnia and can be administered either individually or in group sessions. Access to appropriate CBT for insomnia may be limited and a number of internet based applications are currently being developed.

Most drugs used in insomnia act as agonists at the benzodiazepine site of the GABA<sub>A</sub> receptor; these drugs have effects other than their sedating action, including muscle relaxation, antiepileptic effects, anxiolytic effects, memory impairment, behavioural disturbance (especially in children) and ataxia. Some drugs have a more specific action (e.g. zolpidem, zaleplon and zopiclone) by targeting only specific GABA<sub>A</sub> receptor subtypes. Drugs with longer duration of action may affect psychomotor performance, memory and concentration, and also have prolonged anxiolytic and muscle relaxing effects. Alternatively, benzodiazepines with too short a half-life may result in rebound insomnia and daytime hyperexcitability. Hypnotic drugs such as zolpidem and specific benzodiazepines are indicated for the management of acute insomnia or in the short-term management of chronic insomnia. There is a growing use of sedative antidepressants (e.g. mirtazapine, trazodone and amitriptyline) for longer term treatment of insomnia, and in some melatonin may be helpful.

### Sleep-related breathing disorders

#### Obstructive sleep apnoea/hypopnoea syndrome

Obstructive sleep apnoea/hypopnoea syndrome (OSAHS) is the most common medical cause of daytime hypersomnolence and is associated with significant morbidity including an increased incidence of hypertension, cerebrovascular disease and road traffic accidents. It is associated with nocturnal sleep disturbance, unrefreshing sleep, difficulty in concentration and nocturnal choking. Sleep apnoea refers to a cessation in airflow during sleep >10 seconds while hypopnoea is defined as >50% reduction in airflow associated with oxygen desaturation >4% or arousal on EEG. More than five apnoeas/hypopnoeas per hour (apnoea/hypopnoea index, AHI) is considered significant with AHI 5–15/hour representing mild, AHI 15–30/hour moderate and AHI >30/hour severe OSAHS.

Obstruction of the upper airway usually occurs between the caudal soft palate and epiglottis. It is worsened during sleep when reduced upper airway muscle tone leads to collapse of the upper airway and obstruction. This is exacerbated by obesity (body mass index >28 kg/m<sup>2</sup>), a narrow palate, crowding of the oropharynx and jaw or facial structural anomalies. Patients have difficulty with falling asleep, loud snoring, stridor, coughing spells during sleep and restless sleep with frequent awakenings. There may be snoring and

irregular breathing patterns and prolonged apnoea. Severe obstructive sleep apnoea is associated with morning headache, impaired memory, nocturia, anxiety and the development of Pickwickian features with cor pulmonale.

**Management** The first line management is weight loss, establishing regular sleep patterns and avoidance of alcohol, nicotine, caffeine and sedatives in the evening. Investigation and appropriate treatment of co-morbidity, particularly hypothyroidism, is mandatory. CPAP by nasal or face mask is effective in OSAHS, improving sleep architecture, nocturnal oxygenation and the symptoms of sleepiness, impaired cognition, mood and driving ability and cardiovascular function. However, its use requires considerable educational support and technical back-up. Compliance may be variable in the less severe forms of the condition because of poor mask fitting, dryness of the mouth and airways, claustrophobia, aerophagia and social difficulties. Oral appliances such as mandibular advancement splints may be valuable in improving excessive daytime somnolence (EDS) and the cardiovascular complications of mild OSAHS. They work by holding the mandible forward, thus increasing the upper airway space by advancing the tongue and possibly changing genioglossus activity. Surgical treatment (uvulopalato-pharyngoplasty) does not have a role. Tracheostomy may be necessary in patients with incipient cor pulmonale.

### Hypersomnias of central origin

#### Primary (idiopathic) hypersomnia

Primary (idiopathic) hypersomnia is a rare disorder characterised by EDS but without cataplexy or nocturnal sleep disruption which usually starts in adolescence. The aetiology is unknown but there is a rare familial incidence. This can be associated with prolonged nocturnal sleep times in which the person often sleeps through an alarm clock. Sleep drunkenness is a common feature in the morning when the person may be disorientated, confused, slow, unsteady and sleepy. EDS is unaffected by prolonged sleep or frequent naps. Polysomnography shows shortened sleep latency, increased total sleep time and an absence of sleep onset REM periods. Primary hypersomnia is associated with low or normal levels of CSF orexin/hypocretin. However, it must be distinguished from narcolepsy without cataplexy or other causes of EDS.

#### Recurrent hypersomnia

Recurrent hypersomnia may occur in the Kleine-Levin syndrome. This condition usually occurs in adolescence and in males. The episodes of hypersomnolence are associated with hyper(mega)phagia, cognitive change, aggression and hypersexuality; prognosis is guarded as it does not respond well to treatment with stimulants, carbamazepine, lamotrigine or lithium, but it usually resolves within a decade of onset.

#### Idiopathic recurring stupor

Idiopathic recurring stupor is a rare syndrome occurring in males over 30 years and characterised by episodes of stupor and coma lasting hours to days with no obvious precipitating factors. The EEG demonstrates beta rhythms and the condition responds to the benzodiazepine antagonist flumazenil, raising the possibility that this condition results from endogenous benzodiazepine agonists.

#### Excessive daytime somnolence in neurological disease

EDS can also occur as a consequence of structural brain lesions, following head injury or encephalitis (particularly encephalitis lethargica) and is a complication of neurodegenerative conditions

(e.g. Alzheimer's disease and idiopathic Parkinson's disease) and also MS and myotonic dystrophy.

### Narcolepsy

Narcolepsy is the most cause of central hypersomnia. A primary disorder of alertness with an estimated prevalence of 3–5/10 000, it may develop at any age but the peak onset is between 15 and 30 years with a secondary peak in the fourth decade. Narcolepsy is rarely familial. However, the lifetime risk for developing narcolepsy is increased in first degree relatives of narcoleptic patients to 1%. The presenting symptoms are usually EDS, with irresistible sleep attacks during the day often occurring at inappropriate times. Other symptoms of this syndrome are cataplexy, sleep paralysis, hypnagogic hallucinations or vivid dream-like images, which characteristically occur at sleep onset, disrupted sleep (including occurrence of REM sleep behavioural disorder) and short periods of automatic behaviour during daytime (micro-sleeps).

There may be a range of secondary symptoms related to sleepiness including visual blurring, diplopia and difficulties with memory and concentration. In combination, the symptoms of narcolepsy often have a major impact on relationships, education, employment, driving, mood and quality of life.

### Cataplexy

Cataplexy is the occurrence of brief episodes of muscle weakness or paralysis precipitated by strong emotion, such as laughter, anger or surprise. There is a partial or complete loss of bilateral muscle tone. In its less severe form, cataplexy leads to transient bilateral ptosis, head droop, slurred speech or dropping things from the hands. Cataplexy may be severe enough to lead to complete collapse. The episodes are brief, lasting for seconds or minutes, but they may be followed by a sleep episode or occur recurrently (especially following sudden medication withdrawal) leading to status cataplecticus. Cataplexy is present in over 70% of people who have narcolepsy and can predate or follow the onset of other symptoms.

### Hypnagogic/hypnopompic hallucinations

These are brief vivid dream-like episodes that occur at sleep onset or immediately before waking, and are often frightening or disturbing in nature. They are characterised by brief visual, tactile or auditory events, which continue for several minutes. They can occur during daytime naps.

### Sleep paralysis and automatic behaviours

Sleep paralysis is the inability to move on waking from sleep. The episode can last from a few seconds to minutes but diaphragm and respiratory muscle activity continues. It is caused by the persistence of REM-related atonia on waking. Sleep paralysis is often associated with a hypnic hallucination often of someone pressing down on the chest or choking the person.

Short periods of automatic behaviour occur on wakening, characterised by absent-minded behaviour, nonsense speech or writing nonsense, reflecting the intrusion of sleep into the awake state. Nocturnal sleep disruption is also common, resulting paradoxically in insomnia.

### Pathophysiology of narcolepsy

Narcolepsy is associated with abnormalities of the hypocretin-orexin neurotransmitter system. Low or undetectable levels of CSF orexin/hypocretin are found in most patients although some may have normal or raised levels (low hypocretin levels best correlate

with the presence of cataplexy). This has led to one hypothesis that in most patients there is a deficiency of hypocretin resulting from hypocretin neuronal loss in the hypothalamus. In most, it is likely this is an autoimmune condition – narcolepsy is strongly associated with HLA type and recently it has been found to be associated with anti-tribble homolog 2 (a protein found in hypocretin secreting neurons) autoantibodies (TRIB2). In addition, there has been an association between narcolepsy and the H1N1 influenza vaccination. There may also be a form with 'hypocretin resistance' caused by abnormal hypocretin receptor–post-receptor dynamics leading to overproduction of hypocretin. Narcolepsy can also rarely occur secondary to tumours, encephalitis, head injury and MS. Narcolepsy-type symptoms can develop with inherited conditions such as Niemann–Pick type C disease, Norrie disease, Möbius syndrome and Prader–Willi syndrome.

### Investigations

Polysomnography (PSG) is important in excluding other causes of EDS including obstructive sleep apnoea, periodic limb movement disorder and REM-related behavioural disorder; however, all are more common in people with narcolepsy. Polysomnography may also demonstrate early onset sleep (<10 minutes) and early onset REM sleep (<20 minutes). The Multiple Sleep Latency Test (MSLT) is used to confirm the diagnosis. In this test the patient is allowed to fall asleep 4–5 times at 2-hourly intervals throughout the day and the latency to onset of sleep and REM sleep is measured. In narcolepsy, about 70% of patients will have a mean sleep latency of <5 minutes and a latency to REM sleep of <15 minutes on at least two occasions. These criteria have a specificity of 97% and a positive predictive value of approximately 70%. Most accepted diagnostic criteria require, as a minimum, a mean sleep latency on MSLT of  $\leq 8$  min and two or more sleep onset REM periods following a satisfactory nocturnal sleep (minimum 6 hours) during the night prior to the test. The presence of EDS, cataplexy and a typical MSLT allows a definite diagnosis of narcolepsy. The presence of two of these features renders the diagnosis probable, and other factors (such as the presence of other symptoms) need to be taken into account. Narcolepsy without cataplexy remains a diagnostic challenge and diagnosis is critically dependent on the MSLT and/or polysomnography. MSLT needs to be interpreted with care and the clinical context always needs to be considered. It can be affected by concomitant medication and psychiatric disease (e.g. depression); indeed, studies in the general population have brought into question its specificity.

There is a strong correlation between narcolepsy (with cataplexy) and the HLA-DQB1\*06:02 variant but this subtype is common in the general population and therefore the positive predictive value is low. Measurement of CSF hypocretin levels can be used to make a diagnosis of narcolepsy, but normal levels does not exclude a diagnosis of narcolepsy without cataplexy.

### Management of narcolepsy

**General management** Narcolepsy is a life-long condition with potentially wide-ranging implications. It is essential that patients and their relatives should have access to relevant and accurate information. Narcolepsy is entirely compatible with success both at school and in the workplace, but appropriate supportive provision may be necessary and career choices should take account of the possible hazards caused by EDS and cataplexy. Regular nocturnal sleep habits and attention to sleep hygiene help to minimise EDS, and planned naps can be used to optimise daytime performance.

People with narcolepsy are required to declare the diagnosis to the Driver and Vehicle Licensing Authority and are advised not to drive until satisfactory control of symptoms is achieved.

**Sleepiness** EDS is reduced by amphetamine-like stimulants (usually dexamfetamine, which is licensed for this use, or methylphenidate), and modafinil. The use of modafinil is supported by randomised controlled trials. Advantages of amphetamine-like drugs include long experience, low cost, a possible action against cataplexy and higher efficacy; modafinil has the advantage that tolerance does not develop (which can occur with amphetamines) and possibly a lower rate of side effects. Common side effects of amphetamine-like drugs include irritability and insomnia while modafinil may cause headache, nausea and rhinitis, and may interact with the oral contraceptive pill; a pill with higher dose ethinylestradiol (at least 50 µg) is required.

**Cataplexy** Cataplexy can often resolve with an improvement in nocturnal sleep and daytime somnolence. In addition, cataplectic symptoms often improve with age. Specific treatments include the tricyclic antidepressants (clomipramine) and the serotonin uptake inhibitors (fluoxetine). Other antidepressants, such as venlafaxine, can also be useful. These drugs also treat other narcolepsy symptoms. More recently, sodium oxybate (the sodium salt of gamma-hydroxybutyrate) has shown to be effective in cataplexy and also improves daytime somnolence.

### Circadian rhythm disorders

Intrinsic circadian rhythms maintain a sleep–wake cycle of approximately 24 hours. They are set by environmental day length and are influenced by social activity, which can adjust timings. A mismatch between the internal circadian cycle and the external environment leads to insomnia, EDS and disruptive sleep function and activities of daily living. These may occur because of alterations in the internal circadian cycle (i.e. delayed or advanced sleep phase syndrome) or to changes in the environment (e.g. jet lag). Circadian rhythm disorders have also been associated with neurological and psychiatric disease such as encephalitis lethargica (in which there is circadian rhythm reversal) and schizophrenia (in which there can be a severely disrupted circadian rhythm).

### Delayed or advanced sleep phase syndrome

These conditions are characterised by an inability to fall asleep or remain asleep at a conventional time. The persistence of the pattern distinguishes the condition from alterations in sleep rhythms, change in work timetables or travel across time zones. Advanced sleep syndrome (early to bed and early to wake) has been associated with mutations in clock genes. These conditions may be difficult to manage as attempts to regularise rhythms can lead to prolonged sleep latency and chronic insomnia, resulting in the excessive use of stimulants, hypnotics or alcohol. These conditions can be helped by CBT, and a regimen of planned advancement of bedtime. Bright light therapy and melatonin may also be of some benefit.

### Shift work and jet lag

These conditions occur when the physical environment is altered and there is a mismatch with the internal circadian cycle. Many social factors influence the ability to acclimatise to a change in routine or travel including age, community, work responsibility and stress. They may lead to EDS or insomnia and a deterioration in the

performance at work and a dependence on medication. Melatonin (2 mg 1 hour before bedtime) has been shown to have a benefit in these conditions.

### Parasomnias

Parasomnias are undesirable physical events that occur during the sleep period and may be considered disorders of sleep state transition, partial arousal or arousal. The parasomnias are usually classified according to sleep state of origin (Table 20.31).

#### Non-REM parasomnias

The arousal disorders are abnormal non-REM sleep phenomena and include confusional arousal, sleep walking and sleep terrors. They represent incomplete awakenings from sleep, most commonly deep slow wave sleep (stage 3 and 4), which is preponderant in the first third of the night. These disorders share common underlying pathophysiological and phenotypic features. The onset is usually in childhood and symptoms often resolve spontaneously during adolescence. However, a significant proportion continues to have episodes in adulthood (up to 4%). There is often a family history, autosomal dominant inheritance with reduced penetrance has been suggested, and the first genetic locus was recently identified on chromosome 20.

Sleep walking is common in children, but also occurs in adults. It arises from a deep sleep, typically in the first third of the night, and may be either calm or agitated, with varying degrees of complexity and duration. Repetitive behaviours may occur and occasionally eating may be a feature. The episodes usually last 1–2 minutes but prolonged complex behaviours including driving have been reported. It is often very difficult to awaken the patient who is then confused with variable amnesia for the event. The most important

**Table 20.31** A classification of parasomnias according to ICSD 2.

#### Disorders of arousal (from non-REM sleep)

- Confusional arousals
- Sleepwalking (somnambulism)
- Sleep terrors (night terrors)

#### Parasomnias usually associated with REM sleep

- REM sleep behaviour disorder
- Recurrent isolated sleep paralysis
- Nightmare disorder

#### Other parasomnias

- Sleep-related dissociative disorders
- Sleep enuresis (bedwetting)
- Sleep-related groaning (catathrenia)
- Exploding head syndrome
- Sleep-related hallucinations
- Sleep-related eating disorders
- Parasomnia, unspecified
- Parasomnia due to drug or substance
- Parasomnia due to medical condition

American Academy of Sleep Medicine 2005. Reproduced with permission of AASM.

consideration is protection from injury. Treatment is often unnecessary but precipitating factors such as sleep deprivation and alcohol should be avoided; drug treatment with benzodiazepines or antidepressant medication may be valuable.

Sleep terrors are the most disturbing disorder of arousal for the patient and family. They are often characterised by a loud scream associated with extreme panic and prominent, occasionally violent, motor activity, resulting in bodily injury or property damage. The patient is inconsolable during the terror and amnesic for the event, which may be complete. Often, people report dream-like episodes in which they are being attacked or chased. The patient appears to be in a state of acute terror with tachycardia, tachypnoea, mydriasis and increased muscle tone. They last between 30 seconds and 3 minutes and can occur from early childhood. Treatment is rarely necessary but clonazepam and antidepressant medication are helpful. Sleep terrors characteristically begin during the deep sleep of the first third of the night; however, when episodes are very frequent they may be diffusely distributed across the sleep period and occur in any non-REM stage. Sleep terrors are sometimes familial and are associated with increased incidence of sleep walking and confusional arousals.

Confusional arousals are characterised by partial awakening movements in bed, occasional thrashing about or inconsolable crying and associated with confusion and impaired mentation, disorientation in time and place, and perceptual impairment. Behaviour is often inappropriate and can be aggressive. Confusional episodes are usually brief but may last up to 30 minutes. Confusional arousals can be associated with disorders causing deep or disturbed sleep, including metabolic, toxic and other encephalopathies; idiopathic hypersomnia; symptomatic hypersomnia and sleep apnoea syndrome.

In adults, more complex action may be carried out during non-REM parasomnias including sexual acts (sexsomnia), sleep eating, driving and violent acts. These are of forensic importance, because if a criminal act is committed during sleep then the defence of the act being an 'automatism' can be used.

Disorders of arousal may be triggered by pyrexia, prior sleep deprivation, emotional stress or a variety of medications including sedatives and hypnotics, neuroleptics, minor tranquillisers, stimulants and antihistamines. For some people, alcohol may also be a trigger to episodes or may make the episodes more elaborate. For the majority of people with non-REM parasomnias, identification and avoidance of triggers as well as reassurance are usually sufficient. However, antidepressants and benzodiazepines may be effective if the behaviours are dangerous to persons or property or are disruptive to the family. Safety aspects are important, such as making sure doors and windows are properly locked and that objects people can hurt themselves or others with are not by the bedside.

### REM sleep disorders

REM-related parasomnias include nightmares, sleep paralysis and REM sleep behaviour disorder. Nightmares are dreams with frightening content. They usually last only a few minutes and are associated with movements, mumbling and vocalisation before awakening. They often occur in the second half of the night during REM sleep (in contrast to non-REM parasomnia) and may be related to REM rebound during a period of recuperation after REM sleep deprivation from either stress, drugs or surgery. Terrifying hypnagogic hallucinations (sleep onset nightmares) are part of the narcoleptic tetrad but may also occur in isolation. They are nightmares occurring at sleep onset in association with sleep onset REM. Tricyclic

antidepressants especially clomipramine may be effective both for episodes in non-REM and in REM sleep onsets. Sleep paralysis may also occur as part of narcolepsy or as an isolated phenomenon sometimes running in families. Episodes may be frightening but are harmless and can be triggered by sleep deprivation.

REM sleep behaviour disorder (RBD) is a condition characterised by loss of normal atonia during REM sleep and motor activity causing abnormal behaviour during REM sleep, 'dream enactment'. Movements include generalised limb or truncal jerking which may progress to prominent, violent or more complex disruptive sleep behaviours, which are often aggressive, confrontational and may be violent with patients enacting intense dreams occasionally leading to self-injury. The duration is seconds to minutes. Episodes occur most nights and there may be several episodes per night with varying severity. As opposed to non-REM parasomnias which are more common in childhood, RBD is more common in older patients and there is a male predominance. The condition may be idiopathic in younger adults. However, in older adults, it is very commonly associated with neurodegenerative disorders (parkinsonism, multi-system atrophy, Lewy body dementia), narcolepsy, cerebrovascular disease, MS or Guillain-Barré syndrome. RBD may develop months or years before the onset of any underlying neurological disorder and with prolonged follow-up the proportion of patients developing some neurodegenerative disorder increases up to 40–60%. RBD may also emerge during withdrawal from alcohol or sedative-hypnotic abuse and with anticholinergic and other drug intoxication states leading to loss of REM atonia. Antidepressant medication can also induce RBD and may need to be discontinued if possible. Clonazepam is an effective treatment in RBD in suppressing both the violent behaviour and the intense subjective dream recall by suppression of phasic EMG activity during REM sleep rather than by restoration of REM atonia. Adjunctive or alternative medication may involve melatonin or, less frequently, dopa agonists. Safety measures are important to avoid injury to patient and bed partner.

### Other forms of parasomnia

The exploding head syndrome is also a form of parasomnia and may represent a form of sleep start in which there is a sudden arousal during transition into sleep with a sensation of a loud noise 'bursting' in the head. They can also occur during REM sleep. Hypnic headache is rare, occurring in older patients, regularly at constant times at night. The headache is diffuse, protracted and relatively mild.

Catathrenia (sleep groaning) predominantly occurs during REM sleep and is characterised by apparent breath holding followed by prolonged expiration associated with a groaning sound presumed to be caused by vibration of the vocal cords. The sound can sometimes be high pitched and although the patient is usually unaware of the noise, this often disturbs the bed partner. Desaturations are rare. The cause is unknown and there is no known effective treatment although CPAP and benzodiazepines have been tried, usually with little effect.

Bruxism is intermittent repeated grinding or clenching of teeth during sleep, which is common in children and also in the severely disabled and may appear at any sleep stage. It can be associated with other movement disorders during sleep. Sleep bruxism may be a manifestation of mild REM sleep behaviour disorder. There is no satisfactory treatment although attempts are made at occlusal adjustment and splints particularly if there are signs of dental wear. Bruxism can result in tongue biting, which we have seen confused with tongue biting that can occur during nocturnal seizures.

Facio-mandibular myoclonus is a distinct syndrome and is different from bruxism. It consists of myoclonic jerks involving the masticatory and facial muscles occurring mainly during non-REM sleep. Tooth grinding and temporomandibular pain, which are often associated with bruxism, are usually absent. This syndrome is benign and is only of importance as it can result in lip and tongue biting which can also lead to a misdiagnosis of nocturnal seizures.

## Sleep-related movement disorders

### Restless legs syndrome

Restless legs syndrome (RLS) affects 2–15% of the population, depending on case ascertainment and is more frequent in the older age group. It is twice as common in females as males and there is often a significant family history. There are four essential criteria for diagnosis:

- 1 An urge to move the legs, usually accompanied by uncomfortable dysaesthesiae
- 2 The urge to move or the sensations worsen during periods of rest or inactivity
- 3 The urge to move or the sensations are partially or totally relieved by movement
- 4 The urge to move or the sensations are worse in the evening or during the night.

Symptoms may lead to difficulty getting to sleep, frequent awakenings, reduced sleep efficiency and insomnia. Leg jerking may also occur during wakefulness and be independent of the dysaesthesiae. RLS usually follows a chronic and often progressive course with intermittent fluctuations, but there may be prolonged periods of remission. Periodic limb movements of sleep are commonly associated with RLS. The condition may be idiopathic or secondary to iron deficiency, pregnancy, uraemia or other neurological conditions such as neuropathy and spinal cord disease.

RLS may be difficult to relieve completely. Any underlying cause should be sought and treated. In particular, all patients should be screened for iron store status and iron supplementation should be considered if serum ferritin is below 112 pmol/L (50 µg/L). There are several drugs that can cause or exacerbate RLS including antipsychotics and antidepressants and patients may benefit from discontinuation of these drugs if possible. Non-pharmacological treatment measures include avoidance of alcohol, caffeine and smoking. For patients with severe symptoms, medication may be necessary. Dopamine agonists (ropinirole, pramipexole and rotigotine) are the only agents licensed in the United Kingdom. Although effective, these drugs may be associated with problems including augmentation (the onset of symptoms earlier in the day; increased severity of symptoms). Augmentation may be more likely to occur in those with iron deficiency (emphasising the need to treat this). Pregabalin has also been shown to be effective in placebo controlled trials. Other treatment options include gabapentin, benzodiazepines and opioids. Benzodiazepines have a greater effect on maintaining sleep rather than treating movements. Opioids can be particularly effective when augmentation has occurred and there are reports of the successful use of codeine, morphine, methadone and fentanyl patches.

### Periodic limb movements of sleep

Periodic limb movements of sleep (PLM) are common, with more than 30% of individuals over 65 years having a significant number of periodic limb movements. The movements most commonly affect the legs and are characterised by dorsiflexion of toes, ankles and sometimes also hips. However, movements can also affect the

head and arms. Movements occur periodically every 5–90 seconds and a series of more than four in a row is needed for diagnosis. People with severe PLM have more than 50 per hour. Although PLM may be asymptomatic, patients may have complaints of difficulty falling asleep, frequent awakenings, daytime sleepiness (PLM disorder, PLMD). Further, bed partners may also complain about the movements. PLM can be associated with other sleep disorders in particular RLS, but also sleep apnoea, narcolepsy or REM sleep behavioural disorders. It is most commonly an isolated phenomenon; most people with RLS have PLM but most people with PLMD do not have RLS. Treatment is only justified if periodic limb movements are symptomatic (e.g. causing excessive daytime somnolence) and follows the same principles as RLS.

### Rhythmic movement disorders

Rhythmic movement disorders (*jactatio capitis nocturna*) are a group of behaviours characterised by stereotyped movements (rhythmic oscillation of the head or limbs, head banging or body rocking) which typically occur just before sleep onset and persist into light sleep. They most commonly occur in infants and young children, often associated with autism and mental retardation but have been described in adults with normal IQ. Significant complications include scalp and body wounds, subdural haematoma, retinal petechiae, skull callus formation and significant family and psychosocial problems. There are no EEG signs of arousal during the rocking movements. Behavioural therapy and medication that results in more rapid sleep onset (e.g. benzodiazepines) can be helpful, but often treatment is difficult.

### Isolated symptoms, apparently normal variants

Sleep-wake transition disorders occur in the transition between waking and sleeping. Hypnic jerks (sleep starts) and nocturnal leg cramps all commonly occur in otherwise healthy individuals and are regarded as physiological alterations rather than pathological conditions. Hypnic jerks are brief body jerks at sleep onset, which may involve limbs, trunk or head. The jerks may be single or repetitive and may be spontaneous or provoked by stimuli. Visual, auditory or somatosensory sleep starts may also occur. In non-REM sleep, small flickering movements called sleep myoclonus are associated with very brief, highly localised EMG potentials. In some cases, the amplitude and frequency of these movements increase, at which points they are called fragmentary myoclonus.

### Other sleep disturbances in extrapyramidal disease

In extrapyramidal disorders, particularly idiopathic Parkinson's disease (PD), Huntington's, Tourette's syndrome and torsion dystonia, involuntary movements may persist during sleep. These usually occur during stage 1, 2 and REM sleep and are less common in stage 3 and 4 sleep. Sleep difficulties are particularly frequent in patients with PD and these include difficulty getting to sleep, inadequate time asleep, disrupted sleep and daytime sleepiness which may occur as a result of nocturia, inability to turn over during the nights or on waking, inability to get out of bed unaided, leg cramps and jerks, dystonic spasms of the limbs or face and back pain during the night. There may be an increased prevalence of PLMD, RLS and RBD in association with PD.

The treatment of PD itself may alleviate abnormal motor activity during sleep but separate treatment may be necessary and clonazepam is particularly valuable. Respiratory disturbances, characterised by involuntary movements of laryngeal or respiratory muscles and impaired volitional control, are common in PD, progressive

supranuclear palsy (PSP) and multi-system atrophy. There are also sleep-fragmenting respiratory disorders, such as sleep apnoea or upper airway resistance syndrome, a restrictive type of lung defect caused by an intrinsic defect in breathing control, impaired respiratory muscle function caused by rigidity and faulty autonomic control of the lungs. Patients with PD may also have obstructive respiratory defect, stridor or laryngeal spasm associated with off states or dystonic episodes, diaphragmatic dyskinesias, drug-induced respiratory arrhythmias and dyspnoea and upper airway dysfunction with tremor-like oscillations. Dystonic movements and tics may persist during sleep at a reduced frequency and amplitude but are maximally active during stage 1 and 2 and REM sleep episodes.

### Epilepsy syndromes associated with sleep

It is essential to distinguish the sleep-related paroxysmal events described earlier from nocturnal epilepsy and it may be difficult on history alone to distinguish epilepsy from non-REM parasomnia and RBD, necessitating further investigation with video-EEG telemetry. Epilepsy has a complex association with sleep. Certain seizures are more common during sleep such as frontal lobe seizures that occur from light non-REM sleep. Rarely, nocturnal seizures may be the only manifestation of an epileptic disorder and these can be confused with a parasomnia – this has been especially true for autosomal dominant nocturnal frontal lobe epilepsy (some of which are caused by mutations in the nicotinic acetylcholine receptor), the seizures of which were thought originally to represent a nocturnal paroxysmal dyskinesia. Nocturnal frontal lobe seizures are brief, stereotypical, cluster and occur at any time of night. These features may help to distinguish frontal lobe seizures from parasomnia. In addition, frontal lobe seizures can result in bilateral posturing and head version (rarely seen in parasomnia) and a distinct cessation (in contrast to non-REM parasomnia). Certain features such as fear and confusion are poor distinguishing features. Many cases of episodic nocturnal wanderings are possibly seizures or post-ictal confusion. Rarely, non-convulsive status epilepticus can occur during slow wave sleep (epileptic status epilepticus during sleep, ESES), particularly in children; the clinical manifestation of this is usually intellectual regression and autism and can occur in Landau-Kleffner syndrome (characterised by language regression) and also 'benign' epilepsy with centro-temporal spikes. Lack of sleep can precipitate seizures, especially in the idiopathic generalised epilepsies, and sleep apnoea has been reported to worsen seizure control. Sleep disturbances also commonly occur in people with epilepsy in whom there is a higher incidence of sleep apnoea, fragmented sleep and insomnia as well as daytime somnolence (often drug-related).

### Traumatic brain injury and sleep

Sleep-wake disturbances are common after TBI and in prospective studies have been shown to affect between half and three-quarters of patients. Occurrence of sleep-wake disturbances does not appear to be related to the location or severity of the injury. A variety of sleep-wake disturbances occur, but excessive daytime somnolence, either with reduced ability to stay awake during the day or increased sleep need per 24 hours (increased by more than 2 hours compared with before injury), is the most common. Occasionally, this is caused by disrupted nocturnal sleep; for example, by sleep apnoea or periodic limb movements. Slightly reduced levels of hypocretin have also been found in patients following TBI and may contribute to excessive daytime somnolence. Modafinil can be tried but is rarely helpful. Other stimulants have not been studied systematically but may be beneficial. Fatigue (lack of energy or exhaustion)

can also be seen after TBI and an association with other symptoms such as pain and depression has been noted. A similar association has been found in patients developing insomnia after TBI; this is most common in patients with mild head injuries, anxiety and depression. Screening for and treating concomitant psychiatric disorders should be performed in all patients with post-traumatic insomnia and CBT is also a useful treatment option. Circadian rhythm disorders have been described following TBI; either delayed sleep phase syndrome or irregular sleep-wake patterns. Melatonin and light-box treatment can be used to normalise sleep patterns.

Neuro-oncology covers both the scientific and clinical aspects of central nervous system (CNS) tumours and neurological complications of cancer. In common with many other areas of medicine, a multi-disciplinary approach provides optimal standards of care. The emergence of new therapies throughout neurology has changed the role of neurologists from diagnostic to therapeutic clinicians. This is especially relevant in neuro-oncology. Improvements in radiological and histological diagnosis and surgical technique, advances in molecular neuro-oncology, the application of new biological agents and increasing use of combined radiotherapy and chemotherapy for tumours such as gliomas have led to small but definite improvements in survival.

There is increasing awareness of the large array of CNS tumour types, the spectrum of neurological complications of cancer, particularly paraneoplasia, and the neurotoxicity of chemotherapy and radiotherapy, making it essential to have up-to-date knowledge. This chapter provides a clinically dominated guide to the key issues in neuro-oncology. The initial sections reflect the highly specialised nature of disciplines within neuro-oncology. The multi-disciplinary aspects of care are outlined in the sections on clinical management.

## Epidemiology of common primary intracranial tumours

### Incidence

Brain tumours include primary tumours arising from intracranial structures and metastases from outside the CNS. Primary CNS tumours account for approximately 2% of all cancers in adults and 20% in childhood. They have a high case fatality ratio; broadly, there is a 25% chance of any adult patient who has a brain tumour dying from it. In adults they are second only to stroke as a cause of neurological death. They place a considerable burden of suffering on patients, their families and carers.

Incidence figures for brain tumours depend much on methods of case ascertainment. Incidence of specific tumour types is believed to be much the same worldwide. The crude UK incidence for primary tumours is 15.3/100 000/year and for secondary tumours 14.3/100 000/year. It is likely that the true incidence is higher. One study from the south-west of England ascertaining data mainly from radiology records found the crude incidence for primary tumours to be 21/100 000/year. There are some suggestions that

the incidence of glioma and CNS lymphoma is increasing, particularly in elderly patients. This may simply be because of better case ascertainment and the increasing use of imaging (e.g. for patients presenting with stroke).

Different tumour types present in different age groups. Supratentorial gliomas are uncommon below the age of 30 years but become increasingly prevalent thereafter. They account for over 60% of primary tumours. The most frequent tumours of adolescence are germ cell tumours and astrocytomas, those in middle life astrocytomas, meningiomas and pituitary adenomas and in later life, high-grade gliomas and metastases. Infratentorial tumours are more common in childhood. Seventy per cent of paediatric primary intracranial tumours arise in the cerebellum and brainstem, specifically astrocytomas, ependymomas and medulloblastomas. Meningiomas and schwannomas occur more frequently in women; the reverse is true for astrocytomas.

### Survival

Although brain tumours account for only 2% of all cancers, they are responsible for more years of life lost per patient before the age of 70 years than any other cancer. The latest survival trends have shown only modest improvement over the last 10 years. The prognosis of a brain tumour is largely related to age, performance status, histological type, grade, molecular signature and tumour location. Intra-axial tumours are associated with poorer survival than extra-axial tumours as are tumours growing in eloquent regions of the brain. Although there has been some improvement over the last 30 years, only about 36% of adults with malignant brain tumours in the United Kingdom survive 1 year and 19% survive 5 years or more. This compares to a 5-year survival rate of 17–20% in Europe and 25% in the United States. These discrepancies may be partly because of inclusion of benign brain tumours, certainly in US registries. As a general rule, young patients fare better than older with the same histological types. The 5-year survival is around 50% for patients under 40 years and 60% for children.

Patients with benign tumours (e.g. meningiomas) may survive many decades or be cured permanently. Children with brain tumours survive for longer than adults: 5-year survival in children is around 60%. Histological grading has particular prognostic implications and is an essential part of the neuropathological assessment. This is especially so because brain tumours rarely spread outside the nervous

system. They are therefore not staged according to the familiar TNM (tumour, node, metastasis) system. Prognosis is usually expressed in terms of percentage survival at 5 years. For astrocytomas, 5-year survival is over 90% for World Health Organization (WHO) Grade I tumours, around 50% for WHO Grade II tumours, 30% for WHO Grade III tumours and less than 5% for WHO Grade IV tumours.

### Risk factors

The cause of most brain tumours remains unknown. The only definite environmental risk factor is ionising radiation, either following nuclear explosions or therapeutic radiation. Cranial radiotherapy (RT) at low doses has been shown to increase the relative risk of meningiomas by a factor of 10 and of gliomas by a factor of 3. Other RT-induced tumours include sarcomas and schwannomas. They have been described following RT for tinea capitis, craniopharyngioma, pituitary adenomas and prophylactic cranial irradiation for acute lymphoblastic leukaemia. Secondary tumours tend to lie within the radiation field, usually within lower dose regions, and develop from a few years to many decades after RT. The median time to the development of gliomas is 7 years. Sarcomas develop with a longer lag time and meningiomas may be seen 30–40 years later. Radiation induced meningiomas are more likely than spontaneous tumours to have atypical histology.

No other environmental risk factor has been clearly identified. There has been widespread concern about mobile (cellular) phones. Case-control studies have shown a consistent association between long-term use of mobile and cordless phones and glioma and vestibular schwannoma, but not meningioma, providing support for the hypothesis that radiofrequency electromagnetic fields play a part in the initiation and promotion stages of carcinogenesis. Given the almost universal use of mobile phones nowadays, it is important that brain tumour trends continue to be surveyed.

Genetic causes of brain tumours are rare but important. Occasionally, brain tumours occur in successive generations without any other tumour predisposition. Typically, they are associated with neurocutaneous syndromes such as neurofibromatosis (optic nerve glioma, meningioma, vestibular schwannoma), tuberous sclerosis (subependymal giant cell astrocytoma) and von Hippel-Lindau syndrome (haemangioblastoma). There are also rare familial tumour syndromes, for example Li-Fraumeni syndrome (glioma) and Cowden's disease (dysplastic cerebellar gangliocytoma or Lhermitte-Duclos disease).

### Clinical features

The clinical presentation of a brain tumour depends on location, rate of growth and pathology. Any tumour has the potential to produce a focal deficit and raised intracranial pressure although this is most commonly seen with high-grade tumours because of rapid growth and brain tissue necrosis and with posterior fossa mass lesions. In contrast, low-grade tumours are infiltrative, less destructive than their high-grade counterparts and present more frequently with a seizure disorder.

There are no clinical features that are unique to brain tumours and the first suspicion of a brain tumour can only come from imaging. Even then, there are a number of tumour mimics on computed tomography (CT) and magnetic resonance imaging (MRI) scans for both low-grade and high-grade tumours. Examples of high-grade mimics include brain abscesses, tumefactive multiple sclerosis (MS), tuberculosis and toxoplasmosis; examples of low-grade mimics include cortical dysplasia, viral encephalitis and neurocysticercosis. Close liaison with neuroradiology is

therefore important before subjecting the patient to an invasive procedure such as a biopsy.

Several hospital-based studies have examined the clinical features of brain tumours. A study of over 300 brain mass lesions showed that headache and seizures were the most frequent symptoms followed by neurological deficit and cognitive behavioural changes. Patients with cognitive decline tended to be diagnosed late and had developed focal or multiple symptoms by the time they were seen. Asymptomatic papilloedema and hemianopia was noted in particular, pointing to the need for careful fundoscopy and visual field testing.

### Headache

Tumours can produce raised intracranial pressure either by the mass effect of a rapidly growing lesion with associated vasogenic oedema or by blockage of cerebrospinal fluid (CSF) pathways, typically seen with posterior fossa tumours and with intraventricular tumours. Stretching or distortion of the meninges can give rise to headache without raised pressure. Intra-tumoural haemorrhage can produce an acute rise in pressure leading to severe headache with coma or reduced consciousness. This clinical picture is also sometimes seen with large tumours without any evidence for a bleed, particularly in peri-ventricular locations where encystment of a horn of the lateral ventricles can occur.

Severity of headache is not a helpful diagnostic pointer – indeed, the most severe headaches encountered are almost invariably caused by primary headache syndromes such as migraine or cluster headache. A study of over 100 patients with brain tumours revealed that headaches were present in under 50%, equally for both primary and metastatic tumours, and that the headaches were similar to tension-type headaches or migraine in over 80% of those (i.e. not clinically sinister in themselves). The typical tumour headache was bi-frontal, worse on one side but it was the most prominent symptom in under half of the patients. Brain tumour headaches were made worse by bending in around one-third, unlike true tension-type headaches. Nausea or vomiting was present in 40%. Early morning headache was uncommon. Nausea and vomiting, abnormal physical signs or a significant change in prior headache pattern were particular risk factors for a tumour.

What usually distinguishes headaches of a brain tumour from benign headaches is the gradual evolution of associated symptoms (i.e. focal deficit, seizures, ataxia and vomiting), the latter being seen particularly with posterior fossa tumours. It is quite exceptional for a patient with a brain tumour to present with headache alone.

### Seizures

Tumour-associated seizures may be partial and/or generalised. There is an inverse relationship between tumour grade and occurrence of seizures and certain low-grade tumours (e.g. oligodendrogliomas and gangliogliomas) are associated with seizures in over 90% of cases. The type of seizure is dependent on tumour location and there are no distinguishing features of focal seizures to distinguish a tumour from a non-neoplastic process. In a recent retrospective study of over 80 adults with supratentorial low-grade gliomas, seizures occurred in all but one and only 30% of patients became seizure-free on anticonvulsants. There was no clear association between severity of the seizure disorder and behaviour of the underlying tumour, in particular the return of seizures after a period of seizure freedom did not invariably indicate tumour recurrence.

### Focal deficits

Focal deficits depend on the location of the tumour and are usually gradually progressive. However, stroke-like presentations, and even apparent transient ischaemic attacks (TIAs), are well recognised.

These are sometimes caused by intra-tumoural haemorrhage and sometimes by presumed vascular changes associated with the tumour. Progressive focal deficits occur typically in patients with high-grade tumours (e.g. glioblastoma and brain metastases) rather than with low-grade tumours, presumably because of the ability of the latter to infiltrate normal tissue without interfering with function. Parasagittal tumours (e.g. meningiomas) may present with a spastic paraparesis or monoparesis.

### Brainstem symptoms

Vertigo and disequilibrium are common presenting symptoms of posterior fossa tumours. In cerebellopontine angle tumours (e.g. vestibular schwannomas), unilateral hearing loss is usually the first and only symptom; later symptoms arise from trigeminal, facial nerve and brainstem compression. Facial numbness occurs in about 25% of these patients and is more common at the time of presentation than facial weakness. Objective hypoesthesia involving the teeth, buccal mucosa or skin of the face is associated with larger tumours, but a subjective reduction in sensation that cannot be documented on objective examination occurs commonly with medium-sized and small tumours. Depression of the corneal reflex generally occurs earlier and more commonly than objective facial hypoesthesia. Tumours of the pineal and tectal plate may present with Parinaud's syndrome and hydrocephalus caused by obstruction of the aqueduct.

### Cognitive and behavioural symptoms

A minority of patients with tumours present with cognitive symptoms and/or a behavioural disorder (e.g. abulia or depression caused by a subfrontal meningioma). Specific focal cognitive deficits (e.g. alexia, acalculia) may be seen in tumours affecting the dominant parietal lobe particularly around the angular gyrus. Neuropsychiatric symptoms such as depression, paranoid delusions and personality changes are all well recognised and stress the need for imaging in patients with atypical affective disorders. By contrast, psychosis is a very rare presenting symptom.

### Endocrine symptoms

Patients with pituitary and hypothalamic tumours may present with endocrine disturbances brought about by anterior or posterior pituitary failure or oversecretion (e.g. acromegaly). These may also cause visual failure typically commencing with bitemporal quadrantanopia or hemianopia as the optic chiasm is compressed.

### Rare presentations

Patients with orbital plate tumours (Chapter 13) may present with anosmia without any other symptoms caused by compression of olfactory nerves in the anterior cranial fossa. Visual failure is discussed in Chapter 14. In children, hypothalamic and thalamic tumours may present as a diencephalic syndrome, with failure to gain weight and to grow as expected, and emaciation. Affected infants and children may behave in an alert, happy and outgoing manner, in contrast to their outward appearance. Precocious puberty, particularly in boys, may be caused by a number of tumours including gliomas, pineal tumours and germ cell tumours.

## Histogenesis of brain cancer

The nomenclature of brain tumours according to the WHO classification is still largely based on the historical resemblance of tumour cell shape, morphology and localisation to those of differentiated

cells of the brain or expression of glial or neuronal proteins, identified by immunohistochemical techniques. Thus, gliomas were thought to arise from neoplastic transformation of astrocytes, oligodendrocytes or their precursors. Currently, it is impossible to demonstrate directly which cell of origin gives rise to which specific glioma in humans. This remains a fundamental question in glioma biology. The most likely candidates to give rise to intrinsic brain tumours are cells originating from the stem and progenitor cell compartments of the developing brain (e.g. medulloblastoma) and adult brain (e.g. glioblastoma, oligodendroglioma). A combination of the cell type of origin and the combination of genomic or mutations or epigenetic changes are the most likely determinant of the tumour type.

The increasing interest in the role of stem cells in the origins of brain tumours is the basis of many research programmes. Stem cells are defined as having the ability to perpetuate themselves through self-renewal and to generate mature cells of a particular tissue through differentiation. There are numerous parallels between somatic stem cells and cancer stem cells. Both show self-renewal, differentiation and capacity for histogenesis. Somatic stem cells self-renew in a highly controlled manner and differentiate into mature cells which go on to form normal tissues, whereas cancer cells show poorly controlled self-renewal, often abortive differentiation and go on to form abnormal tissues (i.e. tumours). The observation that only a small minority of tumour cells show an indefinite potential for self-renewal *in vitro* or *in vivo* gave rise to the hypothesis that tumours are composed of both cancer stem cells and more differentiated cells. The existence of a cancer stem cell has been proven for acute myeloid leukaemia, breast cancer (CD44<sup>+</sup>/CD24<sup>-</sup> cells), glioblastoma and medulloblastoma (CD133<sup>+</sup> cells). Implications of the cancer stem cell hypothesis are:

- Cancer cells can be organised hierarchically in that they range from poorly differentiated, highly proliferative cells to more mature, less proliferative forms.
- Cancer cells share cell cycle pathways that are relevant to normal human development and control of growth.

### Molecular mechanisms involved in tumour formation

An intrinsic difficulty in the study of signalling pathways involved in oncogenesis is the multitude of genetic and epigenetic changes that accrue during the multi-step process of malignant transformation of normal cells into tumour cells. An additional obstacle is the heterogeneity of mutations within a single tumour which suggests separate subpopulations of cells are capable of promoting growth in the same malignancy.

Genomics describe the changes in the genetic information of a cell, whilst epigenetic modifications are reversible modifications on the DNA that affect gene expression without altering the DNA sequence.

Three types of genes are involved in tumorigenesis:

- 1 Oncogenes
- 2 Tumour suppressor genes, and
- 3 Repair/stability genes.

The two most common epigenetic changes are:

- 1 DNA methylation, leading to inactivation or attenuation of gene expression, and
- 2 Histone modification, which regulates gene expression by disruption of the contact between nucleosomes and by recruiting chromatin remodelling ATPases.

The more important genetic and epigenetic mutations associated with brain tumours are summarised in Table 21.1.

**Table 21.1** Summary of relevant markers of intrinsic brain tumours.

Tumour	WHO Grade	Mutation	Frequency (%)	Relevance
Pilocytic astrocytoma	I	<i>KIAA:BRAF</i> fusion gene	75, in cerebellar location	D
Pleomorphic xanthoastrocytoma	I	<i>BRAF V600E</i>	66	D
Pleomorphic xanthoastrocytoma with anaplasia	n/a	<i>BRAF V600E</i>	65	D
Gangliogliomas	I		30	D
Diffuse astrocytoma	II	<i>IDH1,2</i> <i>ATRX</i> loss	100	D, P
Oligoastrocytoma	II	<i>IDH1,2</i> 1p/19q codeletion or <i>ATRX</i> loss	82 50–70	D, P P
Oligodendroglioma	II	<i>IDH1,2</i> 1p/19q codeletion	100 100	D, P P
Anaplastic astrocytoma	III	<i>IDH1,2</i> <i>ATRX</i> loss	90	D, P P
Anaplastic oligoastrocytoma	III	<i>IDH1,2</i> 1p/19q codeletion	66 50	D, P D, P
Anaplastic oligodendroglioma	III	<i>IDH1,2</i> 1p/19q codeletion or <i>ATRX</i> loss	100 100	D, P D, P
Primary glioblastoma	IV	<i>MGMT</i> methylation* 7p gain, 10q loss <i>EGFR</i> amplification	40 70 30%	P – –
Secondary glioblastoma (GBM-IDH) (progression from anaplastic astrocytoma)	IV	<i>IDH1,2</i> <i>ATRX</i> loss	100	D, P
Ependymoma and anaplastic ependymoma, post fossa	II, III	<i>LAMA2</i> <sup>†</sup> <i>NELL2</i> <sup>†</sup> <i>LAMA2 + NELL2</i> <sup>†</sup>	32 52 8	P P P
Medulloblastoma	IV	Wnt <sup>‡</sup> SHH <sup>‡</sup> Group 3 <sup>‡</sup> Group 4 <sup>‡</sup>		P P P P

D, diagnostic; P, prognostic.

\*The degree of methylation varies from low to high.

<sup>†</sup>These markers are differentially expressed in Group A and B ependymomas, and *not* mutated.

<sup>‡</sup>These are prognostically relevant subgroups of medulloblastoma.

### Genetic components in oncogenesis

The most common genetic components are oncogenes and tumour suppressor genes, which regulate cell division, control apoptosis or cell cycle arrest. Repair/stability genes become tumorigenic by loss of their DNA repair function. Oncogenes are genes that under normal conditions (i.e. development and cell self-renewal) promote cell birth and growth but when disinhibited (unleashed) become

autonomously active. For example, a point mutation in *c-kit*, which codes for a tyrosine kinase, leads to constitutive activation in the kinase domain and is causally implicated in the pathogenesis of gastrointestinal stroma tumours which arise from interstitial cells of Cajal in the gut. In contrast, tumour suppressor genes are gatekeepers of cell cycle function and under physiological conditions exert a negative regulation on processes promoting the cell cycle. They may

also control apoptosis and therefore mutations in these genes can lead to a failure of apoptosis. Typical examples are:

- *p53*: the ‘guardian of the genome’ which causes induction of apoptosis in response to cell damage. Inactivation leads to less apoptosis of cells that should have undergone programmed cell death.
- *Retinoblastoma (Rb)*: the prototypic tumour suppressor gene that controls the cell cycle at G1.
- *PTEN* (phosphatase and tensin homologue): germ-line mutations are associated with Cowden’s syndrome and other hamartomatous disorders.
- *BRAF* (v-RAF murine sarcoma viral oncogene homologue B1 (BRAF) gene): missense mutations (BRAF V600E) occur in primary nervous system tumours, such as pleomorphic xanthoastrocytomas (PXA) and gangliogliomas, and a fusion between two transcripts (*KIAA:BRAF*) are seen in about 60% of pilocytic astrocytomas.

Repair and/or stability genes normally function by repairing DNA damage—mismatch repair, nucleotide excision repair and base excision repair. Under normal conditions, DNA damage is kept to a minimum, but loss of function results in accumulation of DNA mutations and eventually tumour formation. A commonly observed alteration of a DNA repair gene is the suppression of the DNA repair enzyme MGMT (*O*-6-methylguanine-DNA methyltransferase), which results in a reduction of repair processes of damaged (mutated) tumour DNA. The epigenetic mechanism of DNA methylation of the promoter region of the *MGMT* gene leads to reduction of MGMT expression and DNA repair in response to alkylating chemotherapy agents (e.g. temozolomide).

Mutations in oncogenes, tumour suppressors and repair/stability genes can occur in the germ line, resulting in hereditary tumour syndromes or in somatic cells, causing sporadic tumours. The initial event in the neoplastic process is a single somatic mutation resulting in a growth advantage of a clonally expanding cell population. Additional mutations then accrue and cause further series of clonal expansions, eventually resulting in a tumour.

The cell cycle is controlled by a cascade of genes, which may either promote or suppress it: for example, mutations of *cdk4* and *cyclin D1* in the Rb pathway are oncogenic (i.e. activating), while mutations of Rb and *p16*, both tumour suppressor genes, lead to inactivation. Hence, the combinations of these mutations result in activation of the same pathway. However, despite the detailed knowledge of pathway function, it still remains unclear what eventually determines the phenotype of a brain tumour – is it the initial mutation, the sequence of subsequent mutations or the differentiation state of the cell in which the initial genetic event occurs? As a corollary of this complexity and multiplicity of mutations in an advanced tumour, it is impossible to track back to the primary event. Hence, *in vivo* models are needed in which specific pathways in stem cells can be altered to study the genotype–phenotype correlation of brain tumours.

### Epigenetic events in oncogenesis

Epigenetic events are important mechanisms underlying cancer development and progression, the most common of which are DNA methylation and histone modification. DNA methylation occurs almost exclusively at CpG dinucleotides. Some CpG dinucleotides are clustered in CpG islands, and are often associated with the promoter region, causing downstream gene activation. Generally, unmethylated, promoter CpG island permits initiation of transcription, whereas a methylated promoter CpG island represses promoter activity. In cancer, global hypomethylation and local hypermethylation can occur. One of these biomarkers, MGMT (see Genetic components in oncogenesis), is now important in clinical decision-making. If MGMT is inactivated, DNA damage is not repaired, cells that do not undergo apoptosis

develop a mutator phenotype that drives tumour evolution. However, methylation of the *MGMT* gene renders tumours susceptible to the DNA damaging effects of alkylating drugs and glioblastoma patients with a methylated *MGMT* gene show a survival benefit when treated with the alkylating drug temozolomide in addition to radiation.

Histone modifications and other epigenetic mechanisms establish and maintain gene activity, and regulate a wide range of cellular processes, including gene transcription, DNA replication and DNA repair. Alterations in the function of histone-modifying complexes can disrupt the pattern and levels of histone markers and thus deregulate the control of chromatin-based processes, ultimately leading to oncogenic transformation and the development of cancer. A DNA mutation encoding an enzyme of the anaerobic glucose metabolic pathway, isocitrate dehydrogenase 1 and 2 (*IDH1* and *IDH2*) genes result in the loss of normal catalytic activity necessary for the production of  $\alpha$ -ketoglutarate ( $\alpha$ -KG), and gain of a new activity, the production of an oncometabolite, R-2-hydroxyglutarate (R-2-HG). R-2-HG acts as an antagonist of  $\alpha$ -KG and competitively inhibits the activity of multiple  $\alpha$ -KG-dependent dioxygenases, including both histones and DNA demethylases involved in epigenetic control of gene expression and cell differentiation. It has been shown that cells with mutant *IDH* show stemness properties and a delay in differentiation. *IDH* mutations are present in 70–80% of WHO Grades II and III astrocytomas and oligodendrogliomas. Astrocytomas with mutant *IDH* show a global hypermethylator phenotype, which includes high rates of *MGMT* methylation.

### WHO classification of CNS tumours

Most brain tumour classifications are based on the work of Bailey and Cushing (1926) who named tumours after the cell type in the developing embryo, fetus or adult that most resembled the tumour histologically. The classification system now most widely accepted is that of the World Health Organization (WHO 2007) which recognises more than 120 different tumour types, and is shown in Table 21.2. Consensus guidelines have been recently developed following a meeting in Haarlem, the Netherlands in 2014, in which histology, WHO grade and molecular information will be incorporated to provide an ‘integrated diagnosis’ and this will be introduced into the fourth edition of the WHO classification.

### Neuroepithelial tumours

Neuroepithelial tumours form the vast majority of intrinsic brain tumours and encompass a broad spectrum of neoplasms that arise from or share morphological properties of neuro-epithelial cells. Accordingly, they are further subgrouped into:

- Glial neoplasms, collectively classified as gliomas, which include astrocytic, oligodendroglial and ependymal tumours
- Tumours with predominant neuronal phenotype, such as ganglioglioma, dysembryoplastic neuro-epithelial tumour and central neurocytoma
- Neuroblastic tumours
- Pineal tumours
- Embryonal tumours such as medulloblastoma
- Choroid plexus tumours.

The grading of gliomas and other tumours in the WHO scheme is based on the presence of certain morphological characteristics within the tumour: cellular and nuclear atypia, mitotic activity, vascular endothelial proliferation and necrosis. These features reflect the malignant potential of the tumour in terms of invasion and growth rate. Tumours without any of these features are WHO

**Table 21.2** WHO 2007 classification of nervous system tumours (Grades I, II, III, IV).

Grade I; those with atypia alone are WHO Grade II. Those tumours with atypia and mitosis are WHO Grade III and those with vascular proliferation or necrosis or both are WHO Grade IV. Grade I and II tumours are termed low grade and Grade III and IV tumours high grade. In one subset of astrocytomas the usual four-featured grading system is not used, because of their distinctive cell appearance. Tumours in this subset may have endothelial proliferation and marked cellular atypia;

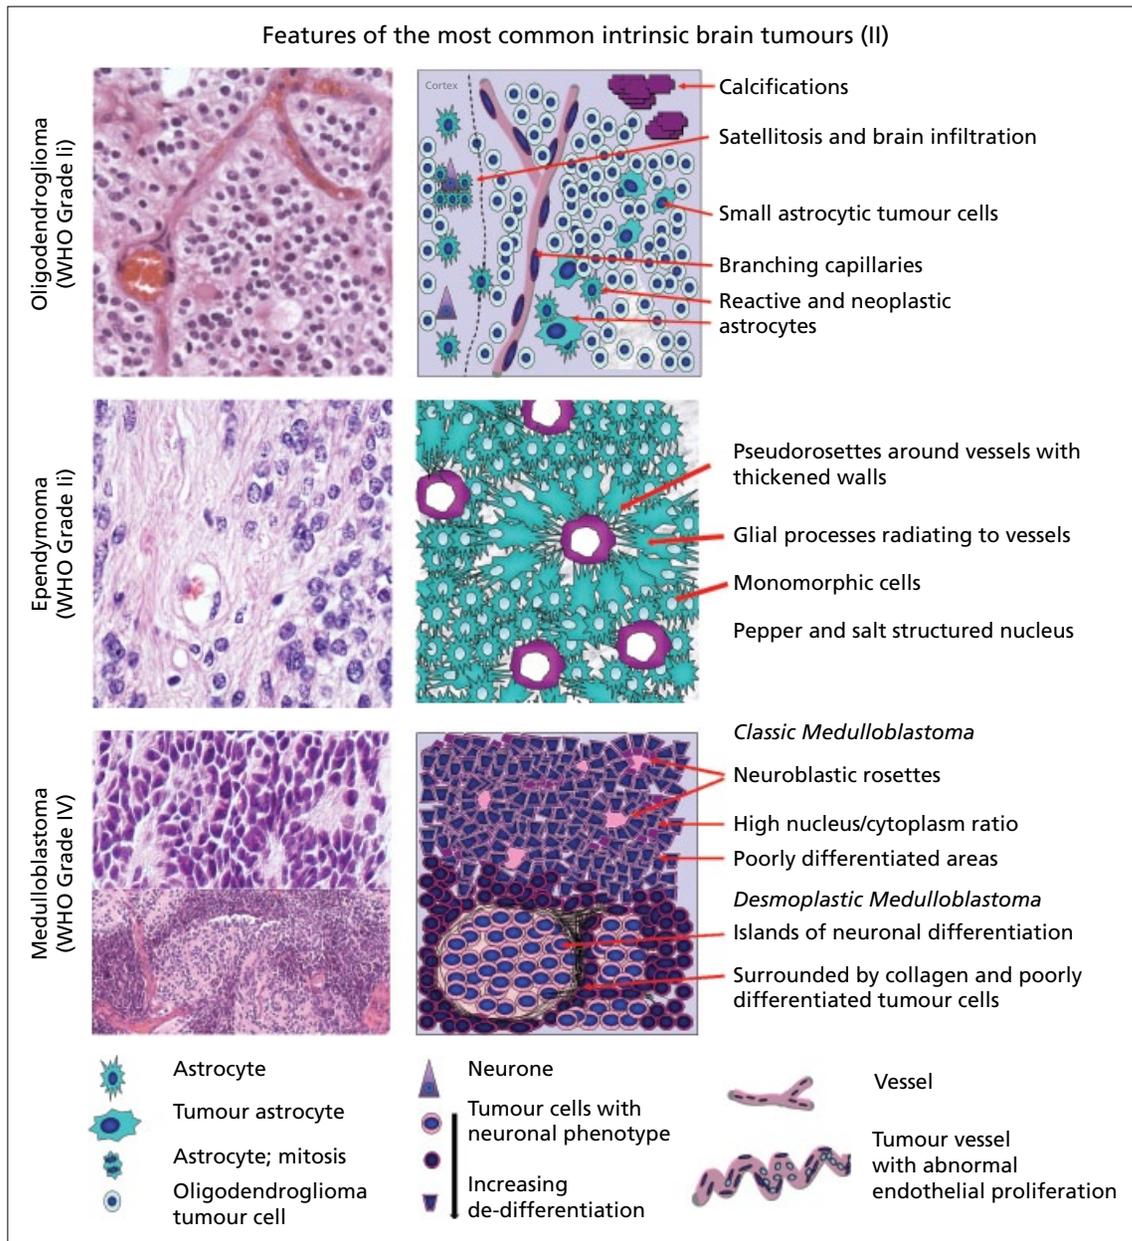

nevertheless, they are slow growing, well circumscribed and thus low grade:

- Juvenile pilocytic astrocytoma
- PXA, and
- Subependymal giant-cell astrocytoma.

Figures 21.1 and 21.2 illustrate the histological features of some common tumours showing the microscopic H&E features on the left and the key pathological pointers to the diagnosis on the right.

**Figure 21.1** Histological features of Grade I–IV astrocytomas.

## Imaging of brain tumours

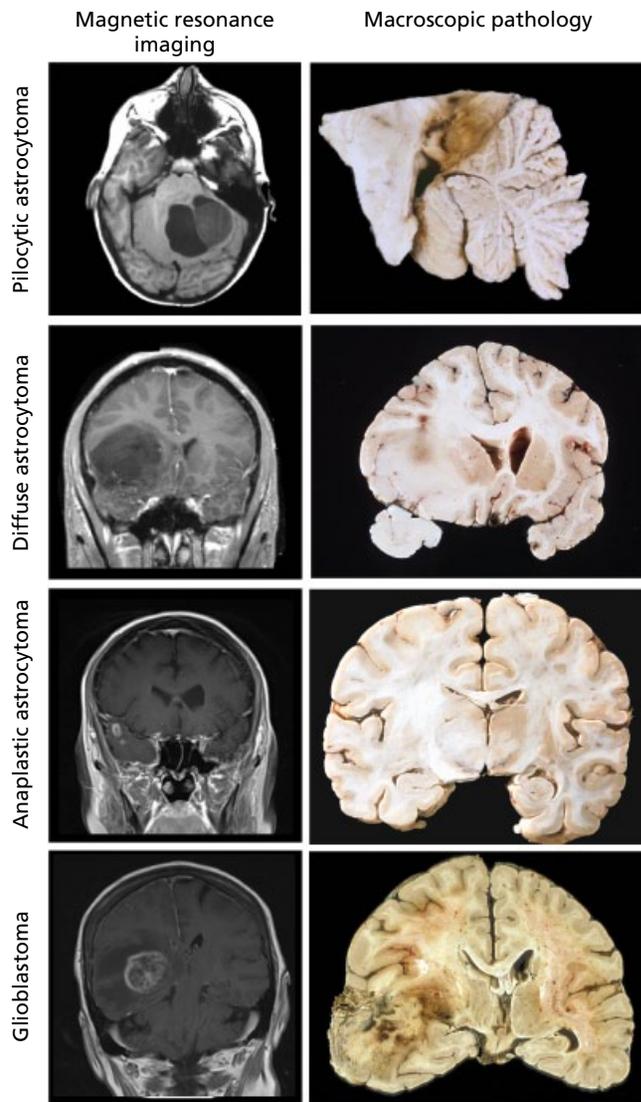

### Structural imaging

MRI is the preferred modality for structural imaging of brain tumours (Chapter 4). MRI provides better soft tissue differentiation and tumour delineation than CT. However, CT demonstrates tumour calcification better than MRI: on MRI, the signal may be difficult to distinguish from intra-tumoural haemorrhage. Structural MRI of brain tumours should include T2-weighted, fluid-attenuated inversion recovery (FLAIR) and T1-weighted images before and after injection of gadolinium. The general imaging and macroscopic appearance of common intracranial tumours are shown in Figures 21.3 and 21.4.

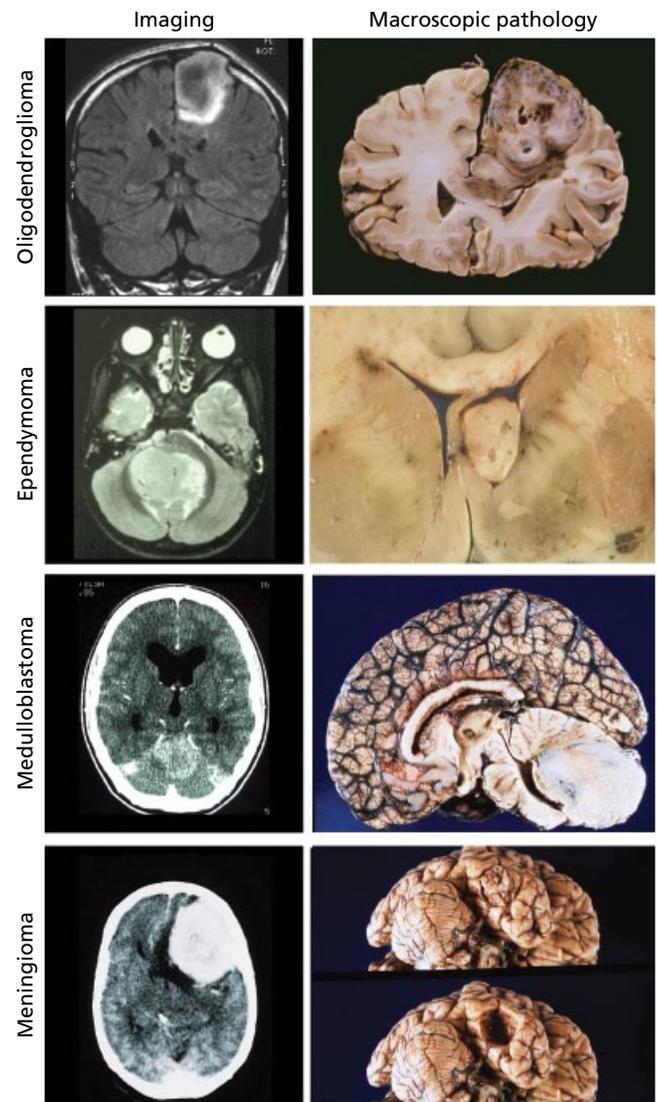

Most tumours appear hypodense on CT, hypointense on T1 and hyperintense on FLAIR and T2 MRI. Highly cellular tumours such as lymphomas, primitive neuro-ectodermal tumours and central neurocytomas have decreased water content and therefore appear

hyperdense on CT and relatively hypointense on T2 MRI. Intra-tumoural haemorrhage and tumour calcification appear usually hypointense on T2 images and become more conspicuous on T2\* gradient echo images. Hyperintensities on T1 images can be because of haemorrhage, calcification, melanin or fat.

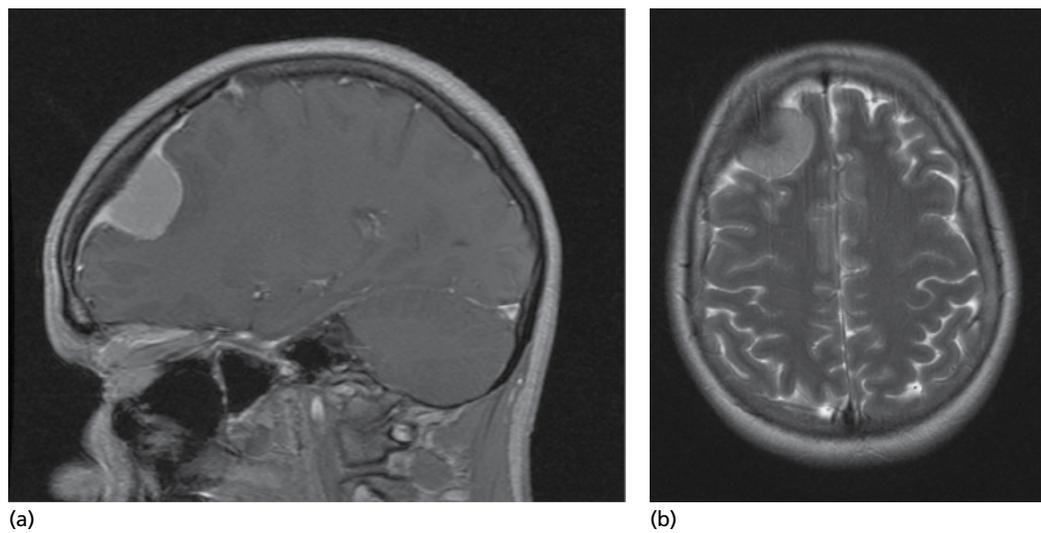

Contrast enhancement on CT or MRI is either seen in highly vascular extra-axial tumours such as meningiomas (Figure 21.5a) or in intra-axial tumours disrupting the blood-brain barrier such as cerebral lymphomas (Figure 21.6). Enhancement is generally a feature of malignant tumours such as high-grade gliomas and metastases but can also be present in certain low-grade tumours, such as pilocytic astrocytomas, gangliogliomas and WHO Grade II oligodendrogliomas. The visibility of contrast enhancement on MRI can be improved by magnetisation transfer imaging, by doubling or tripling the gadolinium dose or by using high relaxivity gadolinium compounds.

**Figure 21.3** Imaging and macroscopic appearance of gliomas.

**Figure 21.4** Imaging and macroscopic appearance of common brain tumours.

**Figure 21.5** (a) Frontal meningioma. Sagittal contrast-enhanced T1 images of a meningioma showing typical appearances of an enhancing durally based mass associated with bony hyperostosis and a dural tail sign. (b) Corresponding axial T2 images demonstrating a grey matter iso-intense mass displacing the frontal lobe with hyperostosis but no associated oedema.

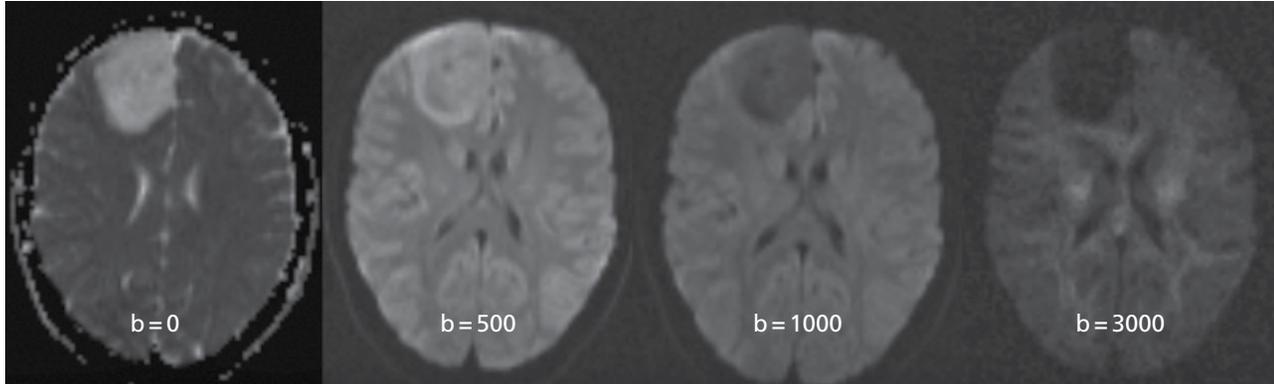

### Physiological imaging

Physiological imaging, as its name implies, provides information about physiological and metabolic processes not seen with standard MRI sequences. Much of the recent progress in tumour imaging is based on these methods, which are now being increasingly implemented in practice. The most frequently used physiological sequences include diffusion-weighted imaging (DWI), perfusion-weighted imaging (PWI), MR spectroscopy (MRS) and functional MRI (fMRI). More recently, CT perfusion imaging has emerged as another technique to assess the relative cerebral blood volume

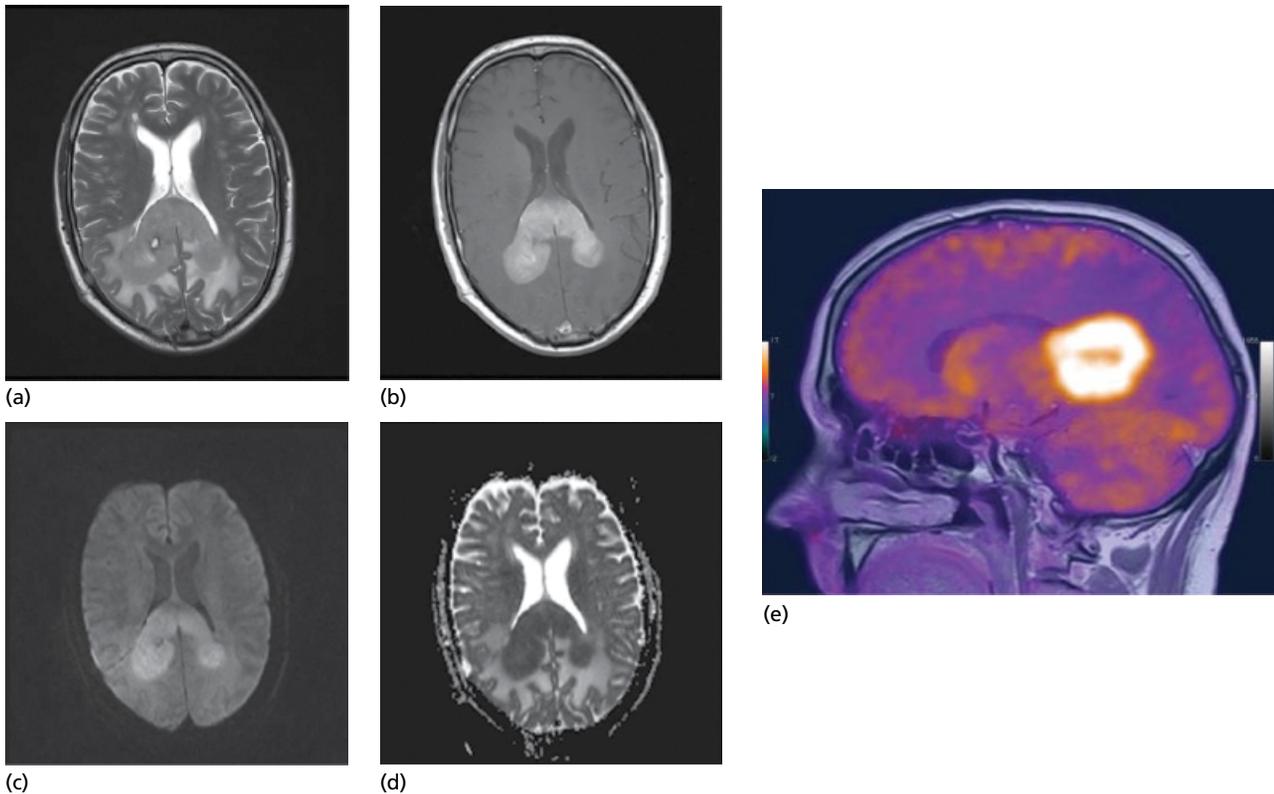

(rCBV) and permeability changes in brain tumours. Compared with MR perfusion techniques it brings limited diagnostic focus to the region of interest despite progress in multi-detector technology.

### Diffusion-weighted imaging

DWI measures Brownian motion of water molecules within tissue. Images are obtained by measuring the signal loss typically on MR T2 images following the application of diffusion gradients (Figure 21.6). The signal loss depends on several factors including the gradient strength and apparent diffusion coefficient (ADC)

**Figure 21.6** Diffusion-weighted images of a frontal low-grade glioma. With increasing diffusion weighting (higher b values) progressive signal loss occurs, first in areas of high water mobility, such as cerebrospinal fluid (CSF) and subsequently also in the tumour.

**Figure 21.7** Primary central nervous system (CNS) lymphoma. A relatively T2 hypointense (a), uniformly enhancing mass (b) is expanding the splenium of the corpus callosum and extends into the peritrigonal regions of both hemispheres. The solid tumour parts appear bright on diffusion-weighted images (DWI) (c) and dark on the apparent diffusion coefficient (ADC) map (d), in keeping with restricted water diffusion in a highly cellular tumour. The sagittal image of a fluorodeoxyglucose positron emission tomography (FDG PET) MRI (e) shows marked uptake of the tracer in the mass centred on the splenium of the corpus callosum.

which describes water diffusion within tissue. As a general rule, the more mobile the water molecules, the higher the ADC and the lower the signal on DWI. DWI is still influenced by T2 effects, which can lead to artefacts known as T2 shine-through, whereas ADC maps provide a quantitative representation of water movement. Therefore, highly cellular tumours (e.g. lymphoma), which are associated with limited water mobility, show up as dark on ADC and bright on DWI (Figure 21.7).

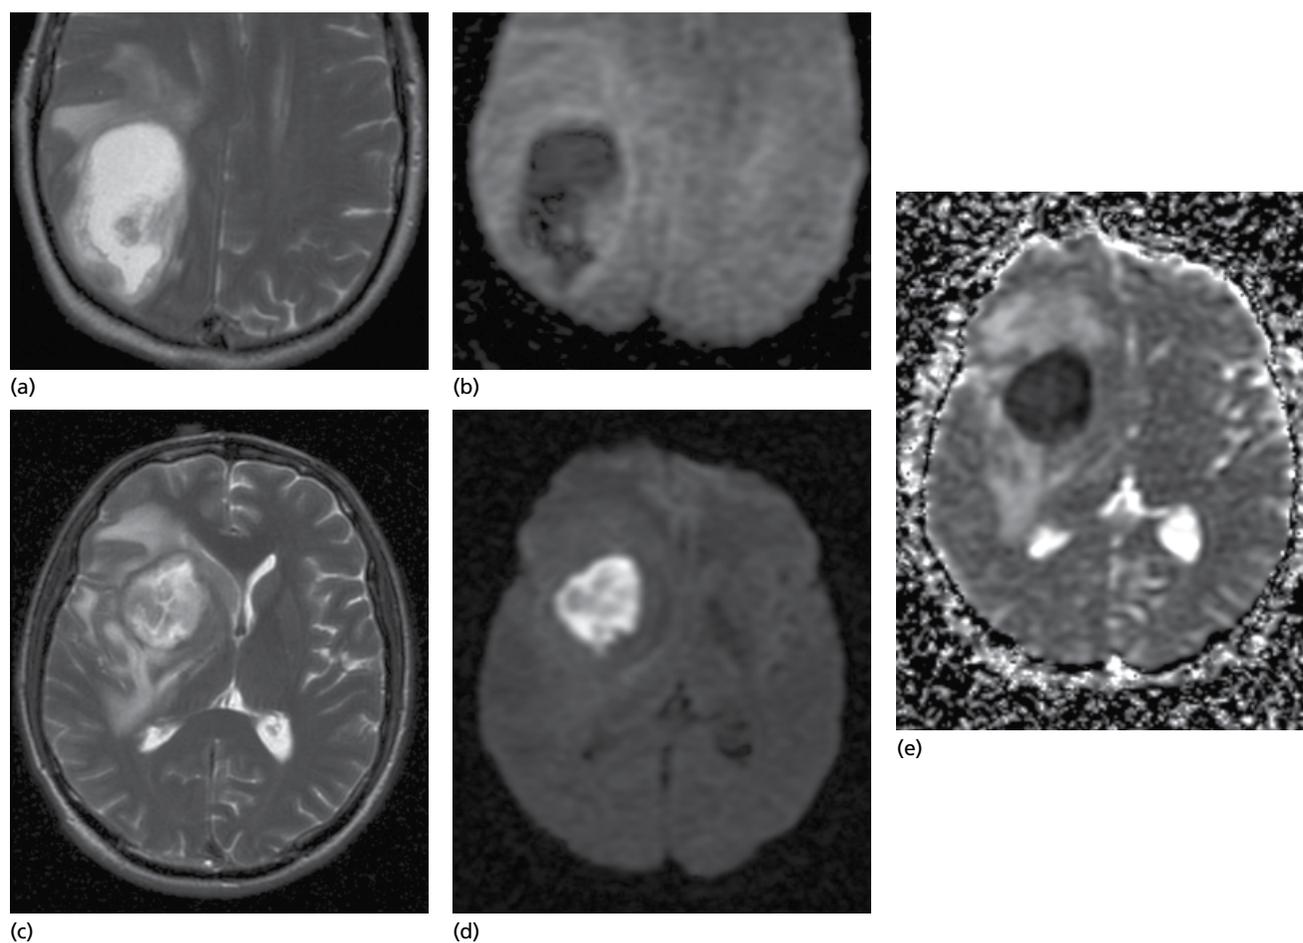

Visual inspection of DWI has a limited role in the diagnosis of brain tumours. However, it may be valuable to identify lesions with severely restricted diffusion, such as acute infarcts or abscesses that can occasionally mimic brain tumours on standard MRI but which appear as high-intensity lesions on DWI and low intensity on ADC maps (Figure 21.8).

ADC measurements provide more detailed information about brain tumours and have been shown to correlate with the histological cell count and with the presence of hydrophilic substances in the tumour matrix. Diffusion tensor imaging (DTI) provides additional information about the direction of water diffusion. Anisotropy is the tendency of water to move in some directions more than others, and can be quantified using parameters such as fractional anisotropy (FA). Compact white matter tracts normally show a high

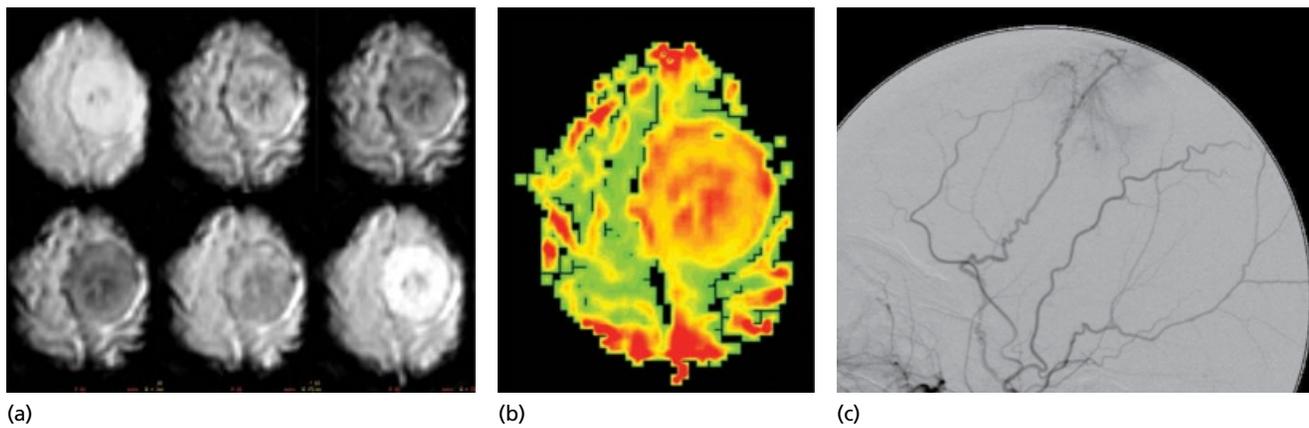

degree of anisotropy which can be lost if they are infiltrated by tumour cells destroying ultrastructural boundaries. Tractography is an application of DTI which depicts white matter tracts and their connections on direction-encoded colour images. Tractography is useful in the pre-operative assessment of brain tumours and can differentiate between displacement and infiltration of white matter tracts.

#### Perfusion-weighted imaging

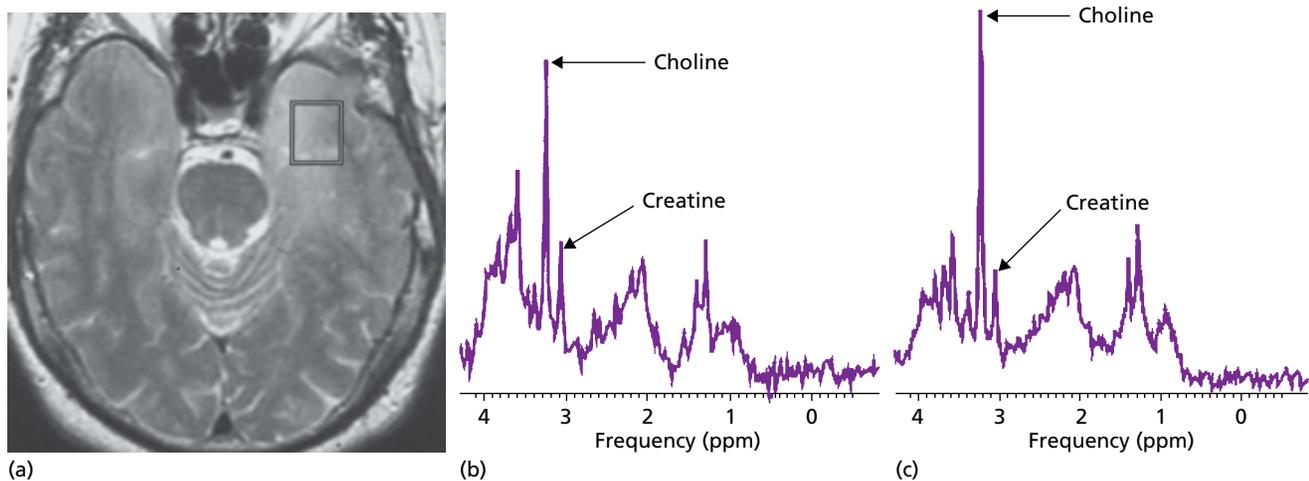

Dynamic susceptibility-weighted contrast-enhanced (DSC) MRI is the most widely used technique of PWI in brain tumours. It can analyse a series of images acquired during the first pass of an intravenously injected bolus of gadolinium (Figure 21.9). rCBV measurement provides an indirect measure of tumour neovascularity. This correlates closely with angiographic and histological markers of tumour vascularity and the expression of vascular endothelial growth factor (VEGF). High-grade glioma tend to have higher rCBV values than low-grade tumours and PWI significantly increases the specificity and sensitivity of conventional MRI in the classification of gliomas. Maps of rCBV can also be a useful adjunct for stereotactic tumour biopsies, directing tissue sampling towards areas of maximal angiogenesis. PWI can also be

**Figure 21.8** (a) T2 image of a cystic high-grade glioma with a hyperintense centre, irregularly thickened rim and vasogenic oedema. (b) The diffusion-weighted image shows loss of signal in the central portion, typical of a necrotic centre in a cystic neoplasm. (c) T2 image of another, undiagnosed cystic frontal lobe mass lesion with a hyperintense centre and surrounding vasogenic oedema. (d) Diffusion-weighted image shows markedly restricted diffusion in this case, typical of an abscess confirmed at biopsy. (e) On the corresponding ADC map the abscess cavity appears dark and vasogenic oedema appears bright.

**Figure 21.9** Parasagittal meningioma. (a) Dynamic susceptibility contrast perfusion weighted sequences in a patient with a left parasagittal frontal meningioma, showing marked loss of signal intensity within the tumour during the first pass of contrast medium bolus. (b) Corresponding colour overlay map showing increased relative cerebral blood volume (rCBV). Red areas indicate regions of most elevated rCBV within the tumour and over brain surface vessels. (c) Digital subtraction angiogram of the external carotid artery showing a tumour blush confirming increased vascularity of the meningioma.

**Figure 21.10** (a) Single voxel magnetic resonance (MR) spectroscopy of a left temporal lobe tumour demonstrating region of interest. (b) Initial MR spectrum of a low-grade primary tumour showing a high choline : creatine ratio. (c) MR spectrum 6 months later, following transformation into a high-grade tumour shows a further increase in the choline peak compared to the baseline study (from 1.6 to 3.1 mmol/L).

used to help distinguish between pseudoprogression and true progression in patients with glioblastoma after treatment with chemoradiation.

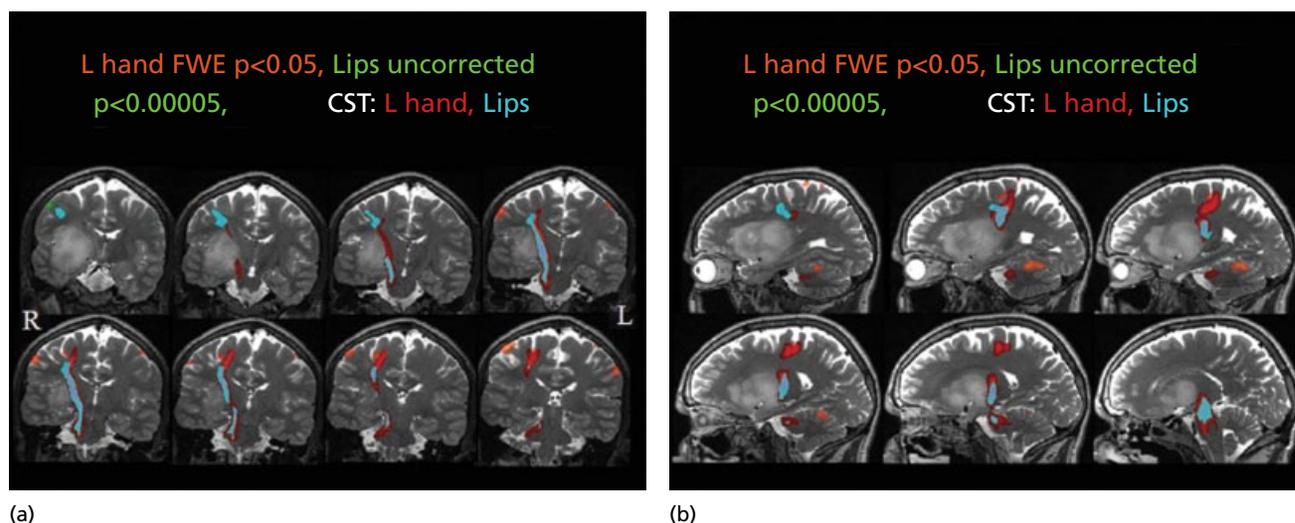

#### Permeability imaging ( $K^{\text{trans}}$ )

Microvascular permeability of brain tumours can be quantified by measuring the transfer coefficient  $K^{\text{trans}}$  which is influenced by endothelial permeability, vascular surface area and flow. This can be measured using a T1 steady state or a first pass T2\* gradient echo technique. The former has a higher spatial resolution and is more accurate but requires longer acquisition times and more complicated post-processing; the latter can be combined with DSC perfusion imaging.  $K^{\text{trans}}$  correlates with tumour grade and is probably more sensitive than rCBV measurements for glioma grading.

However, because of the complex post-processing analysis, this technique is rarely used in clinical practice.

#### MR spectroscopy

Proton MRS analyses aspects of the biochemical make-up of a brain tumour and provides semi-quantitative information about major metabolites. A common pattern in brain tumours is a decrease in *N*-acetyl-aspartate (NAA), a neurone-specific marker, with an increase in choline, lactate and lipids. The concentration of choline is a reflection of the turnover of cell membranes and is more elevated in regions with a high neoplastic activity (Figure 21.10). Lactate is the end product of non-oxidative glycolysis and a marker of hypoxia in tumour tissue, now recognised as a major promoter of tumour angiogenesis and invasion. Lactate probably indicates

**Figure 21.11** (a) Coronal and (b) sagittal fMRI of a motor task involving the left hand in a patient with a right temporal glioma showing activation of motor pathways and relationship with corticospinal tract anatomy showing close approximation of the posterior medial tumour border with motor pathways.

viable but hypoxic tissue, whereas mobile lipids reflect tissue necrosis and breakdown of cell membranes. MRS with a short echo times (20–40 ms) can demonstrate additional metabolites, such as myo-inositol, glutamate and/or glutamine and mobile lipids but is hampered by baseline distortion and artefactual NAA peaks. Chemical shift imaging (CSI) or MRS provides spectral information across a whole tumour region and has been used to inform surgical biopsy targets.

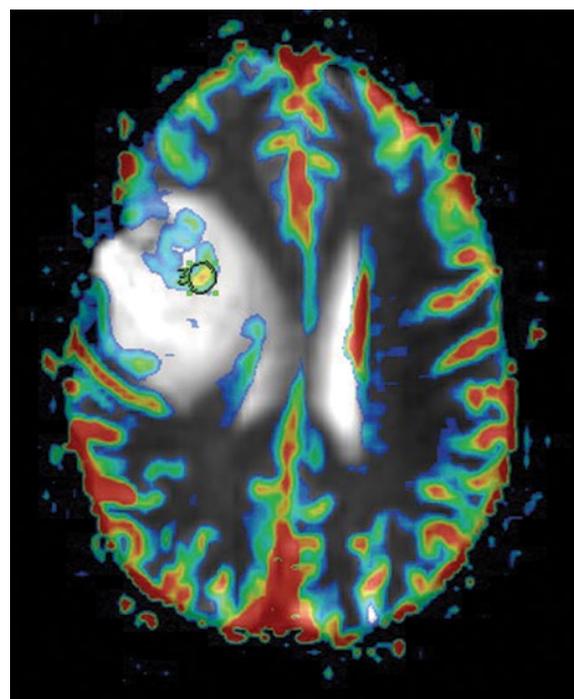

### Functional MRI

Blood oxygen level-dependent (BOLD) imaging detects changes in regional cerebral blood flow during various forms of brain activity (Chapter 4). Paradigms using motor tasks, language and speech production and memory are able to show recruitment of activation within relevant cortical areas. The main use of fMRI in tumour imaging is the pre-operative localisation of eloquent cortical regions which may have been displaced, distorted or compressed by the tumour (Figure 21.11). This can both improve the safety of surgery and allow for a more radical resection. Ideally, fMRI should be combined with MR tractography in order to minimise intra-operative injury to white matter tracts connected to eloquent cortical areas.

### Applications of physiological imaging

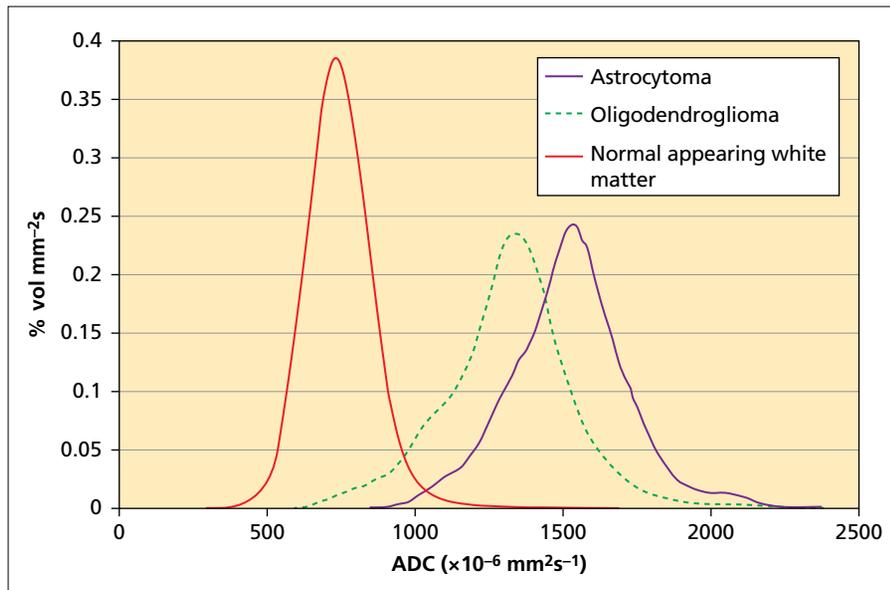

#### Distinguishing between astrocytomas and oligodendrogliomas

PWI and DWI can help to differentiate between low-grade astrocytic and oligodendroglial tumours. WHO Grade II oligodendrogliomas have significantly higher rCBV than WHO Grade II astrocytomas with median values of 3.68 and 0.92, respectively, which concurs with the histological findings of increased vascular density in oligodendrogliomas (Figure 21.12). In addition, rCBV of oligodendrogliomas appears dependent on their genotype, the loss of 1p/19q being associated with significantly higher rCBV values. Measurement of the ADC, using a whole tumour histogram analysis, appears promising for differentiating between

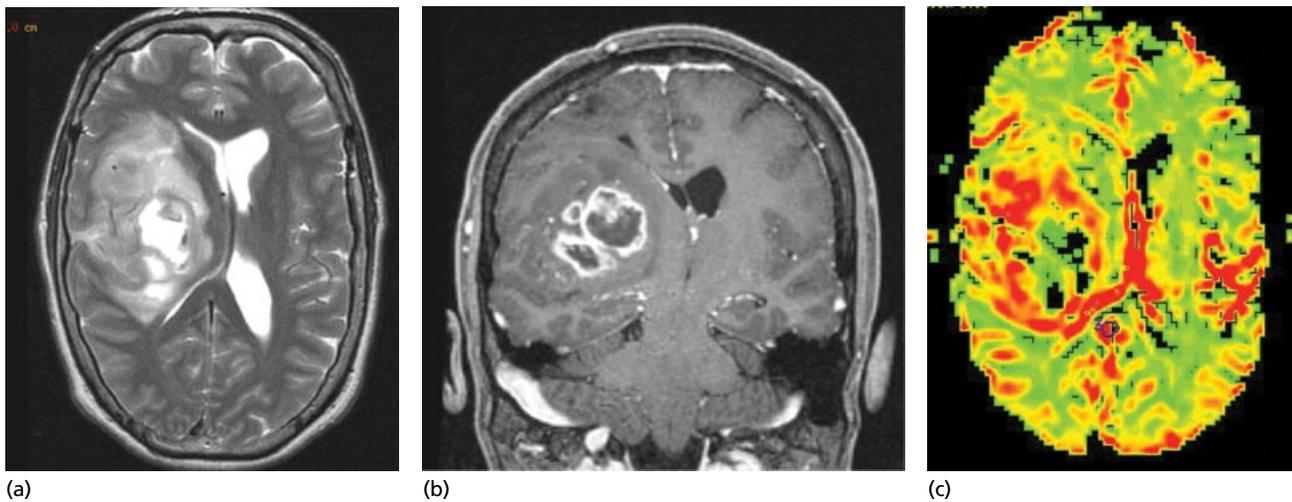

**Figure 21.12** rCBV colour overlay of a right frontal oligodendroglioma showing elevated rCBV within the anterior part of the tumour. This is commonly seen in oligodendrogliomas and does not represent malignant transformation.

astrocytomas and oligodendrogliomas, but requires complex post-processing analysis. Oligodendrogliomas have significantly lower ADC values than astrocytomas (Figure 21.13), reflecting higher cellular density and differences in tumour matrix composition. However, there is considerable overlap between the oligodendrogliomas and astrocytomas that it cannot be reliably used as a substitute for histology.

**Figure 21.13** Whole tumour ADC histograms of a low-grade astrocytoma and a low-grade oligodendroglioma. Both have higher ADC values than normal white matter. Histogram of the oligodendroglial tumour is shifted to the left compared to histogram of the astrocytic tumour, indicating overall lower ADC values in the former.

**Figure 21.14** Right frontal anaplastic oligodendroglioma. (a) Axial T2-weighted sequence showing a heterogeneous mass with a necrotic centre. (b) Coronal T1W MR slices post contrast demonstrates irregular ring enhancement within the mass, central necrosis, mass effect and vasogenic oedema. (c) rCBV map shows large intra-tumoural areas of increased rCBV (red) reflecting new vessel formation (angiogenesis), suggesting areas of high-grade transformation within a previous low-grade tumour.

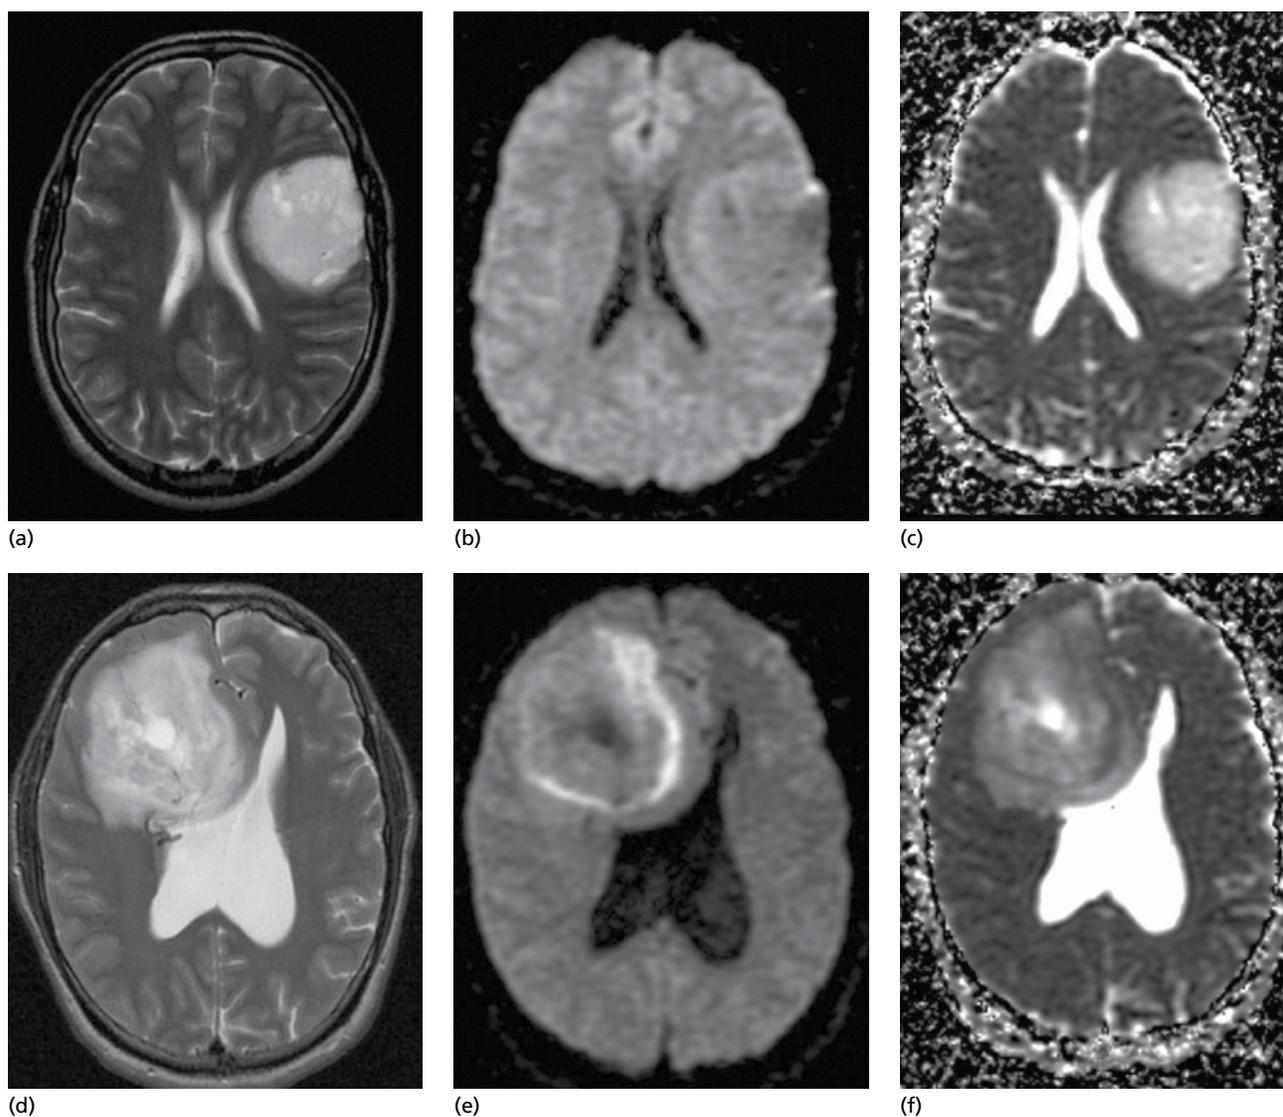

#### Distinguishing between low-grade and high-grade gliomas

Advanced MRI can help distinguish between low-grade and high-grade gliomas. Formation of new blood vessel (angiogenesis) represents an important aspect of glial tumour progression and mean maximum rCBV values correlate closely with histological grades. PWI is also valuable (Figure 21.14). DWI can be disappointing in helping to differentiate high-grade from low-grade gliomas (Figure 21.15).

#### Imaging of peri-tumoural tissue

Investigation of peri-tumoural regions with physiology-based MR techniques is of similar importance to the radiological assessment of the tumour itself. Differences in the peri-tumoural tissues of

low-grade and high-grade gliomas have been demonstrated with DWI, PWI and MRS. The peri-tumoural regions of high-grade gliomas show a more marked decrease in ADC, FA and NAA and increase in rCBV than low-grade tumours. This is a reflection of the more invasive nature of these tumours which infiltrate the adjacent brain tissue leading to an increase in rCBV, destroy ultrastructural boundaries to produce a decrease both in ADC and FA, and replace normal brain tissue with a corresponding fall in NAA. Metastases, on the other hand, are surrounded by pure vasogenic oedema that contains no infiltrating tumour cells. Therefore, peri-tumoural regions in metastases typically show neither increase in rCBV nor decrease in FA.

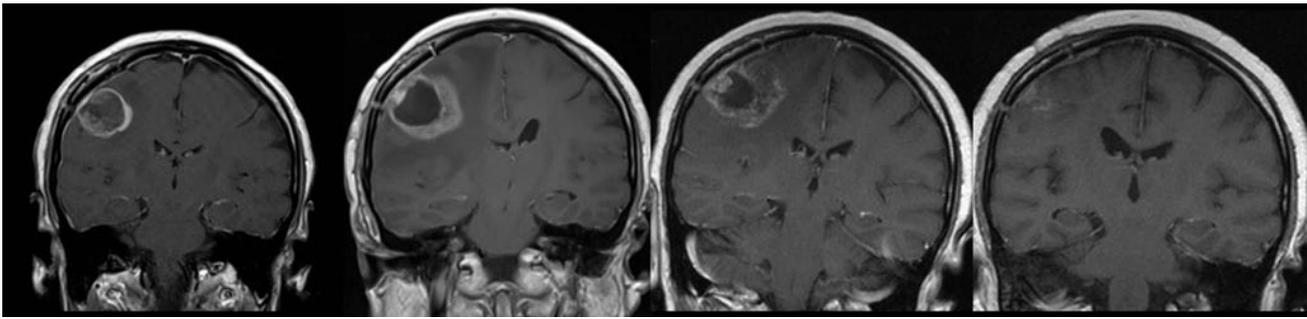

**Figure 21.15** (a) T2 image of a homogeneously appearing left frontal low-grade astrocytoma. (b) The tumour is not very conspicuous on diffusion-weighted images as diffusion and T2 effects cancel each other out (T2 masking). (c) Tumour becomes very conspicuous on the ADC map because of its relatively increased water diffusivity. Overall appearance on the ADC map is also homogeneous. (d) T2 image of a high-grade right frontal anaplastic astrocytoma with a heterogeneous appearance. Note enlarged vessels at posterior aspect of mass. (e) Diffusion-weighted image shows a peripheral hyperintense rim, confirmed to be of restricted diffusion on the ADC map with a cystic necrotic centre. (f) ADC map confirms a centre of increased diffusivity (bright) and rim of decreased diffusivity (dark) as well as surrounding oedema (bright).

### Monitoring tumour growth and response to treatment

Change in tumour size is still the most important imaging criterion for the evaluation of treatment response. Many treatment protocols for solid tumours recommend unidimensional or bi-dimensional measurements of tumour size. Volumetric (three-dimensional) tumour measurements are better predictors of patient survival than linear or two-dimensional tumour measurements. Volumetric contrast-enhanced T1 images are valuable in any serial imaging protocol that aims to assess tumour progression or treatment response. The assessment of tumour response and progression in glioblastoma (GBM) had traditionally been based on measurements of enhancing tumour portions known as Macdonald criteria. With the advent of combined chemo-radiation as standard therapy and antiangiogenic drugs as second line treatment for GBM, new

phenomena such as pseudoprogression and pseudoresponse have to be taken into account and have made an assessment solely based on assessment of enhancing tumour portion unreliable. The Response Assessment in Neuro-Oncology (RANO) Working Group has published recommendations for updated response criteria for high-grade gliomas, which incorporate measurements of non-enhancing signal change seen on T2W and FLAIR sequences, in recognition of the fact that high-grade gliomas are infiltrative in nature, and do not always cause disruption of the blood-brain barrier.

Parameters detectable with physiological MRI have an increasing role in monitoring disease progression and early effects of treatment. This pertains particularly to measurements of rCBV and  $K^{trans}$ . The strength of these perfusion techniques lies in their ability

**Figure 21.16** Pseudoprogression after treatment of GBM. Contrast-enhanced coronal T1weighted images in a patient with a glioblastoma before and at 6 weeks, 16 weeks and 6 months after treatment with chemoradiation (60 Gy in 30 fractions over 6 weeks with concomitant temozolomide). The baseline image shows an irregular ring-enhancing mass in the right posterior frontal lobe. At 6 weeks after treatment the mass has enlarged and shows increased enhancement with thickening of its rim. The enhancement decreases subsequently at 16 weeks and 6 months without altering the treatment. The time course of these appearances is typical for 'pseudoprogression'.

to detect changes within internal tumour architecture in the absence of or prior to an overall change in tumour size.

Serial PWI of conservatively treated low-grade gliomas show an increase in rCBV 12 months before visible tumour enhancement, the conventional marker of tumour progression. PWI and permeability measurements have also been used to monitor antiangiogenic therapy. A significant fall in rCBV occurs within 48 hours of administration of antiangiogenic drugs (e.g. bevacizumab). Measurements of rCBV also correlate better with clinical status than conventional MRI. PWI has also demonstrated a significant reduction of rCBV in enhancing cerebral mass lesions treated with dexamethasone, an important fact to consider when comparing different treatment regimens.

### Pseudoprogression and pseudoresponse

Pseudoprogression is caused by an inflammatory reaction, which results in a temporary increase of contrast enhancement and oedema, usually within 12 weeks of chemoradiation, and subsides subsequently without additional treatment of GBM (Figure 21.16). Pseudoprogression is more frequently observed in patients with methylation of the DNA repair gene *MGMT*, and is associated with a longer overall survival. There are certain histological similarities between the inflammatory response in pseudoprogression and radiation necrosis, the delayed complication of radiotherapy occurring 6–12 months after treatment. Advanced MRI such as DSC and DCE perfusion imaging are helpful in differentiating these two conditions from true tumour progression.

Pseudoresponse is characterised by a decrease of enhancement and oedema following the administration of antiangiogenic drugs without any effect on tumour growth or survival. In pseudoresponse, the tumour continues to progress by an infiltrative pattern without angiogenesis, resulting in an increase of non-enhancing T2/FLAIR hyperintense tumour portions (Figure 21.17). Antiangiogenic treatment can also be associated with non-enhancing areas of markedly decreased ADC, which appear to correspond to atypical gelatinous necrotic tissue rather than tumour, with improved outcome.

### Imaging the effects of radiotherapy

The effect of radiation on the brain has a time-dependent course, with a distinction between acute, early-delayed and late-delayed radiation injury (Chapter 19). Severity depends on the total radiation dose, individual fraction size and volume of brain irradiated.

Imaging is especially helpful in the diagnosis of late-delayed radiation-induced leukoencephalopathy and radiation necrosis.

### Radiation-induced leukoencephalopathy

Radiation-induced leukoencephalopathy is a late-delayed demyelinating process that involves the peri-ventricular region and can extend into the juxtacortical region in more severe cases. On MRI, leukoencephalopathy appears as non-enhancing, confluent, usually symmetrical areas of T2 hyperintensity, typically 6 months or more following radiotherapy (Figure 21.18).

### Radiation necrosis

Radiation necrosis is also a late-delayed complication of radiotherapy and radiosurgery, which can appear as an enhancing mass lesion and thus be difficult to distinguish from recurrent tumour on conventional imaging. PWI and DWI may help to distinguish between radiation necrosis and tumour recurrence (Figure 21.19). In radiation necrosis, the enhancing lesion has a low rCBV, whereas this tends to be high in tumour recurrence as a consequence of increased new vessel formation. ADC measurements of the enhancing components in recurrent tumour are significantly lower than in radiation necrosis, mirroring the higher cellular density in recurrent neoplasm.

### Optic neuropathy

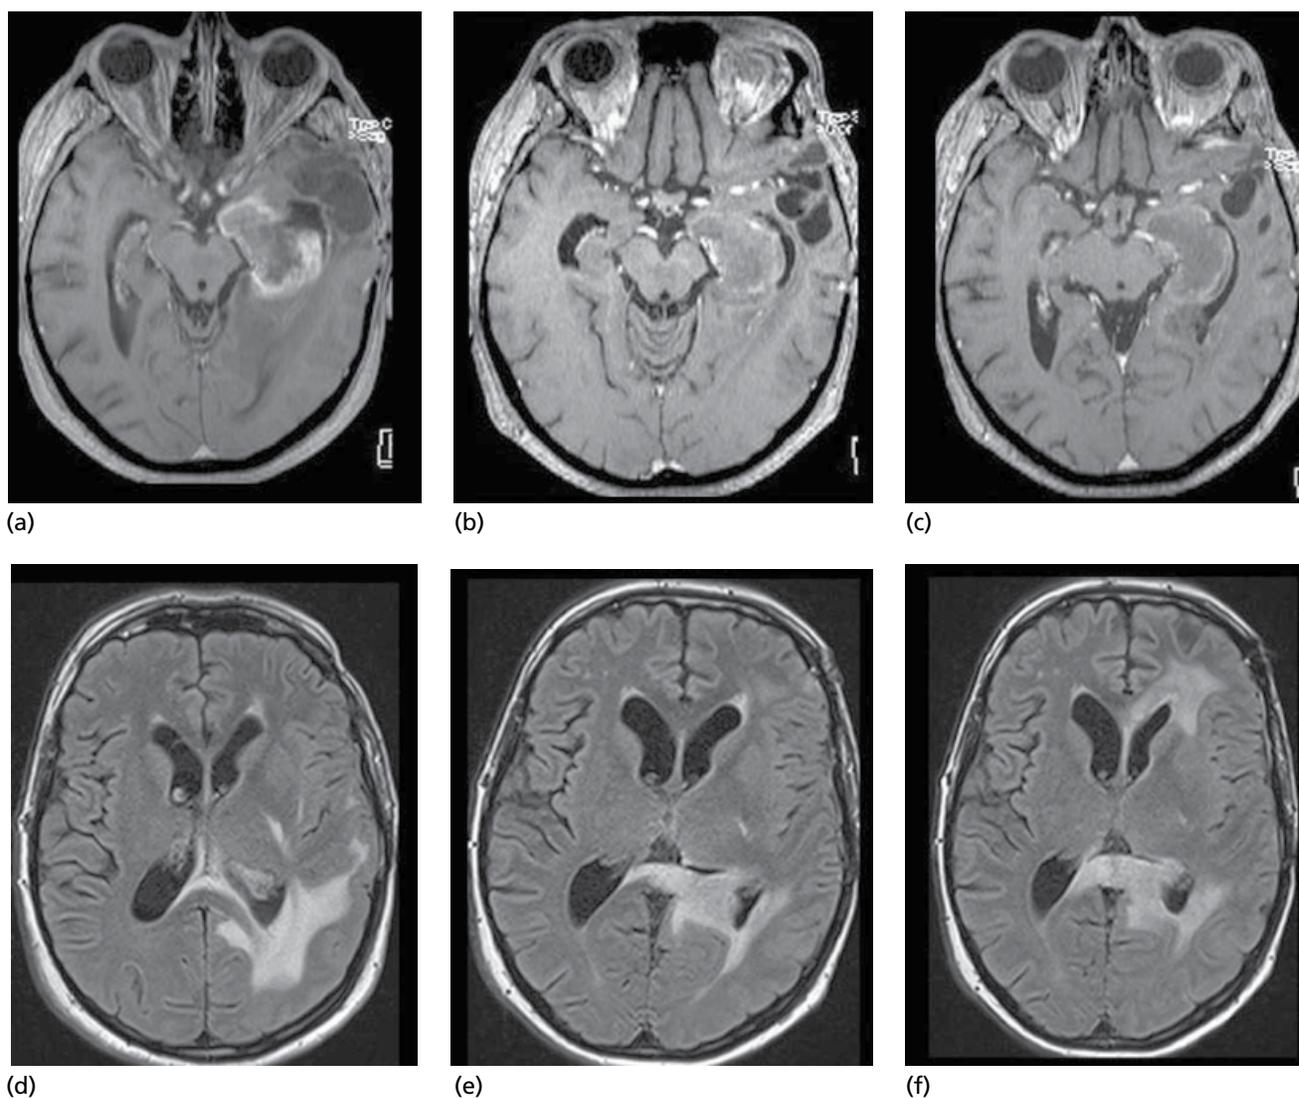

Optic neuropathy is most commonly seen following radiotherapy of sellar and parasellar lesions and is a late-delayed complication of radiotherapy, with T2 hyperintense signal change typically in the intracranial portion of the optic nerve.

### Radiation-induced tumours

Meningiomas are the most commonly encountered radiation-induced tumours, with typical latency periods over 10 years. Gliomas and schwannomas are also seen, developing many years after radiotherapy. Radiation-induced cavernomas are more common than previously assumed; their detection rate is significantly increased with the use of haemorrhage-sensitive gradient echo MR sequences.

### Imaging complications of chemotherapy

Many chemotherapeutic agents are neurotoxic. Combining chemotherapy and radiotherapy can result in additive and synergistic effects. The most frequent imaging findings are leukoencephalopathy

**Figure 21.17** Pseudoresponse after treatment with bevacizumab. Contrast-enhanced T1-weighted image (a,b,c) and FLAIR images (d,e,f) in a patient with glioblastoma receiving anti-vascular endothelial growth factor (anti-VEGF) therapy as second-line treatment. The baseline images show an enhancing tumour component in the left temporal lobe and a non-enhancing FLAIR hyperintense component in the left peritrigonal region (d). Six weeks after anti-angiogenesis treatment there is marked decrease of enhancement (b) and some resolution of oedema in the left peritrigonal region (e) but there is now thickening and increased signal intensity of the splenium of the corpus callosum. 16 weeks post treatment the enhancement remains minimal (c) but there has been a further increase in the non-enhancing infiltrative tumour in the splenium of the corpus callosum and also around the frontal horn of the left lateral ventricle. (f) These appearances are typical for 'pseudoresponse' with progression of the non-enhancing tumour components.

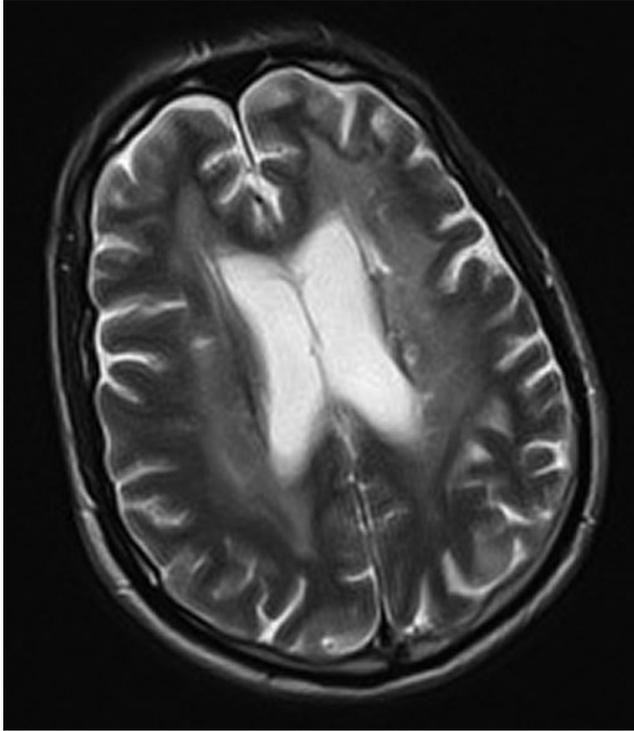

(Chapters 19 and 20), with bilateral, typically symmetrical white matter lesions of low density on CT and T2-hyperintense on MRI (Figure 21.18). These are most commonly seen following methotrexate, even when given alone. In acute methotrexate encephalopathy, abnormalities can be undetectable on T2 images and only become apparent on DWI and ADC maps (Figure 21.20).

### Multidisciplinary management of brain tumours

The optimal management of CNS tumours requires a multidisciplinary approach incorporating the disciplines of clinical neurology, neuroradiology, neuropathology, neurosurgery,

radiotherapy, medical oncology, specialist nursing, general practice and palliative care. Multi-disciplinary working is essential to improve both outcome and experience for these patients, to provide access to specialist services through close collaboration, to recruit patients into clinical trials and to standardise management across regions. The ideal model of service provision promotes a unified care pathway, incorporating medical, psychological, supportive and palliative care for patients and carers. Within the last decade a further dimension has been clearly defined – an approach that unites these disciplines into therapy that is focused on improving not just survival but also the quality of life, with real involvement of both patient and carers in the therapeutic process. There are decisions to be made about

treatment for diagnoses of the utmost gravity. One significant advance, sometimes painful to all, is to discuss frankly the prognosis, the limited choice of therapy and the uncertain but often dismal outlook in many a case.

**Figure 21.18** Radiation-induced leukoencephalopathy. Axial T2 image of patient treated with radiotherapy for frontal oligodendroglioma who developed progressive cognitive decline 1 year after radiotherapy treatment. MRI shows confluent periventricular high signal change and ventricular dilatation.

### Improving outcome and quality of life

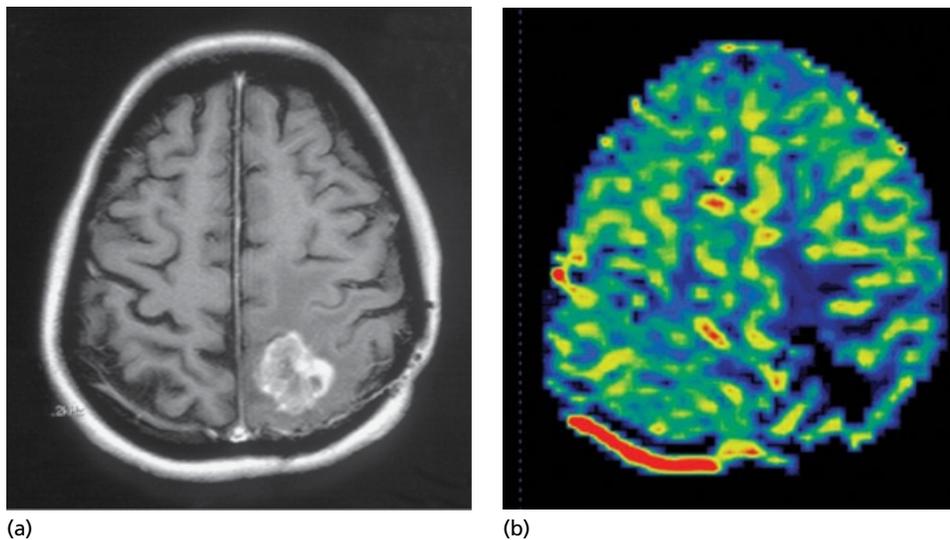

The impact of a diagnosis of a brain tumour upon a person's life is profound and multi-faceted. Patients experience both physical and cognitive effects of the tumour and side effects of treatment. They and their carers have to cope with the emotional impact and psychological effects of living with a life-threatening illness. The diagnosis is likely to be the major life event to date and to colour every aspect of the remaining months or years. Cognitive deficits of memory, speech and language, behavioural changes and physical decline combine to produce a formidable burden. When cognitive problems are prominent, recovery from or preservation of cognitive function has been shown to be, in the main, more important to patients than loss of physical function. To plan treatment and gain consent from patients with cognitive impairment is difficult. Progressive cognitive decline presents a continuing challenge for patients, carers and all involved in providing care.

Quality of life can be enhanced by skilled key workers, good communication with patients and carers, access to high-quality information, specialist rehabilitation, supportive and palliative care. Above all, patient and carer need a central point of contact and a plan for action in emergencies and for intercurrent problems. The development of charitable support networks has helped towards providing non-hospital based support for patients, families and carers.

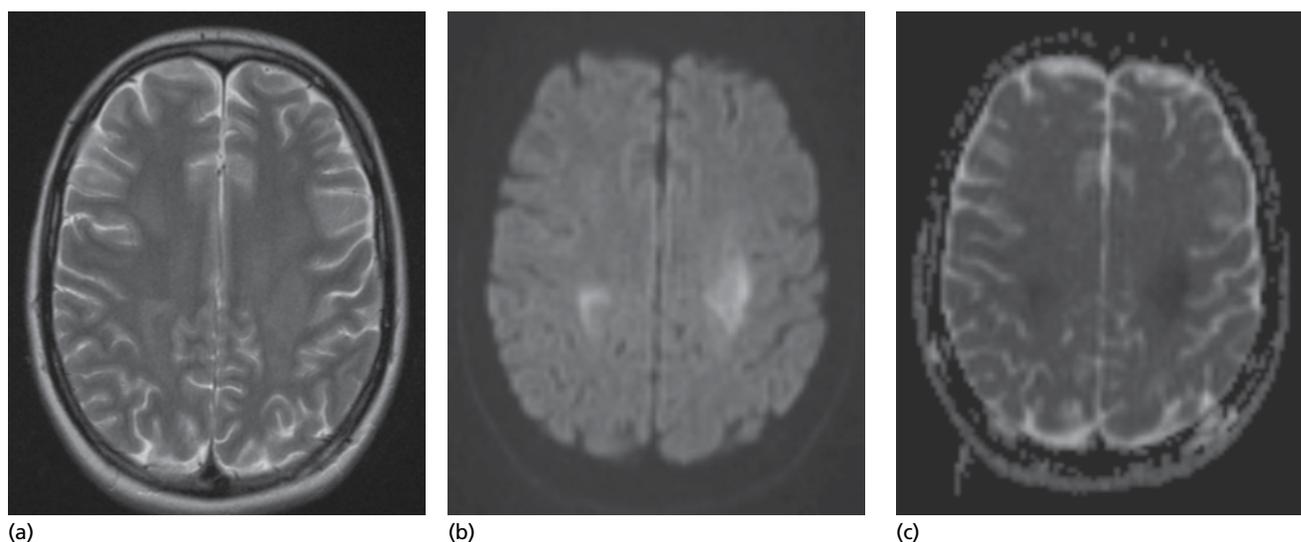

It is often the neuro-oncology clinical nurse specialist who has a primary role in providing information, advice and support to patients and carers at the time of diagnosis, during treatment and disease progression and who facilitates continuity of care across the disciplines involved.

### Surgical management

Surgery remains the mainstay of brain tumour management, providing stereotactic biopsy, open craniotomy and tumour resection in some patients. The aims are to obtain the histological diagnosis, relieve mass effect and improve focal deficits, with an ultimate

**Figure 21.19** Radiation necrosis following radiotherapy 2 years previously for a high-grade glioma. (a) T1-weighted post gadolinium shows typical appearances of irregular contrast enhancement and central necrosis suggestive of tumour recurrence. (b) rCBV map shows mass has a decreased blood volume compared with normal white matter and appears dark, in keeping with radiation necrosis. A recurrent high-grade glioma is likely to have shown an elevated rCBV.

**Figure 21.20** Methotrexate encephalopathy. (a) T2 MR in a 6-year-old child following intrathecal methotrexate for acute lymphoblastic leukaemia (ALL) shows very subtle signal increase in parietal white matter. (b) Diffusion-weighted images show much more conspicuous increase of signal intensity in the posterior part of the centrum semiovale. (c) ADC map confirms restricted diffusion in the posterior white matter, a feature of methotrexate toxicity, potentially reversible.

curative goal in selected cases. Technological advances such as neuro-navigation guided biopsy and resection, awake craniotomies with neurophysiological monitoring, cortical mapping, microsurgical techniques, and intra-operative real-time imaging have made some impact on morbidity and mortality. However, more often than not, radical surgery for highly malignant tumours is inappropriate, as the survival benefit over biopsy and adjuvant therapy is modest in elderly patients with poor performance status, who make up the majority of patients with malignant brain tumours.

### General principles

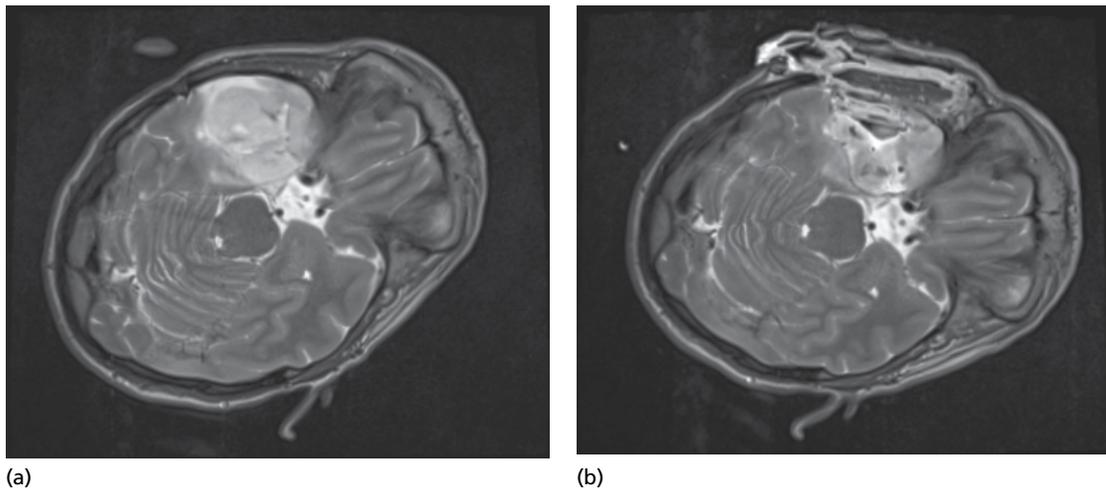

The neurosurgical techniques used for brain tumours include image-directed biopsy, either by frame-based, stereotactic methods or by frameless methods using neuro-navigation techniques, with craniotomy for partial or gross total tumour resection. In addition, specific subspecialty tumour surgery include skull base, pituitary and sellar tumours, which have all benefited from use of neuro-endoscopy and allowed for extensive operative techniques to be converted to minimally invasive surgery, with significantly lower morbidity and mortality.

With all tumours, total macroscopic excision is the surgical aim, but this is only realistic in a limited proportion, given the high eloquence of brain structure. Tumours frequently either infiltrate eloquent brain anatomy or are intimately involved with sensitive anatomical structures such as the optic nerve, cavernous sinus or the petro-clival region. Complete resection is commonly possible with extra-axial tumours, in particular meningiomas or sometimes metastatic tumours, but rarely possible with intrinsic tumours. The most difficult of this category are the low-grade gliomas, given the extensive invasive nature often into eloquent cortical structures. Tumours of the middle and posterior skull base require highly specialised surgical avenues such as trans-oral, maxillotomy, retro- or trans-labyrinthine routes to make access possible, while avoiding injury to critical neural structures, such as specific cranial nerves and sensitive vascular anatomy.

### Surgical instrumentation and methods

**Stereotactic frames** A large variety of CT and MRI compatible rigid stereotactic frames are available which can be applied to the patient's head for biopsy by pins affixed to the outer table of the skull. Frame-based stereotactic biopsy renders an accuracy of about 1–2 mm, with the most accuracy achieved for deep-seated lesions versus more superficial lesions. Frame-based stereotactic biopsy can be used to obtain a histopathological diagnosis of all regions of the brain, including deep structures such as the thalamus, basal ganglia or brainstem. The complication rate associated with stereotactic biopsy is low; the most major complications are a consequence of bleeding. Overall risks include a 1% risk of death, 5% risk of minor reversible morbidity and 2–3% risk of serious morbidity. The method generally achieves a definite histological diagnosis in 95% of cases. The final diagnosis is significantly different from the initial neuroradiological diagnosis in 5–10%.

**Neuro-navigation and frameless stereotaxy** In the past decade stereotactic biopsy techniques have gradually been replaced by frameless stereotaxy, a technique that employs neuro-navigation technology. Neuro-navigation involves computer-assisted technologies to guide or navigate the neurosurgical approach. Using mathematical coordinates to identify structures within a defined space (e.g. the skull), neuro-navigation allows highly accurate localisation of structures. This is achieved by real-time fusion of pre-operative imaging of the patient's brain, using either CT or MRI, which includes fiducial markers on the patient's scalp to define a coordinate system of the desired space. The patient can be registered to the neuro-navigation system pre-operatively; this provides the surgeon with the ability to relate the position of a real surgical instrument within the surgeon's hand or microscope's focal point to the location of the imaged pathology, updated in real time. The neurosurgeon is able to create a three-dimensional model that can be manipulated to examine and explore the location of the tumour in relation to normal anatomical structures, in addition to examine alternative surgical approaches prior to the definitive surgery. Virtual images are displayed on a

**Figure 21.21** Intraoperative MRI. (a) T2 images of patient with right temporal tumour before and (b) after resection, while the patient is still anaesthetised. There has been an extensive resection with a small triangle of signal change remaining medially.

monitor visible to the surgeon, who can interact with this image with a sterile pointer during the operation. Regions of exposed brain can be touched by the pointer and the position in space correlated with the position of the tumour shown on the peri-operative scan. This method is slightly less spatially accurate than frame-based stereotaxy, within the region of 3 mm variation, particularly as there is inevitably some brain shift when the skull and dura are opened; the overall accuracy is within 10 mm.

Neuro-navigation can be used both for biopsy and gross tumour resection. It has been shown to be efficient for biopsy, except for deep small targets in the brain. For tumour resection, its main advantage is being able to tailor and fashion the craniotomy and surgical approach for individual tumours, providing increased confidence, and giving a rough guide to determine extent of tumour resection intra-operatively. Operative mortality is about 2%, with serious morbidity of about 5–6% and minor morbidity of a further 5–6%. The limitations of neuro-navigation are that it is based on previously acquired imaging datasets; the system does not allow for correction of brain shift, a result of dura being opened, pressure changes occurring within intracranial space, CSF leaking out and brain oedema. In an attempt to eliminate the short-comings of neuro-navigation systems, real-time imaging modalities have evolved, such as intra-operative diagnostic ultrasound and intra-operative MRI.

**Intra-operative diagnostic ultrasound** Ultrasound has been used in neurosurgery for over two decades. Precise localisation of lesions in the brain is a challenge, and methods to minimise and eliminate exploration and dissection in the brain parenchyma are constantly being sought. Pre-operative CT and MRI images provide ideal road-maps for surgical planning; however, they are limited in their ability to determine the precise location of lesions intra-operatively, in particular deep lesions beneath the cortical surface. Real-time images obtained from intra-operative ultrasound provide dynamic information on localisation, in depth, orientation, mass effect and presence of cystic components; ultrasound can facilitate cyst drainage and alleviate pressure prior to tumour excision. Ultrasound can also be used to confirm extent of tumour resection.

**Intra-operative MRI** Interventional MRI (iMRI) is a real-time intra-operative adjunct for guiding surgery without ionising radiation,

providing exquisitely detailed imaging compared to CT. Surgical navigation can be repeatedly updated by intra-operative and dynamic images of the brain and lesion while surgery is proceeding, and account for the changes that occur as a result of CSF leakage, oedema and hemorrhage. The main advantage of iMRI is that it allows the surgeon to identify the extent of residual tumour that can still be resected (Figure 21.21). The use of physiological iMRI to understand more clearly the pathology of brain tumours is promising. However, iMRI suites are only available in very few neurosurgical centres. Its real value as an operative adjunct has yet to be established.

**Neuro-endoscopy** Technological advances in neuro-endoscopy, improved optics, video and camera systems have made neuro-endoscopy and minimally invasive neurosurgery a routine technique not only for pituitary but also for skull base tumours. Large and extensive exposures are required for upper cervical spine and clivus lesions, through trans-oral or ‘open door’ maxillotomy approaches and resection of the odontoid which have in the past been associated with significant morbidity. These areas can now be approached using endoscopic trans-nasal approaches. The endoscopic approach possesses some inherent advantages, including decreased exposure to oral flora and excellent visualisation, while at the same time minimising prolonged retraction. Most surgeons who incorporate neuro-endoscopy and minimally invasive surgery do so in close collaboration with their head and neck, and ENT colleagues.

### Radiotherapy

The benefits of surgical treatment for the majority of intrinsic malignant tumours are limited by their aggressive biological behaviour together with considerations surrounding neurological deficits following removal of tumour tissue from infiltrated normal brain or spinal cord. Many CNS tumours, even benign WHO Grade I meningiomas, may recur many years after removal particularly if initial resection is incomplete. For these reasons, radiotherapy and chemotherapy play an important part in the overall management of primary CNS tumours.

### Radiotherapy planning

**Conformal radiotherapy** Radiotherapy planning based on CT and MRI is now the standard approach to primary brain tumour treatment. CT-based planning allows accurate tumour

dose localisation and relative sparing of normal brain. The patient is immobilised in a plastic mask. CT slices (0.3 cm) are obtained in the treatment position. MRI data from diagnostic studies are then fused with CT data, to define the precise volumes to be treated to high dose. The patient is usually treated in the supine position. This position is most easily reproducible and the most comfortable. The field arrangement is chosen to encompass the tumour volume with maximal sparing of surrounding brain, usually utilising 2–3 fixed fields. Using modern conformal radiotherapy techniques, scanning and planning software permits reconstruction of three-dimensional anatomy. The tumour and target volumes are visualised from the plane of the incoming radiation beams. Using these data the radiotherapist can then design shielding that conforms closely to the tumour volume, giving a steep dose gradient between tumour and normal brain. Total radiation doses given are usually in the range 45–60 Gy, with typical daily fractions of 1.8–2 Gy.

**Stereotactic radiotherapy** A refinement of conventional brain radiotherapy is to combine conformal planning with stereotactic techniques for both immobilisation and tumour localisation. This enables a further reduction in the treatment volume because of increased accuracy of tumour localisation; relocation error is often reduced to below 1 mm. Relocatable stereotactic frames permit the dose to be given in a conventionally fractionated regime. These techniques are used more in the treatment of benign brain tumours, such as pituitary adenomas, meningiomas and vestibular schwannomas, with the aim of reducing the amount of normal brain tissue in the high dose treatment volume.

**Radiosurgery** Radiosurgery harnesses image-directed surgical planning with focused high-dose radiation delivery to the selected target. In this sense it is more akin to surgical ablation than to radiotherapy. The technique is used increasingly for cerebral metastases and for relatively inaccessible skull base tumours such as chordomas, meningiomas and vestibular schwannomas.

**Intensity modulated radiotherapy** Intensity modulated radiotherapy (IMRT) enables the radiation dose to be modified throughout the treatment volume. This permits treatment of concave volumes, sparing of nearby critical structures (such as the optic pathways), and reduction of dose to areas such as the temporal lobes. This sparing may reduce the late side-effects of radiation when treating benign brain tumours, and allow dose escalation when treating malignant brain tumours.

**Spinal radiotherapy** For spinal tumour masses, developments in radiotherapy planning have improved accurate delineation using MRI data superimposed on CT scans in the proposed treatment position. In most cases, MRI will be used to define the target lesion and fields designed to encompass this volume with 3–5 cm margins. Attention should be paid to anatomical influences on tumour spread, for example when treating disease in the conus medullaris the anatomical boundary to spread is at S3. Treating below this level will only add toxicity. In most cases, treatment fields do not need to extend further laterally than the lateral processes of the vertebral bodies (to ensure adequate coverage of the exiting nerve roots), that is, some 2 cm lateral to the border of the vertebral body. Patient positioning and immobilisation for treatment are important to prevent dose inaccuracies or inhomogeneity. Radiotherapy doses to the ovaries and uterus in young female patients need to be reduced as

far as possible to minimise effects on fertility. Three-dimensional conformal planning with appropriate shielding will help with this. It is generally safe to irradiate limited volumes of spinal cord to doses of 50–55 Gy. Animal data suggest a relatively small effect of volume once treatment lengths of 8 mm are exceeded. Estimates of the total dose to give 5% toxicity rate at 5 years (TD 5/5) using 2 Gy fractions are between 57 and 61 Gy; previously damaged spinal cord probably has a lower radiation tolerance.

### Radiation neurotoxicity

Radiotherapy-induced neurotoxicity is seen commonly following treatment of even relatively benign CNS tumours, both in children and adults. Radiation damage to the brain and spinal cord is categorised according to the time at which the clinical features develop. Acute, early-delayed and late-delayed radiation effects must be considered. As a general rule, acute and early-delayed toxicity are reversible and improve spontaneously and/or with steroids while late-delayed toxicity is irreversible.

**Diagnosis** Damaging effects of radiotherapy, suspected from symptoms and signs should only be ascribed to it if the following conditions are met:

- Anatomy of the clinical signs corresponds to the radiation portals.
- Dosage and fractionation are sufficient to damage that particular area of the nervous system.
- Time elapsed between radiotherapy and development of the neurological syndrome is compatible with known effects of radiotherapy on the nervous system.
- Tumour recurrence has been excluded, particularly in the brain where clinical and radiological features of radiotherapy necrosis can be hard to differentiate.
- Other differential diagnoses (e.g. spinal intramedullary metastasis, paraneoplastic syndromes, CNS infection and malignant meningitis) have been excluded.

**Acute toxicity** Common acute effects include alopecia, scalp erythema, fatigue, headache, nausea and sometimes vomiting. Neuronal toxicity is thought to underlie the feelings of intense lethargy seen commonly within 2 weeks of starting treatment. The usual daily radiation dose is 1.8–2 Gy.

**Early-delayed toxicity** Acute toxicity can be followed by a longer period of lethargy and exhaustion ('somnia syndrome') lasting up to 3 months after treatment, known as early-delayed toxicity. Worsening of pre-existing deficits and seizures can occur. This condition is usually reversible with steroids but improvement is sometimes slow, over many weeks.

**Late-delayed toxicity** Late-delayed effects include cognitive decline resulting from leukoencephalopathy, vascular damage and radiation necrosis. These late-delayed effects become apparent between 6 months and even up to 20 years following treatment. Other late effects include changes in taste, hearing and vestibular function. Radiation necrosis, usually apparent between 6 and 24 months after radiation, can mimic tumour recurrence both clinically and radiologically. The estimated risk of brain necrosis is 5% following 64 Gy; some data suggest a lower threshold dose of 50–58 Gy. Modern imaging techniques such as PWI and DWI MRI sequences and fluorodeoxyglucose positron emission tomography (FDG PET) scanning can help distinguish between necrosis and tumour recurrence.

ADC and rCBV measurements are also of some value (see Imaging the effects of radiotherapy).

#### Other complications of cranial radiotherapy

**Cataract, chiasm, pituitary and skin** The lens is commonly treated to near-tolerance in frontal tumours, with a substantial risk of cataract development. Other late toxicity may become relevant if other normal structures are included in the high radiation dose volume (e.g. the optic chiasm, pituitary and skin). These toxicities can be avoided to some extent by planning and accurate shielding of normal structures. In some instances, moderate dose irradiation will be unavoidable and patients must be warned of possible consequences.

**Secondary tumours** Radiotherapy also can cause second brain and exceptionally spinal tumours. Meningiomas, gliomas, schwannomas and cavernomas can develop many years after treatment.

**Vascular disease** Radiotherapy can lead to accelerated large vessel arterial disease, most commonly seen in young adults presenting with internal carotid artery occlusion and *moya-moya* disease following treatment in childhood for optic nerve or hypothalamic gliomas.

**Myelopathy, radiculopathy and plexopathy** Myelopathy may ensue in the months following radiotherapy treatment of head and neck cancer. Radiotherapy to the cord rarely causes acute toxicity. Radiation myelopathy is usually late-delayed and presents either as a progressive myelopathy or as a lower motor neurone syndrome. This is most commonly seen in patients with Hodgkin's disease given mantle radiotherapy. Some patients seem especially susceptible to myelotoxic effects of radiotherapy and develop a severe cord syndrome after radiation doses well below usual tolerance. Patients treated with axillary radiotherapy for breast cancer may develop a late-delayed radiation brachial plexopathy, distinguished from tumour recurrence by the absence of pain and sometimes the presence of myokymic discharges on electromyography.

## High-grade gliomas

The most common primary brain tumours are the high-grade glioma, which are either WHO Grade III anaplastic gliomas (astrocytoma, oligodendroglioma or oligoastrocytoma) or WHO Grade IV, glioblastoma, GBM or gliosarcoma. Of these, GBM is the most frequent malignant primary CNS tumour, accounting for about 30% of all primary brain tumours and 60% of all gliomas. Despite aggressive multi-modality treatment, median survival times are poor. GBM tends to occur in older people (peak incidence 60–70 years) and arise in the cerebral hemispheres, most commonly temporal, parietal and frontal lobes. Histological diagnosis is mandatory, except in situations where the condition of the patient is so poor that oncological treatment is not warranted and palliative care is all that can be offered. In all other situations where MRI is suggestive of a high-grade glioma, the main differential is a metastasis or a primary CNS lymphoma; histological diagnosis is essential, to provide clear prognostic information and tissue for molecular analysis.

### Pathology

#### Anaplastic astrocytoma

Anaplastic astrocytomas (WHO Grade III) show an infiltrative behaviour with focal or generalised increase in proliferative potential.

These tumours may progress from a low-grade astrocytoma but they are also seen at first biopsy without evidence for an underlying low-grade lesion. They have an intrinsic propensity to progress to GBM. They are characterised histologically by increased cellularity, higher mitotic activity and more distinct nuclear atypia than WHO Grade II gliomas, but there is no necrosis or vascular proliferation as seen with GBM.

#### Glioblastoma

Typical histological features of GBM include poorly differentiated, often highly pleomorphic glial tumour cells with marked nuclear atypia and brisk mitotic activity. Necrosis and/or microvascular proliferation are essential for diagnosis and in most cases both are present. GBM can vary considerably in their histological appearance, ranging from highly cellular and monotonous to very variable and heterogeneous. This may present a challenge when histological diagnosis is based on small needle biopsies.

**Molecular genetics** Genetic studies suggest that primary GBM (*de novo*) and secondary GBM (evolving from low-grade gliomas by multi-step progression) are different entities. Primary GBMs arise in older patients and are strongly associated with loss of chromosome 10q, gain in chromosome 7, amplification and over-expression of the epidermal growth factor receptor gene (*EGFR*), and show increased murine double minute 2 promoter (*MDM2*) oncogene activity. In contrast, secondary GBMs arise from previous low-grade gliomas, occur in younger individuals and are associated with early p53 loss, *IDH* mutations and over-expression of platelet-derived growth factor gene (*PDGF*).

The identification of *IDH1/2* mutations has been a breakthrough because these mutations are frequent in secondary glioblastomas (80%) but very rare in primary glioblastomas (5%). Primary and secondary glioblastomas with *IDH1* mutations have similar gene expression profiles. These observations suggest that primary glioblastomas with *IDH1/2* mutations have progressed from less malignant precursor lesions (low grade or anaplastic astrocytoma) which escaped clinical diagnosis and were thus misclassified as primary.

MGMT promoter methylation has become the most powerful molecular test in malignant gliomas and is predictive for response to alkylating agent chemotherapy in glioblastoma. As a result, the MGMT status has become a parameter for stratification of patients with glioma within clinical trials.

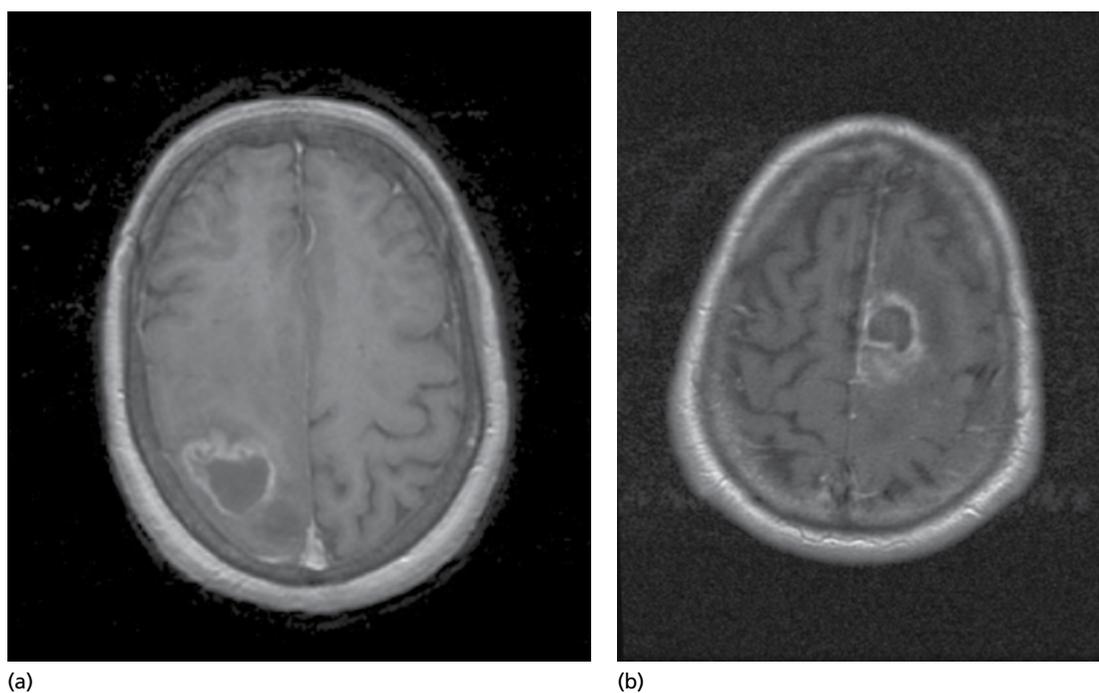

H3 histone family 3A (*H3F3A*) mutations, initially detected in paediatric malignant brainstem glioma (diffuse intrinsic pontine glioma), also occur in young adult GBM and in locations other than brainstem. The frequency has not yet been established but an estimate ranges around 5% of all adult GBM harbouring this alteration.

Telomerase reverse transcriptase (*TERT*) is essential in maintaining telomere length and its activity is pathologically increased in a number of human cancers, including GBM. *TERT* and *IDH* mutations are mutually exclusive in GBM, but co-occur in oligodendrogliomas. Two large studies show conflicting results with regard to *TERT* mutation status and survival, but it is possible that *TERT* may in the future become a useful prognostic marker. Approximately 50% of primary GBM carry a *TERT* promoter mutation.

### Imaging

#### Anaplastic astrocytoma

Anaplastic astrocytomas (WHO Grade III) usually show contrast enhancement and more extensive infiltration of the peri-tumoral

**Figure 21.22** (a) T1-weighted image plus gadolinium MR showing right frontal glioblastoma multiforme with irregular enhancing rim and central area of necrosis, with diffuse hemispheric swelling caused by surrounding vasogenic oedema. (b) Almost identical appearing lesion in left frontal lobe which turned out to be toxoplasma abscess.

tissues than WHO Grade II lesions. They may also be accompanied by vasogenic oedema. In many cases, however, it is not possible to distinguish radiologically between Grade II and Grade III tumours: absence of enhancement does not rule out a high-grade tumour.

### Glioblastoma

As noted earlier, GBM is a poorly differentiated, highly pleomorphic tumour with vascular proliferation and necrosis. Vasogenic oedema and contrast enhancement are more extensive than in anaplastic (WHO Grade III) astrocytomas. Tumour necrosis appears as intra-tumoural areas of approximately CSF signal intensity, frequently surrounded by an irregularly enhancing rim corresponding to regions of active mitosis. Intra-tumoural haemorrhage with T1 hyperintense and T2 hypointense areas contributes to the heterogeneous MR appearance of GBMs. The differential diagnosis includes brain metastases (vasogenic oedema is usually more extensive than in GBM), tumefactive MS, pyogenic abscess, and TB, the latter an important consideration in developing countries (Figure 21.22).

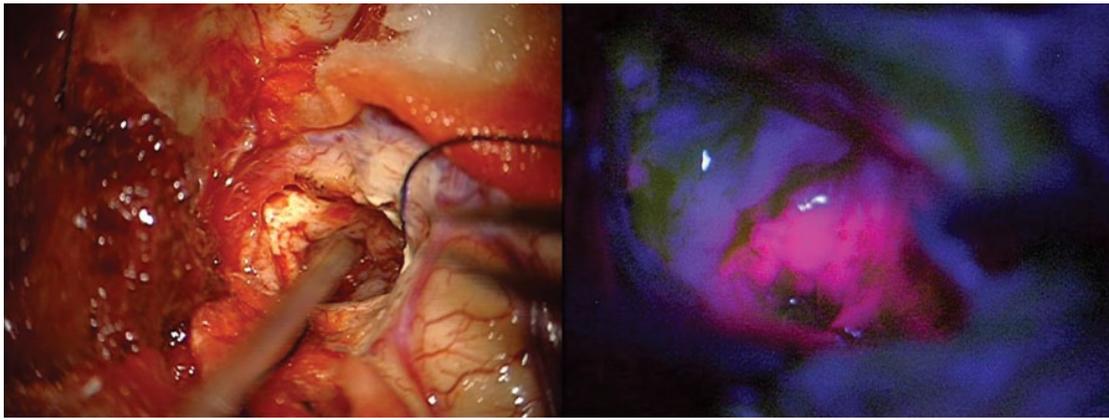

### Surgery

Malignant gliomas infiltrate surrounding normal brain and surgical cure is therefore not possible, even with very extensive resections. Indications for debulking of a tumour are for symptomatic relief of raised intracranial pressure or focal deficits, caused by tumour mass effect and compression of eloquent cortical structures. Invasion of eloquent brain areas is the limiting factor in achieving a complete gross tumour resection. The principle of 'oncological cytoreduction' enhancing the efficacy of adjuvant therapies is invoked in support of macroscopic complete resections and is therefore offered to patients at the better end of the prognostic spectrum (i.e. younger age and higher performance status). There is mounting evidence for survival benefits in patients who have had gross macroscopic

resections. Recently, fluorescence-guided surgery using Gliolan (5-aminolaevulinic acid) has been shown to improve the extent of resection in high-grade gliomas from an estimated 36% to 65% with improvement in progression-free survival at 6 months from 21% to 41%. This is based on the principle that malignant cells take up 5-ALA and are then visible under UV light using a dedicated microscope which circumvents the problems of identifying tumour margins intra-operatively (Figure 21.23). The volume of tumour that could be resected had previously been limited because of the risk of neurological deficits. In general, it is accepted that 80% tumour resection provides oncological advantage by providing cytoreduction and improving response to adjuvant chemo- and radiation therapy. A few centres suggest that resection of 98% is an independent variable associated with longer survival, with an approximate 3-month survival advantage compared to patients with 80% resection. In a small proportion of patients with recurrent disease, a second resection (11%) or a third resection (4%) is performed, again in younger patients with high performance status who have responded well to first line treatment.

### Radiotherapy

The addition of radiotherapy to surgery is standard palliative management for patients with high-grade gliomas. The degree of benefit varies between different prognostic groups; it is typically modest and measured in months. Several studies have demonstrated a dose response to radiation, with improved median survival when fractionated doses of around 60 Gy in 30 daily fractions are given compared to lower doses in the 45 Gy range. No convincing further improvement is apparent when doses are increased above 60 Gy, using either external beam or brachytherapy boost doses. This may be because a potential increase in tumour control is obscured by an increase in early radiation toxicity or because high doses given to a

**Figure 21.23** Intraoperative appearance of glioblastoma multiforme (GBM) in white light and UV light with patient preloaded with 5-aminolaevulinic acid showing 'burning embers' of pink viable tumour cells, not visible in white light.

very localised field do not encompass the whole area at risk for recurrence. For patients in the best prognostic groups with WHO Grade IV gliomas (i.e. those with little deficit), addition of radiotherapy improves survival by 5–6 months but only to a median figure of 9–12 months. In patients with lower than median expected survival, the impact of radiotherapy is even more modest and may be only a matter of weeks. Overall, functional deficit improves in one-third of patients and stabilises the situation, if briefly, in half. In the poorest prognostic groups an alternative approach using shortened course, high-dose palliative radiotherapy regimes is sometimes advocated on the basis that this impinges less on quality of life in the remaining months. When discussing relative risks and benefits of radiotherapy, it is important to take into consideration the limited symptomatic improvement that can be anticipated, the rarity of a prolonged response and the lethargy, hair loss and risks of neurological deterioration resulting from radiation. Very occasionally, radiosurgery (highly focused radiotherapy) using either linear accelerator or gamma knife machines are used for small nodular recurrences.

### Chemoradiation

In GBM, temozolomide chemotherapy given concurrently with radiotherapy and then adjuvantly for a further 6 months has been shown to increase survival when compared with radiotherapy alone. High quality trial data now support the use of daily low-dose temozolomide ( $75 \text{ mg/m}^2$ ) throughout a 6-week course of radiotherapy followed by monthly 5-day courses ( $150\text{--}200 \text{ mg/m}^2$ ) for 6 months. Overall median survival, although modest, increased from 12.1 to 14.6 months; however, 2-year survival increased from 10% to 26% and 5-year survival from 2% to 10%. The addition of chemotherapy produced some increased toxicity, although mild with no measurable impact on quality of life. An important issue was a high incidence of *Pneumocystis carinii* pneumonia during concomitant treatment necessitating prophylaxis with co-trimoxazole or pentamidine. This regime has rapidly become standard treatment for good performance patients with GBM who are considered to be able to tolerate combined treatment. The benefits occur in all clinical prognostic subgroups, including patients aged 60–70 years, with methylation of the MGMT promoter the strongest predictor for outcome and additional survival from the additional temozolomide chemotherapy.

Grade III tumours have a better prognosis than WHO Grade IV and therefore may experience late-delayed toxicity from combined

chemo-radiation that offsets any potential survival benefits. A trial (BR14) is currently underway to assess whether chemoradiation with either concomitant temozolomide, adjuvant temozolomide or both are superior to radiation alone in anaplastic gliomas without the 1p19q deletion, typically seen in anaplastic oligodendrogliomas (which carry a much better prognosis irrespective of treatment modality and timing of chemotherapy). An additional question is whether molecular analysis will enable identification of patients with glioma who are more likely to respond to temozolomide. The mechanism of cytotoxicity of temozolomide relies on DNA base damage that can be repaired by a specific enzyme, *O*<sup>6</sup>-methylguanine-DNA methyltransferase (MGMT). MGMT is responsible for removal of *O*<sup>6</sup>-alkylguanine from DNA induced by alkylating mutagens/carcinogens. Levels of MGMT within tumour cells vary between patients with GBM and depend on whether the MGMT promoter sequence is methylated (and therefore inactivated). Data suggest that patients with high levels of MGMT repair enzymes are unlikely to benefit from the addition of temozolomide chemotherapy. Molecular and chromosomal analysis of all high-grade gliomas is likely to become a standard part of management.

### Chemotherapy

The place of chemotherapy in first line treatment of high-grade gliomas has been assessed in many studies since the 1960s. These have included regimes in which chemotherapy is administered adjuvantly (following surgery and radiotherapy) or neoadjuvantly (prior to radiotherapy). Few have demonstrated a significant benefit in terms of survival compared with surgery and radiotherapy alone. The MRC Glioma Meta-analysis Group concluded that adjuvant chemotherapy given at or around the time of surgery and radiotherapy had a marginal benefit of 6% absolute improved survival at 1 year. The chemotherapy regimes were most commonly procarbazine, CCNU (lomustine) with vincristine (PCV), the most active combination of traditional chemotherapy in this disease. Common UK practice, prior to temozolomide, was to give chemotherapy at first relapse rather than around the time of initial radiotherapy.

### Relapsed high-grade gliomas

Chemotherapy was until recently used almost exclusively in the United Kingdom at the time of relapse of high-grade gliomas. The standard approach in the United Kingdom has been the PCV

combination regime in 6-weekly cycles. Response rates, meaning here temporary symptomatic benefit, are 20–30%. A recent trial has shown that PCV is equivalent in efficacy and tolerability to temozolomide. Radiological improvement and clinical response are associated with increased time to further progression. However, there are no data that suggest significant improvement in overall survival for the majority of patients. Toxicities from this regime include bone marrow suppression, liver function test abnormalities, neuropathy, skin rash and gastrointestinal upset. In most patients the regime is well tolerated; if it is not, it is rarely appropriate to continue in view of the poor response rates. Optimal chemotherapy for patients who have previously received adjuvant treatment with temozolomide is also not resolved. This situation is difficult because of the relative paucity of agents with well-documented response rates in this situation. An alternative approach if the recurrence is operable is to debulk and insert carmustine (Gliadel) wafers into the resection cavity. This tends to avoid systemic side effects but may cause cerebral oedema and poor wound healing. Other potentially useful agents include carboplatin and taxol. Novel agents are being assessed, including antiangiogenic agents. The most interesting agent, bevacizumab (Avastin), has now been tested in two randomised controlled trials in newly diagnosed GBM and has shown a modest improvement in progression-free survival but not overall survival. Because of its antiangiogenic properties, it produces dramatic radiological responses with reduction in contrast enhancement and oedema and reduces steroid requirements, but does not prevent tumour cell migration and infiltration (Figure 21.7).

### Anaplastic oligodendrogliomas

Anaplastic oligodendrogliomas are known to have a better prognosis than other high-grade gliomas. There is clear evidence for an association between deletion of chromosomes 1p and 19q and response to either chemotherapy or radiotherapy. Because many older studies did not distinguish this subgroup, these treatment-sensitive patients were probably an important source of heterogeneity in randomised trials. Current data suggest that response rates to nitrosurea-based chemotherapy in anaplastic oligodendrogliomas are 60–70%. This is compared to figures of 20–30% for other high-grade gliomas and reflects the fact that about 70% of anaplastic oligodendrogliomas have loss of heterozygosity (LOH) at chromosomes 1p/19q associated with 100% chemosensitivity. The exact relationship between these chromosomal losses and the mechanisms underlying the chemo-sensitivity is unclear. Despite this, large clinical studies were not able initially to demonstrate a survival benefit for either neoadjuvant or adjuvant chemotherapy in this patient group when compared with patients given their first chemotherapy at relapse. A more recent review of long-term follow-up data looking at patients with anaplastic oligodendrogliomas and oligoastrocytomas have now shown a survival benefit after 12 years but only in patients with co-deletion of 1p and 19q chromosomes treated with adjuvant PCV chemotherapy after radiotherapy compared with radiotherapy alone. However, the toxicity of PCV is not to be underestimated and only 30% of patients managed to complete the six cycles of adjuvant chemotherapy as originally prescribed. Current practice for anaplastic oligodendroglioma is therefore to assess chromosome loss as a prognostic rather than a predictive factor. Based on these data, there is now more enthusiasm for adjuvant PCV in 1p19q deleted anaplastic oligodendrogliomas for patients fit enough to tolerate this extra treatment.

## Low-grade gliomas

Low-grade gliomas are a heterogeneous group of slow-growing primary brain tumours (WHO Grades I and II) and account for 15–20–30% of all gliomas. They occur in both children and adults, with a peak incidence in the second and third decades of life. The most common low-grade gliomas are pilocytic astrocytomas (WHO Grade I) and diffuse astrocytomas/oligodendrogliomas and oligoastrocytomas (WHO Grade II). Pilocytic astrocytomas are mostly seen in children and young adults, and are associated with a 90% cure rate with surgery and/or radiotherapy. In contrast, Grade II gliomas are less histologically stable than Grade I tumours, with the majority transforming to higher grades over time. Median survival varies according to histology – the prognosis for WHO Grade I tumours is so good that median survival is never reached while for WHO Grade II tumours, it varies from 5–7 years for astrocytic tumours to 10–15 years for oligodendroglial tumours.

### Pathology

#### Pilocytic astrocytoma

Pilocytic astrocytomas are composed of bipolar cells with long hairlike GFAP-positive processes, leading to the term pilocytic. Some pilocytic astrocytomas may be more fibrillary and dense in composition. Rosenthal fibres, eosinophilic granular bodies and microcysts are often present. Myxoid foci and oligodendroglia-like cells may also be present, though non-specific. Long-standing lesions may show haemosiderin-laden macrophages and calcifications.

**Molecular genetics** The *KIAA:BRAF* fusion in pilocytic astrocytomas has been detected across all age groups and in various tumour locations, including cerebellum, cerebral hemispheres, hypothalamus, optic nerve and brainstem. *BRAF* duplication/fusion is more frequently present in cerebellar pilocytic astrocytomas. It is a very rare event in diffusely infiltrating gliomas, which may rarely contain *BRAF* point mutations.

#### Diffuse astrocytoma

Diffuse astrocytomas (WHO Grade II) tend to develop within the cerebral hemispheres, especially in the frontal and temporal lobes. These account for 10–15% of all gliomas and occur predominantly in adults. This tumour is further subdivided into fibrillary, gemistocytic (i.e. large swollen cytoplasm) and the very rare protoplasmic variant. They are slowly growing tumours that typically affect young adults and have an intrinsic tendency to progress into higher grades (WHO Grades III and IV). This process, known as malignant transformation, distinguishes WHO Grade II tumours from WHO Grade I tumours with more stable histology and a considerably better prognosis.

The characteristic morphology of the cells of WHO Grade II astrocytomas resembles well-differentiated astrocytes, embedded in a fibrillary or microcystic matrix. Mitotic activity is rarely present and there is no microvascular proliferation or necrosis. The gemistocytic astrocytoma is a more aggressive subtype and is particularly prone to progress to high-grade glioma.

**Molecular genetics of diffuse and anaplastic astrocytomas** Molecular classification of low-grade gliomas is increasing in importance, mainly because the histological diagnosis of diffuse gliomas can be difficult in a substantial number of cases, with marked interobserver variability. Diffuse astrocytomas show mutations at the codon 132 in the isocitrate dehydrogenase 1 (*IDH1*) genes, primarily of the *IDH1R132H* type, and less commonly in the *IDH2* gene.

These mutations occur early, with a high frequency, in WHO Grade II and III astrocytic and oligodendroglial tumours and in secondary GBMs, which develop from astrocytomas. *IDH* mutations in gliomas are early, if not initiating events in their pathogenesis, and are associated with several clinically relevant parameters including patient age, histopathological diagnosis, combined 1p/19q deletion, TP53 mutation, MGMT promoter hypermethylation and patient survival. Another useful biomarker is *ATRX* (alpha-thalassemia/mental retardation syndrome X-linked), which when lost can aid in the refinement of the diagnosis of *IDH* mutant astrocytomas, and may be used to delineate these tumours from oligoastrocytomas and oligodendrogliomas. *ATRX* loss and *IDH* mutant anaplastic astrocytomas have a favourable prognosis compared to anaplastic astrocytomas with *IDH* mutation only. Overall, the integration of genomic data has delineated three molecular classes of LGG: those with *IDH* mutation and either 1p/19q codeletion (best prognosis); those with *IDH* mutation and *TP53* mutation (intermediate prognosis); and those with an *IDH* mutation that had the worst prognosis as they were molecularly and clinically similar to glioblastoma.

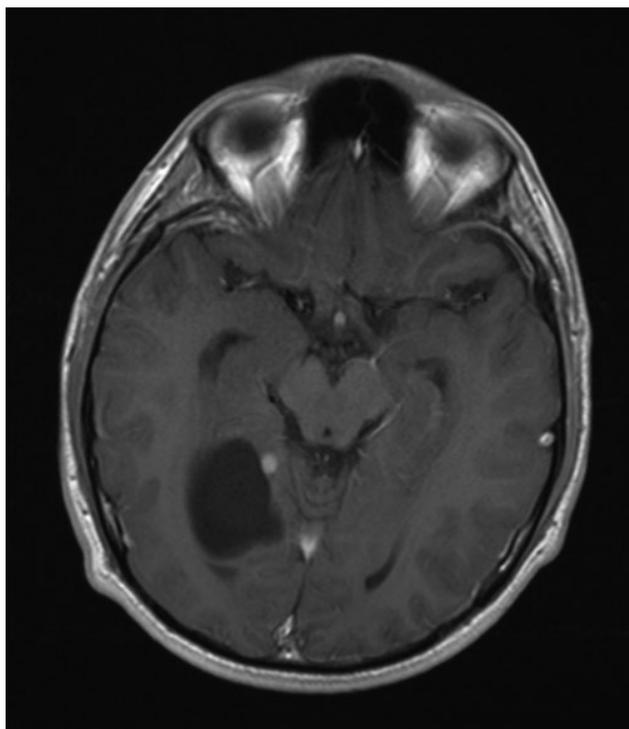

### Oligodendroglioma

Oligodendrogliomas (WHO Grades II and III) are diffusely infiltrating neoplasms found almost exclusively in the cerebral hemispheres, most commonly in the frontal lobes and typically involving subcortical white matter and cortex. Despite their name, their origin from oligodendrocytes or their precursors has not been proven. They comprise a continuous spectrum ranging from well-differentiated tumours to highly malignant neoplasms. The WHO grading system distinguishes two malignancy grades. Grade II oligodendrogliomas are slowly growing, well-defined hemispheric tumours composed of rounded homogeneous nuclei. Paraffin embedding results in a reproducible artefact, the formation of clear cytoplasm around the nucleus giving rise to a perinuclear halo, often referred to as fried egg or honeycomb cells. Further typical features are branching capillaries and calcification. Grade III oligodendrogliomas show increased tumour cell density, mitotic activity, presence of microvascular proliferation and necrosis. These are graded WHO Grade III rather than Grade IV.

**Molecular genetics of oligodendroglioma** Oligodendrogliomas carry *IDH1* or *IDH2* mutations, and are characterised by the codeletion of chromosomal arms 1p/19q, in the past often also referred to as combined loss of chromosomal arms (LOH). 1p19q codeletions are frequent in oligodendrogliomas (50–70%), less common in oligoastrocytomas (30–50%) and rare in astrocytomas (0–15%). Numerous studies on this genotype–phenotype correlation have subsequently shown that 1p/19q co-deletion is related to survival. This improved prognosis (and response to radiotherapy and chemotherapy) is present whether observed at initial diagnosis or at recurrence. Oligodendrogliomas with 1p/19q co-deletion also tend to progress more slowly at recurrence. *TP53* mutations are the most frequent in astrocytomas (50–90%) and oligoastrocytomas (40–50%) but are uncommon in oligodendrogliomas (5–10%).

### Oligoastrocytoma

Some gliomas have intermixtures of astrocytic and oligodendroglial cellular elements and are appropriately called oligoastrocytomas or mixed gliomas. Like astrocytomas and oligodendrogliomas, they have a propensity to transform into high-grade gliomas. However,

**Figure 21.24** Pilocytic astrocytoma. Contrast-enhanced T1 image of an adult patient with a pilocytic astrocytoma showing a cystic lesion with a small enhancing mural nodule anteromedially.

this entity, based on morphological assessment, is likely to be phased out, as the combination of the *IDH* mutation with *ATRX* loss defines astrocytomas, and the combined *IDH* mutation and 1p/19q co-deletion defines oligodendrogliomas (i.e. *ATRX* loss and 1p/19q co-deletion are almost always mutually exclusive).

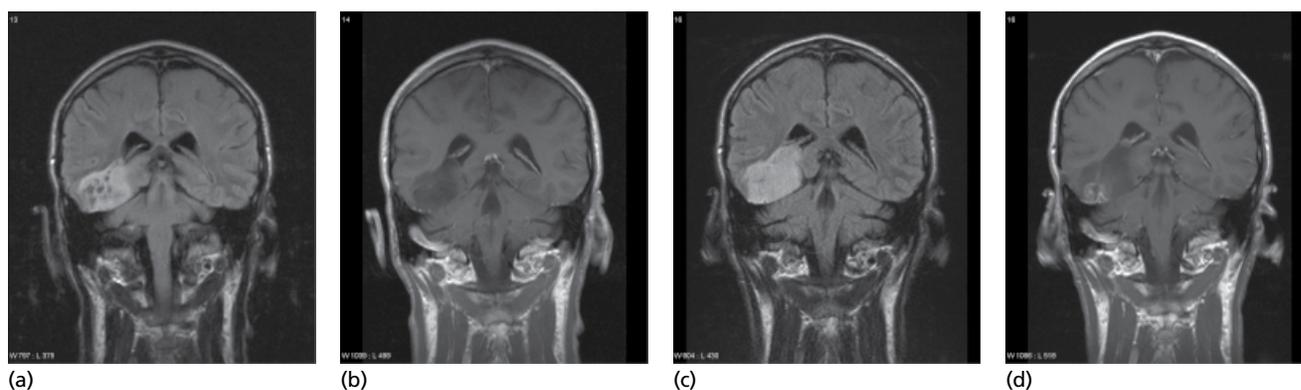

### Imaging

#### Pilocytic astrocytoma

Pilocytic astrocytomas (WHO Grade I) have a predilection for the cerebellum and midline structures such as the hypothalamus, thalamus, optic chiasm and brainstem. Optic pathway gliomas (OPG) are seen commonly in neurofibromatosis type 1 (NF1). In adults they may be also found in the cerebral hemispheres. They usually have a significant cystic component and show mural enhancement which can be nodular or ring-like (Figure 21.24). Infratentorial pilocytic astrocytomas in adults may be mistaken for haemangioblastomas.

#### Diffuse astrocytoma

Diffuse astrocytomas (WHO Grade II) typically occur in the cerebral hemispheres of young adults, involve cortex and white matter and have less well-defined borders than pilocytic astrocytomas. Mass effect is variable and contrast enhancement usually absent. They appear isodense or hypodense on CT which shows areas of calcification in up to 20%. On MRI, diffuse astrocytomas are hypointense or isointense on T1 images and hyperintense on T2 and FLAIR images, which provide the best contrast between tumour and normal brain tissue. WHO Grade II astrocytomas show a low mitotic activity but have a propensity to progress to a higher histological grade, as suggested by the development of new gadolinium enhancement (Figure 21.25).

**Figure 21.25** (a) Coronal FLAIR image of a WHO Grade II astrocytoma presenting as well-demarcated hyperintense temporal lobe mass containing small cysts. (b) Corresponding contrast-enhanced T1 image does not demonstrate any pathological enhancement. (c) 12 months' follow-up FLAIR image demonstrates tumour enlargement with disappearance of cystic elements. (d) 12 months' follow-up contrast-enhanced T1 image: pathological enhancement at the inferior aspect of tumour. Repeat biopsy confirmed progression to WHO Grade III astrocytoma.

### Oligodendroglioma

Up to 90% of oligodendrogliomas contain calcification visible on CT, central, peripheral or ribbon-like. Both low and high-grade oligodendroglial tumours express pro-angiogenic mitogens and may contain regions of increased vascular density with finely branching capillaries which have a chickenwire appearance seen as contrast enhancement on MRI and increased rCBV on PWI. However, contrast enhancement is variable and often heterogeneous. It is a much less reliable indicator of tumour grade than in astrocytic tumours. Oligodendrogliomas with intact 1p/19q tend to have a more homogeneous signal on T1 and T2 images with sharper borders than tumours with 1p/19q co-deletions.

### Surgery for low-grade gliomas

#### Pilocytic astrocytoma

Maximal resective surgery (with minimal morbidity) is the mainstay of treatment and results in a greater than 90% 10-year survival. The choice between focal radiotherapy and chemotherapy depends upon the age of the patient and consequent risk of radiation-induced cognitive deficits. Chemotherapy is now preferred up to the age of 8; previously the cut-off was up to 3 years.

Optic pathway gliomas in NF1 follow a very indolent course. Surveillance is preferred for these cases, with surgery and radiotherapy or chemotherapy reserved for progression with symptomatic visual impairment. These children with NF1 have a higher risk of long-term effects of radiation, especially vasculopathy and second tumours, so radiation is avoided where possible.

#### Diffuse astrocytoma and oligodendroglioma

In adults, the optimal management of diffuse astrocytomas and oligodendrogliomas is uncertain. The typical patient is a young adult presenting with seizures without neurological deficit or raised intracranial pressure. Management is difficult because of the tremendous variability in natural history of these tumours. Although morphologically and radiologically indistinguishable at diagnosis, some low-grade gliomas transform within a few months while others remain low-grade for several years. Radiologically, a high-grade glioma may present as a low-grade glioma and so early tissue diagnosis should be obtained if there is any suspicion that the tumour may be higher-grade (e.g. tumour growth within 3 months), the presence of contrast enhancement, presentation in an older

(>40 years) patient, or with neurological deficits or raised intracranial pressure.

The timing of neurosurgical intervention, either in the form of image-directed biopsy or tumour resection, depends on many factors. However, with technical advances in pre-operative structural and functional imaging, there is a trend towards earlier and more extensive tumour resection, particularly as research has shown that all low-grade gliomas grow steadily and that the vast majority transform into high-grade gliomas at some point in their natural history. A recent study comparing outcomes between two Norwegian university hospitals with different treatment philosophies suggests that early resection is associated with significantly improved survival rates compared with watch-and-wait. Five year survival was 60% in the watch-and-wait group compared with 74% in the surgical group. This difference increased to 24% at 7 years. Importantly, there were no significant differences in surgical complications between the two hospitals or acquired neurological deficits. These data suggest that all patients with low-grade gliomas should be thoroughly evaluated after radiological diagnosis with additional physiological sequences and functional imaging to consider whether the surgical option is feasible. Following this, a thorough discussion with a surgeon who has experience in low-grade glioma surgery, including awake craniotomy, should be the standard of care.

Many tumours can be resected via a standard craniotomy performed under general anaesthesia. Awake craniotomy is advocated for tumours that are located in eloquent cortex or adjacent subcortical white matter. Management of low-grade gliomas is therefore best carried out in centres that support awake craniotomies and cortical mapping. A battery of diagnostic tests can be performed pre-operatively to aid in characterising the relationship of tumour to eloquent cortex. MRI is helpful in defining the anatomical sulcal and gyral patterns correlating tumour location to motor, sensory and speech cortex. In addition, MRA may be helpful in defining critical vascular structures surrounding and often involving tumour boundaries. fMRI provides more accurate localisation of motor and sensory cortex in addition to expressive speech centres, with receptive speech or comprehension being less accurately identified (Figure 21.11). DTI can identify white matter tracts adjacent to or infiltrated by tumour, which can help planning surgery pre-operatively. Neuropsychological testing is used to establish dominance for

speech and memory, in addition whether any functional compromise has occurred from mass effect or infiltration by tumour into the mesial temporal structures.

Information gathered from pre-operative diagnostic tests is combined with data obtained during intra-operative neurophysiological testing to identify areas of critical function, the area of pathology and safe corridors of entry into the cortex. Therefore the surgeon is given greater confidence, because great variability exists in the morphology of cortical structures and their landmarks, and recognition of sulcal and gyral patterns intra-operatively is rarely straightforward. During cortical stimulation, the patient is asked to perform tasks testing motor and sensory function. Language testing is more accurately carried out using specific language paradigms and visual cards than counting or naming of objects, days or the alphabet. If the patient is under general anaesthesia, although the extent of cortical mapping will not be to the same accuracy as in awake craniotomy, somatosensory evoked potentials can be used to identify motor and/or sensory cortex. Patient preference, the surgeon's considered view and experience, availability of pre-operative and intra-operative tests along with a skilled neuro-anaesthesia team are key factors for performing awake craniotomies.

In any event, fewer than 30% of adult low-grade gliomas are truly resectable in their entirety either because of location or diffuse infiltration. Partial resections provide tissue for histological diagnosis and prognostication but have not been shown to be of prognostic benefit. Many patients are therefore treated with antiepileptic drugs and remain well for many years. This group is monitored closely with imaging surveillance, usually at 6-month intervals. Treatment at progression may include biopsy and radiotherapy/chemotherapy or partial resection particularly where there is mass effect.

### Radiotherapy for low-grade gliomas

The role of radiotherapy early in the course of disease is still not clear. Several trials have examined dose–response and timing of radiotherapy for WHO Grade II gliomas. WHO Grade I tumours are rarely treated with radiotherapy. Contrary to the situation in high-grade gliomas, there is little evidence with WHO Grade II tumours for a dose response beyond 50 Gy. The timing of radiotherapy for these patients has also been contentious. Some centres have advocated early postoperative radiotherapy on the basis that it is likely to be radio-biologically most effective when tumour volume is small and that the incidence of malignant transformation will be reduced. Others have felt that the long natural history of the disease means that such early intervention is unwarranted. This issue has been addressed in a randomised trial. The results suggest that while time to progression is improved from 3.4 to 4.8 years in the treated group, early irradiation to 54 Gy does not improve overall survival. Thus, many oncologists advocate early treatment only for those patients at highest risk of progression, such as those with tumours in eloquent areas or for whom surveillance is inappropriate.

Radiotherapy is also used in patients with intractable seizures in the absence of tumour progression. In about 75% seizures improve. In a trial comparing radiotherapy with no radiotherapy in low-grade gliomas with seizures, 25% of patients who had been irradiated had had seizures at 1 year, compared to nearly 50% who had not been irradiated.

### Chemotherapy for low-grade gliomas

The role of chemotherapy in adult low-grade gliomas has also not yet been fully established, and is usually reserved for large tumours requiring extensive radiation fields. However, both low and high-grade

oligodendrogliomas are more chemo- and radiosensitive than astrocytomas, attributed to a specific chromosomal loss of both 1p and 19q.

Two small prospective Phase II trials have shown radiological and clinical response to single agent temozolomide chemotherapy. Although the objective response rates were quite different between the two trials (10% in the British compared with 47% in the Italian trial), the tumour regression rates were almost identical (57% and 56%, respectively) when minor responses were also considered. A recently published North American trial has shown a highly significant survival advantage of 5 years with the addition of PCV chemotherapy to radiotherapy in patients with low-grade gliomas, particularly in oligodendrogliomas and tumours with IDH mutations. On this basis, adjuvant chemotherapy should become the standard of care for LGG patients treated with radiotherapy.

An international multi-centre trial comparing chemotherapy with temozolomide against radiotherapy for patients with low-grade gliomas, stratified for chromosomal 1p loss. Preliminary results suggest that radiotherapy is superior to chemotherapy.

## Other low-grade tumours in childhood

There are a number of other rarer tumours in childhood that often present with seizures and behave in a benign fashion. They are usually treated with surgery alone. The likelihood of recurrence is highly dependent on the amount of residual tumour.

### Tumours of predominantly neuronal cell origin

#### Gangioglioma and gangliocytoma

Gangiogliomas and gangliocytomas (WHO Grade I) are slow-growing tumours that grow preferentially within the temporal lobes of children and young adults. CT and MRI show peripherally located mixed solid and/or cystic lesions that commonly calcify. Enhancement is variable and often peripheral.

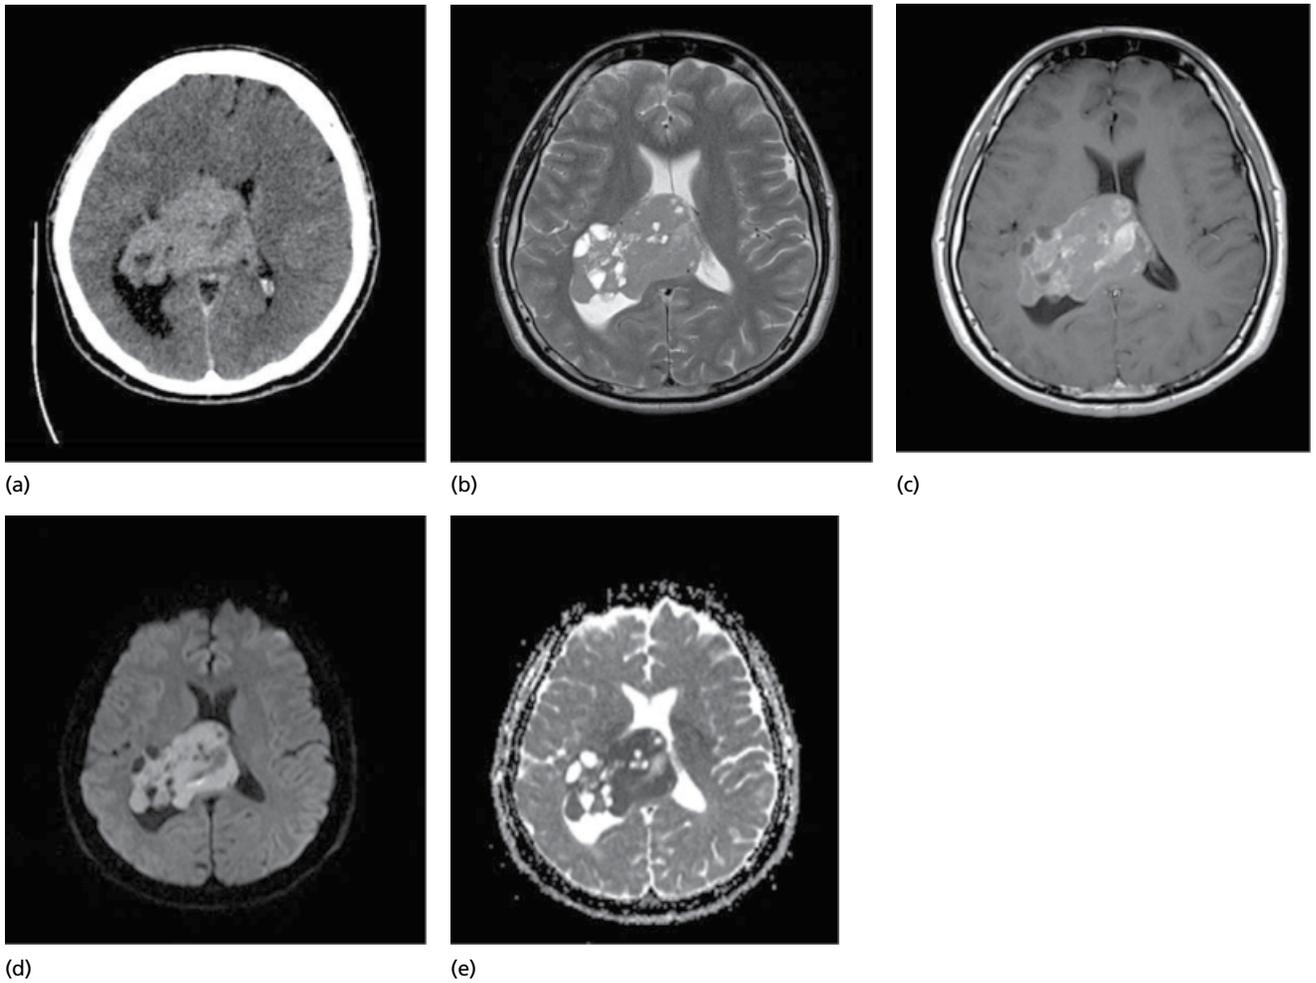

#### Central neurocytoma

Central neurocytomas (WHO Grade II) occur predominantly in the second and third decades of life and are the most common masses within the lateral ventricles in this age group. They typically arise from the septum pellucidum and occupy the frontal horns and bodies of the ventricles and sometimes extend through the foramen of Monro. Obstructive hydrocephalus is common. CT frequently demonstrates calcification and small cysts. MRI shows a heterogeneously enhancing mass with septated cysts and isointense grey matter nodules with susceptibility artefact from calcification. These tumours also show restricted water diffusion (Figure 21.26).

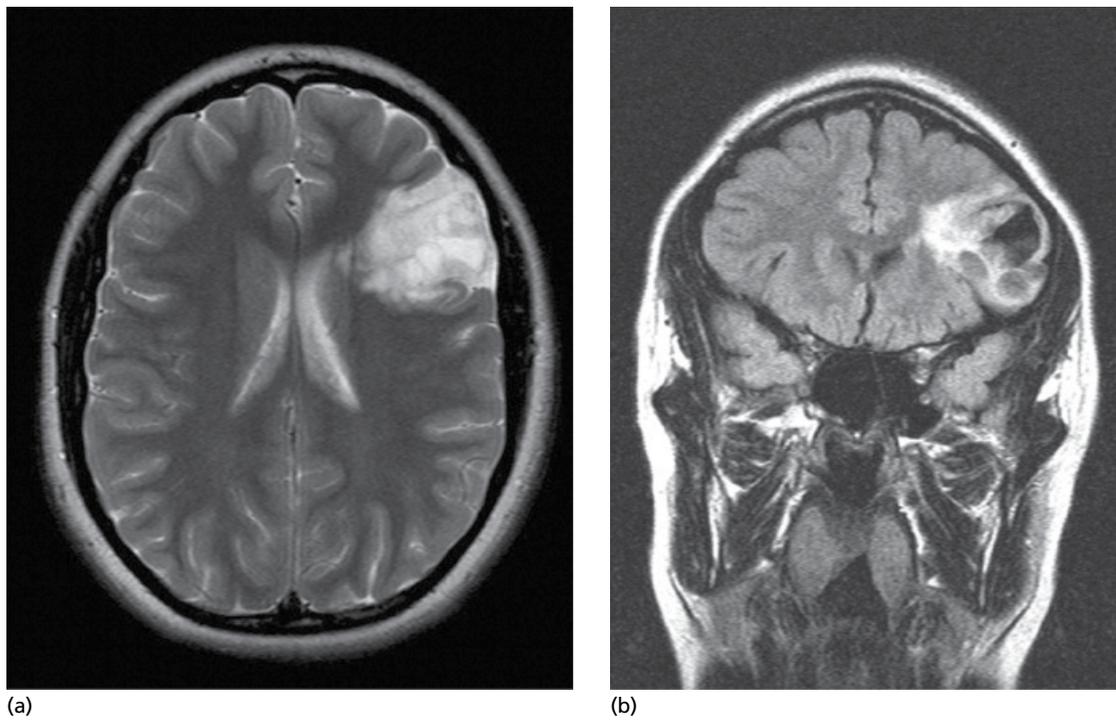

#### Dysembryoplastic neuroepithelial tumour

Dysembryoplastic neuroepithelial tumours (DNET) are WHO Grade I and usually located in the cerebral cortex. On CT, DNET are usually hypodense. On MRI they are T1-hypointense and T2-hyperintense. Small intra-tumoural cysts may cause a bubbly appearance; calcification is seen in about 25% and enhancement is uncommon. Thinning of the overlying bone is present in approximately half of the cases, reflecting the extremely slow growth of these tumours which allows bone remodelling to occur (Figure 21.27).

*Molecular genetics of low-grade glioneuronal tumours* A range of low-grade glial and glioneuronal tumours, many clinically presenting

**Figure 21.26** Central neurocytoma. (a) Unenhanced CT shows a hyperdense intraventricular mass containing small cysts. (b) It has a relatively low signal intensity on T2-weighted images and enhances with intravenous gadolinium (c). The solid tumour parts appear bright on DWI images (d) and dark on the ADC map (e), which indicates restricted water diffusion in a highly cellular tumour.

**Figure 21.27** Left frontal dysembryoplastic neuroepithelial tumour (DNET). (a) T2 image of left frontal hyperintense mass that proved to be a DNET. (b) Coronal FLAIR image shows cystic components within DNET giving rise to the classical 'soapbubble appearance'.

with long-standing epilepsy in children and adults have been identified as *BRAF V600E* mutant. The mutation is most commonly seen in PXA and the anaplastic form of PXA (65%), followed by gangliogliomas (25%) and DNETs (30%). It is occasionally seen in desmoplastic infantile ganglioglioma/astrocytoma (16%) and rarely pilocytic astrocytomas (10% or less). The prognostic value of the *BRAF V600E* mutation is less well established than that of *IDH* mutations in astrocytomas and oligodendrogliomas

### Choroid plexus tumours

Choroid plexus tumours are either papillomas or carcinomas, papillomas being much more common than carcinomas. The location and incidence of choroid plexus papillomas varies with age. They are more common in childhood, presenting as a cauliflower-like mass in the trigone of the lateral ventricle. In adults, papillomas occur predominantly in the 4th ventricle. CT shows an isodense to hyperdense mass with punctate calcification and homogeneous enhancement. On MRI, the papillomas appear as lobulated, intraventricular masses of heterogeneous, predominantly intermediate signal intensity on T1 and T2 images with intense contrast enhancement.

## Meningiomas

### Pathology

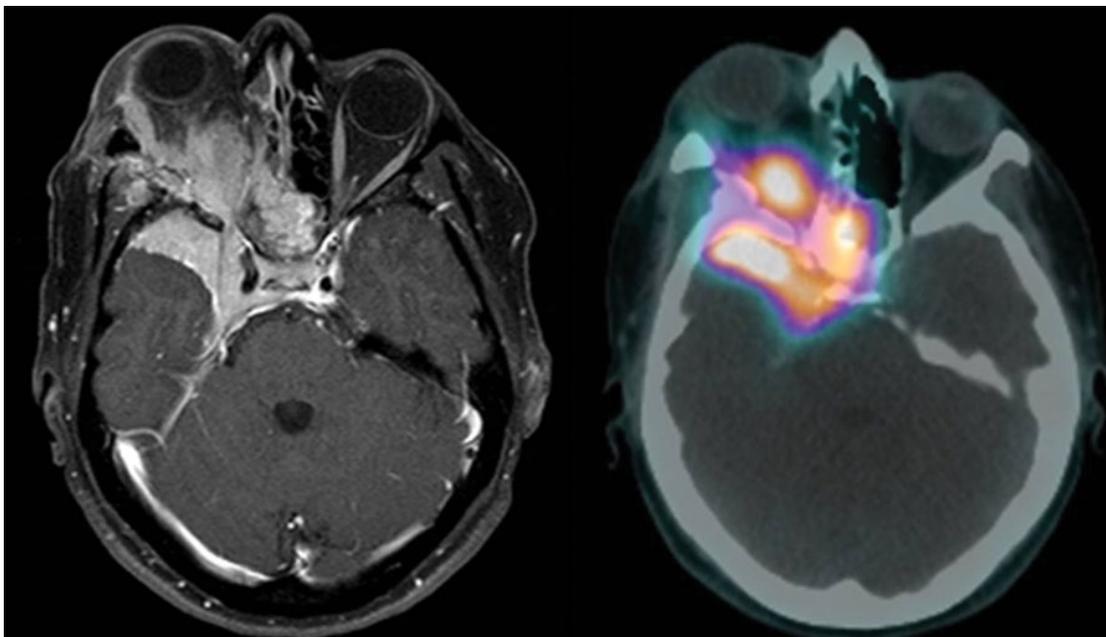

Meningiomas are common extra-axial intracranial tumours that grow slowly, are well demarcated and usually do not infiltrate the brain. They originate from meningotheial cells which are most abundant in the arachnoid villi and occasionally from the cranio-spinal arachnoid. They are most common in elderly patients with a peak in the sixth and seventh decade, with a slight predominance for female gender. The most common meningioma types are meningotheial, fibrous/fibroblastic, transitional and psammomatous (abundant whorls with calcifications), and more than 10 additional variants are listed in the WHO classification. Most of them correspond to WHO Grade I and behave similarly. Atypical features

in meningioma are increased mitotic activity (greater than 4 mitoses per 10 high-powered field [HPF]), patternless growth and necrosis corresponding to WHO Grade II (atypical) or WHO Grade III (anaplastic meningioma), when there are greater than 20 mitoses per 10 HPF. The higher grade meningiomas have a propensity for recurrence, as one might expect. In rare cases they behave almost as aggressively as malignant gliomas.

### Imaging

Meningiomas (WHO Grades I–III) can be spherical and well-circumscribed, craggy and irregular or flat, infiltrating en plaque lesions. They arise within the parasagittal area, convexities, sphenoid wing, tuberculum sellae, olfactory groove, tentorium and foramen magnum. Spinal meningiomas usually arise dorsally in the thoracic spine and almost exclusively in women. On CT, 60% of meningiomas are hyperdense without contrast and some 20% contain calcification. Hyperostosis, best seen on bone window settings indicates the site of the tumour attachment to the meninges. On MRI, meningiomas frequently appear isointense to cerebral cortex on both T1 and T2 images and may occasionally be difficult to detect without IV contrast. They can have capping cysts of CSF signal intensity. Associated vasogenic oedema is not infrequent and often disproportionate to tumour size.

Meningiomas enhance vividly and usually homogeneously on MRI. Linear enhancement can extend along the adjacent dura mater (Figure 21.5). This sign, known as the dural tail, was once thought to be pathognomonic for meningioma but can also be seen with other tumours such as schwannomas or even metastases. MRS may show an alanine peak, characteristic for meningioma though seen in less than 50% of cases. PWI of meningiomas shows typically a markedly elevated rCBV, which can be of help in differentiating these benign tumours from dural metastases which tend to have a lower rCBV. PET CT using a somatostatin analogue can help differentiate meningiomas from other extra-axial masses, because of the high density of somatostatin receptors in meningiomas (Figure 21.28).

**Figure 21.28** Meningioma. Contrast-enhanced fat-saturated T1-weighted axial MRI (a) show a right sphenoid wing meningioma extending into the cavernous sinus and orbit. (b) PET CT using the somatostatin analogue  $^{68}\text{Ga}$ -DOTATOC shows high uptake of the tracer in the enhancing extra-axial tumour.

## Surgery

The majority of meningiomas are benign, with recurrence rates frequently less than 10% after total excision. Radical surgery remains the mainstay of treatment. Pre-operative embolisation in very vascular meningiomas is sometimes advocated to reduce peri-operative blood loss. A minority of meningiomas present management problems if they cannot be fully excised or if there are aggressive histological features. Various characteristics of meningiomas have been used to predict tumour recurrence, such as anatomical location, extent of tumour resection and histopathological features, with the single most important prognostic factor being the completeness of surgical resection. Simpson introduced a classification system that predicts recurrence rates based on extent of tumour resection (Table 21.3). Tumour histology is also an important factor in predicting recurrence, if the tumour exhibits anaplastic and malignant features (WHO Grade II–III), the rate of recurrence is significantly higher, with 3% recurrence predicted for benign meningiomas, 40% for atypical and 80% for malignant meningiomas over a 5-year period.

## Radiotherapy

Several retrospective series have suggested that radiotherapy improves local control when these tumours are aggressive, but no randomised series are available. In one retrospective series of WHO Grade I meningiomas, local recurrence rates following presumed total resection and subtotal resection were 52% and 77%, respectively at 7 years median follow-up. Subtotal resection with radiotherapy achieved local control rates of 91% compared to 38% with subtotal resection alone. There was no influence on survival with adjuvant radiotherapy treatment. Although these data argue in favour of radiotherapy as adjuvant treatment after subtotal resection, they do not address its long-term side effects, particularly in younger age groups. Long-term risks include induction of a second tumour, pituitary failure and cognitive decline. Radiotherapy is therefore not offered routinely after subtotal resection of meningiomas because of these concerns. A common approach is to reserve radiotherapy for adjuvant treatment at first or subsequent relapse or in subgroups with higher risks of local relapse, including Grade II and Grade III meningiomas.

Newer radiotherapy planning techniques, such as iMRT and radiosurgery can be used to reduce the volumes of normal brain irradiated in these patients, as these tumours can often be treated with a very small margin (5–7 mm) beyond visible tumour on MRI.

**Table 21.3** Simpson classification for prediction of recurrence rates for meningiomas.

Recurrence (%)	Grade	Description
10	I	Macroscopically complete removal, excision of dural attachment
20	II	Macroscopically complete removal, coagulation of dural attachment
30	III	Macroscopically complete removal, without resection or coagulation of dural attachment
40	IV	Partial removal
	V	Decompression/biopsy

However, there are no data that show the reduction in late toxicity by this approach.

## Chemotherapy

There are no chemotherapy agents that are routinely used in meningiomas, not amenable to either surgery or radiotherapy (e.g. multiple or recurrent tumours). A number of drugs including hydroxyurea and mifepristone have been shown to have modest efficacy and can be tried in individual cases.

## Brain metastases

### Pathology

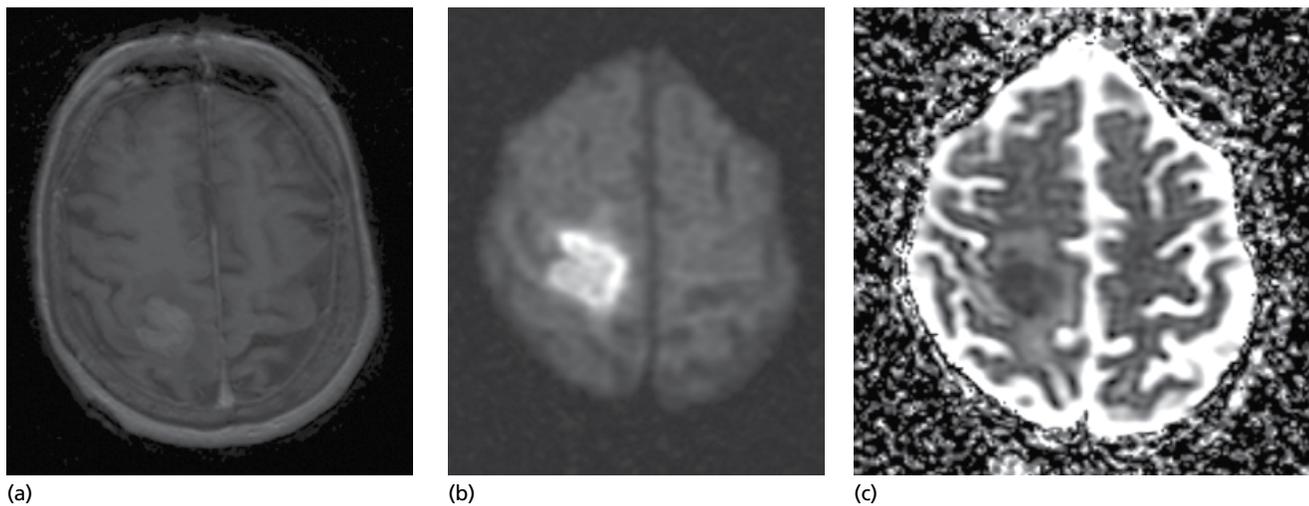

Metastases are macroscopically well demarcated. The tumour is often firm because of the growth of fibrous tissue from without; the surrounding oedematous brain is soft. Microscopically they are discrete and well demarcated in the brain; they tend to have an architecture of septa and often lymphocytic infiltrates. Diffuse infiltration can occasionally be seen in small cell carcinomas of the lung, melanoma and with lymphomas. Necrosis is a feature of many metastases. Carcinoma of the lung may be squamous, glandular or undifferentiated. Breast carcinoma metastases can reproduce architectural features of the primary lesion, with ducts, chords and cellular columns. Gastrointestinal metastases can show features of intestinal epithelium. Melanoma metastases are often haemorrhagic; they may contain melanin and can appear with a diffuse growth pattern. Most metastatic carcinomas are reactive for cytokeratins. Antibodies to thyroid transcription factor 1 can be useful in identifying metastatic lung cancer. Melanomas express S-100, HMB-45 and Melan-A.

### Imaging

Brain metastases most commonly arise from carcinoma of the lung, breast, kidney and malignant melanoma. Most metastases enhance strongly with contrast media, either uniformly or they are seen as ring-like structures if the metastasis has outgrown its blood supply. Metastases are frequently associated with vasogenic oedema, often disproportionate to the size of the tumour. Haemorrhage occurs in about 10% of metastases, resulting in high signal on T1 images and low signal on T2 images. Similar signal characteristics can also occur in non-haemorrhagic metastases from melanoma, because of the paramagnetic properties of melanin. Increasing the dose or relaxivity of gadolinium compounds can improve the sensitivity for detection of metastases on MRI.

DWI may help to predict the histology of brain metastases. Small cell lung cancer metastases and neuro-endocrine metastases have a lower ADC than adenocarcinoma metastases and appear bright on DWI (Figures 21.29). PWI and MRS of the peri-tumoural rather than intra-tumoural region help to differentiate a single metastasis from a high-grade glioma. DWI is helpful in distinguishing cystic metastases from cerebral abscesses. Abscesses contain more viscous fluid and pus; they show a more marked restriction of water diffusion than necrotic tumours.

Brain metastases have traditionally been considered as terminal event, carrying a very poor prognosis, with only palliative measures appropriate. Even today, the treatment for most brain metastases is purely palliative. However, the last two decades have seen both increased early diagnosis, as improvements in systemic chemotherapy have led to more patients surviving and developing brain metastases, and the emergence of a younger, fitter population suitable for more aggressive approaches. Diagnostic imaging advances are allowing earlier, asymptomatic diagnosis.

**Figure 21.29** SCLC metastasis. (a) Contrast-enhanced T1 image of a right parietal metastasis from a small cell lung carcinoma. (b) Mass appears markedly hyperintense on diffusion-weighted image. (c) ADC map confirms decreased water diffusivity within the tumour (dark), consistent with a highly cellular metastasis.

As a result management options and paradigms for patients with brain metastases are evolving.

### Surgery and/or radiotherapy

Brain metastases can be treated focally, by surgical excision and radiosurgery, or with the well-established standard treatment of whole-brain radiotherapy (WBRT). Chemotherapy may have a role in certain chemo-sensitive tumours, such as germ cell neoplasms and trophoblastic disease, which are rare examples in which cure may be achieved with aggressive treatment. Novel treatment paradigms should combine these various treatment modalities in order to provide the most comprehensive and tailored therapeutic option for individual patients. Management of these patients must be carefully considered in the context of their overall disease burden and prognosis. Several oncology groups have attempted to categorise these patients into prognostic groups with the aim of predicting those most likely to benefit from treatment. Clearly, these decisions depend on having accurate and up-to-date information about disease status within and outside the brain and a careful assessment of the patient's performance status.

Surgery has a role in the management of brain metastases in both diagnosis and treatment. In some patients with no previous malignant history or in whom there is diagnostic doubt, biopsy may be necessary to confirm the diagnosis even if no other surgical intervention is planned. The most difficult group in this respect are elderly patients with concurrent medical conditions and no obvious primary site. In these cases even biopsy may not be appropriate. However, caution in diagnosis is essential: about 10% of patients with suspected brain metastases harbour unsuspected histology including abscesses, inflammatory/infective lesions such as neurocysticercosis or gliomas.

Surgical resection may be used for the definitive treatment of oligometastases (one, two or three lesions) or solitary metastases unsuitable for radiosurgery, for example with significant associated oedema and mass effect, greater than 3 cm diameter and in the setting of low volume or controlled extracranial disease. Palliative debulking may be appropriate for symptomatic relief, improved quality of life and to allow tapering of steroids. Some patients may

need treatment of hydrocephalus. Surgery is usually contraindicated in cases with several brain lesions, as surgical results are so poor, a reflection that many patients will die in any event from uncontrolled disease outside the brain within a few months of surgery.

Stereotactic radiosurgery with either a cobalt source (gamma knife) or linear accelerator (LINAC based) may be used as an alternative to surgery, particularly for solitary metastases in eloquent regions of the brain or oligometastases. Outcome is considered equivalent, although no head-to-head comparison with surgery has ever been carried out. Most radiotherapists limit the size of lesions to be treated to those less than 3 cm diameter because of the high radiation doses administered.

There is now a move away from routine use of adjuvant WBRT following surgery or radiosurgery as a result of randomised trial data confirming neurocognitive deficits as early as 4 months following WBRT, and no survival benefit. Previously, the standard approach was to add a short course of palliative radiotherapy (e.g. 20 Gy given in five daily fractions of 4 Gy in 1 week). The European EORTC 22952-26001 study addressed whether adjuvant WBRT increased the duration of functional independence after either surgery or radiosurgery in good performance status patients with up to three brain metastases and with controlled extracranial disease. Although the addition of WBRT reduced both local and distant recurrence in the brain, there was no impact upon duration of functional independence or survival. It was concluded that when using regular MRI-based follow-up, salvage treatment is effective in preventing neurologic progression as a cause of death.

Radiotherapy alone to the whole brain has also been standard treatment for patients with unresectable metastatic brain lesions and/or with uncontrolled systemic disease. However, the palliative value of short course radiotherapy is dubious and it is hard to know whether improvements are a result of the radiation or concomitant use of steroids.

### Chemotherapy

In all CNS malignancies the blood–brain barrier is at least a theoretical limitation to drug penetration, but the exact contribution that this makes to the poor response to chemotherapy is unclear.

A distinct minority of tumour types presenting as brain metastases are known to demonstrate clinically useful chemo-sensitivity. These metastases include small cell lung cancer (SCLC), germ cell tumours and breast cancer. Response rates up to 66% at first treatment in SCLC have been documented. Some studies have shown that breast cancer brain metastases can respond to agents used for systemic disease in over 50% of cases. Median survivals after chemotherapy are similar to those after WBRT. Therefore, chemotherapy is probably most appropriate for those who are relatively chemo-naïve, as many patients will have been exposed to multiple chemotherapy agents prior to presenting with brain metastases.

New approaches are clearly needed in the treatment of brain metastases. Combinations of conventional chemotherapy agents with molecularly targeted drugs such as gefitinib (Iressa), a tyrosine kinase inhibitor, have been shown to produce responses at primary tumour sites such as lung tumours and may help metastases. Temozolomide has also been studied alone or in combination with radiotherapy.

The use of dexamethasone to improve symptoms of raised intracranial pressure, brain oedema and focal deficits is part of standard treatment of brain metastases and brain malignancies generally. The optimal dose has not been defined but some data suggest that low-dose dexamethasone (4 mg/day) is as effective as the usual higher dose (16 mg/day) in the majority.

### Primary spinal cord tumours

In comparison with brain tumours, primary spinal cord gliomas (Figure 21.30) are relatively rare and are usually astrocytomas or ependymomas, usually low-grade, affecting commonly the cervical cord or, in the case of ependymomas, the conus. Other more common primary spinal tumours are meningiomas arising from the dura, and schwannomas arising from the spinal nerve roots and lipomas, either intramedullary or extramedullary. The symptoms and signs at presentation are a combination of the effects of nerve

root involvement at the level of the tumour (e.g. girdle pain), and the effects of long tract involvement at that level (e.g. paraparesis or tetraparesis). MRI is usually diagnostic.

### Surgery

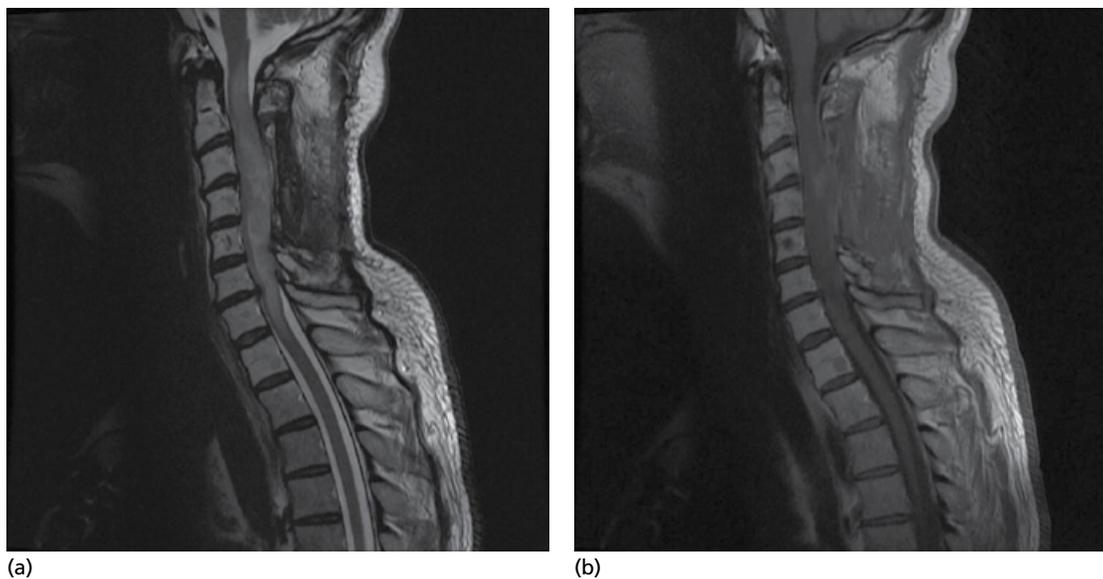

Radical surgery is indicated for presumed extramedullary tumours via laminectomy at the appropriate level(s). Occasionally, more extensive approaches are required (e.g. with dumb-bell schwannomas), where thoracotomy or abdominal surgery may be required. With intramedullary astrocytomas, it is sometimes possible to enter the spinal cord posteriorly in the midline, between the posterior columns, or alternatively through the dorsal root zone and removed the tumour without encroaching on functioning pathways. Tumours associated with a cyst can occasionally be dissected free from the normal structures with little morbidity, with an apparently total macroscopic removal.

### Chemotherapy for intrinsic cord tumours

Overall, there are few data about the chemo-sensitivity of intrinsic cord malignancies. The literature addressing responses to chemotherapy in intracranial ependymoma suggests a low response rate to combination chemotherapy regimes and no evidence that it improves survival. Low chemo-sensitivity has been attributed to over-expression of *MDR1* (multi-drug resistance gene) in ependymoma tissue. Paediatric literature suggests a modest response to chemotherapy in high-grade spinal astrocytomas. However, these small studies do not allow firm conclusions to be drawn about responses in adult patients.

### Spinal ependymomas

The most common primary spinal intramedullary tumour in adults is ependymoma, some 50–60% of such neoplasms which occurs most commonly in mid adult life. It is common for the diagnosis to be made after months or years of slowly progressing symptoms. Surgery is usually the first treatment, to make a histological

**Figure 21.30** Intramedullary cervical cord glioma. (a) Sagittal T2-weighted image of expansile high signal intrinsic cord lesion extending from cervicomedullary junction down to C7, occupying the whole spinal canal. An extensive laminectomy has been performed to decompress the cord. (b) Sagittal T1-weighted post gadolinium images showing faint central enhancement. A biopsy of the tumour showed an anaplastic astrocytoma.

diagnosis and attempt gross removal. A postoperative MRI at 2–3 months is often recommended to record residual disease and serve as a baseline for follow-up. In low-grade fully resected tumours, recurrence rates are low, in the region of 5–10%. However, this does not fully take in to account the problems of defining grade and extent of resection in these tumours. A recent series suggests that local relapse rates may be higher than generally appreciated at long-term follow-up: there is a significant recurrence rate beyond 5 years, with only 50% of patients progression free at 10 years. Local postoperative radiotherapy is usually recommended in all patients. There are not enough data available to be able to assess whether there is a dose response to radiation in these circumstances. Most studies reporting outcome after radiotherapy are small series that use a narrow range of doses. It is clear though that recurrences distant from the original ependymoma site are very rare, therefore extended field or cranio-spinal treatments are not recommended unless there is evidence of distant spread. The maximum radiation dose that can be administered is limited by the tolerance of the spinal cord. Current practice is to treat low-grade ependymomas to a dose of 50 Gy in 1.8 Gy fractions and higher grade tumours to 54 Gy.

### Spinal astrocytomas

Primary spinal cord astrocytomas are most often low-grade fibrillary subtypes. Clinically and radiologically these tumours often present in a very similar way to ependymomas although they may be less well defined than a typical ependymoma. Surgery is often not appropriate in patients with significant neurological deficit or with high-grade lesions for whom extensive resection does not improve survival. Prognosis is less good than in ependymoma. High-grade astrocytomas have a median survival of around 20 months.

No large studies have addressed the role of radiotherapy in spinal glioma patients. Small series suggest that less extensive surgery plus postoperative radiotherapy can produce local control in around 50% of patients with low-grade tumours, with 5-year survival rates of around 60%.

### Spinal meningiomas and schwannomas

With spinal meningiomas, excision is usually curative and recurrence is uncommon, even when it has not been feasible to excise the dura widely. Schwannomas affecting spinal nerve roots can usually be cured by total excision. However, in some cases these tumours may have an aggressive course and not be surgically curable.

### Metastatic spinal cord compression

The spine is a common site for metastatic disease, commonly with bony involvement, but sometimes with extradural deposits and, rarely, with intramedullary spread. These tumours usually spread haematogenously into the vertebral bodies and cause epidural spinal cord compression. Typically, the clinical history is much shorter than with primary spinal tumours. Thus, patients may present as an emergency, with rapidly progressing paraparesis with urinary incontinence and/or retention. Referral may be delayed when there is no previous history of cancer, unless the true nature of the problem is identified. Oncologists are well aware of syndromes caused by spinal metastases, and in patients with a previous known history of malignancy, the diagnosis tends to be made promptly.

Speed of diagnosis followed by urgent imaging is of the essence in preventing or minimising permanent neurological deficit. Where there has been a short clinical history and the patient has a severe paraparesis with sphincter function lost for more than 12 hours, the results of surgical decompression are poor. A randomised trial of

surgery followed by radiotherapy against radiotherapy alone for metastatic spinal cord compression showed that significantly more patients in the surgery group were able to walk after treatment and retained the ability to walk significantly longer than in the radiotherapy group. The benefits of this trial cannot be applied to patients with multiple metastases and in this group urgent radiotherapy is usually offered, particularly where the tumour is likely to be radio-sensitive and the patient is deemed sufficiently well to survive for a number of months.

Patients with rapidly advancing neurological deficits and with severe cord compression by tumour, as well as spinal disease, generally need urgent surgery if stabilisation of their deficits is to be achieved. There has been a clear trend towards adjusting the surgical approach to the exact site of the metastatic tumour in order to obtain maximum decompression, coupled with fixation to stabilise the diseased spine. Major anterior or lateral approaches are suitable for anteriorly or laterally placed spinal metastases, but these often require a neurosurgeon to have assistance from a thoracic or abdominal surgeon. Single or multiple level corpectomy of the vertebral body with subsequent repair by bone cement, titanium-based cages or bone graft and concomitant posterior spinal fixation with metal instrumentation are performed more frequently than in the past. Posterior decompression should not be performed for anteriorly placed tumours as the resulting laminectomy can lead to spinal instability and rapid neurological deterioration when the patient is mobilised.

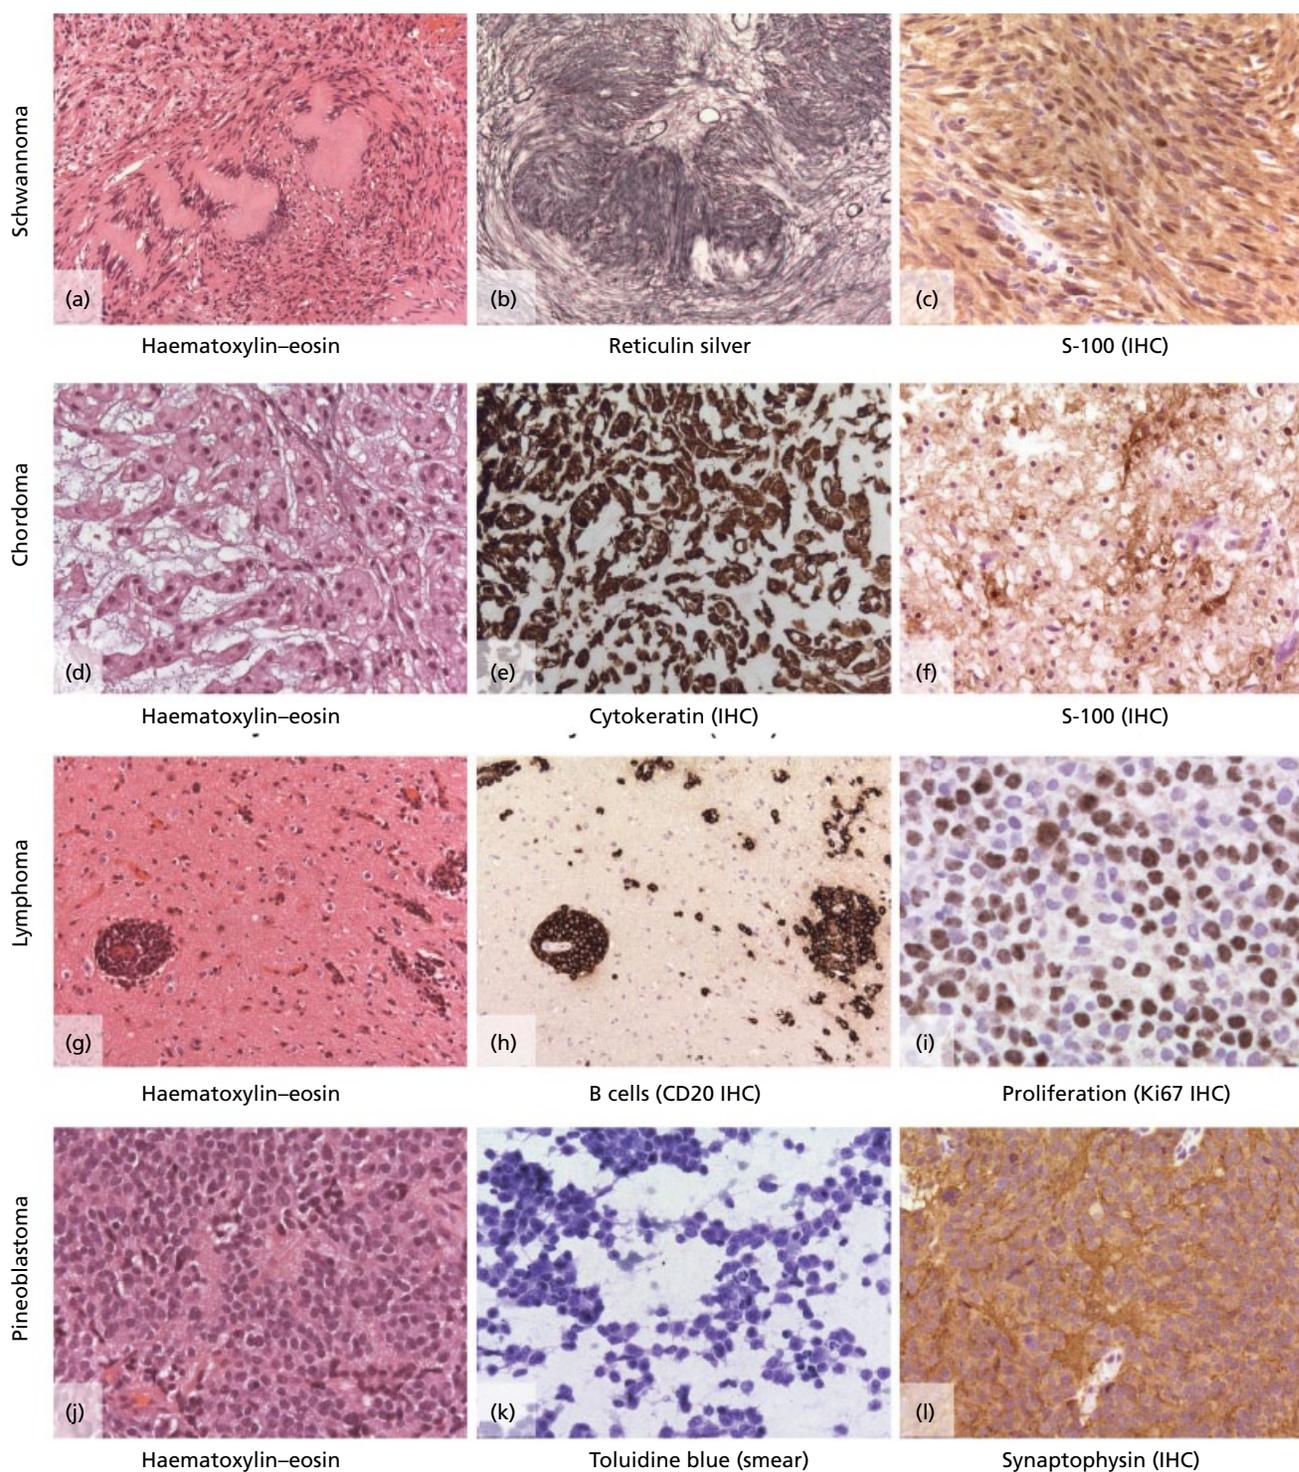

## Skull base tumours

### Chordoma

These are rare tumours arising from remnants of the embryonic notochord and may therefore develop at any point along the length of the neuraxis, in particular the skull base and clivus, vertebral column and sacrum. They are locally aggressive malignant tumours that invade into bone and soft tissues and occasionally metastasise to distant sites. Patients usually die of locally recurrent disease. Clival chordomas present with headache and diplopia caused by VIth nerve palsy. This may progress to involve the Vth nerve and then the lower cranial nerves with vertigo, tinnitus and bulbar palsy causing dysphagia and hoarseness. Rarely, brainstem compression may occur with pyramidal tract dysfunction, ataxia and emotional lability. Chordoma is the most common neoplasm of the sacrum and it may often be extensive before diagnosis. Slowly progressive low back pain with radicular or sciatic radiation involves the sacral nerve roots leading to peri-anal numbness, sphincter disturbance with urinary retention, incontinence and impotence. Involvement of the true vertebrae is uncommon. There may be bone destruction and infiltration into the paraspinal soft tissues. Dorsal expansion leads to nerve root displacement with severe localised radicular pain and sensory loss. Chordomas arising in the cervical region may cause direct oesophageal compression and rarely myelopathy.

### Pathology

There are three histological types of chordoma: classic, chondroid and dedifferentiated. The histological appearance (Figure 21.31) of classic chordoma is of a lobulated tumour composed of groups of cells separated by fibrous septa against a background of myxoid stroma (Figure 21.31d). Typical immunohistochemical profiles include positive labelling of the tumour cells with cytokeratin (Figure 21.31e) S100 protein (Figure 21.31f). The cells have small round nuclei and abundant vacuolated cytoplasm, sometimes

**Figure 21.31** Histological features of schwannoma, chordoma, lymphoma and pineoblastoma.

described as physaliferous. Chondroid chordomas histologically show features of both chordoma and chondrosarcoma.

#### Imaging

Imaging of clival chordomas on CT shows tumour calcification, eroded bone and focal areas of hyperintensity and hypointensity within the tumour. On MRI, the margins are clearly delineated; T2

shows hyperintense areas with extension either anteriorly into the paranasal sinuses and nasopharynx or posteriorly towards the brainstem.

#### Treatment

Chordomas are difficult to treat because of their infiltrative behaviour and complete resection is rarely feasible. Partial resection is

usually combined with radiotherapy to try to eradicate residual disease, but these tumours are highly radio-resistant. Chordomas require doses in excess of 75 Gy for local control rates of around 80% at 5 years. For this reason, there is interest in the use of high-energy proton beam therapy. The specific characteristics of proton beam therapy, with very sharp dose fall off, allow the delivery of such high doses adjacent to critical structures (such as the brainstem and optic pathways). This is not possible with standard conformal radiotherapy from a linear accelerator, but doses of up to 65–70 Gy may be delivered using intensity modulated radiotherapy (IMRT). However, there are no convincing data that suggest protons are superior to standard radiotherapy in terms of overall survival. The overall 5-year survival is approximately 65%; older women with large tumours tend to have the worst prognosis. The prognosis is variable with a better outlook for chordomas in the clivus or sacrum than in the vertebral column. Morbidity and mortality occurs because of the erosive nature of the tumour and the location within eloquent regions of the brain and skull base.

### Chondrosarcoma

Chondrosarcomas are rare slowly growing tumours thought to arise from embryonal rest cells, most commonly in the petro-occipital synchondrosis. They resemble chordomas superficially in that they present as a locally aggressive skull-base tumour causing cranial nerve compression with facial weakness or sensory loss, hearing impairment, vertigo or bulbar involvement, but they have a consistently better prognosis. Although they are similar in management, distinction between the two is important because of the different prognoses and outcome. The majority of chondrosarcomas of the skull base are located off the midline, a helpful sign when compared with chordomas which are usually midline. The primary treatment is surgical resection, as with chordomas. These tumours are relatively resistant to radiotherapy, and again preferably treated with proton beam therapy.

### Neurofibromatosis and schwannomas

Schwannomas are benign tumours derived from Schwann cells (Chapter 20) and account for about 8% of primary intracranial neoplasms. Their most common location is in the cerebellopontine angle but they can occur on any cranial nerve as well as on spinal nerve roots and peripheral nerves.

#### Pathology

The schwannoma shown in Figure 21.31 has typical arrangements of palisading nuclei against a fibrillary background, with formations known as Verocay bodies. Around those structures are loosely textured tumour areas: Antoni B areas (Figure 21.31a). Reticulin silver stain visualises the dense pericellular basement membranes (Figure 21.31b). S100 immunohistochemistry typically shows nuclear and cytoplasmic staining in schwannoma (Figure 21.31c).

#### Molecular genetics

Bilateral vestibular schwannomas are the hallmark of neurofibromatosis type 2 (NF2). NF2 occurs in individuals who have a defective tumour suppressor gene located on chromosome 22q12.2. The defective protein produced by the gene is called merlin or schwannomin. Other manifestations, including peripheral neurofibroma, meningioma, glioma and juvenile posterior subcapsular lenticular opacities, are often present as well. Many patients with NF2 present in late adolescence or early adulthood but occasionally

may present later in the fifth to seventh decade with slowly growing tumours. Peripheral neurofibromata and café-au-lait spots are much less frequently observed than with neurofibromatosis type 1 (NF1).

NF1 is associated with a mutation on chromosome 17, and presents with more peripheral tumours as well as optic pathway gliomas and spinal neurofibromas. These patients also have Lisch nodules in the iris (Chapter 14), café-au-lait patches, subcutaneous schwannomas or neurofibromas and possibly other intracranial or intraspinal tumours, such as gliomas and meningiomas.

#### Clinical features

Clinical features of vestibular schwannomas include progressive hearing loss, tinnitus and vertigo. Unilateral hearing loss is overwhelmingly the most common symptom present at the time of diagnosis and is generally the symptom that leads to diagnosis. Assume that any unilateral sensorineural hearing loss is caused by a vestibular schwannoma until proven otherwise. An MRI is mandatory in patients of any age presenting with unilateral sensorineural hearing loss. Headaches are present in 50–60% of patients at the time of diagnosis, but fewer than 10% of patients have headache as their presenting symptom. Headache appears to become more common as tumour size increases and is a prominent feature in patients who develop obstructive hydrocephalus associated with a very large tumour. Large tumours (>4 cm) can obstruct the flow of spinal fluid through the ventricular system by distorting and obstructing the 4th ventricle. In the early decades of the twentieth century, most patients are said to have presented with hydrocephalus and papilloedema.

Vestibular schwannomas are managed in three ways:

- 1 Serial observation (wait, scan, surveillance)
- 2 Stereotactic radiosurgery
- 3 Microsurgical excision.

Management depends on multiple factors: patient age, the size and growth rate of the tumour, hearing status, co-morbidities and patient preference. Patients should be seen in a multi-disciplinary team so that all management options can be discussed. In older patients, serial imaging with 12-monthly MRI is appropriate, particularly if hearing has been lost. In younger patients with a tumour that has been shown to be growing, treatment is necessary. The majority of patients will have active treatment and, in this respect, the pendulum has swung heavily away from surgical microdissection to stereotactic radiosurgery or fractionated stereotactic radiotherapy. This can be performed with either the multiple source cobalt unit (gamma knife, often used to deliver single fraction radiosurgery treatments) or a linear accelerator (LINAC) which can deliver single or multiple fraction radiotherapy using either frameless or relocatable frame-based systems. Both are carried out in an outpatient setting without the need for a general anaesthetic. The goal is to deliver a high dose of radiation to the tumour volume with minimal doses to surrounding structures (i.e. cranial nerves, brainstem and vessels). This will slow down or stop the growth but does not cause the tumour to disappear. Single fraction radiosurgery can only be applied to tumours up to 3.5 cm in diameter. Tumour reduction occurs in 70–90% of cases although there is a temporary volume increase in about 25% of patients. Facial nerve damage occurs in about 10–15% but hearing is preserved (in small tumours) in more than 50% of cases. The main disadvantages of radiosurgery include its limitation to small tumours, the possibility of deteriorating cranial nerve function after treatment and potential risk of malignant change within the remaining schwannoma. Risks of developing a secondary malignancy from radiosurgery are small – 1 in 1000 patients followed over 30 years.

In contrast, microsurgical tumour resection remains the treatment of choice for tumour eradication and potential cure. It is the only treatment option for large tumours (>3.5 cm). Three surgical approaches are used: retrosigmoid, translabyrinthine and middle fossa. The retrosigmoid approach can be used for any tumour but is advantageous for large vestibular schwannoma or for small tumours where hearing preservation is attempted. In translabyrinthine surgery, the cerebellum is hardly ever retracted and facial nerve preservation rates may be higher. The middle fossa approach has largely been abandoned in the United Kingdom. The main long-term complication is facial paralysis. Incomplete facial recovery occurs in about 20% of patients and there is a 5% rate of complete facial palsy, which may require facial nerve reconstruction.

## Skull base meningiomas

Skull base meningiomas account for approximately 25–30% of all intracranial meningiomas. They occur in the olfactory groove/platum sphenoidale, parasellar region, cavernous sinus, sphenoid wing and petroclivus/petrous apex. The clinical presentation, typically insidious, is caused either by involvement of the cranial nerves or mass effect on the cerebellum and/or brainstem. Raised intracranial pressure can result from the tumour mass or obstructive hydrocephalus. Patients with small asymptomatic meningiomas who are elderly, who have medical co-morbidities or both may be observed and treatment initiated if and when tumour progression is documented.

Surgery is the treatment of choice for patients with apparently resectable meningiomas. The likelihood of accomplishing a complete resection depends upon the site and extent of the tumour. Skull base meningiomas can be particularly challenging because they often cannot be completely resected, and surgery is associated with significant complications. The overall recurrence rate is therefore disproportionately high. Like vestibular schwannomas, skull base meningiomas can be treated with stereotactic radiosurgery. Conformal radiotherapy can also be used and is indicated if the tumour is irregular, too large to be treated with radiosurgery, or both.

## Pituitary tumours

The pituitary is a tiny organ, uniquely supplied by two separate circulations: the systemic and portal systems. The sellar and parasellar regions are the sites of many disease processes (Table 21.4) of which pituitary tumours account for the majority. Pituitary tumours represent 10–15% of all intracranial neoplasms. They can be classified by biological behaviour, size or histological and functional criteria (Tables 21.5 and 21.6).

### Biological behaviour

Tumours may be either benign, invasive adenomas or carcinomas. Benign forms are most common but up to 50% show evidence of capsule invasion and about one-third invade the dura or the sphenoid sinus. Pituitary carcinomas are exceedingly rare.

### Size

Microadenomas are less than 10 mm and macroadenomas greater than 10 mm in diameter. Microadenomas are the more common and typically lie within the sella but can extend into the suprasellar space. Macroadenomas erode the sellar floor as they enlarge and eventually cause its destruction. The anatomy of adenomas is defined most accurately by MRI which clearly displays anterior and posterior lobes of the pituitary and its relation to the paranasal air and venous sinuses.

**Table 21.4** Lesions of the sellar region.

<b>1 Tumours</b>
Primary pituitary tumours
Craniopharyngioma
Meningioma
Germ cell tumours
Glioma – hypothalamic, optic nerve
Granular cell tumours
Lymphoma
Ependymoma
Metastases
<b>2 Others</b>
Cysts – Rathke's pouch, epidermoid, dermoid
Empty sella syndrome
Carotid and anterior communicating artery aneurysm
Lymphocytic hypophysitis
<b>3 Granulomatous disease</b>
Sarcoidosis
Wegener's granulomatosis
Histiocytosis X
<b>4 Infections</b>
Pituitary abscess – bacterial or fungal infection
Tuberculosis
Syphilis

## Histology

Cells forming a pituitary adenoma are defined by histological, hormonal and immunological characteristics. Acidophilic and chromophobe cells usually produce prolactin, growth hormone (GH) or thyroid-stimulating hormone (TSH). Basophilic cells produce adrenocorticotrophic hormone (ACTH),  $\beta$ -lipotrophin, luteinising hormone (LH) and follicle-stimulating hormone (FSH).

## Functional criteria

Radioimmunoassay allows precise measurement of pituitary hormones. The most common type of pituitary adenoma (approximately 30%) are functionally inactive and typically chromophobe adenomas. Of those adenomas that secrete hormones, 60–70% produce prolactin, 10–15% secrete growth hormone and some 5% secrete ACTH. Gonadotrophin and TSH secreting tumours are exceptionally rare.

## Clinical presentation

Patients with pituitary adenomas present typically with chronic mass effects, particularly affecting visual structures, chronic headaches, endocrine abnormalities resulting from hormonal hypersecretion and/or hyposecretion, or a combination of these factors. Occasionally, acute pituitary apoplexy occurs. Macroadenomas are the most common cause of chiasmal compression in adults and cause bi-temporal hemianopia. Partial patterns of visual loss develop, depending on the anatomical relationship of the tumour and the chiasm, leading to asymmetrical superior bi-temporal hemianopia or optic nerve

**Table 21.5** Classification of pituitary tumours.

Cell of origin	Hormone	Clinical features
Non-functioning	None	Cause symptoms only when they extend beyond the sella Most common type of macro-adenoma (30–35%)
Lactotroph	Prolactin	Typically intrasellar but may enlarge The most common hormone producing pituitary adenoma (40% of cases)
Corticotroph	ACTH	Secretion of ACTH leading to Cushing's syndrome (approx. 10% of cases) Usually confined to sella. May enlarge and become invasive particularly after adrenalectomy (Nelson's syndrome)
Somatotroph	GH	Gigantism in children and adolescents; acromegaly in adults Suprasellar extension relatively common Approximately 15% of cases
Thyrotroph	TSH (also occasionally GH and Prl)	Hyperthyroidism without TSH suppression May be large and invasive Rare, approx. 1–2%
Gonadotrophin	FSH or LH	Usually non-functioning May result in ovarian overstimulation, increases testosterone level, testicular enlargement or pituitary insufficiency due to compression of the stalk or destruction of pituitary tissue by the tumour Uncommon
Plurihormonal	More than one hormone	May have one cell population producing two or more hormones or two or more distinct cell types
Carcinoma		Usually functional (ACTH and Prl producing) Varying degrees of nuclear atypia and cellular polymorphism but often high mitotic rate and cell proliferation Rare (<0.2%)
Metastatic		Breast and lung cancer are most common neoplasms metastasing to pituitary. Also lymphoma, leukaemia, melanoma and prostate

ACTH, adenocorticotrophic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinising hormone; Prl, prolactin; TSH, thyroid-stimulating hormone.

**Table 21.6** Endocrine syndromes associated with pituitary tumours.

Prolactinoma (hyperprolactinaemia)	Amenorrhoea, infertility, galactorrhoea, loss of libido, erectile dysfunction
Corticotroph (Cushing's syndrome)	Obesity with centripetal fat distribution, hirsutism, abdominal striae, acne, hypertension, glucose intolerance, muscle wasting and weakness, osteoporosis, neuropsychiatric disturbance, immunosuppression
Nelson's syndrome	Due to growth of residual tumour after bilateral adrenalectomy in Cushing's patients Occurs when high plasma ACTH levels persist despite adequate glucocorticoid replacement Hyperpigmentation, mass effect. Tumours resistant to therapy
Growth hormone (acromegaly or gigantism)	Growth of hands and feet, prognathism, coarsening of facial features, carpal tunnel syndrome, diabetes, osteoarthritis, arthralgia, excessive sweating, obstructive sleep apnoea
TSH (thyrotoxicosis)	Features of thyrotoxicosis, weight loss, anxiety, palpitations, tremor, insomnia, menorrhagia
Gonadotrophin	Rare: testicular enlargement, ovarian stimulation

ACTH, adenocorticotrophic hormone; TSH, thyroid-stimulating hormone.

involvement. Oculomotor palsies develop if the pituitary adenoma extends laterally into the cavernous sinus through which pass cranial nerves III, IV and VI, the first two divisions of V and the sympathetic nerves to the eyes. Extension into a temporal lobe can lead to epilepsy. Rarely, hydrocephalus may occur because of direct compression of the 3rd ventricle leading to raised intracranial pressure or erosion through the sella to cause CSF rhinorrhoea. Compression of the internal carotid artery may lead to cerebral ischaemia. Hypothalamic invasion may affect temperature regulation and cause hypersomnolence, autonomic dysregulation and diabetes insipidus. Hormonal abnormalities caused by pituitary adenomas depend on the cell type and hormone produced (Table 21.6).

### Pituitary apoplexy

Pituitary apoplexy results from acute haemorrhagic or ischaemic infarction of the pituitary, often with a previously unrecognised secreting or non-functioning pituitary adenoma, and is believed to occur because a tumour has outgrown its blood supply. Extensive haemorrhagic infarction leads to mass effect in the suprasellar space and cavernous sinus. Apoplexy is rare and presents with sudden headache, meningism, vomiting, visual loss, ophthalmoplegia, visual field defect and occasionally impairment of consciousness. Secondary pituitary dysfunction and hyponatraemia can follow. The CSF shows evidence of haemorrhage with a pleocytosis and elevated protein. Predisposing factors include pregnancy, postpartum haemorrhage, trauma, diabetic ketoacidosis, radiotherapy and angiography. The condition may occur after bromocriptine has been started. Steroids are required urgently to treat pituitary apoplexy. Surgery may be necessary. Pan-hypopituitarism commonly follows and requires lifelong replacement therapy.

### Drug therapy and surgery

Management of pituitary tumours is directed at normalising hormonal secretion, reversing endocrine manifestations of excess secretion and preventing progressive neurological deficit, especially visual loss. Treatment options include surgery, medical management and radiotherapy. The choice is determined by the histological typing of the tumour, the nature of its hormonal expression, the size and its extension into surrounding structures. Surgical treatment is preferred for GH, TSH and ACTH producing and endocrinologically inactive tumours. Transphenoidal pituitary surgery is the most widely employed approach, particularly for non-functioning macroadenomas causing chiasmal compression. It allows direct visualisation of the gland and tumour and is well tolerated. It is successful in debulking tumours even if there is a considerable suprasellar extension and regrowth is uncommon. Advances in MRI, using high-field techniques, allow peri-operative assessment of the completeness of surgery and the planning of postoperative management. However, transphenoidal surgery is less effective if there is an hour-glass narrowing between the intrasellar and suprasellar component of the tumour or if there is infection within the sphenoid sinus. In these situations, surgery via a craniotomy using a subfrontal approach may be necessary.

GH secreting tumours may be treated initially with medical treatment using the GH receptor antagonist, pegvisomant, or somatostatin analogues (e.g. octreotide, lanreotide) which normalise GH level and decrease the tumour size in refractory acromegaly. Prolactinomas are usually treated medically with dopamine agonists (e.g. cabergoline or bromocriptine), which are effective in shrinking the size of the adenoma and lowering serum prolactin levels. Prolactin levels are often maintained after the drug has been

discontinued but if medical therapy fails then transphenoidal surgery and radiotherapy may be indicated.

### Radiotherapy

Radiotherapy is an effective adjunct to the treatment of pituitary tumours and contributes to the high rates of cure. Radiotherapy is indicated where surgery is contraindicated, following incomplete removal, especially around the cavernous sinus, when there is a large tumour mass at diagnosis (the large silent corticotrophs are at high risk of early local recurrence), following recurrent disease or where surgery has failed to cure a hormone producing tumour. Pituitary carcinoma requires radical resection followed by adjuvant radiotherapy and the consideration of temozolomide chemotherapy, dependent on histological subtype.

Hormonal responses to radiotherapy are typically slow over months to years. Radiotherapy may eventually lead to hypopituitarism and the need for full hormonal replacement. This risk needs to be balanced against the risk of further recurrence, and take patient preference into account – especially in young patients wanting to maintain fertility and with longer to develop a radiation-induced second tumour. The risk to visual function from conventionally fractionated radiotherapy is very low. Radiotherapy is usually CT-planned and conventionally fractionated. A stereotactic set-up or radiosurgery may be able to exclude the hypothalamus from the high dose volume and reduce the risk of hypopituitarism in small tumours confined to the sella. More rapid falls in hormone levels have been seen with radiosurgery but there are concerns about radiation-induced optic neuropathy.

### Craniopharyngioma

These are slow-growing benign extra-axial cystic tumours in the parasellar region. Cysts, sometimes multiple, contain thick proteinaceous material, often shiny because of a high content of cholesterol crystals. A cyst can extend in any direction and project into the hypothalamus, basal cisterns, 3rd ventricle, cerebellopontine angle, posterior fossa or the foramen magnum. Presentation is usually as a slow-growing tumour but there may be a sudden onset with rapid deterioration because of increase in volume or rupture causing a chemical meningitis or ventriculitis. The most common symptoms are headaches, visual disturbance and endocrine dysfunction. The clinical features may be similar to pituitary adenoma with progressive chiasmal compression except that craniopharyngiomas typically compress the superior aspects of the chiasm and cause inferior field defects. There may also be involvement of the optic nerves if the tumour is pre-chiasmal causing progressive optic atrophy with impaired acuity and constriction of the fields. Endocrine dysfunction is brought about by involvement of the pituitary stalk leading to hypothyroidism, adrenal insufficiency, diabetes insipidus, growth failure and reduced sexual drive. Compression of the 3rd ventricle leads to hydrocephalus and raised intracranial pressure with headache and papilloedema. Secondary hypothalamic involvement is common leading to hyperphagia and obesity. Craniopharyngiomas can infiltrate the frontal lobes, mammillary bodies and limbic system, eventually spreading to the Sylvian fissure leading to emotional, psychiatric and behavioural disturbances, apathy and short-term memory deficits.

Radical cure is the exception – the cysts are often multiple, adherent and inaccessible. Surgical resection is rarely possible and in any event surgery carries considerable morbidity, with risks of cyst rupture and hypothalamic damage. Recurrence is common. Incomplete removal must be followed by radiotherapy. The risks of side effects related to

radiotherapy are relatively low but intellectual decline, optic neuropathy and hypothalamic damage may occur. There may also be residual endocrine deficits including diabetes insipidus and cognitive impairments. New techniques of intracyst chemotherapy, stereotactic radiotherapy or internal irradiation are also used. Prognosis is highly variable with a significant morbidity and mortality from local extension. A poor outcome may be predicted by a young age of onset, pre-operative visual impairment, papilloedema, hydrocephalus and hypothalamic involvement. Subtotal resection, tumour calcification and adhesive tumour wall also predict a poor outcome.

### Primary CNS lymphomas

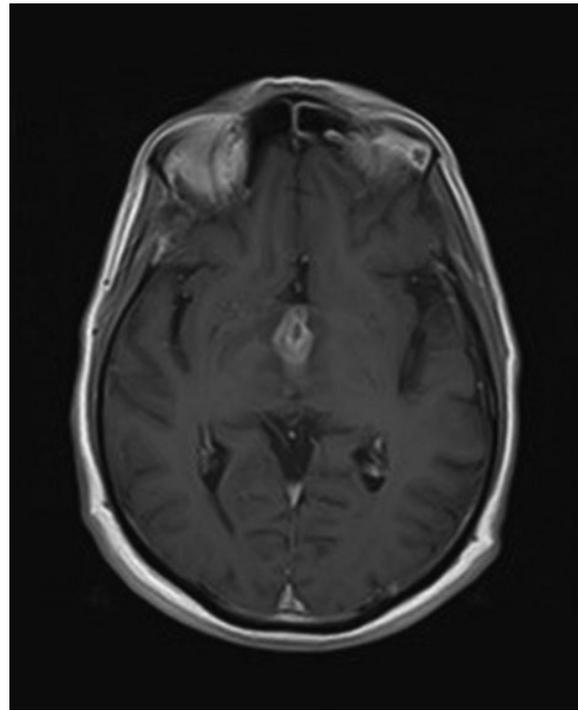

The term lymphoma encompasses a large heterogeneous group of malignant lymphoid neoplasms. When these tumours are confined to the brain, spinal cord or leptomeninges they are known as primary CNS lymphomas (PCNSL). These account for about 3% of primary CNS tumours, occurring predominantly in older people with a slight male preponderance. Immunosuppressed patients, most commonly HIV-positive, are about 1000 times more likely to develop PCNSL than immunocompetent adults. Indeed, PCNSL were rarely seen at all before the AIDS epidemic. However, there is also sound evidence that the incidence of PCNSL has increased in the immunocompetent population over the last two decades, particularly in those over 65 years.

### Imaging

PCNSL usually present as a single, lobulated enhancing mass, often abutting an ependymal (Figure 21.7) or meningeal surface. Occasionally, PCNSL are multiple. Enhancement is uniform in immunocompetent patients but tends to be ring-like in immunocompromised patients because of areas of central necrosis. The high cellular density of PCNSL accounts for its hyperdensity on CT and hypointensity on T2 MRI. The ADC of PCNSL is lower than in gliomas or toxoplasmosis which is an important differential diagnosis in immunocompromised patients. PCNSL grows in an angiocentric fashion around existing blood vessels without extensive new vessel formation. PWI therefore shows only a modest increase in rCBV, much less marked than in high-grade gliomas where angiogenesis is a prominent feature. In contrast to PCNSL which presents as an intraparenchymal mass, secondary CNS lymphoma (i.e. arising as relapse in the CNS from a previously treated extracranial lymphoma) involves more frequently the dura, ependymal, leptomeninges and cranial nerves, which show pathological enhancement with gadolinium (Figure 21.32). Both PCNSL and secondary CNS lymphomas show avid tracer uptake on FDG PET imaging.

### Pathology

Lymphomas are arranged in dense patternless sheets and infiltrate adjacent brain tissue diffusely and also in characteristic peri-vascular arrangements (Figure 21.31 g). Most primary intracerebral lymphomas are of B-cell type and are positive for the B-cell marker CD20 (Figure 21.31 h). These tumours are highly malignant and exhibit a very high mitotic index; Ki67 proliferation can be as high as 90%. The lymphoma shown in Figure 21.31(i) has a proliferation index of approximately 50%. Anaplastic large cell and T-cell variants are also described. They rarely metastasise outside the CNS but may spread along CSF pathways into the spinal cord. Approximately 20% of cases have intraocular involvement at diagnosis. Even in the majority of patients who have a single supratentorial mass lesion, the disease should be regarded as multifocal from outset. There is therefore no benefit in resection of the tumour except where there is life-threatening intracranial hypertension.

**Figure 21.32** Secondary CNS lymphoma. Axial T1-weighted image post gadolinium showing enhancing tumour within the 3rd ventricle lining the ependymal surfaces in a patient who had received treatment for Stage IV non-Hodgkin's lymphoma and who had relapsed in the brain.

### Clinical presentation

PCNSL usually present as either solitary or multiple mass lesions with raised intracranial pressure, progressive focal neurological deficit and seizures. Intracranial lesions are usually supratentorial; more than 60% are peri-ventricular, involving the splenium, corpus callosum, basal ganglia and the thalamus. Rarely, the tumour invades and proliferates within the small vessels of the brain, spreading along intravascular spaces. This is known as intravascular lymphoma or malignant angioendotheliomatosis. This presents as either progressive multifocal cerebrovascular events or as a subacute encephalopathy. Very rarely, PCNSL develop in the meninges, leading to a progressive leptomeningeal syndrome with cranial nerve palsies, hydrocephalus and myelopathy. Ocular lymphoma presenting with visual loss can predate the appearance of intracranial lymphoma.

### Diagnosis

Diagnosis is usually suspected from initial imaging which typically shows one or several homogeneously enhancing masses, often in a peri-ventricular location. In immunocompetent patients, in about 30% of cases the tumours are multiple, rising to some 50% in patients with AIDS. Once the diagnosis is suspected, steroids should be withheld because of their lympholytic properties until a stereotactic biopsy has been carried out, unless the patient has life-threatening intracranial symptoms. There are many reported cases of these tumours disappearing after even a few days on steroids. This phenomenon is not diagnostic of CNS lymphoma; it is seen also with inflammatory masses (e.g. acute demyelination) and even with gliomas.

The diagnosis may be confirmed from a CSF sample if the brain lesion is sufficiently small to allow safe lumbar puncture. CSF cytology is positive in about 30% of cases and the sensitivity increases with two or three lumbar punctures. Flow cytometric studies and

polymerase chain reaction (PCR) looking for clonal rearrangements of immunoglobulin heavy chains can improve sensitivity but are not universally available. In situations where CSF is negative or a lumbar puncture cannot be carried out for fear of coning, a stereotactic biopsy will usually establish the diagnosis. A contrast-enhanced MRI of the spine should also be carried out to look for leptomeningeal tumour deposits. Open craniotomy and resection can lead to seeding of tumour cells into the leptomeningeal space and does not confer any survival benefit. Once the diagnosis is suspected, the patient's HIV status should be determined and the eyes examined by an experienced ophthalmologist for evidence of intraocular disease. Asymptomatic ocular involvement occurs in some 20% of patients and specific additional treatment may be required. Staging body CT and bone marrow aspirate are seldom required as systemic lymphoma is found rarely in PCNSL. Such a finding has no effect on subsequent disease course. Serum lactate dehydrogenase is often greatly raised, sometimes useful as a diagnostic pointer and as a prognostic factor in PCNSL.

### Treatment

Current treatment of PCNSL is based around the use of high-dose intravenous methotrexate (HDMTX: 3 g/m<sup>2</sup>) regimens followed by whole brain with or without spinal or ocular radiotherapy, in contrast to systemic non-Hodgkin's lymphoma where the standard first line regimen is R-CHOP. In an effort to intensify chemotherapy and avoid the use of radiotherapy altogether (to minimise neurotoxicity), some centres have treated good performance patients with HDMTX alone followed by myeloablative chemotherapy and then autologous stem cell rescue. Long-term data have not been published. The additional benefit of intrathecal chemotherapy either via the lumbar route or via an Ommaya–Rickman reservoir directly into the ventricles is also not proven. WBRT in combination with corticosteroids leads to a response in about 70% of patients. This regimen is best reserved for elderly patients with poor performance status who would otherwise not tolerate HDMTX-based therapies.

The major dilemma facing oncologists arises in patients over the age of 60 years in whom the combination of methotrexate and WBRT is associated with an almost 100% risk of cognitive decline, ataxia and incontinence 1–2 years after treatment. This has led to the development of protocols based around chemotherapy alone although there is a risk of renal and bone marrow failure with these intensive regimens. Furthermore, as there are no randomised Phase III studies that prove that this can produce a long-term survival benefit, our own practice has been to irradiate to a dose of 30 Gy after obtaining radiological remission with chemotherapy.

The prognosis depends on age and performance status, as with other CNS tumours, but also on the extent of spread along CSF pathways and whether or not the patient is HIV-positive. Average survival of elderly patients treated with steroids alone is in the region of 6 months, increasing to 1 year with the addition of radiotherapy. This rises to 2 years in those under the age of 60 years. The combination of HDMTX chemotherapy followed by radiotherapy in patients under the age of 60 years is associated with 5-year survival rates of 65%, clearly much higher than any survival for high-grade gliomas.

## Primitive neuroepithelial tumours and medulloblastomas

Primitive neuroepithelial tumours (PNET) account for about 20% of childhood brain tumours overall and are the second most frequent childhood primary brain tumour after the relatively benign

cystic astrocytomas. They are rare (less than 1% of brain tumours) in adults. They are highly malignant (WHO Grade IV) with a propensity for spread through the CSF. They are called medulloblastoma when found in the posterior fossa, pineoblastoma in the pineal region, and supratentorial PNET when present in the cerebral hemispheres. Medulloblastomas typically occur in children, declining sharply in incidence after the age of 15 years; they are the most common highly malignant brain tumour of childhood. About 1 in 20 metastasise outside the CNS. Overall 5-year mortality of medulloblastoma cases is 60%. Supratentorial PNETs carry a significantly worse prognosis than medulloblastoma with only about 50% surviving 3 years, thought to be the result of a combination of biological differences and the difficulty of complete surgical resection.

### Pathology

Macroscopically, these tumours vary in growth pattern, ranging from firm and discrete to soft and less well-defined masses. Medulloblastomas mostly arise in the cerebellar vermis, but with increasing age tend to develop within the cerebellar hemispheres. There is increasing experimental evidence that most medulloblastomas originate from the external granular layer (EGL) of the cerebellum. Histologically, they vary in their appearance. The undifferentiated or classic medulloblastoma is the most common form, characterised by densely packed, round or oval cells with a high nucleus to cytoplasm ratio and showing neuroblastic rosettes formed by circular arrangements of tumour cells around a virtual centre (Figure 21.2c). The nodular or desmoplastic variant is characterised by extensive formation of nodules that show neuronal differentiation and are surrounded by thin collagenous septae and undifferentiated cells. A more recently defined entity is the large cell anaplastic variant (approximately 4%) composed of markedly irregularity and atypia, frequent mitoses and apoptosis. This variant is associated with a particularly poor prognosis. Medulloblastoma can show a variable degree of differentiation into neuronal, and rarely glial, ependymal, muscular (medullomyoblastoma) or melanocytic (melanotic medulloblastoma) lineages.

### Molecular genetics and histogenesis of medulloblastoma

Four major subgroups have been identified: Wnt, sonic hedgehog (Shh), Group 3 and Group 4.

The best known of the medulloblastoma subgroups is the Wnt subgroup because of its very good long-term prognosis in comparison to other subgroups, with long-term survival exceeding 90%. The Shh group of medulloblastomas are named after the sonic hedgehog signalling pathway, which is thought to drive tumour initiation in many, if not all such cases; it is frequent in both infants (0–3 years) and adults (>16 years), but much less frequent in children (3–16 years). The prognosis of Shh medulloblastoma is similar to Group 4 medulloblastomas, and intermediate between that of Wnt medulloblastomas (good prognosis) and Group 3 medulloblastomas (poor prognosis). Group 3 tumours are mostly 'classic' medulloblastomas, but they also encompass the majority of the large cell anaplastic histological type. They have a poor prognosis. The molecular pathogenesis of Group 4 tumours is currently not well understood. The title Group 4 has been chosen for the current consensus nomenclature until further analysis has been done. Group 4 patients have an intermediate prognosis, similar to individuals with Shh tumours.

There are several histological variants including the classic (undifferentiated) medulloblastoma, which is the most common in adults, desmoplastic nodular and large cell (anaplastic), the latter associated with a particularly poor prognosis.

## Imaging

Medulloblastomas usually arise in the cerebellar midline in children and the cerebellar hemispheres in adults. In contrast, PNETs are usually supratentorial. The high nuclear : cytoplasmic ratio of both these tumours is responsible for their hyperdense appearance on CT and hyperintense appearance on DWI. A three- to fourfold elevation of choline and lipid on MRS is caused by their intense cellularity and cell turnover. PNETs enhance and have a propensity for dissemination in the subarachnoid space with leptomeningeal deposits. Staging of these tumours requires contrast-enhanced MRI of the entire neuraxis.

## Clinical features

Clinical features include gait ataxia, headache, vomiting and visual loss resulting from hydrocephalus. Children tend to have midline tumours that are well-defined and enhance homogeneously, whereas in adults tumours usually arise within the cerebellar hemispheres and are poorly enhancing. All patients require staging with MRI of the spine, ideally prior to surgery, as well as CSF examination either prior to surgery or 10–14 days after. Postoperative imaging to determine the extent of resection should be carried out ideally within 24–48 hours after surgery.

## Treatment

The main adverse factors in children are: age less than 3 years; post-operative macroscopic residual disease >1.5mL; anatomical site; anaplastic and large cell variants; and CSF metastases. These factors are used to determine the standard and high risk groups for prognosis and management. Current therapy for good prognosis, standard risk children comprises cranio-spinal irradiation (CSI) and adjuvant chemotherapy. An 85% 5-year survival is now seen in the standard risk group, but this falls to between 30 and 50% in those with adverse factors. Aggressive chemotherapy schedules and hyperfractionation of CSI (treating twice a day) are being investigated in the high risk population to try and improve the poor survival rates.

Surgery has three aims – histological diagnosis, maximal safe tumour resection and relief of hydrocephalus – thus avoiding the need for a CSF diversion procedure with attendant risks of upward brainstem herniation, CSF dissemination and infection. Mortality should be less than 1%, morbidity 5–10%, with an unusual complication being cerebellar mutism. This is thought to arise from damage to the dentate nuclei but it gradually improves; it should not delay the start of adjuvant radiotherapy.

All patients are then treated with CSI. In adults the dose is usually 36 Gy to the whole neuraxis followed by a boost to the posterior fossa of 18 Gy. The CSI dose has been safely reduced to 24 Gy in the standard risk group in children, in an attempt to avoid the significant cognitive, endocrine and growth deficits, with the addition of Packer chemotherapy (cisplatin, vincristine and CCNU). However, chemotherapy brings its own side effects of hearing loss, infertility, renal failure, peripheral neuropathy and myelosuppression. Higher doses (46 Gy) are given to nodular metastases in the spine. The delivery of CSI is complex and the technical quality of radiotherapy shown to be closely related to outcome in PNET. It has been proposed that it should only be delivered in designated paediatric and young adult radiotherapy centres as these have the necessary expertise through treating a significant number of cases.

The majority of reported cases of adult medulloblastoma (MB) come from retrospective studies from single institutions spanning many decades. It is therefore difficult to draw firm conclusions about the best treatment. Being an adult is itself considered an adverse factor and therefore immediately high risk. Certain principles are clear,

namely the need for maximal resective surgery followed by CSI. The role of chemotherapy is not yet established for adults with MB, as standard treatment (surgery plus CSI) yields a 60% 5-year progression-free survival. There is a perception that radiotherapy is less harmful to adults than to children in the long term and that survival benefit from chemotherapy in adults is less convincing than in children. However, most neuro-oncologists would treat high-risk adult patients with MB with adjuvant chemotherapy.

Relapse in adult patients with MB occurs in 20–50% by 5 years and is usually in the posterior fossa or in the spine. Treatment at relapse is therefore directed at resection or highly focused radiotherapy (e.g. stereotactic radiosurgery) to the posterior fossa followed by high-dose myeloablative chemotherapy and stem cell rescue. Unfortunately, almost all patients experience eventual recurrence either in the CNS or at distant non-CNS sites and succumb. Overall survival ranges are 25–85% at 5 years and 35–50% at 10 years. Clinical trials are needed for adult patients, but until further results become available we must be guided by paediatric trials.

## Pineal region tumours

### Introduction

A variety of tumours occur in the pineal region (Table 21.7), including germ cell tumours (germinomas and non-germinomatous germ cell tumours), pineal parenchymal tumours (pineocytoma and pineoblastoma) as well as gliomas and metastases.

**Table 21.7** Tumours of the pineal region.

<b>Tumours of pineal origin (20%)</b>

<b>Vascular lesions</b>
Aneurysm of vein of Galen
AVM
Cavernous malformation

AVM, arteriovenous malformation.

## Pathology

Pineoblastomas belong to the group of PNETs and arise in the pineal region. Histological features include the formation of neuroblastic rosettes as shown in (Figure 21.31j). In intraoperative smear preparations, these tumours typically spread out to monolayers with fine synaptic networks (Figure 21.31k). They almost invariably express the neuronal marker synaptophysin, as shown in (Figure 21.31l).

## Clinical features

The clinical syndromes associated with pineal region tumours are determined by the close anatomical relationship of the gland with the quadrigeminal plate and midbrain tectum ventrally, the 3rd ventricle rostrally and the cerebellar vermis caudally. Typical syndromes include:

- *Obstructive hydrocephalus*: headache, nausea, vomiting and obtundation
- *Parinaud's syndrome*: vertical gaze palsy, light-near dissociation mid-point pupils, loss of convergence and convergence-retraction nystagmus (Chapter 14), and
- *Ataxia*: caused by involvement of the superior cerebellar peduncle.

Germ cell tumours can produce diabetes insipidus, amenorrhoea, growth arrest and pseudo-precocious puberty. The diagnostic work-up of a pineal region tumour includes a gadolinium-enhanced MRI scan and tumour markers in serum and CSF alpha-fetoprotein (AFP) and human chorionic gonadotrophin ( $\beta$ -HCG). High levels are pathognomic of malignant germ cell tumours and obviate the need for biopsy.

## Treatment

There is a high morbidity and mortality associated with pineal region surgery and thus debate about the pros and cons of biopsy alone versus open resection. The ultimate choice of procedure will depend largely on the individual surgeon but, as a general rule, a stereotactic biopsy is preferred where there is disseminated disease, clearly invasive malignant tumour or the patient has multiple other medical problems. The mortality and morbidity of stereotactic biopsy in modern series is around 1.3% and <1.0%, respectively. In contrast, open resection should be reserved for patients with benign lesions, in whom surgery can be curative or rarely for debulking of malignant tumours, particularly where the biopsy diagnosis has been hampered by small amounts of tissue or has been inconclusive.

The subsequent treatment and prognosis depends much on histology. Germinomas are exquisitely sensitive to radiotherapy and are associated with good long-term survival. Patients with non-germinomatous germ cell tumours have a significantly worse prognosis and are usually treated with a combination of chemotherapy and radiotherapy. Pineoblastomas are managed like medulloblastomas with a pre-operative MRI spine and CSF, which if negative should be followed by maximal tumour resection, followed by CSI and chemotherapy. If either of these is positive, then the risks of surgery probably outweigh the benefits and patients should be treated with upfront CSI and chemotherapy.

## Germ cell tumours

Germ cell tumours (GCT) arise from primitive embryonic cells and usually present as ovarian or testicular tumours. The CNS is the second most common extragonadal site for germ cell tumours (after the mediastinum). They generally arise in the midline in the region of the pineal gland and the suprasellar region, accounting for approximately 50% of pineal tumours. Each of the histological germ cell variants are derived from cells of a normal stage of embryonal development and may be classified as follows:

- 1 Undifferentiated germ cell tumours derived from primordial germ cells:
  - Germinoma
- 2 Differentiated non-germinomatous germ cell tumours (NGGCT):
  - Teratoma
  - Embryonal carcinoma
  - Endodermal sinus tumour (yolk sac tumour)
  - Choriocarcinoma.

When a GCT is suspected, MRI of the cranio-spinal axis, serum tumour markers, and CSF sampling for tumour markers and cytology are required for diagnosis, management and staging. High levels of AFP and  $\beta$ -HCG in either compartment are pathognomic of secreting NGGCTs. They replace the need for biopsy and can be used to monitor response to chemotherapy and remission status on surveillance. However, these tumour markers are not sensitive as many tumours do not produce them and others are of mixed histology.  $\beta$ -HCG is elevated in choriocarcinoma. Bifocal disease (concurrent primary tumours in the suprasellar/parasellar and pineal regions) is seen in 30% of germinomas and is also considered pathognomic. Less than 10% of GCTs have metastatic disease at presentation.

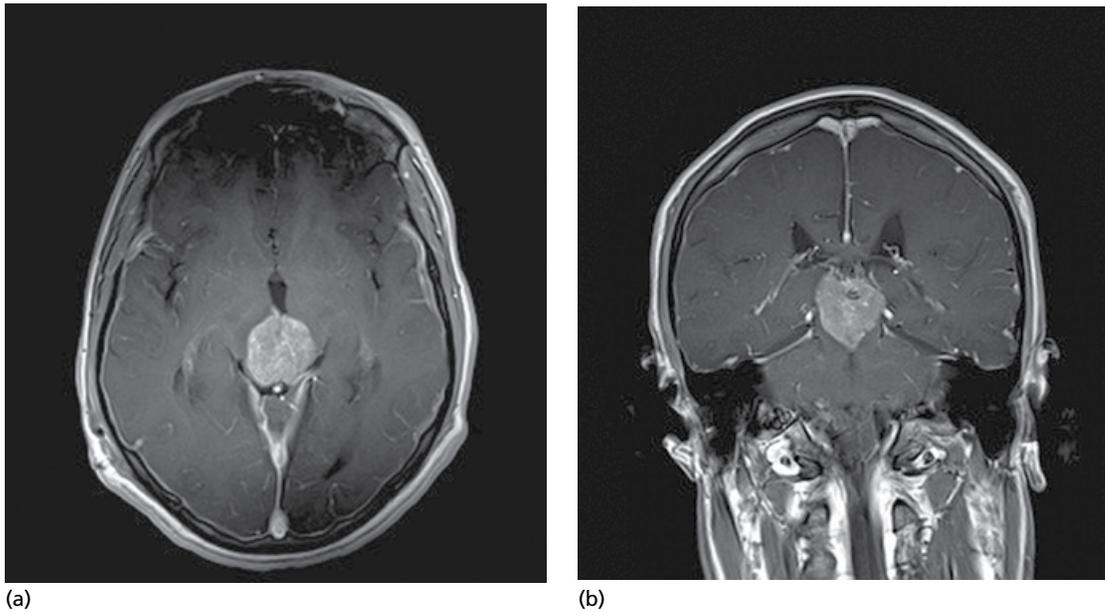

The diagnosis determines the prognosis. Germinomas (Figure 21.33) are histologically identical to testicular seminomas and are not usually associated with raised CSF tumour markers. They are extremely radio-sensitive with a 90% cure rate with cranio-spinal radiotherapy alone, and this is the mainstay of treatment. NGGCTs have a worse prognosis than germinomas and require multi-modality therapy to attain a 5-year survival around 70%. The standard regimen is for platinum-based chemotherapy, followed by surgery and/or radiotherapy. The radiotherapy is focal in localised disease and cranio-spinal for metastatic disease. Teratomas require surgery only.

NGGCTs have a mixed density on MRI and CT and often present as large cysts or areas of calcification with distinct margins. Occasionally, formed tissue may be identified within the cyst and more aggressive NGGCT show heterogeneous enhancement. Choriocarcinoma may show extensive haemorrhagic change.

## Optic pathway glioma

Optic pathway gliomas (OPG) are rare astrocytic neoplasms arising from the optic pathway that occur most commonly in children. They comprise 0.6–1.5% of all intracranial tumours, 1.7–7% of all gliomas, 3.5% of all orbital tumours and 66% of all optic nerve tumours. They usually have an indolent but progressive nature, which may result in blindness and eventually death, despite attempts at timely treatment.

The majority of patients are diagnosed below the age of 10 and the most common histology in this group is pilocytic astrocytoma. There is an association with neurofibromatosis type 1 (NF1) and in this group the prognosis is more favourable. Approximately half of all patients with OPG have NF1. Adult patients with optic nerve gliomas are thought to represent a separate group of glioma with a highly aggressive phenotype that presents with signs and symptoms of acute optic neuropathy, progresses to blindness within a few weeks and death within a few months. There is a relationship between age of diagnosis and tumour grade, with a tendency to high grade tumours in older patients. Many patients are diagnosed on the basis of imaging as the tumours are intrinsic to the axons of the visual pathway and are therefore not easily amenable to biopsy unless there is an extrinsic component. On MRI, optic nerve gliomas appear as diffuse enlargement of the

**Figure 21.33** Germinoma. (a) Axial and (b) coronal T1-weighted post gadolinium images of midline germinoma presenting with bi-ventricular hydrocephalus.

optic nerves with spread into the chiasm and the optic radiation. There may be a fusiform appearance and commonly the lesions are isointense on T1-weighted images and iso- to hyper-intense on T2 sequences. Those not related to NF1 usually enhance with gadolinium.

#### Treatment of optic pathway glioma

For children younger than 8 years of age and those with NF1, primary chemotherapy treatment is recommended, to delay or obviate the need for radiotherapy and the associated morbidity. Response rates are good and endocrine, intellectual and overall neurological function may be preserved. The recommended agents are vincristine and carboplatin given for 18 months. For those children having radiotherapy, protons are advised to avoid morbidity to normal tissues. It is unusual for surgery to be used in children with low grade OPG.

For the majority of adult patients the untreated clinical course is that of progressive blindness and death from local tumour progression. Lesions that are localised to the optic nerve can be cured by surgical excision and postoperative radiotherapy is not given if the lesion has been completely excised unless it recurs. In the care of posterior lesions extending into the chiasm, hypothalamus and contiguous structures, total resection is not possible without substantial morbidity; the role of surgery is to provide histological confirmation and to perform shunting if necessary.

Radiotherapy is an effective treatment in those unsuitable for surgery, after partial resection and in patients who progress after surgery alone. Local failure rates after radiotherapy are greater for posterior than for anterior tumours. Fractionated stereotactic radiotherapy with MRI and CT fusion to assist treatment planning has the advantage of delivering a higher dose more accurately to the tumour and a lower dose to adjacent normal brain tissues and is recommended if available. The advantage of this treatment is that it spares the pituitary gland in optic chiasm lesions. A dose of 50.4–52.2 Gy in 1.8 Gy fractions, aiming to keep within normal tissue tolerance for the eyes and optic apparatus is recommended. Intensity modulated radiotherapy may also be used to good effect

to reduce morbidity. Following treatment visual fields and endocrine function should be monitored.

#### Ependymomas

Ependymomas are slowly growing tumours, derived from the ependymal lining cells, which present at any age but are most common in the first and second decades of life. They account for 4–9% of neuroepithelial tumours. They occur at any site along the ventricular system, most commonly in the 4th ventricle in children and the cervical spine or conus medullaris in adults.

#### Pathology

They are well-defined but can encase peripheral nerves when they grow laterally from the 4th ventricle. Characteristic histological features are the formation of pseudorosettes, the concentric arrangement of ependymal cells around a vessel. Fibrillary glial processes of ependymal cells radiate to centrally located vessels and form a nuclei-free area, which creates this distinctive histological appearance. There are further variants of ependymoma which are named according to prevailing features such as cellular, papillary, clear cell and tanycytic but these distinctions have little or no clinical importance. A distinct variant is the WHO Grade I myxopapillary ependymoma of the spinal filum terminale.

Grade II ependymomas are well defined, show monomorphic nuclei and rare mitotic activity while Grade III (anaplastic) ependymomas show increased cellularity, increased mitotic rate and often vascular proliferation and necrosis. In adults, ependymomas account for about 2% of all intracranial tumours and are associated with a high survival rate compared with other glial tumours (5 and 10-year survival 85% and 76%, respectively). Overall survival correlates well with histological grade, extent of resection, age and performance status.

**Molecular genetics of ependymomas** Despite histological similarities, ependymomas arising from the spinal cord and the infratentorial and supratentorial compartments of the CNS show diverse clinical behaviour. Using unsupervised clustering, two distinct molecular

subtypes of infratentorial ependymoma were identified. These correlated by differences in progression-free survival and overall survival. Expression of the markers laminin alpha 2 (LAMA2) and neural epidermal growth like factor 2 (NELL2) in the transcriptome subgroups showed the following pattern: LAMA2 is over expressed in Group A ependymomas, occur in younger patients (mainly children) and have a better progression free and overall survival and a longer time to metastasis. Group A ependymomas often have Chr 1q amplifications. NELL2 expression is significantly higher in Group B ependymomas, with poorer progression-free survival, overall survival and shorter time to metastasise.

### Imaging

Ependymomas (WHO Grades II and III) in the brain are usually intraventricular, although extraventricular rests of ependymal cells may also give rise to hemisphere tumours. They are well-demarcated lobulated mass lesions with calcification on CT in over 50% and mixed signal intensity on MRI (predominantly hyperintense on T2 and isointense to hypointense on T1 images). Enhancement is mild to moderate and often heterogeneous.

### Treatment

All patients should have staging with MRI of the whole cranio-spinal axis and CSF obtained either preoperatively or more commonly 2 weeks post surgery. The goal of surgery for ependymomas is gross total resection, which is achievable in 70–90% of cases, and should be confirmed with an early postoperative scan (<24 hours). The rates of long-term tumour control are high after gross total resection. Radiotherapy is typically indicated for subtotally resected tumours, irrespective of grade and for completely resected anaplastic ependymomas. Cranio-spinal treatment is now only used now for patients with disseminated disease as evidenced by MRI 'drop metastases' or positive CSF, as the risk of relapse down the cranio-spinal axis for local disease is less than 3%. Areas of bulky disease can be boosted to 50 Gy for spinal metastases or to 55–60 Gy for

primary tumours and brain metastases. Chemotherapy with cisplatin and/or etoposide may be indicated for relapsed disease but is not usually effective. In rare cases of localised relapse, radiosurgery or re-irradiation may be considered on a case by case basis.

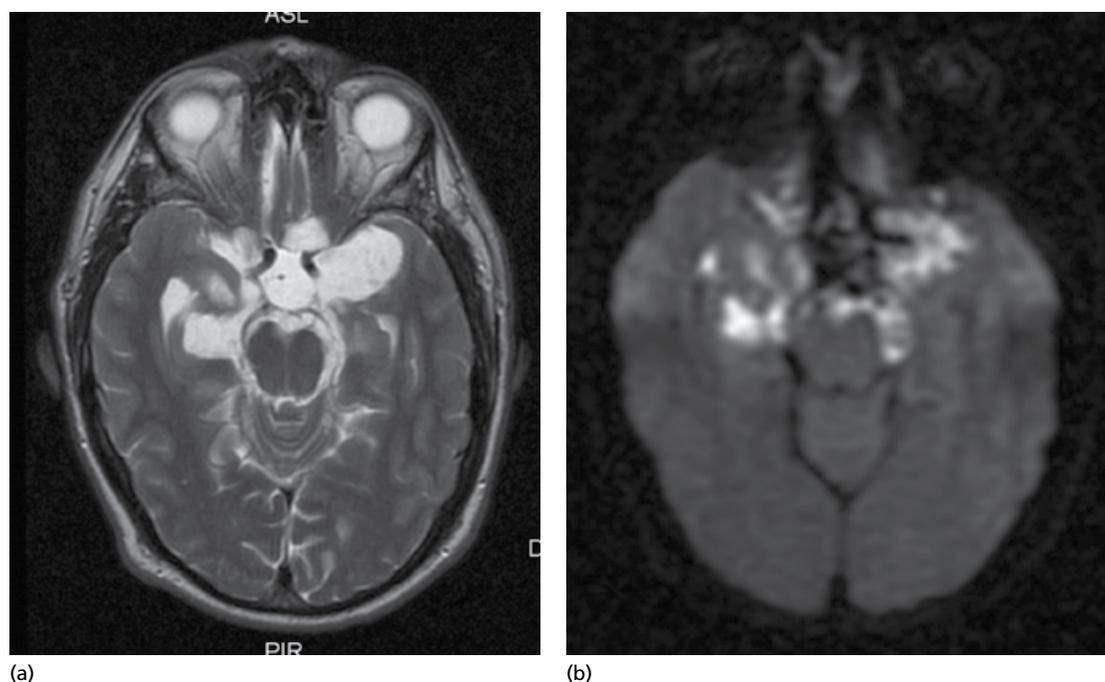

### Dermoids and epidermoid cysts

These are cystic lesions arising from inclusion of ectodermal tissue during neural tube development and sequestration cysts which may accompany dysraphism (e.g. spina bifida) with communication to the skin surface through a sinus tract. Dermoid cysts contain hair follicles, sweat glands and sebaceous glands. They arise in the posterior fossa in the region of the midline, vermis or 4th ventricle or in the suprasellar cistern and present with local mass effects or by rupture of their contents into the CSF causing granulomatous meningitis. Management is by total surgical excision. Incompletely resected cysts may recur.

Epidermoid cysts are more common and arise in the cerebello-pontine angle or middle cranial fossa causing mass effect, facial pain and cranial nerve deficits. Surgical removal of epidermoid cysts may be difficult because of their tendency to spread along cranial nerves but is usually curative. Very rarely epidermoid cysts undergo malignant transformation.

### Imaging

Intracranial dermoid cysts lie usually near the midline and contain all skin elements, including fat, which appears as very low density on CT and high signal intensity on MR T1 images. Epidermoid cysts, formerly known as pearly tumours, grow slowly over many years by accumulating desquamated epithelium. They conform to the contour of the subarachnoid space they occupy, sometimes invaginating into the brain parenchyma. On CT and standard T1 and T2 MRI, epidermoid cysts are non-enhancing lesions of signal intensity to CSF, a reason why they can be confused with arachnoid cysts. DWI easily distinguishes epidermoid tumours from arachnoid cysts, as water diffusion is markedly restricted in the former but not in the latter (Figure 21.34).

**Figure 21.34** (a) T2 image of an extensive epidermoid tumour spreading through the basal cisterns and invading the temporal lobes. (b) Diffusion-weighted image of the epidermoid tumour: characteristically bright and well delineated from surrounding CSF and brain parenchyma.

### Haemangioblastomas

These are benign, cystic, highly vascular tumours. They are formed by vessels that range in size from small capillaries to large vessels and there may be one or more associated cysts. They generally arise in the posterior fossa and cause symptoms either because of raised intracranial pressure or cerebellar dysfunction. Less commonly there may be brainstem involvement leading to motor and sensory deficits. Polycythaemia may occur in 10% of patients from tumour production of erythropoietin. They may also arise within the spinal cord causing radicular pain, posterior column loss and pyramidal involvement with weakness, spasticity and bladder disturbance. There may be an associated cavity within the cord and clinical syringomyelia. Rarely, haemangiomas arise supratentorially.

Haemangioblastomas are most commonly associated with von Hippel–Landau (VHL) syndrome (Chapter 26). This condition is caused by a germ line defect in a tumour suppressor gene on chromosome 3p25. VHL is associated with multiple haemangiomas which may be asymptomatic. There is also retinal angiomas, renal cell carcinoma, visceral cysts and pheochromocytoma.

Haemangioblastomas are relatively sharply demarcated: invasion and remote metastases are rare. Surgical resection is generally possible and total resection curative. Residual or inoperable tumours may be treated with external beam radiotherapy or stereotactic radiosurgery. The overall outcome is good with 5-year survival of 75%, particularly with small tumours and complete surgical removal. Screening for VHL is necessary in all patients with haemangioblastoma.

### Colloid cysts, Rathke's pouch tumours and neuro-enteric cysts

These benign cystic lesions represent developmental malformations. The cysts are lined by columnar, mucin-producing epithelial cells which resemble respiratory or enteric lining. Colloid cysts are characteristically located in the roof of the 3rd ventricle and may block the foramen of Monro leading to obstructive hydrocephalus. Characteristically, this may be postural with intermittent headache and drop attacks. Rathke's pouch cysts arise in the sellar region. Neuro-enteric cysts arise in the spinal cord or within the brain. Imaging shows isodense or hypodense lesions on CT and MRI. Symptomatic lesions require surgical excision and a ventriculoperitoneal shunt may be necessary if there is hydrocephalus.

## Neurological complications of cancer

Neurological complications of cancer (NCC) are common, serious, potentially disabling and often treatable when correctly diagnosed. The most frequent neurological complaints in patients with cancer overall are pain, confusion, headache and weakness. NCC are common reasons for admission to hospital. Many oncologists have had little formal training in neurological assessment. Many neurologists see relatively few cancer patients and are unlikely to know in detail the recent advances in cancer management and the way in which the nervous system can be affected by them, especially neurotoxicity of modern biological agents. Radiation treatment can lead to delayed neurological problems which may emerge years after the original treatment, possibly when the original cancer has been cured. It is thus essential that neurologists have a broad overview of NCC in order to focus on the differential diagnosis and appropriate tests, that they can gain access to specialist neuro-oncological advice, often in liaison with an oncologist. Table 21.8 outlines the main neurological problems in cancer patients.

**Table 21.8** Neurological complications of cancer.

<b>Direct effects</b>
Infiltration by primary tumour or draining lymph nodes: e.g.
Nasopharyngeal carcinoma – multiple cranial nerve palsies
Lung cancer, e.g. Pancoast tumour causing T1 radiculopathy with Horner's
Breast cancer – brachial plexus lesions
<b>Metastases</b>
Brain
Skull base and vault
Dura
Spinal cord – extradural, intradural, intramedullary
Leptomeninges (malignant meningitis)
Brachial and lumbar plexus
Perineural
<b>Indirect effects</b>
Metabolic encephalopathies (e.g. hyponatraemia due to SIADH)
Vascular disorders (e.g. hypercoagulable states, haemorrhage and non-bacterial thrombotic endocarditis)
CNS infections
Paraneoplastic neurological disorders
<b>Unwanted effects of treatment</b>
Chemotherapy neurotoxicity
Radiotherapy neurotoxicity
Intrathecal administration
Compression neuropathies (e.g. after surgery)

SIADH, syndrome of inappropriate antidiuretic hormone.

As with any neurological presentation, the history is key. With respect to patients with known cancer the following points should be ascertained: details of the histology and staging (Tumour Node Metastasis) of the primary tumour, site, presence of known metastases, treatment received to date including hormonal treatments and current medication, both for the cancer, for pain and any other symptoms (e.g. vomiting).

### Direct effects and infiltration

The majority of NCC are caused by direct invasion of the nervous system or metastatic spread. This is usually easily diagnosed clinically and/or with appropriate imaging. As the sensitivity of imaging increases, it has become evident that the highest resolution imaging is frequently needed to reach a diagnosis. MRI with contrast enhancement or PET may well be necessary if less sophisticated imaging is negative. Although there are common patterns of tumour spread (e.g. bony metastases with breast, bronchus, prostate, kidney and thyroid cancer), almost any malignancy can spread anywhere within the neuraxis.

Invasion or compression of neurological structures occurs when a primary or secondary tumour or draining lymph node is in direct contact with a nerve, nerve root, spinal cord or brain. Tumour invasion of nerve roots is sometimes associated with severe pain: this may be helpful to differentiate malignant infiltration from effects of

**Figure 21.35** Perineural spread. Coronal T1-weighted post gadolinium images of squamous cell carcinoma extending across the base of skull into the left cavernous sinus and intradurally into the left temporal lobe. Note high signal change within left pterygoid resulting from denervation.

previous treatment. In some cases (e.g. Pancoast tumour), neurological symptoms of radiculopathy can be the presenting complaint. Less commonly, microscopic growth of tumour cells, particularly lymphoma along nerve sheaths, occurs after the primary tumour has been treated. Examples of direct perineural invasion include multiple cranial nerve palsies with nasopharyngeal carcinoma or squamous cell head and neck cancer (Figure 21.35), brachial plexopathy from breast cancer in the axillary tail, T1 radiculopathy with Horner's syndrome from apical lung cancer (Pancoast's syndrome) and, in children, paraganglioma and/or neuroblastoma causing spinal cord compression via paravertebral spread through the neural foramina into the epidural space.

### Metastases

Metastases are a major cause of neurological problems in patients with cancer. They are commonly fatal when they involve the CNS. They occur by haematogenous spread, the usual mechanism of brain metastases; by lymphatic dissemination, usually to peripheral nerves; or by dissemination through the CSF, producing leptomeningeal metastases. The likelihood of metastasis increases with increasing primary tumour size and the duration of patient survival following treatment to the primary site. The site to which a tumour metastasises depends on the anatomy of the venous and lymphatic drainage of the organ harbouring the tumour, the micro-environment of the receiving organ and the molecular phenotype of the tumour, particularly the propensity to express surface adhesion molecules. As an example, colorectal cancer usually metastasises to the posterior fossa and prostate cancer to the epidural space via Batson's venous plexus, a system of paravertebral veins that connect pelvic and thoracic vessels to the intraspinal veins.

### Malignant meningitis

Malignant meningitis (MM) is one of the most sinister complications of any cancer, occurring in 3–8% of patients often at the later stages of the disease but occasionally presenting in a patient with no known tumour. The median survival is typically 2–3 months, although patients with breast cancer can survive for up to 2 years, as this is a more chemosensitive tumour. MM is becoming more frequent because of the improved prognosis of patients with systemic cancer and earlier diagnosis with MRI. It is characterised by invasion of the leptomeninges and/or CSF by cancer cells and can affect either brain, the spinal cord and nerve roots. Tumours that commonly cause MM are lung and breast cancer, melanoma and leukaemia/lymphoma, where bloodstream spread is the route into the CNS. However, almost any tumour can cause MM, including colorectal and urogenital cancer. MM occurs, if rarely, as a complication of primary brain tumours. This is seen in paediatric practice with medulloblastomas, ependymomas and oligodendrogliomas and in adult practice in the terminal stages of glioblastoma.

In adult practice, breast is the most common solid tumour associated with MM followed by lung cancer, both small cell and non-small cell. In some 5% of these cases, the patient presents *de novo* with MM. In some cases the primary may never be found. Although haematogenous invasion is the most common route for cancer cells to reach the leptomeninges, direct invasion from metastases in contact with the meninges (i.e dural), subdural and intraparenchymal metastases and perineural invasion occurs. Iatrogenic seeding during surgical resection of posterior fossa metastases has even been implicated in the pathogenesis of MM.

### Clinical features

MM can present with cerebral, cranial nerve, spinal and/or radicular symptoms and signs (Table 21.9), either in isolation or as a multifocal process. The initial symptoms are often vague: unexplained nausea, vomiting, drowsiness and intermittent confusion. Patients may then develop combinations of cranial nerve palsies, sensorineural deafness, papilloedema resulting from communicating hydrocephalus, seizures or patchy radiculopathy. Patients should be asked about numb patches in the body and examined for evidence of nerve root involvement.

### Diagnosis

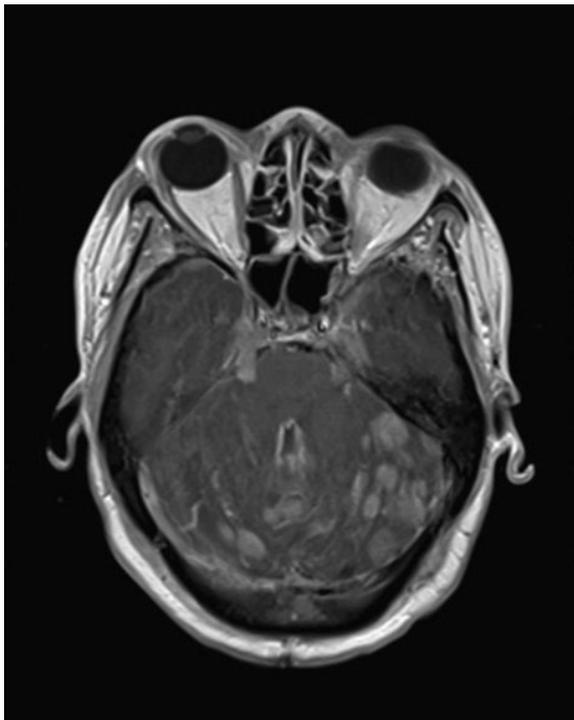

Gadolinium-enhanced MRI provides the most sensitive imaging modality. Abnormal enhancement, which may be linear or nodular, is seen in 70% of patients with MM, compared to about 30% with contrast-enhanced CT. Linear enhancement may be seen in cerebral sulci and within the ponto-medullary cisterns. This gives rise to a characteristic pattern of sugar coating of the brainstem, within the cerebellar folia or along the spinal cord appearing as tramlines over the cord or nodular meningeal deposits (Figure 21.36). Communicating hydrocephalus occurs in 10% of patients. A meningitic syndrome is sometimes seen but not commonly. Many MM patients simply feel generally unwell. Imaging should always be carried out prior to lumbar puncture as the procedure itself may lead to artefactual meningeal enhancement. In contrast to its role in diagnosis, MRI is of little use for monitoring the response to therapy.

CSF examination with cytology of a large volume (at least 10 mL) of fluid is the single most useful investigation both for diagnosis and monitoring treatment. CSF biochemistry is nearly always abnormal in MM irrespective of the CSF cytology. Abnormalities include raised CSF protein (usually <2 g/dL except in cases of spinal block),

**Table 21.9** Clinical presentations of malignant meningitis.

Location in neuraxis	Symptoms	Signs
Cerebral	Headache, nausea and vomiting	Papilloedema
	Cognitive changes, impaired consciousness	Encephalopathy
	Gait problems	Hemiparesis, ataxia
	Seizures	
	Focal deficits	
Cranial nerves	Diplopia	III, IV, VI lesions
	Visual loss	Optic neuropathy
	Facial weakness/numbness	V, VII lesions
	Deafness/vertigo	Sensorineural hearing loss, nystagmus
	Dysphagia, dysarthria	IX, X, XII nerve lesions
Spinal cord and roots	Back/neck/radicular pain	Nuchal rigidity
	Weakness	LMN weakness, reflex asymmetry
	Patches of numbness	Dermatomal sensory loss
	Sphincter dysfunction	e.g. Urinary incontinence, constipation

LMN, lower motor neurone.

**Figure 21.36** Malignant meningitis. Axial T1-weighted image post gadolinium showing extensive nodular leptomeningeal enhancement from metastatic breast cancer.

low CSF : plasma glucose ratio and elevated CSF white count. There is little correlation between CSF white cell count and the likelihood of detecting malignant cells. Sensitivity of CSF cytology rises from 65% after one lumbar puncture to 90% after three punctures. Ideally, fluid should be taken to the cytology laboratory immediately after collection in order to minimise cell autolysis. Certain tumours (e.g. leukaemias) are more likely to shed cells into the CSF than others – in cytology negative cases flow cytometry using specific lymphoma markers may be helpful in suggesting the diagnosis. There is no benefit in measuring tumour markers within the CSF.

### Treatment

Treatment of MM is solely palliative. Thus, the decision to treat a patient with MM and metastatic disease depends on the patient's tumour status in the rest of the body and their overall physical condition. In general, MM once diagnosed has a median survival of 2–6 months. Particularly poor prognostic factors include low performance status, presence of encephalopathy and melanoma/lung cancer/brain tumour as the primary. Patients with breast cancer and MM have a median survival of 7.5 months and are therefore more often eligible for aggressive treatment.

Corticosteroids, non-steroidal anti-inflammatory drugs and opiates form the basis of palliative treatment. Anticonvulsants may be needed. Cranio-spinal radiotherapy is rarely indicated because of significant morbidity associated with treatment, particularly myelosuppression and the time taken for planning and carrying out treatment. More commonly, radiotherapy is used for treatment of isolated sites of symptomatic bulky disease, particularly in the posterior fossa and spinal cord.

Drug therapy, when appropriate, consists of systemic and intrathecal chemotherapy and hormonal therapy (e.g. tamoxifen for breast cancer). Systemic chemotherapy is often ineffective because of difficulties in achieving significant levels of cytotoxic drug within the CSF and the intrinsic chemoresistance of the underlying primary tumour. It is limited largely to treatment of chemosensitive tumours such as breast cancer and lymphoma. High dose methotrexate (3–8 g/m<sup>2</sup>) or cytarabine (3 g/m<sup>2</sup>) produce high enough serum levels to allow for therapeutic levels in the CSF, despite their low permeability.

Intrathecal chemotherapy via an Ommaya reservoir connected to the lateral ventricles or via repeated lumbar punctures is usually reserved for patients with good performance status and no or limited evidence of systemic disease. It is not useful in patients with bulky tumour deposits or where there is partial or complete obstruction to CSF flow. In cases of doubt, CSF flow studies may be helpful in evaluating CSF dynamics. It is debatable whether intrathecal chemotherapy offers any advantages over standard therapy for breast cancer and so is rarely used by medical oncologists.

The most commonly used intrathecal drugs are methotrexate and cytarabine, active against leukaemia and lymphoma, and methotrexate and thiotepa for breast cancer. Cytarabine is now available in a depot liposomal formulation which reduces the need for lumbar punctures from two per week to one every 2 weeks. None of these agents has intrinsic activity against melanoma and lung cancer. Novel agents that have been used intrathecally include topotecan and gemcitabine. The most serious toxicity is acute aseptic meningitis, which can be treated or prevented by corticosteroids.

## Indirect effects of cancer

### Toxic and metabolic encephalopathy

Toxic and metabolic encephalopathy is a frequent occurrence in cancer patients, particularly in the terminal phases, and presents when fully developed with delirium or an acute confusional state. There are numerous causes (Table 21.10). A thorough evaluation is required: many causes are reversible. The earliest manifestations are subtle deficits of concentration and attention which progress through towards inappropriate behaviour, cognitive disturbance and into a full-blown state of delirium, characterised by either a state of lethargy and apathy (quiet delirium) or by hyperactivity and

restlessness, similar to that seen in the delirium tremens of alcohol withdrawal. These symptoms may be initially mistaken for anxiety and depression, particularly as neurological signs are often absent and rarely focal. The neurological examination reveals deficits in orientation, attention, concentration and language, short-term memory problems and visuo-spatial disorientation. Tremor, myoclonus and asterix are also sometimes seen. Investigation of these patients consists of excluding a primary neurological cause such as brain metastases or MM and identifying any treatable extracerebral or metabolic condition. A careful drug history is mandatory.

### Vascular disorders

Cerebrovascular problems are relatively common in cancer patients. They are brought about either by direct effects of a tumour and/or its treatment on blood vessels, or by a coagulopathy caused indirectly by the neoplasm. Cerebral haemorrhage can be the presenting symptom of a primary intracranial tumour or, more commonly, metastases, particularly from melanoma, extracranial germ cell tumours and rarely colonic carcinoma. The most common primary brain tumours associated with intra-tumoral haemorrhage are oligodendrogliomas, glioblastomas and germ cell tumours. Bleeding is also sometimes seen in meningiomas, medulloblastomas, choroid plexus papillomas and ependymomas. Intracerebral haemorrhage can also follow thrombocytopaenia caused by either tumour or leukaemic invasion of bone marrow, chemotherapy or radiotherapy.

A hypercoagulable state leading to arterial or venous thrombosis is sometimes seen in patients with widespread metastatic disease caused by multiple pro-coagulant effects of cancer on platelet function and coagulation factors. This was first described in 1865 by Trousseau who noted accelerated clotting times and thrombophlebitis in more than 60% of the cancer patients he saw. Haemostatic abnormalities occur in more than 90% of cancer patients, most commonly presenting as deep vein thrombosis or disseminated intravascular coagulation (DIC) with depletion of platelets and clotting factors. In general, venous thrombo-embolism is more frequent in solid tumours while DIC causes both venous and arterial occlusions and is seen in widespread metastatic cancer and haematological malignancies. Occasionally, drug therapy causes abnormal coagulation (e.g. cerebral vein thrombosis associated with L-asparaginase in acute leukaemia). Rarer causes of cerebral infarction include tumour emboli (usually intracardiac tumours such as atrial myxoma), non-bacterial thrombotic endocarditis (NBTE) and cerebral vasculitis. A diffuse brain syndrome with multiple small infarcts can develop. Occlusion of venous sinuses may also result from compression or invasion by metastatic tumour, particularly breast cancer and lymphoma. Other causes of hypercoagulability include hyperfibrinogenaemia, seen in some 50% of cancer patients, and antiphospholipid syndrome.

### Non-bacterial thrombotic endocarditis

This form of endocarditis, also known as marantic endocarditis, is a rare but well-recognised cause of ischaemic stroke in the cancer population, particularly patients with mucinous adenocarcinomas from the lung, pancreas, stomach and ovary. This condition is poorly understood. NBTE results from predisposition for platelets and fibrin plugs to deposit on cardiac valves, usually aortic and mitral, giving rise to sterile vegetations, which can cause arterial emboli. One-third of patients with NBTE have a purely neurological presentation either with a diffuse encephalopathy, focal signs, including transient ischaemic attacks or rarely spinal cord infarction. Coagulation testing is usually normal although a few cases

**Table 21.10** Causes of toxic/metabolic encephalopathy with cancer.

Tumour	Brain or meningeal metastases
Drugs	Opioids, benzodiazepines, corticosteroids, chemotherapy
Infections	Pneumonia, UTI, intra-abdominal abscess, CNS infection
Hypoxia	Pneumonia, pulmonary emboli
Electrolytes	Hypercalcaemia, hyponatraemia, hypophosphataemia
Endocrine	Adrenal insufficiency (e.g. rapid steroid withdrawal)
Hepato-renal	Uraemia, hepatic failure
Nutritional	Thiamine deficiency (Wernicke's encephalopathy)
Unrelated	Alcohol or drug abuse or withdrawal, cardiac/respiratory co-morbidity

UTI, urinary tract infection.

have evidence of DIC. In some cases, NBTE may precede the diagnosis of malignancy and can thus be the first presentation of an occult tumour. Treatment is directed to the underlying cause. Anticoagulation is rarely helpful and carries substantial risks of haemorrhage.

### CNS infections in cancer patients

Infections of the CNS occur more frequently in patients with cancer than in the general population. They are one of the least common neurological complications of cancer and are usually seen in patients with haematological malignancies. Nevertheless, they are important to keep in mind because these patients rarely have the florid symptoms and signs of infection seen in immunocompetent patients. The most common presentation of CNS infection in a cancer patient is simply an altered mental state with headache and fever. Neck stiffness can be mild or absent. There should be a low threshold for imaging and lumbar puncture in such patients presenting with drowsiness and irritability. The causative organisms are different from those in the general population. In some 40% of patients, multiple pathogens infect the CNS simultaneously. *Cryptococcus neoformans* and *Listeria monocytogenes* are the major causes of meningitis in cancer patients while enteric Gram-negative bacilli, *Toxoplasma gondii*, *Aspergillus fumigatus* and *Nocardia asteroides* are major causes of brain abscesses. Gram-negative organisms such as *Pseudomonas aeruginosa* and *Escherichia coli* are common causes of meningitis in neutropenic patients: the paranasal sinuses should always be considered as possible sources of CNS infection. Accurate microbiological diagnosis is essential in order to institute vigorous and appropriate antibiotic therapy. Despite this, treatment of CNS infections in this patient group is far less successful than in immunocompetent patients. There is a mortality of some 85% in neutropenic patients with CNS infection. Survival depends on bone marrow recovery in addition to correct antibiotic treatment. Even when antibiotic treatment cures the infection, relapse and superinfection are common. The treatment of individual infections is discussed in Chapter 9.

### Paraneoplastic neurological disorders

Paraneoplastic neurological disorders (PND) are uncommon neurological complications of cancer. They are important because they frequently present before the malignancy becomes symptomatic, because they cause severe neurological disability and because of the putative immunological mechanism by which some forms of PND have been shown to arise. Tumours can cause neurological symptoms through indirect mechanisms such as hyponatraemia and hypercalcaemia. However, the term paraneoplastic is usually reserved for disorders thought to be caused by autoimmune attack triggered by tumour antigens against nervous system components. Because PND are much less common than direct, metastatic and treatment-related complications of cancer, a neurological condition should only be regarded as paraneoplastic if a particular neoplasm associates with a remote but specific effect on the nervous system more frequently than would be expected by chance. For example, subacute cerebellar ataxia in the setting of ovarian cancer is sufficiently characteristic to be called paraneoplastic cerebellar degeneration (PCD), so long as other causes have been excluded. Conversely, carpal tunnel syndrome in a cancer patient is not paraneoplastic because both conditions, being reasonably common, are likely to coexist. In patients without known cancer, the more common causes of neurological problems such as inflammatory and/or

autoimmune conditions and hitherto undiagnosed tumours or metastases should be excluded before concluding that a patient is likely to have a PND.

### Incidence and prevalence

The precise incidence and prevalence of PND in the overall cancer population remains largely unknown. Certain common cancers that frequently associate with PND (e.g. SCLC), have been extensively investigated, but the majority of studies tend to concentrate on specific antineuronal antibodies and their neurological and tumour associations rather than provide prospective data on PND frequency.

The incidence of PND depends on the stringency of criteria used. In one early systematic study of PND, the term carcinomatous neuromyopathy was used to describe cancer patients with a combination of neuromuscular abnormalities, usually proximal muscle weakness, ataxia and distal sensory loss. Some 4% of women with breast cancer, 7% of patients with all cancers and 16% of men with lung cancer had evidence of PND compared with 2% of age-matched controls. The most frequent PND is Lambert–Eaton myasthenic syndrome (LEMS): this occurs in 2–3% of patients with SCLC. Overall, PND affect less than 1% of all patients with cancer. Cerebellar degeneration with ovarian cancer is the next most common form of PND occurring in about 1% of cases.

The median age of onset of PND is over 60 years. Less than 10% of cases are in those under 50 years. PND occur relatively rarely in young people – except with the typical tumours of the 20–40 age group – Hodgkin's disease (PCD), testicular cancer (brainstem and limbic encephalitis), breast cancer (many different syndromes) and in children, neuroblastoma (opsoclonus-myoclonus). The sex ratio of patients with PND is variable and probably depends on the underlying syndrome. In most studies there is a female preponderance of around 3 : 1 which cannot be accounted for by association with breast and ovarian gynaecological cancer alone.

Detailed long-term observational data for PND are not available. Response to treatment is frequently disappointing but LEMS may respond well. Spontaneous resolution of PND has occasionally been reported. PND cause serious disability. Most patients who do not succumb to either the neurological syndrome or the underlying tumour usually remain dependent on their carers.

### Clinical features

PND are summarised in an anatomical classification in Table 21.11. Some CNS syndromes such as cerebellar degeneration are typically focal at presentation but frequently progress to involve other anatomical structures. Other PND are characterised by patterns of widespread dysfunction early on, for example the combination of limbic encephalitis of the medial temporal lobes and projections with a sensory neuropathy affecting dorsal root ganglia. As more antibodies are recognised, the range of PND phenotypes is ever widening. Atypical forms (e.g. parkinsonism and other movement disorders) are being reported increasingly.

PND usually begin abruptly and present within days to weeks, progressing rapidly. Stroke-like presentations are seen; imaging is usually negative. Most patients become significantly disabled within a few weeks of onset and then plateau. Urgent investigation is indicated, especially in CNS syndromes, so that tumour therapy is started early to prevent progressive neuronal death and irreversible disability. Less frequently, patients may develop a second PND clinically different from the first.

There are no unique clinical features that define a syndrome as paraneoplastic but certain clinical syndromes in association with

**Table 21.11** Classification of paraneoplastic neurological disorders by anatomical location within the nervous system.

Site	Syndrome	Typical primary tumours
Brain	Cerebellar degeneration	SCLC, breast, ovarian, Hodgkin's disease
Brain	Limbic encephalitis	SCLC, ovarian teratoma, testicular tumours
Brainstem	Brainstem encephalitis	SCLC
Brain and cord	Encephalomyelitis with rigidity	Breast, SCLC
Brain	Opsoclonus-myoclonus	SCLC, neuroblastoma, breast
Retina	Retinopathy	SCLC
Cord	Necrotising myelopathy	Any
Cord and anterior horn cells	Motor neurone syndromes	Any
Dorsal root ganglia	Sensory neuronopathy	SCLC
Motor neurones	Subacute motor neuronopathy	Non-Hodgkin's lymphoma
Peripheral nerves	Vasculitic neuropathy	B-cell lymphoma
Peripheral nerves and roots	Acute inflammatory demyelinating polyradiculoneuropathy (as Guillain–Barré syndrome)	Hodgkin's disease
Peripheral nerves	Sensory/sensorimotor neuropathy	Any
Peripheral nerves	Mononeuritis multiplex	Any
Autonomic system	Autonomic neuropathy	SCLC
Peripheral nerves	Neuromyotonia	SCLC
Gut	Neurogastrointestinal enteropathy	SCLC
Neuromuscular junction	Lambert–Eaton myasthenic syndrome	SCLC
Neuromuscular junction	Myasthenia gravis	Thymoma
Muscle	Polymyositis and dermatomyositis	Any
Muscle	Acute necrotising myopathy	Any

SCLC, small cell lung cancer.

tumours are so recognisable as to be called classic. A recent study carried out by the PNS Euronetwork consortium of 979 patients found that 78% of patients had such classic syndromes, the most frequent being paraneoplastic cerebellar degeneration, sensory neuronopathy and limbic encephalitis. These well-recognised syndromes are as follow:

- 1 Encephalomyelitis
- 2 Limbic encephalitis
- 3 Subacute cerebellar degeneration
- 4 Opsoclonus-myoclonus
- 5 Sensory neuronopathy (dorsal root ganglionopathy)
- 6 Lambert–Eaton myasthenic syndrome

7 Dermatomyositis

8 Chronic gastrointestinal pseudo-obstruction.

### Paraneoplastic cerebellar degeneration

Patients with paraneoplastic cerebellar degeneration (PCD) typically present with the subacute onset of disequilibrium with increasing ataxia of gait, trunk and limbs. Complex eye movement abnormalities are seen with combinations of disordered pursuit movements, multi-directional nystagmus (often down-beating) and gaze palsies. Severe disability develops rapidly with dysphagia and dysarthria. The condition usually stabilises within 6 months although PCD sometimes evolves into a multi-focal neurological degeneration

particularly in patients with anti-Hu antibodies. PCD occurs in a variety of tumours, most commonly ovarian and breast cancer, lung cancer and Hodgkin's disease. Tumours, if not previously diagnosed, usually appear within weeks to months of the onset of symptoms, although there may be a lead time bias because of the neurological diagnosis prompting a search for an underlying tumour.

Long intervals between PCD and tumour appearance are rarely seen, for example PCD with characteristic clinical features and high titre anti-Yo antibodies has been diagnosed 13 years before breast cancer became evident. Occasionally, PCD occurs after tumour diagnosis and treatment and in the case of Hodgkin's disease may be a harbinger of relapse.

A diagnosis of PCD is usually suspected when imaging of the posterior fossa is unremarkable in the presence of severe cerebellar ataxia. Unusual imaging abnormalities include diffuse oedema of the cerebellum and very early cerebellar atrophy. In PCD, the cerebellum gradually becomes atrophic, over months. Other investigations (e.g. CSF examination) are rarely helpful but are useful to rule out leptomeningeal metastases which can occasionally cause isolated gait ataxia. CSF oligoclonal bands are usually positive in PCD.

The diagnosis of PCD is usually supported by finding antineuronal antibodies, specifically anti-Yo (38%), anti-Hu (32%), anti-Tr (14%), anti-Ri (12%) and anti-mGluR (4%). In a study of PCD, the functional outcome was better with anti-Ri and anti-Tr and worse with anti-Yo and anti-Hu. Patients receiving antitumour treatment, with or without immunosuppressive therapy, lived significantly longer than those who remained untreated.

Pathologically there is severe and sometimes complete loss of cerebellar Purkinje cells with relatively minor thinning of the molecular layer. The deep cerebellar nuclei are spared except in cases of encephalomyelitis, when extensive inflammatory changes are seen.

### Paraneoplastic encephalomyelitis and limbic encephalitis

Paraneoplastic encephalomyelitis (PEM) syndromes are one of the more common PND affecting the CNS and characterised by multi-focal inflammation with predilection for limbic and brainstem structures. This process may occur with or without sensory neuropathy, autonomic neuropathy and LEMS.

Limbic encephalitis is usually seen in association with SCLC and presents with personality changes, irritability, depression, seizures, memory loss and sometimes dementia. The majority of these patients have anti-Hu antibodies. The main finding on examination is severe impairment of episodic memory. This can improve with treatment of the underlying tumour. Investigations are usually non-specific – CSF may be inflammatory with pleocytosis and an elevated protein concentration. MRI may show high signal change within one or both medial temporal lobes. Epileptic discharges may be seen on EEG. Pathological changes affecting limbic and basal ganglia structures include neuronal cell loss, reactive microglial proliferation and peri-vascular lymphocytic infiltration. Other commonly associated tumours are testicular cancer (approximately 20%) and breast cancer (approximately 10%). Neurological symptoms precede cancer diagnosis in around half of cases by several months.

In one series over half of limbic encephalitis patients had antineuronal antibodies: most commonly, anti-Hu, anti-Ma1 and anti-Ma2. Anti-Hu antibodies usually associated with SCLC patients, multi-focal neurological symptoms and a poor outcome. Patients with anti-Ma2 antibodies tend to be young men with testicular tumours,

hypothalamic involvement and a poor outcome. In patients with neither anti-Hu nor anti-Ta antibodies, lung cancer remains the most common tumour.

Recent studies have identified new antibodies against cell surface antigens that are associated with diffuse and limbic encephalitis. The most frequent example is encephalitis associated with the NR1 subunit of the *N*-methyl-D-aspartate (NMDA) receptor (Chapter 20) which is characterised by dramatic neuropsychiatric presentation, limbic and then diffuse encephalitis, autonomic instability and stereotyped movement disorders particularly orofacial dyskinesias. Unlike the classic paraneoplastic syndromes, this disease most commonly occurs in young women with ovarian teratomas, and responds to immunotherapy. Occasionally, children may be affected and usually present with seizures and abnormal movements.

### Brainstem encephalitis

Brainstem encephalitis accounts for some 15% of cases of PEM. The clinical syndrome is characterised by brainstem dysfunction, cranial nerve palsies, long tract signs and cerebellar ataxia. Less common features include movement disorders such as parkinsonism, chorea, jaw-opening dystonia and laryngospasm, the latter sometimes seen in association with anti-Ri antibodies. Occasionally, brainstem encephalitis can cause central alveolar hypoventilation with recurrent respiratory failure or coma. As with limbic encephalitis, imaging and CSF examination are usually non-specific. The diagnosis is usually confirmed by finding antineuronal antibodies. An important differential diagnosis is *Listeria monocytogenes* rhombencephalitis.

### Paraneoplastic encephalomyelitis with rigidity

This rare syndrome causes truncal and limb rigidity, stimulus-sensitive myoclonus, painful spasms and brainstem and spinal cord inflammatory involvement. It is usually fatal. By contrast, the typical (non-paraneoplastic) stiff person syndrome with anti-GAD antibodies (Chapter 6), characterised by axial and proximal lower limb stiffness, spasms with continuous motor unit activity on EMG behaves in a more indolent fashion. However, typical stiff person syndrome may rarely be a presenting feature of breast cancer and associated with antiampiphysin antibodies.

### Paraneoplastic opsoclonus-myoclonus

Paraneoplastic opsoclonus-myoclonus (POM), often called dancing eyes syndrome, is a rare syndrome seen typically in young children with neuroblastoma. It also occurs in adults with breast cancer and SCLC. Dramatic, chaotic, saccadic, multi-directional eye movements (opsoclonus) are associated with myoclonus of the trunk, limbs and head including the diaphragm and palate. There is also cerebellar ataxia. This syndrome is associated with cancer in about 20% of adults. As with other PND affecting the CNS, routine investigations are usually normal or non-specifically abnormal. Several autoantibodies have been described in POM, particularly anti-Ri (breast, SCLC) and antineurofilament antibodies in children with neuroblastoma. POM can also follow viral infections, drug overdose and as part of a post-infective encephalitis.

### Paraneoplastic retinal degeneration

PND can cause visual failure. Retinal photoreceptors, rods, cones and optic nerves can all be affected. Paraneoplastic retinal degeneration, otherwise known as cancer-associated retinopathy, is usually seen in SCLC and gynaecological tumours and associated with antibodies against recoverin, a photoreceptor protein. Visual loss is painless, bilateral and presents with loss of colour vision, night

blindness and initial photosensitivity. There is loss of visual acuity. Field testing shows peripheral and ring scotomas. There may be arteriolar narrowing and mottling of the fundus caused by changes in the retinal pigment epithelium.

### Necrotising myelopathy

The spinal cord can be the main target of paraneoplastic autoimmunity, in most cases as part of an encephalomyelitis. Rarely, patients develop a rapidly progressive isolated necrotising myelopathy, characterised pathologically by extensive necrosis of both white and grey matter, most marked in the thoracic segments. This is usually associated with a CSF pleocytosis and extensive (more than three segments) T2 signal abnormality on MRI, with gadolinium enhancement. The most common antineuronal antibodies are anti-amphiphysin and CV2 (CRMP5), associated with breast cancer and SCLC. The prognosis is very poor.

### Motor neurone syndromes

There is controversy and generally doubt about whether typical motor neurone disease (MND) can be regarded as a paraneoplastic syndrome. However, three motor neurone syndromes are seen in patients with cancer. The first is a rapidly progressive MND-like condition with anti-Hu antibodies, presenting with subacute motor paralysis resulting from anterior horn cell damage (subacute motor neuronopathy). The second is primary lateral sclerosis with breast cancer, lymphoma and myeloma. The third is apparently typical MND developing some years after a diagnosis of cancer. It seems likely that the first two groups are indeed paraneoplastic: the third is probably not, reflecting the occurrence of two reasonably common diseases in the same patient.

### Paraneoplastic sensory neuronopathy

Also known as dorsal root ganglionitis, paraneoplastic sensory neuropathy (PSN) causes subacute, rapidly progressive asymmetric and painful sensory symptoms dominated by severe proprioceptive loss, which affects upper limbs more than lower limbs. All sensory modalities are affected. In contrast, motor function is preserved. Nerve conduction studies show absent sensory action potentials but normal motor velocities. The CSF is typically inflammatory, particularly if the neuropathy is associated with encephalomyelitis. The differential diagnosis includes Sjögren's syndrome and cisplatin toxicity. The pathology centres on dorsal root ganglia where there are lymphocytic infiltrates and loss of ganglion cells.

### Paraneoplastic neuropathies

The peripheral nervous system is more commonly involved by PND than the CNS. Distal, predominantly sensory neuropathies are seen frequently in cancer patients and are more commonly caused by metabolic, nutritional and treatment-related axonal degeneration than paraneoplastic disease. However, in any patient presenting with a severe peripheral, predominantly sensory neuropathy in whom standard investigations are negative, about 10% will eventually be diagnosed with cancer, particularly if there is rapid progression to severe disability and absence of regeneration in a sural nerve biopsy (Chapter 10).

Paraneoplastic neuropathies are clinical and immunologically heterogeneous and are associated with antineuronal antibodies in over 50% of cases. Anti-Hu antibodies are the most frequently identified. Patients with sensorimotor neuropathies also tend to have anti-CV2 antibodies in association with SCLC or high-titre antinuclear antibodies in association with breast cancer.

**Sensory and sensorimotor neuropathy** Paraneoplastic sensory and sensorimotor neuropathy is well recognised in many different cancers. Nerve conduction studies typically show a mixed sensory and motor axonal neuropathy. An occasional case may have typical demyelinating features and respond to intravenous immunoglobulin. Patients with an apparent chronic inflammatory demyelinating polyradiculoneuropathy with atypical features including resistance to first line treatments, an unusually aggressive course or the presence of myopathy and long tract signs should be investigated for an underlying cancer. The CSF is usually acellular in contrast with sensory neuropathy but the protein is usually raised. The unusual osteosclerotic form of myeloma can cause the combination of endocrine, dermatological and neurological features encapsulated within the acronym POEMS (polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes). This neuropathy is typically demyelinating (Chapter 11).

**Acute inflammatory demyelinating polyradiculoneuropathy** Motor neuropathies are much less common than sensory neuropathies in paraneoplastic neurological disease. However, patients with Hodgkin's disease can present with acute inflammatory demyelinating polyradiculoneuropathy, a syndrome clinically and electrophysiologically indistinguishable from Guillain-Barré syndrome. Similarly, neuralgic amyotrophy (brachial plexitis) occasionally occurs in association with lymphoma, but a true paraneoplastic association is uncertain. Focal monomelic motor neuropathy has also been described.

**Motor neuropathy** A subacute lower motor neuropathy is occasionally seen with non-Hodgkin's lymphoma presenting as a slowly progressive lower motor neurone syndrome affecting the lower limbs.

**Vasculitic neuropathy** Vasculitis is occasionally associated with haematological malignancies and usually presents with rashes. Paraneoplastic vasculitic neuropathy has been described in patients with high grade B-cell lymphoma.

**Autonomic neuropathy** Paraneoplastic autonomic neuropathies are rare and patients present subacutely with gastrointestinal pseudo-obstruction, bladder dysfunction, orthostatic hypotension, labile blood pressure, pupillary abnormalities and pseudomotor dysfunction, impotence and xerophthalmia. Autonomic neuropathy can be the sole manifestation of an anti-Hu syndrome or part of a more widespread encephalomyelitis. In recent series of patients with anti-Hu antibodies, autonomic dysfunction was present in some 25% of cases and was the predominant symptom in approximately 5%.

### Neuromyotonia

Neuromyotonia is a rare PND described with thymomas or SCLC. Muscle cramps, stiffness, twitching, sweating and abnormal relaxation after voluntary contraction occur. This is caused by hyperexcitability of peripheral nerve fibres. Electromyography shows abnormal doublet and triplet discharges with high intra-burst frequency as well as myokymic and neuromyotonic discharges. Fasciculations and fibrillation potentials are common.

Acquired neuromyotonia typically is not paraneoplastic but an immune-mediated disorder (Isaac's syndrome) with elevated antibody levels against presynaptic, voltage gated potassium channels. These antibodies may also be detected in the even rarer Morvan's syndrome, also non-paraneoplastic, characterised by neuromyotonia, hyperhidrosis, agitation, confusion and insomnia.

### Lambert–Eaton myasthenic syndrome

LEMS (Chapter 10) is caused by SCLC in 60% of cases and is characterised by proximal weakness, predominantly affecting lower limbs in association with autonomic disturbance such as impotence, constipation and dry mouth. The paraneoplastic syndrome is usually more severe than the autoimmune form but is electrophysiologically indistinguishable. The characteristic finding, consistent with presynaptic neuromuscular dysfunction and impaired quantal release of neurotransmitter, is of small compound muscle action potentials that decrement at low-frequency stimulation but increment at high-frequency stimulation. The diagnosis of LEMS is confirmed by finding antibodies against P/Q type voltage gated calcium channels (VGCC). Some patients with LEMS also have a cerebellar syndrome – and some patients with cerebellar syndromes but without LEMS have anti-VGCC antibodies. A recent study of over 200 patients with LEMS identified seven clinical predictors of SCLC: age, smoking, weight loss, Karnofsky Performance Status, bulbar dysfunction, male impotence and Anti-SOX1 antibodies – a score higher than 3 indicated a probability of SCLC of greater than 80%. In new cases of LEMS, the current recommendation is screening for lung cancer for up to 2 years after diagnosis.

### Myasthenia gravis

Myasthenis gravis is the prototypical autoimmune disease with antibodies to post-synaptic acetylcholine receptors at the neuromuscular junction. In some 10% of cases of myasthenis gravis there is an underlying thymoma. Myasthenis gravis can thus be considered a paraneoplastic condition. No other tumour is associated with myasthenis gravis.

### Polymyositis and dermatomyositis

Polymyositis or dermatomyositis can be paraneoplastic conditions. In general, patients with paraneoplastic myositis are older and

have a more severe course than their autoimmune counterparts. Dermatomyositis in the elderly is much more likely to be paraneoplastic than polymyositis in the same age group.

### Acute necrotising myopathy

Acute necrotising myopathy is rare. It is proximal, rapidly progressive, associated with rhabdomyolysis and usually fatal.

### Diagnosis of PND

Frequently, a PND will be suspected from the clinical features and confirmed by finding usually well-characterised paraneoplastic autoantibodies. A pattern of symptoms and signs can be diagnosed as possibly or definitely paraneoplastic using a descending hierarchy:

- 1 Presence or absence of known cancer
- 2 Presence or absence of a classic syndrome
- 3 Presence or absence of well-characterised antineuronal antibodies, and
- 4 Exclusion of other causes of a similar neurological syndrome, particularly malignant meningitis.

### Paraneoplastic antineuronal autoantibodies

The detection of serum paraneoplastic antineuronal autoantibodies (PNA) is highly specific and forms the cornerstone of diagnosis of PND. Sensitivity varies between different syndromes. At best it is only 80–90% and therefore a diagnosis of PND cannot be excluded if PNA testing is negative. Tables 21.12 and 21.13 show the more common antineuronal antibodies, their clinical associations, immunohistochemical staining patterns and putative antigens. There is a bewildering array of PNA which can be divided into those against intracellular antigens (Table 21.12) and cell surface antigens (Table 21.13). It is therefore reassuring that a detailed knowledge of specific antibodies is rarely required as most laboratories test

**Table 21.12** Well-characterised paraneoplastic autoantibodies against intracellular antigens and their clinical and immunological associations.

Antibody	Neurological syndrome	Immunohistochemistry	Western Blot	Antigen	Associated tumour
Hu (ANNA 1)	PEM/PSN, LE, PCD, LEMS, intestinal neuropathy	Neuronal nuclei in CNS and PNS	36–40 kD	Hu family triplet bands	SCLC, neuroblastoma, non-SCLC, prostate
Ri (ANNA 2)	POM, PEM, PCD	Neuronal nuclei in CNS	55 and 80 kD	Nova 1 and 2	Breast, SCLC, gynaecological
Yo (PCA 1)	PCD	Purkinje cell cytoplasm	34 and 62 kD	Cdr 1 and 2	Breast, ovary, uterus
Tr	PCD	Purkinje cell cytoplasm (molecular layer)	No reactive protein	DNER (delta/notch-like epidermal growth factor-related receptor)	Hodgkin's disease
Amphiphysin	Stiff person syndrome, rapidly progressive myelopathy	Synaptosomes	128 kD	Amphiphysin	Breast, SCLC
CV2/CRMP5 Ma	PEM, chorea, uveitis, optic neuropathy, intestinal neuropathy, chorea PEM, PCD, BE	Diffuse neuropil, cytoplasm of oligodendrocytes Nuclei and cytoplasm	66 kD 37 kD	CRMP-5	SCLC, breast, thymoma Miscellaneous
Ma2 (Ta)	BE, LE, hypothalamic syndrome	Nucleolus, perikaryon	40 kD	Ma 2	Testicular cancer

BE, brainstem encephalitis; LE, limbic encephalitis; LEMS, Lambert–Eaton myasthenic syndrome; PCD, paraneoplastic cerebellar degeneration; PEM, paraneoplastic encephalomyelitis; POM, paraneoplastic opsoclonus/myoclonus; PSN, paraneoplastic sensory neuropathy.

**Table 21.13** Autoantibodies against cell surface or synaptic antigens associated with paraneoplastic neurological syndromes.

Antibody	Neurological syndrome	Immunohistochemistry	Antigen	Associated tumour
NMDA receptor	Diffuse encephalitis with prominent neuropsychiatric features, autonomic dysfunction, movement disorder	Hippocampal neurophil Membrane glutamate receptors Glial nuclei in cerebellum	NR1/NR2 heteromers	Ovarian teratoma
mGluR5	Limbic encephalitis	Membrane glutamate receptors	mGluR1	Hodgkin's disease (two cases reported)
mGluR1	Cerebellar ataxia	Membrane glutamate receptors	mGluR5	Hodgkin's disease (two cases reported)
GABA <sub>A</sub> R	Limbic encephalitis	GABA receptors	GABA receptors	SCLC
CASPR2 (contactin associated protein 2)	Morvan's syndrome (neuromyotonia, muscle fasciculations, hyperhidrosis, insomnia, agitation and confusion)			Thymoma
AMPA	Limbic encephalitis with prominent psychiatric symptoms and aggression	AMPA receptors	AMPA receptors	SCLC, breast, thymus

**Table 21.14** Chemotherapy-related neurotoxicity.

Acute encephalopathy	Methotrexate, cisplatin, vincristine, asparaginase, ifosfamide
Chronic encephalopathy	Methotrexate, 5-fluorouracil/levamisole
Cerebellar syndrome	5-fluorouracil, cytosine arabinoside, ciclosporin, vincristine
Visual loss	Tamoxifen (retinopathy), cisplatin (cortical blindness)
Deafness	Cisplatin
Myelopathy/aseptic meningitis	Intrathecal methotrexate, cytosine arabinoside
Neuropathy	Vinca alkaloids, cisplatin, oxaliplatin, taxol

patients sera against crude homogenates of CNS tissue (usually rat or mouse) both by immunohistochemistry and Western immunoblotting. Further characterisation of the specific antigen can then be carried out using recombinant proteins.

### Imaging

There is no single imaging modality that can identify a PND with a high degree of sensitivity and specificity. The role of MRI is predominantly to rule out structural disease. Body CT imaging of the thorax, abdomen and pelvis is used for detection of an underlying tumour. Whole body FDG-PET scanning is useful when conventional imaging is unremarkable or equivocal as it detects small (6–8 mm) tumours if metabolically active.

### Treatment for PND

The treatment of PND is distinctly unsatisfactory. Early detection and treatment of the tumour seems to offer the greatest chance of stabilisation of PND. By contrast, immune-modulating therapies aimed at reducing levels of circulating antineuronal antibodies (e.g. plasma exchange, intravenous immunoglobulin, steroids and immunosuppressants) usually have no or modest effects on CNS syndromes,

although they be helpful in LEMS (Chapter 10). Palliative symptom-directed therapy is usually the most appropriate management.

### Neurological complications of chemotherapy

Many chemotherapeutic drugs are neurotoxic, causing particularly neuropathy and encephalopathy (Table 21.14). In many instances, diagnosis of treatment-induced disease is based on clinical experience and exclusion of other causes. Frequently, combination therapy causes previously unrecognised syndromes as some drugs act synergistically with others and with radiotherapy. Neurotoxicity from cancer chemotherapy tends to be frequent and severe in patients with pre-existing neurological disease.

### Polyneuropathy

A pure sensory neuropathy, often painful, is most commonly associated with vinca alkaloids, taxol and cisplatin. Oxaliplatin, commonly used in metastatic colorectal cancer, causes a reversible syndrome characterised by tingling, painful dysaesthesiae on contact with cold, laryngospasm, thought to be caused by a reversible sodium channelopathy. It also causes a chronic sensory neuropathy or neuronopathy which may start some weeks after the end of chemotherapy. Motor neuropathies are rare but are occasionally seen with suramin and vincristine. They are usually reversible on cessation of the drug.

### Encephalopathy

Almost any cancer chemotherapy can cause an acute encephalopathy characterised by seizures and confusion. The most notable example is the combination of methotrexate and cranial irradiation causing an irreversible leukoencephalopathy. Methotrexate can also cause an acute encephalopathy, mainly in children and teenagers, characterised initially by emotional lability and alternating hemiplegia such that the initial diagnosis is often thought to be psychogenic, particularly as standard MRI sequences are usually normal. However, high signal on diffusion-weighted imaging may occur confirming the diagnosis (Figure 21.20). Ifosfamide is the other drug, used mainly in the treatment of sarcomas, that can produce an encephalopathy.

Eileen Joyce

UCL Institute of Neurology

Requests for neuropsychiatric consultations are usually for one of three reasons. The first is when patients present with neurological symptoms but no organic cause can be found and the features do not fit with a known neurological illness. Symptoms include convulsions, disordered movement such as apparent dystonia, paralysis or tremor, sensory disturbance, amnesia, blindness and dysphonia. In this context, these symptoms are described as 'functional' as opposed to 'organic' and they may be psychologically determined. This presentation is common – up to 30% of general neurology clinic attendees have functional neurological symptoms (FNS) – and they are a significant cause of disability.

The second type of request is for assessment of psychiatric symptoms in the context of a known neurological disorder. For example, depression is a common feature of many neurological disorders and leads to high rates of morbidity as it can worsen a patient's subjective experience of symptoms and interfere with response to treatment and the ability to participate in rehabilitation. Low mood may either be a premorbid feature, a consequence of the illness itself, or a reaction to the diagnosis or to the disability. It is therefore important to determine the nature of the depression in order to optimise its treatment and that of the underlying neurological condition. Another problem that falls into this category concerns the adverse effects of drug treatment for neurological disorders. Examples include steroids, which can induce mania, depression and psychosis; drugs for Parkinson's disease, which can induce psychosis or impulsive behaviour; certain antiepileptics, which can induce depression, suicidal ideation and psychosis; and sedative drugs such as opiates and benzodiazepines, which can cause delirium.

The third type of request is when patients develop prominent psychiatric symptoms but there is concern that these are the product of an underlying neurological process. Examples include an autoimmune encephalopathy presenting primarily as psychosis, as in NMDA receptor encephalitis, or a mood disorder, as in systemic lupus erythematosus (Chapter 20); a temporal lobe tumour presenting as severe anxiety; and multiple sclerosis presenting as depression (see Neuropsychiatric aspects of white matter disorders).

The key to understanding the interplay of neurological and psychiatric symptoms is to assess the patient within a biological, psychological and social context. This means taking a detailed history which addresses family history, personal development, life

events and social circumstances, and performing a mental state examination. Often this process, the bread and butter of psychiatry, is enough to clarify and formulate the diagnosis and, if relevant, suggest a treatment plan.

### The mental state examination

The mental state examination is a strictly laid-out process for systematically assessing psychiatric symptoms. It is analogous to the process of eliciting neurological signs. It is the cornerstone of determining whether abnormal behaviour is a feature, a consequence or an imitator of neurological disease. The essential elements are listed here.

#### Appearance and behaviour

This can give important clues to particular diagnoses and is valuable for ascertaining a patient's level of functioning:

- *Clothing and personal care*: self-neglect may point to depression, psychosis or dementia.
- *Behaviour*: agitation and distractibility may indicate psychosis, delirium or dementia. Abnormal movements such as tremor, chorea or tics may indicate a neurological disorder.
- *Activity level*: retardation may point to depression and excitability to mania.
- *Appropriateness*: disinhibition may reflect a frontal syndrome and inappropriate crying or laughing may suggest pseudobulbar palsy.

#### Speech

How a patient speaks can provide a clue to diagnosis. Dysarthria and dysphasia (Chapter 4) are commonly seen with neurological conditions and affect the quality and clarity of a patient's voice. In a psychiatric assessment the qualities of speech that should be noted are as follows:

- *Quantity*: can be reduced in depression and dementia
- *Rate*: often rapid in mania and slow in depression
- *Tone*: can be monotonous in depression and Parkinson's disease
- *Rhythm*: normal intonation and rhythm can be lost in psychotic illnesses
- *Volume*: can be loud in mania and quiet in depression and Parkinson's disease.

### Mood and affect

Mood is documented both subjectively and objectively. Subjective feelings of depression may be described as 'down', 'low' or 'sad'. In mania this might be 'high'. Objectively, a patient may appear depressed, hypomanic/manic or euthymic (i.e. normal). Affect is how mood varies. This can be reactive in euthymia, flat and unchanging in depression, and labile or exaggerated in mania. Associated symptoms to ask about include:

- *Anhedonia*: the inability to enjoy usually pleasurable activities.
- *Sleep*: commonly disrupted in mood disorders; manic patients often report a decreased need for sleep and depressed patients can be troubled by initial insomnia, broken sleep or early morning waking.
- *Appetite*: poor appetite and weight loss are common in depression.
- *Energy levels and libido*: can be reduced in depression and elevated in mania.
- *Suicidal ideation*: it is important to ask about this and document findings clearly (see Identifying and managing risk secondary to abnormal mental states).

### Thoughts

These are described in terms of form (i.e. the natural progression from one idea to the next) and content.

#### Formal thought disorder

- *Speed of thinking*: can be increased in mania with flight of ideas (rapid shifting between topics but with a logical flow), and slowed in depression and cognitive impairment.
- *Ordering of thoughts*: can be disrupted in organic brain syndromes and psychosis, for example perseveration (repetition of the same thought) in frontal lobe damage and thought block (abrupt cessation of speech) in psychosis.
- *Psychotic formal thought disorder*: can be difficult to follow what a patient is saying because of abnormal transitions in thought processes. This can be described as derailment (speech shifts gradually off the point); tangential speech (speech is related to the topic but off the point); or 'knight's move thinking' (abrupt illogical shifts between statements).

#### Thought content

Delusions are firmly held false beliefs. They can be persecutory, grandiose, nihilistic, hypochondriacal or bizarre (completely implausible). They can be elicited in the primary psychiatric disorders of schizophrenia, depression with psychosis and mania and as secondary phenomena in certain neurological disorders such as temporal lobe epilepsy, the neurodegenerative dementias and Parkinson's disease. Abnormalities of possession of thought (thought insertion, withdrawal and broadcasting) or beliefs that the body and emotions are under the control of an outside force can be experienced in psychosis.

Obsessional thoughts or images are recurrent and persistent ideas which the patient sees as senseless and coming from within (cf. hallucinations and delusions) but is unable to prevent intruding into the mind. They may then be compelled to carry out ritualistic acts to relieve the associated anxiety that the obsessive thought or image elicits (e.g. having to wash repeatedly because of intrusive thoughts about contamination).

### Perceptions

These abnormalities can be in any sensory modality. Illusions are false perceptions in the presence of an external stimulus (i.e. misinterpretations). Misinterpretation of the surroundings, such as seeing

faces in hospital curtains, are common in delirium and advanced Parkinson's disease. Hallucinations are perceptions in the absence of an external stimulus. Visual hallucinations are indicative of an organic cause such as delirium, epilepsy, Lewy body dementia, advanced Parkinson's disease and the Charles Bonnet syndrome (Chapter 14). Auditory hallucinations are typical of primary psychotic illnesses such as schizophrenia and the affective psychoses. When a patient experiences 'voices' it is important to ask about what exactly is being heard, as they may act on the content and put themselves at risk. For example, some patients with schizophrenia experience 'command hallucinations' where voices tell them to harm others and this may be difficult to resist. In psychotic depression voices may tell the patient that they are worthless or guilty of a crime and in mania the voice of 'God' might be experienced. Whereas illusions and hallucinations are perceived in external space, pseudo-hallucinations are experienced internally (i.e. 'inside the head'). They are indicative of severe distress and can be seen in anxiety or personality disorders.

Depersonalisation is a distorted sense of self in which patients describe feeling outside their body. Derealisation is a distorted sense of reality and is described as a feeling of looking on the world from the outside rather than being in it. These often occur together and can be indicative of a temporal lobe seizure. In temporal lobe epilepsy, depersonalisation and derealisation are normally transient experiences, lasting seconds to minutes; if they last longer (i.e. hours to weeks) they are suggestive of a dissociative or anxiety disorder. In some people depersonalisation and derealisation are persistent in the absence of other symptoms, a condition known as depersonalisation/derealisation disorder (see Depersonalisation/derealisation disorder). Similarly déjà vu, an abnormal feeling of familiarity, can be experienced in these conditions.

### Cognition

A brief cognitive assessment is required to interpret any elicited mental phenomena. For example, anxiety in the context of mild memory impairment may point to incipient dementia (Chapter 8).

### Insight

This refers to the patient's understanding of their symptoms and whether they believe them to be a sign of illness. Insight can be impaired in many conditions and make adherence with treatment problematic. Many organic illnesses can impair insight. For example, patients with parietal lesions may show anosognosia and fail to identify deficits caused by their illness such as hemiparesis and inattention. Lack of insight is common in dementia and psychosis.

### Formulation

Having carried out a mental state examination, it is helpful to provide a formulation, which is a summary of the history and mental state with a diagnostic interpretation.

## Identifying and managing risk secondary to abnormal mental states

### Agitation and aggression

Agitation and aggression commonly occur together, have numerous causes and should be managed quickly to prevent harm to the patient or others. Often patients are frightened and confused because of hallucinations or paranoid delusions. De-escalation techniques should always be employed first; for example by assessing the patient in a quiet and calm environment, standing away from

the patient to give them space, speaking clearly and slowly, and listening to the patient to try to understand what has triggered the situation. Medication should only be used if this fails and if the patient is risking the safety of themselves or others. Small doses of lorazepam orally or intramuscularly is a useful first choice. An antipsychotic can also be used if a longer action is needed, such as olanzapine orally and haloperidol or aripiprazole intramuscularly.

### Lack of insight

Lack of insight and awareness of risk is especially common in dementia. Risks include wandering, leaving keys in the door or the house unlocked, leaving the gas and taps running, continuing to drive when it is not safe and not taking medication. If there is lack of insight, collateral information should be sought from a relative or carer. Risk can be reduced by home adaptations, care packages, 'dosette' boxes for medication or institutional care, if required.

### Suicidal ideation/suicidal behaviour

Thoughts of suicide are common in neuropsychiatric conditions and should be actively identified. It is important to understand that asking about suicidal thoughts does not increase the risk of suicidal behaviour and patients often find it a relief to be able to speak about them. Risk of suicide is increased if there have been previous attempts and with chronic illness, older age, unemployment, social isolation, a past psychiatric history and drug and alcohol dependence. It is important to distinguish between a passive wish to die and active thoughts and plans to end life. The latter, being more serious, should trigger immediate intervention from the local psychiatry team.

### Legal issues: use of mental health and capacity acts

There are legal frameworks in place to cover the treatment of patients who may lack capacity to make decisions or refuse treatment because of mental disorder. All doctors should be competent in assessing capacity, which is decision or issue specific (i.e. someone may have the capacity to agree to a blood test but not to decide on major surgery).

For a person to have capacity they must:

- Be able to understand relevant information
- Be able to weigh up the pros and cons of the decision
- Retain information long enough to come to a decision
- Be able to communicate their decision.

People are assumed to have capacity unless they have a disorder of mind that affects their decision-making ability. It is the responsibility of the treating team to assess capacity. The assessment and reasoning behind the decision must be clearly documented by the responsible medical doctor.

## Psychiatric symptoms commonly seen in neurological disorders

### Personality change

The DSM-5 classification of psychiatric conditions describes personality disorders as being 'associated with ways of thinking and feeling about oneself and others that significantly and adversely affect how an individual functions in many aspects of life.' Ten types of personality disorder are recognised and these are clustered according to common attributes. Patients often have attributes of more than one personality disorder, especially those within a cluster.

- *Cluster A* (odd or eccentric): paranoid, schizoid and schizotypal personality disorders.
- *Cluster B* (dramatic, emotional or erratic): antisocial, borderline, histrionic and narcissistic personality disorders.
- *Cluster C* (anxious or fearful): avoidant, dependent and obsessive-compulsive personality disorders (OCPD).

Each personality disorder represents a specific set of personality traits that are pervasive, maladaptive and present from young adulthood. Personality disorders are often preceded by childhood disorders of conduct or emotion. In neurology, it is important to differentiate these from newly acquired changes in behaviour or emotion as this may be indicative of an organic process. For example, the antisocial personality disorder is characterised by callousness, hostility and disinhibition. If such personality changes develop *de novo* later in life, it may be indicative of a frontal lobe tumour or of frontal neurodegenerative changes as seen in Huntington's disease or progressive supranuclear palsy. Typical personality changes seen in other neurological conditions include emotional lability in multiple sclerosis, apathy in Parkinson's disease and persistent dysphoria in epilepsy. Closed head injury can lead to a range of personality changes from apathy to disinhibition.

Functional, that is non-organic, neurological symptoms often develop in the context of a personality disorder, especially borderline and obsessive-compulsive types. Borderline personality disorder, also known as emotionally unstable personality disorder, is characterised by difficulty maintaining personal relationships, unstable mood and impulsivity which often leads to self-harm such as cutting or displays of intense anger. OCPD, also known as anankastic personality disorder, is characterised by maladaptive and rigid perfectionism, preoccupation with detail and persistence with fruitless behaviours. It is often associated with difficulty in expressing emotion (alexithymia). The recognition of these personality disorders in individuals with functional neurological symptoms is important as this will inform the approach to psychological treatment.

### Obsessions and compulsions

OCPD is different from obsessive-compulsive disorder (OCD). Both disorders are associated with compulsive behaviours. In people with OCPD, these are performed to impose order on their environment, compatible with their way of thinking about how the world should be ordered. People with OCD, on the other hand, are highly anxious and preoccupied about perceived threats from the world and compulsive behaviours are performed to reduce this anxiety, for example repetitive hand washing to prevent contamination. Other sources of anxiety in OCD are obsessions which are unwanted, repetitive, intrusive thoughts or images and in many people with OCD, obsessions and compulsions coexist. Another distinguishing feature is that people with OCD realise that their thoughts and behaviours are irrational but cannot resist them whereas people with OCPD think that their way of thinking and behaving is correct.

OCD is normally a mental illness without antecedent but it can also be the sequel of basal ganglia disease with features that are indistinguishable. Compulsive behaviours, in the absence of the rigid perfectionism of OCPD and the anxiety of OCD, can also be witnessed as separate phenomena in neurological disorders. For example, compulsive behaviours are very common in Tourette's syndrome and it can be difficult to distinguish complex motor tics from compulsions as both are preceded by an urge and result in a coordinated stereotyped set of movements. One difference is that

compulsions, unlike complex motor tics, are usually goal directed, for example touching, tapping and evening-up. Compulsions can also be seen in patients with Parkinson's disease secondary to levodopa or dopamine agonist therapy; this is witnessed in the so-called impulse control disorders (see Impulse control disorder).

### Anxiety

Anxiety is characterised by the subjective emotion of fear accompanied by physical symptoms reflecting over-activation of the autonomic nervous system: palpitation, dyspnoea, throat constriction (globus) and abdominal sensations. Neurological symptoms may be prominent such as tremor, dizziness and paraesthesiae (e.g. secondary to hyperventilation). When disabling symptoms of anxiety are triggered by certain events or circumstances they are classified as specific disorders, for example post-traumatic stress disorder after a life-threatening experience and social anxiety disorder when meeting new people or performing in public.

People with neurological disorders are commonly anxious. If this anxiety is a source of disability, the diagnosis of a separate anxiety disorder may be appropriate. The anxiety disorders most commonly seen are panic disorder and generalised anxiety disorder where the symptoms are 'free floating' in that the triggers are no longer obvious. In the former, anxiety symptoms are paroxysmal whereas in the latter they are pervasive. On occasion, patients with these disorders and no pre-existing neurological disorder may be referred to a neurologist because the symptoms of anxiety may also be accompanied by prominent fatigue, poor concentration and memory and urinary retention. Particular constellations of symptoms in general anxiety disorder and panic disorder may be misinterpreted as complex partial seizures, neuro-otological dysfunction, multiple sclerosis, movement disorder or neurodegenerative disorders and require expert assessment to prevent over-investigation.

### Mood

Disturbance of mood is a very common accompaniment of neurological disorders. This can be a reaction to receiving a diagnosis with a poor prognosis or to the disability or pain that ensues. In some conditions, mood disturbance appears to be a reflection of how the disease process interacts with the forebrain systems that mediate emotion and cognition, as in epilepsy, Parkinson's disease and multiple sclerosis.

Depression is both a specific and colloquial term. Often, people refer to being depressed when they have a transient and mild lowering of mood (dysphoria) in response to specific circumstances or events. It is only when depression is of sufficient frequency and severity and substantially affects quality of life that it becomes a specific disorder. Disorders of mood are classified as depressive disorders or bipolar disorders. Major depression refers to a specific syndrome characterised by persistent low mood, anhedonia (lack of enjoyment) and disturbances of the so-called vegetative functions of sleep and appetite. Cognitive function may be impaired, sometimes to the extent that it may resemble dementia, especially in the elderly (see Pseudodementia). Major depression is episodic but may be recurrent. When symptoms of major depression are persistent it is classified as 'persistent depressive disorder (dysthymia)'.

Mania is a state reflecting an excessive heightening of mood; hypomania is a less severe clinical presentation of mania. In both mania and hypomania there is an increased sense of well-being accompanied by euphoria, racing thoughts, pressure of speech and diminished need for sleep. In mania, there is also thought disorder with speech characterised by rhyming, punning and wordplay;

patients may develop grandiose delusions and auditory hallucinations. In mania, dysphoric mood often follows a period of elation, associated with irritability or frank aggression. Bipolar disorder refers to a condition whereby major depression alternates with episodes of hypomania or mania. Cyclothymic disorder refers to a mild form of bipolar disorder which may appear as a constitutional state rather than a mental illness unless formally assessed.

Mood disorders are distinguished from disorders where there is a transient lability of mood. For example, unstable mood is a feature of borderline personality disorder (see Personality change). In pseudobulbar palsy or frontal lobe syndrome frequent changes in mood may be witnessed, such as excessive laughing and crying.

### Pseudodementia

The term pseudodementia is most commonly used to describe cognitive impairment in elderly patients with depression. Depressive pseudodementia can resemble true dementia. It is important to distinguish the two as in depression, the cognitive impairment generally improves with treatment of the underlying condition (Table 22.1).

### Psychosis

Psychosis refers to a set of symptoms that indicate that the patient has lost contact with reality and that their thought processes have become disconnected. Hallucinations and delusions are the most frequently encountered psychotic symptoms. Thought disorder can be seen in association with hallucinations and delusions or, less commonly, on its own (see The mental state examination for definitions). Psychosis can arise in the context of brain neurodegeneration as in Alzheimer's disease and Parkinson's disease, or brain neurotoxicity as in delirium, alcohol withdrawal and certain forms of substance abuse. People with epilepsy can also develop psychotic conditions either in relation to seizure activity (peri-ictal or ictal psychosis) or as an inter-ictal state presumed to reflect progressive and permanent brain changes. Psychosis can also arise in types of mental illness where there is no neurological antecedent, most commonly schizophrenia and the affective disorders.

The form of hallucinations and the content of delusions point to the nature of the underlying disorder. In the 'organic psychoses' (neurodegeneration, neurotoxicity, ictal or peri-ictal psychosis) hallucinations are usually visual, that is patients see objects that are not there. These can take the form of animals, people or even whole scenes which are often vivid and frightening. Hallucinations in other modalities are less common but notable types include tactile hallucinations, experienced as insects crawling under the skin

**Table 22.1** Clinical features that help to distinguish dementia from depressive pseudodementia.

	Dementia	Depressive pseudodementia
Behaviour	Relatively unconcerned	Distressed and frightened
Memory	Greater impairment for recent than remote memories	Complaints of generalised memory impairment but performs better than described
Cognitive testing	Cooperative	Gives up easily, 'don't know' answers

(formication), seen in alcohol withdrawal or cocaine intoxication, and olfactory or gustatory hallucinations in complex partial seizures. Auditory hallucinations are less common in organic conditions and usually point to schizophrenia or an affective disorder. The exception to this is epilepsy, when psychosis can develop as an inter-ictal condition that typically resembles schizophrenia.

Psychosis can arise in the context of severe depression. Hallucinations are characteristically of a voice speaking directly to the patient (i.e. in the second person). The voice is usually highly critical (e.g. telling the patient that they are worthless). Delusions are 'mood congruent' and include beliefs about being guilty of some terrible act and deserving to be punished. Nihilistic delusions are also typical and take the form of believing the body is dysfunctional, rotting or even disappearing (Cotard's syndrome). In mania, hallucinations are less common than in both depression and schizophrenia, but if present resemble those of schizophrenia. Delusions are grandiose in nature and include beliefs about being a famous person or having special powers.

Psychosis is central to the concept of schizophrenia. A diagnosis of an affective disorder can be made without the presence of psychosis whereas in schizophrenia at least one psychotic symptom is mandatory – one of hallucinations, delusions and thought disorder. The psychotic symptoms of schizophrenia tend to be much more bizarre and 'ununderstandable' than in other disorders, so much so that Schneider listed symptoms of the 'first rank' which are highly indicative of schizophrenia (Table 22.2). First rank symptoms can also be present in the inter-ictal psychosis of epilepsy.

There are some notable types of delusion that can be seen in schizophrenia and sometimes in dementia or following brain injury. These are the misidentification syndromes. For example, the Capgras delusion occurs when a patient believes that somebody familiar to the patient has been replaced by an imposter. In contrast, the Fregoli delusion, or delusion of doubles, occurs when a patient believes that different people are the same person in disguise. More commonly associated with brain injury than schizophrenia is reduplicative paramnesia, which occurs when the patient believes that he or she is in a familiar place (e.g. their house), at the same time admitting it is also located elsewhere.

**Table 22.2** The first rank symptoms of Schneider.

If present in the setting of clear consciousness are highly supportive of a diagnosis of schizophrenia

**Delusional perception:** abnormal significance attached to a real perception with no logical explanation

**Delusions of possession of thought:** the belief that an outside force is inserting or withdrawing thoughts or that one's own thoughts are being broadcast to the world

**Delusions of control**

- **Somatic passivity:** belief that bodily sensations are imposed from outside
- **Made acts, thought or emotions:** belief that affects, impulses and motor actions are under outside control

**Auditory hallucinations**

- Hearing own thoughts spoken aloud (thought echo)
- Hearing voices arguing about or discussing the patients
- Hearing voices commenting on the patient's actions

Mental phenomena experienced during the transition from wakefulness to sleep (hypnagogia) or vice versa (hypnopompia) are common in narcolepsy but also occur in those who have neither psychiatric nor neurological disease. They can occur in any modality. Auditory hallucinations include simple noises (bumps in the night), one's name being called out loud or fragments of speech. They are experienced 'outside the head' and, although they can be vivid and frightening, insight is rapidly gained. Visual hallucinations are typically of geometric shapes but sometime hallucinations of people are reported as are olfactory and tactile phenomena.

**Catatonia**

Catatonia is a rare mental and behavioural state that can be seen in a range of psychiatric and neurological conditions including schizophrenia, severe depression and the encephalitides. Typically, the patient is mute and displays a range of bizarre motor abnormalities. An example is catatonic posturing whereby an unusual position is held for long periods of time but a body part can be passively moved to another position which is then maintained (waxy flexibility). This form of immobility can be interspersed by periods of purposeless hyperactivity (catatonic excitement). In its most severe form, patients can become rigid and immobile for prolonged periods (catatonic stupor) accompanied by an involuntary resistance to passive movement (geigenhalten). This can progress to a life-threatening state of 'lethal catatonia' where autonomic instability and hyperpyrexia develop and rigidity can give rise to dangerously elevated creatine kinase levels. This syndrome resembles the neuroleptic malignant syndrome and should be considered a medical emergency.

**Non-organic disorders in neurology**  
**Functional neurological symptoms**

Functional neurological symptoms (FNS) manifest as neurological problems, for example tremor, paralysis, seizure or sensory disturbance, but the clinical examination points away from an organic cause and investigations fail to find one. They are clinically significant because of associated disability.

The term 'functional' therefore refers to the fact that the nervous system is not functioning normally despite there being no explanation in terms of known neurological disease. FNS are very common. Approximately 30% of patients referred to general neurology clinics from primary care have FNS. In the population at large, 4–12/100 000 are estimated as having clinically important FNS at any one time. Despite the health burden that these symptoms cause, the importance of FNS remains largely unrecognised with regards to treatment: all neurologists know that such symptoms are most difficult to help.

**Terminology**

For over a century FNS were considered to be associated with distressing psychological events or conflict occurring at some point in the individual's history. The term 'conversion' was coined by Freud to denote his theory that the mind defends against conscious psychic pain by unconsciously converting emotional symptoms into physical ones. The term 'conversion disorder' was subsequently incorporated into both the International Classification of Diseases (ICD) and the Diagnostic and Statistical Manual of Mental Disorders (DSM) classification systems of psychiatric illness as a collective descriptor of FNS; for example DSM-IV required the fulfillment of the diagnostic criterion: 'Psychological factors are

**Table 22.3** Alternative terms used for functional neurological symptoms.

**Hysteria** An ancient term attributed to Hippocrates to describe the physical consequences of a 'wandering womb', a view that is hard to understand today. It was revived by Charcot in nineteenth century to describe functional symptoms which he saw as developing mainly in women. Hysteria remains in colloquial use, to describe florid emotional responsiveness in both sexes

**Conversion disorder** Conversion is an historical term coined by Freud to denote the hypothetical process by which the experience of psychological distress caused by conflict or trauma is avoided by the unconscious conversion of anxiety into physical symptoms. The term 'conversion disorder' is retained in DSM editions to denote physical functional neurological symptoms (e.g. paralysis, tremor); in DSM-5 the term 'functional neurological symptom disorder' is given as an alternative

**Non-organic neurological symptoms** This is essentially shorthand communication between doctors but says nothing about the nature of the problem for the patient

**Psychogenic neurological symptoms** This directly implies a psychological cause and can cause offence

**Somatisation** This is used to denote the attribution of anxiety to a physical problem. Somatisation can concern any organ or system of the body, not only the nervous system

**Pseudoseizure** Like 'non-organic', this term is used to communicate between clinicians that a seizure is false because it is not epileptic. Not useful for patients and can cause offence

**Non-epileptic seizure, non-epileptic attack disorder, non-epileptic event** These are common descriptors of functional convulsions. They are neutral in tone but like 'non-organic' say nothing about the nature of the problem

judged, in the clinician's belief, to be associated with the symptom or deficit because conflicts or other stressors precede the initiation or exacerbation of the symptom or deficit. A diagnosis where the stressor precedes the onset of symptoms by up to 15 years is not unusual. However, while there may be a causative stressor, there is no research evidence to support such a psychodynamic formulation and clinicians often fail to elicit any history of psychological trauma or conflict. Patients themselves usually misinterpret the explanation of the term 'conversion disorder' as the clinician inferring that their symptoms are 'all in the mind' or even fabricated. This situation has not been helped by the use of other value-laden labels for FNS (Table 22.3). DSM-5 has retained 'conversion disorder' as the main label but the term 'functional neurological symptom disorder', which has no emotive connotations, is also given in parentheses as an alternative.

### Diagnosis

Many patients with FNS are often told what they do *not* have, for example a brain tumour, multiple sclerosis or Parkinson's disease, but not what they *do* have. Although the exclusion of serious neurological disease is reassuring, it can leave the patient discontented because they still do not understand what is causing their symptoms. They may believe that the doctor has missed the proper diagnosis and then embark on a round of consultations with different specialists. As different specialists usually give different

**Table 22.4** Physical signs that help in the differentiation of organic and functional motor symptoms.

### Functional tremor

*Entrainment test:* copying a 3-Hz tapping movement from the examiner with one hand either results in a significant shift in tremor frequency in the other hand or bizarre difficulty in performing the tapping task

### Functional weakness

*Give-way or collapsing weakness:* the examined limb collapses from a normal position with a light touch. Normal power can often be achieved with encouragement. NB Organic weakness can also be collapsing in 30%.

**Inconsistency** (i.e. normal strength can be demonstrated)

- *Hoover's sign:* with the patient supine on a couch, the examiner places their hand under the subjectively weak leg and asks the patient to flex the contralateral hip (the strong leg) against resistance. If the examiner feels pressure from the apparently weak leg, the weakness is likely non-organic. This is a positive Hoover's sign (If no pressure is felt from the extensor muscles, this suggests that the weakness is organic.)
- *Chair test:* Patients with a disordered functional gait when walking may show that they can propel themselves with their legs when sitting in a chair with wheels, and/or imitate walking movements when sitting in a chair.

### Fahn and Williams criteria (1988)

- Abrupt onset, inconsistency/incongruity, distractibility, false weakness, false sensory changes, pain, exhaustion, excessive startle, bizarre movements, concomitant somatisations
- 96% specificity, 97% sensitivity

explanations of their symptoms, some contradictory, this can cause more confusion and the feeling that 'nobody is taking them seriously' and serve to maintain or worsen the symptom complex.

Neurologists use particular physical signs to show and confirm that symptoms are not organic (Table 22.4). They often then refer to a psychiatrist to 'confirm the diagnosis' on the assumption that he or she can elicit a presumed underlying psychiatric disorder or relevant psychological factors. There are two problems with this approach. First, the diagnosis is essentially a neurological one based on the incongruity of symptoms and signs with known neurological disorders. Secondly, patients frequently do not have a major psychiatric illness such as major depression or generalised anxiety disorder. Any psychological component may be subtle and, if present, the link between it and the development of physical symptoms may not be evident to anyone. Thus, psychiatrists find themselves uncomfortable at labelling physical symptoms unfamiliar to them as psychologically determined. Patients can then fall between neurological and psychiatric stools, with neither side feeling confident to offer help.

The recent advance in providing the label 'functional neurological symptom (FNS) disorder' as an alternative to 'conversion disorder' has helped to resolve this impasse. In addition, DSM-5 has introduced a new diagnostic criterion requiring positive evidence that the clinical features are not compatible with a known neurological disorder, and has removed the need for a demonstrable psychological prerequisite (Table 22.5). This should enable neurologists and psychiatrists to work collaboratively, with neurologists making a positive diagnosis of FNS disorder, explaining to patients why this

**Table 22.5** DSM-5 criteria for conversion disorder (functional neurological symptom disorder).

<p><b>Criteria A, B, C and D must all be fulfilled to make the diagnosis</b></p> <p>A One or more neurological symptoms such as altered voluntary motor, sensory function, cognition or seizure-like episodes</p> <p>B The symptom, after appropriate medical assessment, is found not to be caused by a general medical condition, the direct effects of a substance or a culturally sanctioned behaviour</p> <p>C The physical signs or diagnostic findings are internally inconsistent or incongruent with recognised neurological disorder</p> <p>D The symptom causes clinically significant distress or impairment in social, occupational or other important areas of functioning or warrants medical evaluation</p>
---

is so on the basis of symptoms and signs, and with psychiatrists treating any mental illness and coordinating therapy.

FNS can be present in isolation or as part of a more general disorder involving unexplained symptoms affecting other bodily systems (e.g. the gastrointestinal tract or the genitourinary system). Here, the older diagnostic terms include Briquet's syndrome and somatisation disorder. DSM-5 has abolished 'somatisation disorder' as a diagnosis, because the criteria were overly complex and ultimately not useful, and introduced 'somatic symptom disorder' instead. Another major change is that DSM-5 now acknowledges that organic and non-organic symptoms can coexist, something long recognised by neurologists. For example, patients with epilepsy can also have non-epileptic seizures.

In somatic symptom disorder, patients must have 'one or more chronic somatic symptoms about which they are excessively concerned, preoccupied or fearful. These fears and behaviours cause significant distress and dysfunction, and although patients may make frequent use of health care services, they are rarely reassured and often feel their medical care has been inadequate.' This is distinguished from illness anxiety disorder or hypochondriasis in which patients 'may or may not have a medical condition but have heightened bodily sensations, are intensely anxious about the possibility of an undiagnosed illness, or devote excessive time and energy to health concerns, often obsessively researching them. Like people with somatic symptom disorder, they are not easily reassured. Illness anxiety disorder can cause considerable distress and life disruption, even at moderate levels.'

## Specific types of functional neurological symptoms

### Functional seizures

Functional seizures are one of the most common functional neurological presentations. In the general population the best estimate of the prevalence is of 4.6/100 000. About 20% of patients referred to seizure clinics have functional seizures and it is not uncommon for patients admitted to intensive care units with apparent status epilepticus to eventually receive this diagnosis (23% in one study). Functional seizures occur more often in women than men by 4 : 1. They are associated with high rates of personality disorder, anxiety and dissociation. Functional seizures, contrary to other forms of FNS, are often associated with childhood physical or sexual abuse, estimated as 25%. It used to be thought that functional seizures commonly developed in people with epilepsy but recent estimates are that 5–10% of functional seizure cases have a double diagnosis.

As with other FNS, there are a number of different labels used for functional seizures (Table 22.3), the most common being 'non-epileptic seizures'.

Non-epileptic seizures are characterised by episodes of loss of motor control. The majority (60%) resemble grand mal seizures (i.e. convulsive attacks), and the rest are blank spells where the patient is motionless and uncontactable. There are a number of features that can usefully discriminate grand-mal epileptic seizures from the convulsive type of non-epileptic seizures. Seizures are most likely to be non-epileptic if the prodrome or seizure itself lasts longer than 5 minutes; the eyes are closed and resist passive opening; and there are side to side head movements. Importantly, non-epileptic seizures can be associated with features considered more typical of epilepsy, such as tongue biting; urinary incontinence; an aura; post-ictal confusion or drowsiness; attacks appearing to emerge from sleep; and apparent status epilepticus. These are not therefore discriminators. Injuries are also frequently seen in patients with non-epileptic attacks including cuts, bruises and even fractures. During an attack, the patients are conscious, though may appear not to be so. On questioning, they often describe their subjective experience during a non-epileptic attack, of being aware of their surroundings but feeling detached, as in depersonalisation/derealisation, and unable to speak.

It is important not to dismiss an apparent non-epileptic attack. In practice, non-epileptic attacks are often unrecognised panic attacks. This is especially so if the patient does not describe subjective fear but displays paroxysmal autonomic symptoms such as tremor and depersonalisation/derealisation. Other apparent non-epileptic attacks may be syncopal episodes especially if associated with brief myoclonic jerks.

A useful diagnostic finding is of a normal electroencephalogram (EEG) during a typical attack. However, in this circumstance it is important to consider the possibility of frontal seizures, in which seizures may manifest as bizarre uncoordinated movements with a normal EEG. The interictal EEG is not helpful, as 20% of patients with non-epileptic seizures have non-specific EEG abnormalities. Another distinguishing factor is that serum prolactin levels are often raised 10–20 minutes after a generalised epileptic seizure. However, this is an unreliable finding and other clues to the diagnosis should be sought. About 70% of patients with epilepsy respond well to standard antiepileptic therapy. Failure to respond, with continuing frequent attacks, should raise doubts about the diagnosis.

### Fixed dystonia

Dystonia is characterised by sustained, often painful, contractions of groups of muscle. It causes repetitive involuntary movements or abnormal postures and can affect any body part. Dystonia-like movements can be functional and, as with other functional symptoms, differentiated by their incongruity. Fixed dystonia is an extreme form of functional dystonia in which an abnormal posture becomes permanent or fixed. Fixed dystonia has several characteristic features. There is often a history of a mild physical injury (e.g. being hit by a ball), followed by the rapid development and spread of abnormal movements. For example, in the upper limb, dystonia begins with contraction and flexion of the fingers, then affects the wrist and eventually moves up the arm. In the legs, classically, the foot becomes inverted. Eventually the patient begins to walk entirely on the lateral border of the foot and even on the dorsum, or is confined to a wheelchair as the contraction moves up the leg or across to the other leg.

On examination, the patient is unable to move the affected part voluntarily and an attempt at passive movement is met with resistance. Examination in the fixed posture at rest often shows that the muscles are not actively contracting and the patient is usually unable to contract opposing muscle groups. Patients with fixed dystonia can become dissociated from their affected limb in the sense that they feel that it is not part of them and they sometimes request amputation. Over time, the involved joints in fixed dystonia can become ankylosed, meaning there is no prospect of regaining movement. If this is suspected, examination under anaesthetic is indicated to determine the range of movements before embarking on physiotherapy.

### Treatment of functional neurological symptoms

Many patients when confronted with the notion that there is no organic condition underlying their complaints are initially reluctant to accept the diagnosis because their symptoms are so physical; they feel offended at the concept of a non-organic cause. However, a clear presentation of the diagnosis, with the demonstration of positive signs, is often sufficient to significantly reduce symptoms, especially in the case of non-epileptic seizures. Psychotherapy is the cornerstone of treatment. There are few clinical trials comparing particular types but the evidence that does exist favours cognitive-behavioural therapy (CBT).

Inpatient treatments are available in a small number of centres in the United Kingdom. These provide multi-disciplinary therapy combining CBT with occupational and physiotherapy. The approach is similar to rehabilitation services for organic disorders but with a greater emphasis on CBT.

There is no evidence that drug treatment is effective. Antidepressant drugs can be helpful in patients with prominent symptoms of depression.

### Dissociative disorders

Dissociation is a term derived from psychoanalytic theory to denote the separation of memory, sense of identity or sense of reality from consciousness. The most common precipitant is a psychological trauma. The dissociative disorders are categories that describe the behavioural expression of these phenomena. Although both conversion disorder and dissociative disorders refer to non-organic neurological symptoms, DSM-5 classifies them separately because conversion is a somatic complaint and dissociation is a mental complaint. In neurology, the most common dissociative disorders present as amnesia, fugue or depersonalisation/derealisation.

### Dissociative amnesia

Dissociative amnesia is sometimes referred to as psychogenic amnesia and denotes the inability to recall important personal information, usually related to psychologically traumatic or stressful events, but is sometimes more global. There is preservation of the ability to comprehend environmental information and to perform complex learned skills.

### Dissociative fugue

The word fugue refers to an episode of wandering in which the patient appears to be behaving normally in a goal-directed manner but has no recollection of the event and is confused about their personal identity. Rarely, a new identity may be adopted if autobiographical memory is not fully recovered. Episodes of dissociative fugue can last hours to days. Similar events may be seen in the context of other neurological disorders. In epileptic automatism, the episode

is usually shorter in duration, the patient is in a more obvious state of altered consciousness and the behaviour is more stereotyped and purposeless. In transient global amnesia, the patient is aware, during the episode, that they cannot remember preceding events and they do not lose their sense of personal identity.

### Depersonalisation/derealisation disorder

These two mental states are grouped together as a single disorder because they usually occur together. Patients describe depersonalisation as a feeling of disconnection from their body or not being fully inside their body; they may describe out-of-body experiences. These symptoms are very unpleasant and can be pervasive and associated with substantial risk of suicide. Depersonalisation and derealisation (a feeling of being cut-off from the world) can also be experienced in complex partial seizures and epilepsy should be considered as a possible diagnosis.

Dissociative disorders can be difficult to treat. As they are sometimes considered a manifestation of anxiety, a common strategy is to recommend an anxiolytic antidepressant (i.e. an SSRI), and CBT, either separately or in combination.

### Psychiatric disorders of epilepsy

Psychiatric symptoms are common in people with epilepsy, up to 50% in some studies. They can manifest either as transient phenomena directly related in time to the seizure (peri-ictal or ictal) or as more persistent inter-ictal conditions.

### Peri-ictal and ictal psychiatric symptoms

Recognised prodromal symptoms are pre-ictal depression, labile mood and irritability. These can last for hours to days and are usually alleviated by the seizure.

Psychiatric symptoms during the ictus itself are most commonly witnessed in complex partial seizures. If they precede a secondary generalised tonic-clonic seizure, they are often referred to as an aura but in fact represent ictal phenomena arising from a temporal lobe focus. Patients may describe intense fear, depersonalisation/derealisation or *déjà vu* and they may hallucinate an unpleasant taste or smell. These symptoms are often accompanied by motor symptoms such as staring, stereotyped lip smacking or purposeless plucking movements. These ictal phenomena are usually short lived lasting a few minutes only.

The most common post-ictal psychiatric syndromes are delirium and psychosis. Post-ictal delirium usually presents with confusion and behavioural withdrawal. Agitation with hyperactivity can occur but is less common. Post-ictal delirium is usually self-limiting; patients with prolonged and frequent seizures tend to have longer episodes and these can last from hours to days. During the delirium the patient needs to be kept safe but no specific treatment is usually necessary. If delirium lasts longer than normal for that particular patient, non-convulsive status and other causes of delirium should be suspected.

The most significant risk factor for developing post ictal psychosis is temporal lobe epilepsy. The classic presentation is of a cluster of seizures followed by a 'lucid interval' lasting several hours to days. During this period the patients may exhibit unusual behaviour such as lethargy, irritability or restlessness. Psychotic symptoms then emerge, typically as visual and/or auditory hallucinations with delusional beliefs of a religious or paranoid nature. Patients can be floridly paranoid and aggressive and be a risk to themselves or others. Suicide is a particular risk and tends to be impulsive and

violent, for example jumping in front of a train or jumping off buildings. The mean duration is 10 days but some people can remain psychotic for several months. Early and active treatment is required using a benzodiazepine (e.g. lorazepam) in combination with an antipsychotic (e.g. risperidone or haloperidol). If post-ictal psychosis is a regular occurrence following a cluster of seizures, immediate treatment before the onset of psychotic symptoms is often recommended. People with a history of post-ictal psychosis are at risk of developing an inter-ictal psychosis.

### Inter-ictal psychiatric disorders

The most common inter-ictal psychiatric disorder is depression (estimated prevalence 22–40%). This has been particularly linked to temporal lobe epilepsy. Further, the risk of depression in the 3 months following neurosurgery for epilepsy, either *de novo* or as a recurrence is relatively high at 25%; this may become persistent in 10%. Depressive symptoms, such as pervasive low mood and biological disturbances of sleep and appetite, conforming to a DSM diagnosis of major depression, are well recognised. In addition, the presence of a group of more atypical symptoms has been recognised and labelled as ‘inter-ictal dysphoric disorder’. This refers to a persistent state of irritability, anergia, depressed mood, insomnia, atypical pain and anxiety, sometimes with intermittent euphoria. It was initially thought that this syndrome was a specific disorder of temporal lobe epilepsy and linked to the underlying pathology. More recently this has been challenged with evidence that this symptom cluster is essentially a stable mood disorder variant and not specific to temporal lobe epilepsy. Depression in epilepsy can be effectively treated with psychotherapy, including CBT, antidepressants and electroconvulsive therapy (ECT). The newer antidepressants, such as selective serotonin re-uptake inhibitors (SSRIs), have a much lower liability to lower the seizure threshold (<0.5%) than the older tricyclic antidepressants and therefore should not be a barrier to their use.

Inter-ictal psychosis is well recognised, mainly in temporal lobe epilepsy, with a maximum estimated prevalence of 10%. This typically develops a long time after the onset of seizures, often more than 15 years. It has a schizophrenia-like presentation, often including Schneider’s first rank symptoms (Table 22.2) and is therefore referred to as ‘schizophrenia-like psychosis of epilepsy’. The reported difference between this and schizophrenia proper is a better preservation of personality and fewer negative symptoms. The risk factors for developing an inter-ictal psychosis are: early age of onset of seizures; left-sided epileptic focus and treatment resistance. Treatment is with long-term antipsychotic medication. Atypical antipsychotics, with the exception of clozapine, are less likely to lower the seizure threshold than older antipsychotics.

### Forced normalisation

Forced normalisation refers to the observation by Landolt that psychosis, or more rarely depression, anxiety or agitation, can emerge when the EEG becomes normal. This EEG definition has since been extended to include the clinical observation that psychosis can emerge when seizures come under control with anticonvulsant medication. This can occur especially if there is an abrupt improvement in seizure control with the addition of a new drug in a patient with long-standing epilepsy. If seizures return, there is usually an improvement in psychosis and hence the term ‘alternative psychosis’ is often used to describe this clinical phenomenon.

### Personality changes in epilepsy

The prevalence of a DSM-defined personality disorder is higher in people with epilepsy than in the general population (14%) with various studies estimating this as between 18% and 61%. In addition, there are behavioural traits that are characteristically seen in people with epilepsy, especially temporal lobe epilepsy. These do not conform to DSM diagnoses, suggesting that the pathological process that gives rise to seizures can also affect personality development. Certain traits have been grouped together as the Gastaut–Geschwind interictal behaviour syndrome and include viscosity or ‘stickiness’ of thought, when patients adopt circumstantial speech; hypergraphia or the tendency to compulsive and excessive writing often about minutiae; hyper-religiosity or the tendency to form deep and intense mystical or religious beliefs; and altered sexuality which is most often hyposexuality and decreased libido. Although personality changes are commonly seen in people with epilepsy, the concept of an inter-ictal syndrome is controversial and the elements of the syndrome rarely co-occur.

### Psychotropic effects of anticonvulsants

When considering how to treat inter-ictal psychiatric disorders, it is important to recognise that the prescribed antiepileptic drug may have had psychotropic effects. For example, some studies have attributed 30% of cases of depression to antiepileptics and this has been reported with tiagabine, topiramate, vigabatrin and felbamate. Anticonvulsants that promote GABA neurotransmission, as a rule of thumb, tend to be sedative, anxiolytic and mood stabilising (e.g. pregabalin, gabapentin and sodium valproate) whereas those that inhibit glutamate neurotransmission tend to be activating and have antidepressant properties (e.g. lamotrigine). Other antiepileptics may increase the risk of developing psychosis (e.g. vigabatrin and topiramate).

## Neuropsychiatric aspects of movement disorders

### Parkinson’s disease

Parkinson’s disease is traditionally considered a movement disorder caused by degeneration of dopamine neurones in the midbrain substantia nigra. These neurones give rise to the dopaminergic nigrostriatal pathway which innervates the dorsal striatum. Here it modulates information flow through the opposing direct and indirect fronto-striato-thalamic motor output pathways and the net balance of output determines whether movement is initiated or inhibited. Reduced dopamine neurotransmission favours inhibition and, in Parkinson’s disease, tonically diminished dopamine release results in the cardinal motor symptoms of bradykinesia, tremor and rigidity.

The neuropathology that is associated with cellular degeneration in Parkinson’s disease – the Lewy body and Lewy neurite – is not restricted to the substantia nigra or even to dopaminergic neurones. Lewy pathology can be found in neurones throughout the central nervous system and even in peripheral nerves, for example the enteric, sympathetic and cardiac nervous systems and even in glandular tissue. As Lewy pathology can be widespread, non-motor symptoms associated with neuronal damage outside motor pathways are frequently present in people with Parkinson’s disease and these include abnormalities of the mental state.

Anxiety, depression, apathy, psychosis and cognitive impairment, including dementia, are well-recognised neuropsychiatric syndromes of Parkinson’s disease. Not all patients develop these complications and, if present, they develop at different time points.

For example, anxiety and depression tends to present early whereas dementia is a relatively late feature of the illness.

One way of conceptualising the development of psychiatric symptoms in Parkinson's disease is with respect to what we know about the spread of Lewy pathology. This has been found to occur in predictable stages, beginning in the medulla and olfactory bulb. From the medulla this spreads forward in the brain to successively involve the pons, midbrain, limbic cortex and neocortex. Because the appearance of motor symptoms has been shown to correlate with Lewy body pathology affecting the midbrain substantia nigra, it is likely that psychiatric non-motor symptoms of Parkinson's disease develop at a time when Lewy pathology affects the neural systems thought to be important for regulating cognition, mood and other emotions and behaviours.

### Depression

The best estimate for the prevalence of all forms of depression in Parkinson's disease is 30–35%, when measured either by fulfilling diagnostic criteria or reaching specified levels of symptom severity on clinical scales. DSM-defined major depressive disorder accounts for 10–17%. Depression is a common disorder and the prevalence is also known to increase in people with chronic debilitating medical conditions. It is therefore likely that some people with Parkinson's disease would have become depressed anyway, as a result of a combination of genetic susceptibility and pre-morbid life events. Others may develop depression as a reaction to the impact of their illness on their quality of life. However, because depression is far more frequent in those with Parkinson's disease than in either the population at large or in populations with other disabling long-term conditions, it is likely to be intrinsic to the disorder in some people. Features of depression that seem to characterise a Parkinson's disease-specific mood disorder are lack of family history, onset within the 5 years preceding the development of motor symptoms and lack of symptoms of guilt or self-blame.

The observation from epidemiological studies that show that depression frequently precedes the onset of the motor symptoms of Parkinson's disease tallies with what is known about the spread of Lewy pathology. The brainstem nuclei of the serotonergic raphe and noradrenergic locus coeruleus can be involved before the midbrain dopamine nuclei. As antidepressants exert their action by increasing the neurotransmission of serotonin, noradrenaline, or both, the corollary is that early damage in these nuclei may precipitate a mood disorder. Neurochemical imaging studies have provided some evidence in support of this. Other evidence suggests that reduced neurotransmission of dopamine itself may cause depressed mood. The midbrain ventral tegmental nucleus, which is immediately adjacent to the substantia nigra, also contains dopaminergic cell bodies that can be affected by Lewy pathology. These cell bodies give rise to the mesolimbic and mesocortical pathways that innervate the ventral striatum (also known as the nucleus accumbens), limbic and frontal association cortex. In contrast to the dorsal striatum being involved in motor control, the ventral striatum is involved in reward processing. Thus, reduced dopamine neurotransmission at this site can arguably give rise to depressed affect. In support of this as a phenomenon, some patients on dopamine replacement therapy report a significant lowering of mood as the current dose of levodopa wears off with concomitant improvement following the next dose.

A difficulty with the diagnosis of depression in Parkinson's disease is that there is an overlap in clinical features such as reduced facial expression and psychomotor slowing. In practice, however, it has been shown that current DSM diagnostic criteria can be used

unchanged to accurately distinguish patients with Parkinson's disease and depression from those with Parkinson's disease alone. Thus, careful assessment to include the whole range of DSM clinical criteria can reliably determine the presence of depression.

Given the varied aetiology of depression in Parkinson's disease, it is important to understand the context of depressive symptoms. Thus, it is crucial to take a full personal, family and social history to formulate the likely precipitants as this will guide the optimum type of intervention required. For example, when depression is secondary to social factors such as isolation or difficulty with dressing and bathing, changes to the immediate environment may significantly improve quality of life and therefore mood. The prescription of non-psychotropic medications may also help causes of low mood related to pain, urinary incontinence and sleep disturbance. Psychological interventions may also help; for example CBT has been shown to be very effective in helping a proportion of depressed patients with Parkinson's disease and it is worth considering this for those who have pessimistic thoughts and hopelessness about their future.

Between one-fifth and one-quarter of patients with Parkinson's disease take antidepressants, thus emphasising the significance of the problem in this disorder. When antidepressant medication is indicated, the choice is between drugs that specifically enhance serotonin neurotransmission (SSRIs); those that specifically improve both serotonin and noradrenaline neurotransmission (serotonin and noradrenaline reuptake inhibitors [SNRIs] or mirtazapine – a receptor antagonist) and those that have more diverse actions, including the older tricyclic drugs. There have been relatively few randomised controlled trials to guide pharmacotherapy. Further, the evidence from these is often contradictory, probably because of the small numbers of participants and the heterogeneous nature of depression in Parkinson's disease. As a rule of thumb, optimisation of dopamine replacement therapy should be the first tactic, especially for those patients whose mood fluctuates or dips as the current dose is wearing off. Smoothing of dopamine replacement therapy, by increasing the frequency of dosage and/or modifying the dose using motor function as a guide, can often stabilise and improve mood. Furthermore, some trials have shown that adding dopamine agonists to levodopa, such as pramipexole or rotigotine patches, can improve mood in depressed Parkinson's disease patients. There are also case studies showing the benefit of bupropion, an indirect dopamine agonist.

If this strategy does not help, either because of ineffectiveness or disruption of motor control, traditional antidepressants are then indicated. The evidence does not favour any particular class or particular antidepressant. Head to head studies have shown equivalent efficacy for SSRIs and SNRIs and for SSRIs and tricyclics, but again there are negative examples. The choice is therefore a pragmatic one and it is advisable to prescribe medications with the least potential for adverse effects first, such as SSRIs, then moving to SNRIs or mirtazapine and finally tricyclics. In severe depression, ECT can be effective and has the benefit of transiently improving motor control. A study has found repetitive transcranial magnetic stimulation beneficial but the evidence is insufficient to recommend this for clinical practice. Monoamine oxidase inhibitors (MAOIs) are rarely used these days to treat depression and are absolutely contraindicated in Parkinson's disease because of a potentially lethal interaction with levodopa.

### Anxiety

Anxiety frequently accompanies low mood in affective disorders but general anxiety disorder, panic disorder and social phobia frequently present as separate disorders in Parkinson's disease.

The estimated point prevalence of all DSM anxiety disorders in Parkinson's is around 34%. Less is known about the specific pathophysiology and treatment of anxiety disorders in Parkinson's disease than depression. However, clinical experience suggests that as a levodopa wearing-off phenomenon, anxiety is more prominent than depression. Anxiety can be intense, especially at night. Like depression, a link between anxiety and reduced dopaminergic neurotransmission should be considered in patients whose anxiety fluctuates throughout the day, for example when marked anxiety is inter-dispersed with periods of calmness and normality of the mental state. Given this link and the fact that antidepressant medication is also anxiolytic, the same principles of treatment for depression also apply to anxiety, in other words, optimisation of treatment with levodopa or dopamine agonists, followed by the use of antidepressants if the response is unsatisfactory.

### Apathy

Apathy has many features in common with depression but distinguishing factors include impaired motivation in the absence of low mood or sadness. In Parkinson's disease, there is some neuroimaging evidence that apathy and depressed mood are mediated by distinct neural systems, with depression reflecting abnormalities of the subgenual cingulate cortex, an area associated with major depression, and apathy being related to motor and frontal cortex dysfunction. In practice, pure apathy is rare and it is most often co-morbid with depression and/or cognitive impairment. Some studies suggest that apathy is a predictor of dementia in Parkinson's disease. There is no specific treatment for apathy; for example there is currently insufficient evidence for the use of stimulants such as modafinil.

### Psychosis

Minor abnormal experiential phenomena commonly occur early in Parkinson's disease. They are regarded as benign because insight is retained and they are not frightening or distressing. These include visual illusions – the abnormal perception or misinterpretation of objects – whereby nearby objects are seen to 'morph' into living things. Another is a form of hallucination – a sensory perception without an object – in the form of people or animals moving past the periphery of the visual field. Yet another common phenomenon is the intense feeling of a benign human presence located outside of the visual field. This is sometimes referred to as an extracampine hallucination but this is not strictly correct as there is no abnormal sensory perception – the patient 'feels' the presence of the object but does not 'see' it.

Frank psychotic phenomena commonly develop later in the illness. These can be present in clear consciousness (i.e. in the absence of delirium), as in primary psychotic disorders. However, the conjunction of Parkinson's disease and an independent psychotic disorder, such as schizophrenia, is rare and the type of psychotic symptoms in Parkinson's disease is different from these and the range is more restricted. For example, the most prominent type of hallucination in Parkinson's disease is visual, as opposed to auditory. Cross-sectional estimates vary between 16% and 37% for visual hallucinations and 2% and 22% for auditory hallucinations. Delusions (i.e. fixed abnormal beliefs) can also occur in Parkinson's disease but again they are much less frequent than in the primary psychoses (1–14% in Parkinson's) and tend to be less bizarre, persecutory or grandiose. Other first rank psychotic symptoms, commonly witnessed in schizophrenia, such as passivity phenomena and abnormalities of thought control, are not seen in Parkinson's disease.

Visual hallucinations are usually stereotyped and commonly take the form of children or animals; they disappear if approached and, if multiple, they interact with each other but ignore the patient. They occur mostly in situations of diminished ambient light such as in the evening or in the context of visual impairment, in the periphery of vision. Again, if insight is retained these are non-threatening and usually ignored. However, as the disease progresses they usually worsen in intensity and frequency and become real to the patient, causing significant distress. This feature of late Parkinson's, estimated to develop in over 50% of cases, is the strongest factor causing admission to nursing homes because families are unable to cope.

It is often assumed that because hallucinations in Parkinson's disease occur mainly in treated patients, these are caused by medication-induced increased dopamine neurotransmission in limbic areas. However, the majority of studies have not found differences between non-psychotic and psychotic Parkinson's disease patients in the total dose of levodopa being received or in the types of drug being prescribed, including dopamine agonists. In addition, psychosis in Parkinson's disease was seen in the era before levodopa therapy. The factors associated with hallucinations are older age and longer illness duration; impaired visual input because of ophthalmic disease; abnormal cortical visual processing; sleep disturbance indicative of impaired brainstem dysfunction such as vivid dreams; and cognitive impairment.

The treatment of psychosis in Parkinson's disease is difficult. The use of first generation antipsychotics, such as haloperidol, runs the considerable risk of worsening motor symptoms and these are contraindicated. The second generation antipsychotic drugs were thought to be more promising because they are much less likely to produce extrapyramidal symptoms in non-Parkinson's disorders, especially olanzapine and quetiapine. However, this has not been borne out in practice. In placebo controlled trials, olanzapine was not effective for the treatment of psychosis and worsened motor symptoms. Similarly, there is no strong evidence for quetiapine ameliorating psychosis although it tends not to worsen motor symptoms and if given at night can improve sleep. The only medication with proven efficacy is clozapine, an atypical drug commonly used for patients with treatment-resistant schizophrenia. Clozapine has the potentially lethal adverse effect of neutropenia and therefore requires regular blood monitoring by a specialist service. Fortunately, the doses required in Parkinson's disease psychosis (50 mg maximum) are much lower than for schizophrenia, making leukopenia less likely, but the need to admit to hospital to initiate the drug and regular blood monitoring has made the uptake of this option uncommon. The use of the cholinesterase inhibitor rivastigmine has been shown to be effective in small studies, especially in patients showing signs of dementia where reduced acetylcholine neurotransmission is likely. As a rule of thumb, it is worth trying rivastigmine before moving on to clozapine in patients with troublesome hallucinations.

### Cognitive impairment

It has been estimated that approximately 50% people with Parkinson's disease will ultimately develop dementia. The exact pathological basis may vary but it is highly likely that formation of Lewy bodies in the cortex is the main contributing factor. Another possible mechanism is degeneration of the acetylcholinergic neurones in the basal forebrain. As in Alzheimer's disease, reduced cortical acetylcholine is likely to contribute to impaired attention in addition to cortical pathology itself. This is supported by studies that have shown that drugs that enhance cholinergic neurotransmission, especially rivastigmine, improve cognitive function in Parkinson's disease.

The main predictors of dementia are age, severity of motor impairment and mild cognitive impairment especially visuospatial problems and reduced semantic fluency.

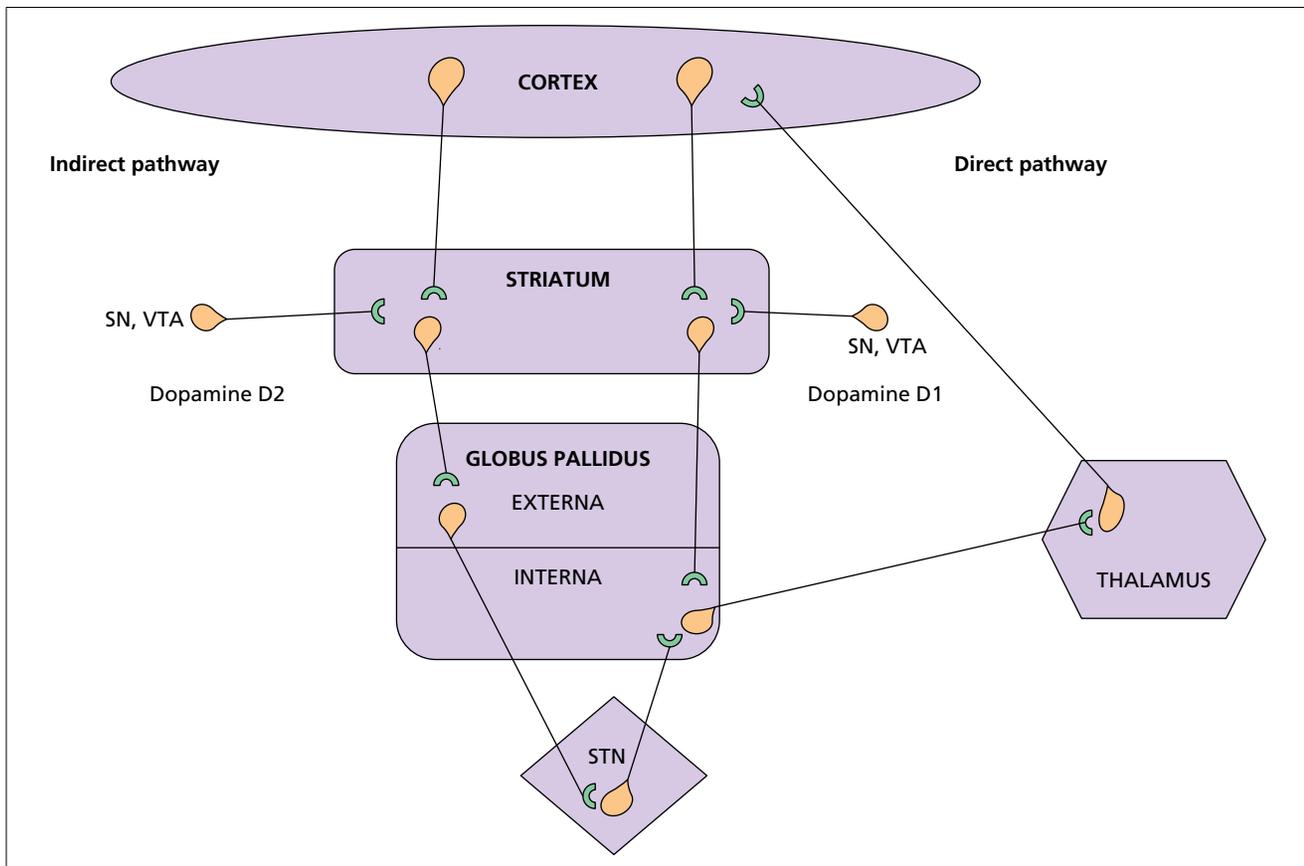

The presence of executive dysfunction alone, reflecting frontal cortical impairment, does not predict dementia. Executive impairment is frequently found in patients with Parkinson's disease on neuropsychological testing and reflects reduced dopaminergic input into non-motor cortex such as the dorsolateral prefrontal cortex and can improve with levodopa treatment.

### Iatrogenic neuropsychiatric problems

**Impulse control disorder** The use of dopamine receptor agonists such as ropinirole as first-line treatment in Parkinson's disease, to spare the use of levodopa and thus delay development of dyskinesias, has highlighted a significant adverse effect of these drugs. This is the development of reduced impulsive control, known as impulse control disorder (ICD) with the emergence of features such as gambling, overspending, inappropriate sexual behaviour in men (e.g. seeking out pornography or prostitutes) and overeating. These behaviours can

become compulsive and seriously affect the life of the individual and their family. Another type of compulsive behaviour is punding. This word describes a behaviour that was originally goal-directed, such as packing a bag or sorting out clothes, but becomes senseless, repetitive and time-consuming. Such ICDs are more common in men with young onset Parkinson's disease treated with dopamine agonists, with a family or premorbid personal history of sensation seeking. The main way of managing ICDs is to reduce and stop the dopamine agonist. Treatment with medications used for OCD, such as SSRIs, do not seem to help. In those patients where ICDs persist following reduction or cessation of dopamine antagonist, CBT shows modest benefit.

**Deep brain stimulation** Deep brain stimulation (DBS) has become a relatively common treatment for managing motor symptoms including drug-induced dyskinesias. The electrode placements are mainly in the motor section of the subthalamic nucleus (STN) but the globus pallidus interna is also used. As these sites are close by the non-motor circuitry mediating cognitive and emotional processes (Figure 22.1), the effect of DBS on cognition and mood

**Figure 22.1** Generic schema of cortical-striato-thalamo-cortical feedback circuits. Information from cortex concerning movement, cognition and emotion is processed in direct and indirect pathways. Activation of the direct pathway facilitates the initiation and control of action and thought. Activation of the indirect pathway, via the subthalamic nucleus (STN), inhibits information in the direct pathway being relayed to the thalamus and inhibits action and thought. Dopamine innervation from substantia nigra (SN) or ventral tegmental area (VTA) to striatum modulates information processing in these pathways via D2 receptors (indirect) and D1 receptors (direct) neurotransmission. Increased dopamine release in striatum has the net result of increasing activity in the direct pathway. Reduced dopamine release, as in Parkinson's disease, facilitates the indirect pathway thereby causing bradykinesia and bradyphrenia. There are five circuits that follow the same general scheme; they project from different areas of frontal cortex and follow distinct but topographically parallel routes through the same structures. The cortical areas of origin are dorsolateral prefrontal and orbitofrontal cortex (cognitive circuits); anterior cingulate (emotional circuit); supplementary motor area (motor circuit); and frontal eye fields (oculomotor circuit). Neuropathology that involves any of these grey matter structures will cause a movement disorder and cognitive and emotional dysfunction.

has been a subject of interest. Cognitive decline has been reported but if DBS parameters are such as to restrict current spread to non-motor areas as much as possible, this can be prevented. The most common finding is impaired verbal fluency but this is usually mild and can be transient. The effect on mood is more controversial. Postoperative depression and apathy is a risk of DBS but this seems more a reflection of excessive reduction in levodopa therapy than the effect of stimulation per se. This is particularly predictable in patients with premorbid non-motor fluctuations in mood and can be averted by less drastic reduction in levodopa. There is a distinct increased risk of suicide following DBS thought to be 12–15 times higher than the general population. Risk factors are being single, a previous history of ICD and a current diagnosis of depression. STN DBS is associated with euphoria or even hypomania but this usually develops soon after the onset of stimulation and can be averted by reducing the stimulation parameters.

### Other movement disorders

Understanding how the neuropsychiatric symptoms of Parkinson's disease are related to the dysfunction of neural networks mediating emotion and cognition is a model for understanding the symptom complex of other movement disorders (Figure 22.1). In addition to a movement disorder, most are additionally characterised by emotional and cognitive dysfunction and the expression over time mirrors the distribution and evolution of the particular pathology.

Like Parkinson's disease, Lewy body dementia (LBD) and multi-system atrophy (MSA) are alpha synucleinopathies associated with parkinsonian movement disorder. In LBD, pathology is prominent in the cerebral cortex giving rise to an early presentation of dementia and visual hallucinosis. In MSA, pathology is more posterior with early involvement of brainstem autonomic nuclei and the cerebellum causing ataxia, bladder problems and blood pressure instability. Frontal executive deficits can be demonstrated in MSA but frank dementia is rare and mood disturbance is best characterised by emotional lability.

Progressive supranuclear palsy is a tauopathy involving the amine and cholinergic neurotransmitter nuclei (substantia nigra, nucleus basalis, locus coeruleus and raphe nuclei), basal ganglia and oculomotor complex. This explains the development of a complex range of symptoms including motor symptoms of parkinsonism and ophthalmoplegia, frontal executive dysfunction, and psychiatric symptoms of apathy, mood lability, disinhibition and compulsive behaviour.

Wilson's disease is caused by copper deposition in the basal ganglia, thalamus and cerebellum. Rigidity dystonia and choreo-athetosis is accompanied by cognitive impairment, personality change depression and even psychosis.

Huntington's disease is caused by the abnormal protein huntingtin being deposited in GABA neurones of the caudate nucleus and frontal cortex. The prominent abnormal movement is chorea and there is progressive cognitive impairment. Psychiatric problems develop early, even before chorea, and characteristically are of personality changes including irritability, aggression and disinhibition. Depression occurs in 40–50% of patients, often with psychotic features. Suicide is a major complication of depression and can occur in the absence of knowledge of the diagnosis. Psychosis occurs in 5–15% of patients with Huntington's disease and is typically paranoid rather than schizophrenia-like.

Other forms of chorea that are particularly relevant for neuropsychiatry include Sydenham's chorea and the paediatric autoimmune neuropsychiatric disorders associated with streptococcal infection

(PANDAS). Sydenham's chorea is associated with the development of OCD, while PANDAS is characterised by tics and OCD. Affective disturbances and behaviour abnormalities are reported and patients sometimes appear hypomanic.

Tourette's syndrome is thought to be a neurodevelopmental abnormality of GABA and/or dopamine synaptic function in the striatum and is characterised by the onset of motor and vocal tics usually in or before teenage years. Tics are characterised by a build-up of the urge to perform them which can be resisted to varying degrees. Suppression of tics is invariably effortful and usually results in a period of rebound worsening. The symptoms characteristically wax and wane over the years. Tics can be simple and brief (e.g. blinking) or more complex coordinated movements. The latter can lead to secondary neurological damage. For example, repetitive head and neck tics can cause cervical spine damage, root lesions and myelopathy. Vocal tics are characteristic and necessary for the diagnosis and these can be so disturbing that the patient becomes socially reclusive. Coprolalia is often thought to be the hallmark of Tourette's but in fact occurs in about 10% of patients. Secondary forms of this disorder, tourettism, can be seen following stroke, the prescription of various stimulant drugs or after withdrawal from neuroleptics.

There are two co-morbidities associated with Tourette's syndrome. In childhood, attention deficit hyperactivity disorder (ADHD) is common, occurring in about 50% of patients. Obsessive-compulsive behaviours occur in 30–40% of patients. These can emerge during childhood but are more common in the teenage and adult years. The symptoms are not typical of OCD. For example, hand-washing rituals and phobias of contamination are not common. Instead, arithmomania (a strong need to count actions or objects) and the compulsive need for symmetry and order are more often found. Self-injurious tics may be seen whereby tics are performed to inflict pain, for example body punching or eye-poking. Compulsive touching is also often seen and can be directed at strangers thus causing social difficulty. Tic suppression can be helped with dopamine receptor antagonist drugs, in particular aripiprazole and risperidone, and clonidine which is more helpful in children than adults. Obsessive-compulsive behaviour, like OCD, is often helped with SSRIs, and ADHD, like the pure form, with methylphenidate.

### Neuropsychiatric aspects of white matter disorders

While many neuropsychiatric disorders reflect grey matter dysfunction, psychopathology can also be seen in disorders affecting predominately white matter. The classic disorder is multiple sclerosis (MS) but other acquired disorders of white matter such as the leukoencephalopathies can also present clinically with psychiatric symptoms.

In MS, the main neuropsychiatric problem is disturbed cognition which occurs early in the course of the illness and can be detected in 40–65% of patients when tested formally. Demyelination most commonly affects speed of information processing, working memory and attention.

Psychiatric symptoms are also very common in MS and take the form of depression (50%), agitation (40%), anxiety (40%) and irritability (35%). Symptoms are often associated with the slow development of rigid and inflexible thinking. The prevalence of these symptoms is higher than that for patients with other chronic CNS conditions suggesting that they are not only a reaction to the

effect of disability, but also are related to forebrain demyelination and cortical shrinkage. Mania is also more common in MS than the rest of the population. Of relevance to the aetiology of mood change in MS is the observation that, in general psychiatry practice, patchy deep white matter lesions seen on MRI scans are associated with bipolar disorder and treatment-resistant depression, especially after the age of 50 years. It is also important to recognise that severe depression is a side effect of  $\beta$ -interferon treatment where suicide is a distinct risk.

A mental state consisting of euphoria and eutonia (a sense of bodily well-being) has been described as being specific for MS and seen in about 10% of cases. This can be considered as a form of 'pseudobulbar affect', whereby mood and affect are disconnected leading to a denial of the severity of the illness. It is thought to reflect a physical disconnection between the frontal lobes and subcortical structures including the cerebellum.

Whereas MS is an acquired condition, the leukodystrophies are genetic demyelination disorders. In metachromatic leukodystrophy, patients with juvenile or adult onset forms characteristically present with personality changes and a schizophrenia-like illness which, if treated successfully, uncovers a progressive dementia. In adrenoleukodystrophy, dementia, learning difficulties and behaviour changes are the most frequent presenting psychiatric problems but again schizophrenia-like states have been reported.

## Minor head injury and post-concussion syndrome

The neuropsychiatric features following severe traumatic brain injury and the value of multi-disciplinary rehabilitation are discussed in Chapter 18.

Post-concussion syndrome is often used as a term to infer that the physical symptoms that follow a minor closed head injury are psychological in origin. However, it is important to recognise that similar symptoms may be the result of shearing forces giving rise to subtle white matter damage. Typical complaints are of persistent headache, dizziness, blurred vision, fatigue, noise sensitivity and poor concentration. Recovery over several weeks is the norm but some remain symptomatic for months or years.

National Hospital for Neurology &amp; Neurosurgery

In neurology, as in all specialties within medicine, accurate diagnosis of the cause of symptoms is seen as an essential prerequisite for rational management. This is undoubtedly true, but in the assessment and management of pain, elucidating the primary neurological diagnosis is very much the beginning, not the end, of the evaluation of the problem. This is because the phenotypic characteristics of pain in the context of neurological disease are – with a few exceptions – not disease-specific, but occur in disorders of widely diverse aetiology. For example, neuropathic pain of burning quality can occur in the limb of a patient with peripheral neuropathy, syringomyelia or a cerebral infarct. Conversely, a patient with multiple sclerosis (MS) may have constricting neuropathic pain of the trunk, shooting neuropathic pain in the face and painful spasticity of the lower limbs. Knowing the diagnosis does not automatically inform the clinician of the nature of the pain; knowing the nature of the pain does not provide an automatic diagnosis. Confronted in the neurology clinic with a patient with pain, the clinician should aim to elucidate the likely mechanistic nature of the generation of the pain – or pains – before embarking on a management plan.

### Definitions

For a phenomenon that is such a universal part of the human experience, it is perhaps surprising that pain is difficult to define. The International Association for the Study of Pain (IASP) defines it as ‘an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage’. This definition highlights the important points that pain can occur in the absence of damage and that there is an emotional component to it, but it has shortcomings.

The definition excludes those with severe cognitive impairment, infants and young children, patients with aphasia and animals. Some elements of the unpleasant sensory experience of those with neuropathic pain are not perceived as associated with tissue damage and are better covered by the term ‘dysaesthesia’. In addition, the affective associations of pain are highly situational and, it can be argued, are not invariably unpleasant (consider eating chilli peppers). However, clinical pains generally are unpleasant, and may be especially so because of the patient’s lack of control over the pain, and its association with disease and disability.

All pain may be classified into one of two categories: nociceptive (or nocigenic) and neuropathic (or neurogenic). Nociceptive pain is more common and more familiar, and is of the type experienced when tissue damage occurs (or is threatened), activating specific nociceptive neurones that transmit their signals within a functionally intact nervous system. Neuropathic pain is defined as ‘pain arising as a direct consequence of a lesion or disease affecting the somatosensory system’; it is often qualitatively different from nociceptive pain, responds differently to various therapeutic interventions and is generally more difficult to treat.

Neuropathic pain can be further subdivided into peripheral or central, on the basis of the location of the lesion or disease. However, this may tend to engender an over-simplistic view in terms of pain mechanisms, because even when the lesion is initially entirely restricted to the periphery (e.g. trauma to a peripheral nerve), central mechanisms typically develop and may dominate the clinical picture.

Allodynia is pain produced in response to a stimulus that is normally innocuous. It may be mechanical (evoked by light touch or brushing) or thermal (evoked by application of gentle warmth or cooling). Hyperalgesia is an increase in pain response, with lowering of the pain threshold, to a stimulus that is normally painful (such as pinprick). Both allodynia and hyperalgesia may be subdivided into three types, depending on the pattern of applied stimulus that evokes the response: static (e.g. light sustained pressure); punctate (e.g. a single or repetitive pinprick at a single location); or dynamic (such as light brushing), where the stimulus is applied over a larger area.

Hyperpathia is a specific form of painful sensory disorder, pathognomonic of neuropathic pain and indicative of somatosensory neuronal loss. There is an increased threshold of sensory perception, so that a stimulus such as light touch or warmth may not be felt on initial application. However, with sustained or repetitive application of the stimulus, after a delay there is an explosive pain response reflecting central sensitisation.

Dysaesthesia is defined by IASP as any unpleasant abnormal sensation, whether spontaneous or evoked. The term is sometimes used as if to exclude pain in all its manifestations, but within the terms of this definition this is incorrect. Abnormal forms of pain (e.g. tactile allodynia associated with neuropathy) fall within the definition of dysaesthesia. However, many forms of dysaesthetic

sensation that occur in a disordered somatosensory system fall outside the definition of pain. Examples include feelings of liquid running over an affected limb, or insects crawling on the skin. Patients frequently have difficulty describing dysaesthetic sensations, which is not surprising as these sensations are beyond normal experience.

## Mechanisms of neuropathic pain

By no means all clinical pains encountered in the neurology clinic are neuropathic. However, pain is often of neuropathic type in patients with diseases affecting the somatosensory system, and aside from the obvious observation that such pains will commonly present to neurologists, the distinction between nociceptive and neuropathic pain is of practical importance because the treatment of each is different.

The following section focuses on some of the pathophysiological processes that may contribute to neuropathic pain (see also Chapter 2). However, it should be emphasised at the outset that most of the scientific literature on neuropathic pain mechanisms relates to data from animal (largely rodent) models measuring behavioural responses to sensory stimulation. Such studies therefore use models of stimulus-evoked pain and this is only one element of clinical neuropathic pain. Moreover, the models of nerve injury are usually to peripheral nerves (e.g. the various types of experimental rodent sciatic nerve injury). Caution should be exercised in extrapolating the findings of these studies uncritically to human disease and, in the account that follows, reference will be made to instances where evidence from human disease and pharmacotherapy give some support to the validity of such extrapolation. A recent exciting line of research is the development of a technique for transfecting human channel mutations into cell cultures.

A core concept in considering mechanisms of neuropathic pain is neuropathic hypersensitivity. At its most basic this means that in neuropathic pain states, neurones involved in nociception and pain exhibit increased excitability, manifest by spontaneous impulse discharge or discharge evoked by minimal (and normally sub-threshold) stimulation, producing the clinical phenomena of allodynia and hyperalgesia. A number of mechanisms can contribute to this.

### Peripheral neuropathy

#### Abnormal ion channel expression

Voltage-gated sodium channels are subdivided into two groups based on their sensitivity or relative resistance to block by a potent neurotoxin found in puffer fish, tetrodotoxin (TTx). There are currently nine known subtypes, designated Na<sub>v</sub>1.1–1.9, of which Na<sub>v</sub>1.7 and Na<sub>v</sub>1.8 (which are TTx resistant) probably have the greatest influence on nociception. In peripheral nerve injury a variety of changes occur, with combinations of up-regulation, down-regulation and translocation of individual subtypes at different locations on the neurone and characteristic changes involving the dorsal root ganglion. Recent work has also demonstrated gain of function mutations in painful diabetic neuropathy.

Drugs that produce use-dependent block at sodium channels, such as the local anaesthetics, show clear evidence of efficacy in treating clinical neuropathic pain. Mutations of the *SCN9A* gene, which encodes the Na<sub>v</sub>1.7 sodium channel, occur in three disorders of pain in humans: a loss-of-function mutation gives rise to congenital insensitivity to pain, while gain-of-function mutation causes two painful conditions – primary erythromelalgia, a clinical

syndrome of severe burning pain and erythema of the extremities, and the very rare paroxysmal extreme pain disorder.

Calcium channel activation is essential in the release of neurotransmitters, and antagonists of N-type calcium channels can reduce hypersensitivity to mechanical and thermal stimuli in models of neuropathic pain. There is also some evidence that L-type calcium channels may have an important role in pain and hypersensitivity phenomena. Cannabinoid receptor agonists, which are analgesic in nerve injury models, may exert their analgesic effect through an inhibitory action at these receptors. Of particular interest in terms of clinical relevance is the  $\alpha_2\delta$ -1 subunit, which exhibits up-regulation in dorsal root ganglion (DRG) nerve cells and within the dorsal horn of the spinal cord in rodent models of nerve injury, and which is the probable site of action of gabapentin and pregabalin.

Transient receptor potential (TRP) ion channels are normally present in nociceptive primary afferent neurones where they are involved in chemically and thermally evoked pain. The subtypes TRPV1 and TRPA1 are activated by noxious heat/capsaicin and noxious cold/mustard oil, respectively, in either case giving rise to a sensation of burning. Following nerve injury, these ion channels may be increased in small diameter fibres, giving rise to cold hyperalgesia, and in addition may be expressed in non-nociceptive sensory neurones, for example in A $\beta$  fibres, providing a possible peripheral mechanism for mechanical allodynia.

### Spinal cord

#### Central sensitisation and ‘wind-up’

Hypersensitivity phenomena in neuropathic pain may be largely the result of changes in the central nervous system (CNS), even if the initiating event is entirely peripheral. Mechanisms may conveniently be divided into excitatory and inhibitory. The term ‘central sensitisation’ is frequently used to describe a state of hyperexcitability of second-order nociceptive neurones in the dorsal horn of the spinal cord, clinically manifest by allodynia and hyperalgesia. The term ‘wind-up’ is sometimes used as though synonymous with central sensitisation, but this is strictly incorrect; wind-up is the increasing response of dorsal horn neurones to repetitive C-fibre volleys (i.e. it is a neurophysiological event observed in the laboratory) and its relevance to persisting central sensitisation is uncertain. Evidence to date indicates that an ongoing afferent input is necessary to maintain wind-up; it is unclear whether this occurs via C fibres or sensitised large diameter afferents, or both.

#### Excitatory mechanisms

Glutamate is the principal excitatory neurotransmitter released in the dorsal horn in response to noxious stimulation. It acts on a number of different receptors including the N-methyl-D-aspartic acid (NMDA) receptor, activation of which appears to be a key element in producing central sensitisation. NMDA receptor activation is a complex process involving phosphorylation and removal of a magnesium ion channel block but, once activated, a positive feedback loop, induced through increased concentrations of glutamate, tends to maintain sensitisation. The NMDA antagonists MK-801 in animal studies, and ketamine in humans, are effective in reducing sensitisation.

There is also evidence that anatomical reorganisation occurs in the site of termination of A $\beta$  afferents following nerve injury, with these afferents sprouting to terminate in lamina II of the dorsal horn, rather than their usual deeper location. This provides an additional explanation for the phenomenon of tactile allodynia.

### Inhibitory mechanisms

GABA ( $\gamma$  aminobutyric acid) and glycine are the major neurotransmitters inhibitory to nociceptive activity present in the spinal cord. Decreased concentrations of GABA and loss of GABA receptors in the dorsal horn have both been demonstrated in peripheral nerve injury models. There is also evidence of loss of GABA interneurons, with reintroduction of GABA interneurons into the dorsal horn in experimental models of neuropathic pain reversing some of the behavioural manifestations of hypersensitivity.

The endogenous opioid system is also affected by nerve injury, with loss of  $\mu$  receptors in the DRG and dorsal horn, accompanied by increased synthesis of cholecystokinin (CCK) which is an opioid antagonist. This provides an explanation of the relative ineffectiveness of opioids in the treatment of neuropathic pain. In contrast, the endogenous cannabinoid system appears unaffected by nerve damage in the periphery, providing a rational basis for the use of cannabinoids for neuropathic pain.

### Role of inflammation and the immune system

There is now abundant evidence that there are major influences of non-neuronal cells in the development of neuropathic pain in traumatic nerve injury, largely the cells of the immune system and their associated chemical mediators, and these effects occur both in peripheral nerve and in the spinal cord. In peripheral nerve injury, a number of chemical mediators are released from macrophages, mast cells and Schwann cells, including the cytokines tumour necrosis factor- $\alpha$  (TNF $\alpha$ ) and interleukins 1 $\beta$  and 6 (IL- $\beta$  and IL-6), chemokines, prostaglandin and nerve growth factor (NGF).

The combined effects of these substances are complex and incompletely understood, but include local influences on ion channels and retrograde transport to the DRG where they may give rise to alteration of neuronal gene expression. In the dorsal horn of the cord, activation of microglia results in similar cascades of release of largely pro-inflammatory mediators with a net effect of increasing neuronal hypersensitivity. There is evidence for a role of the parasympathetic system in modulating and reducing inflammation and sensory neural hypersensitivity. It is interesting to speculate on the importance of these mechanisms in the clinical condition of complex regional pain syndrome.

### Supraspinal influences

Descending pathways from the peri-aqueductal grey (PAG) and rostral ventromedial medulla (RVM) can modulate the transmission of pain at spinal level, in the form of either facilitation or inhibition. In conditions of neuropathic pain, there may be a shift in the normal balance of this system in favour of facilitation, resulting in an increase in central sensitisation.

## Assessment of pain in the patient with neurological disease

The overall clinical assessment of the patient with neurological disease is set out in Chapter 4; this section highlights issues of particular relevance in the assessment of pain.

### The pain history

The following information concerning the presenting pain – or pains – should be sought, with the main aim of establishing diagnosis.

- *Location:* in some cases, the patient's account of where their pain is located may be vague; in other cases, it may be quite precise in which case it should be recorded in detail. In a few

conditions, the diagnosis can be made with near-certainty on the basis of this information alone (e.g. meralgia paraesthetica). In other situations, precise identification and documentation of the pain location may challenge preconceptions regarding diagnosis. For example, a patient with unilateral lower limb pain following a stroke may be presumed to have central post-stroke pain, but if the pain is restricted to a single dermatome it may be likelier to indicate a lumbar root lesion. It may be helpful for the patient to indicate the site of their pain on a line drawing of the body.

- *Onset:* was this sudden, rapid or insidious? A sudden onset should raise suspicion of an acute neurovascular event; a rapid early course of symptom development may suggest an inflammatory origin, while metabolic conditions typically are characterised by an insidious onset and slow deterioration. Sometimes there will be an obvious precipitating event (e.g. in cases of trauma).
- *Intensity:* likely to be at least moderate if pain is the presenting symptom, but variation in intensity is important.
- *Temporal pattern:* frequently yields useful information. Is the pain continuous or intermittent? Is it of constant intensity or fluctuating? Pain that is constantly present is frequently neuropathic. In addition, central pain is characteristically worse when the patient is trying to rest and relax, and better when active and concentrating on a task.
- *Quality:* burning, shooting or electric shock sensations are characteristic of neuropathic pain; nociceptive pain is more likely to be described as dull, aching or cramp-like. Difficulty in describing the pain is quite common with neuropathic pain.
- *Exacerbating/alleviating factors:* when asked about this, patients often focus on treatments, but in this context questioning is intended to identify pain modifiers that the patient has noticed – the effects of activity (both general and specific to the painful part), mechanical and thermal stimulation and the presence of allodynia, hyperalgesia or hyperpathia.
- *Current trend:* is the pain state static or evolving? If evolving, it may be improving or deteriorating over time, but may also be changing in other respects, for example becoming more widespread or changing in quality.

In addition, patients may identify more than one pain phenotype, in which case each pain should be analysed along the same lines.

The following questions should additionally be asked in patients presenting with pain to the neurology clinic:

- Is the pain in an area of sensory deficit?
- Is there accompanying paraesthesia/dysaesthesia?
- Are there, or have there been, associated abnormalities of skin colour, temperature or sweating, oedema or deformity?
- Is there evidence of an associated motor system disorder?

### Treatment history

It is self-evident that a current drug history should be obtained as part of the assessment of every patient, but in the case of the patient with chronic pain more than this is required. It is important to obtain details of previous as well as present treatments, and non-pharmacological as well as drug therapy. The effectiveness of each treatment should be inquired into, as well as unwanted effects; drug dosages should be established if possible. This should enable the clinician to answer the question 'Why was this treatment stopped?' Possible answers are that it was ineffective, that it gave rise to adverse effects or that it was discontinued by default.

**Figure 23.1** Quantitative sensory testing equipment.

### Physical examination

In the general neurology clinic, sensory examination can often quite reasonably be kept to a minimal level, or even omitted if the patient denies any abnormality of sensation. However, in patients with neuropathic pain, far more emphasis on assessment of abnormalities of the somatosensory system is required. Full laboratory quantitative sensory testing is, in the author's view, not necessary as part of routine assessment, but some simple tools that can readily be used at the bedside can provide useful information, on hypersensitivity phenomena as well as deficits (Figure 23.1).

Von Frey hairs can be used to detect (and map) subtle degrees of tactile sensory deficit as well as static or punctate tactile allodynia; dynamic tactile allodynia can be assessed by stroking with a cotton wool ball or soft-haired brush. Mechanical hyperalgesia can be assessed with a pricking roller device. Appreciation of non-noxious cold and heat, and the presence of thermal allodynia, can be assessed with constant temperature thermorollers.

The next section gives an account of the manifestations of pain in some specific disorders, with emphasis on those conditions liable to be encountered in the neurology clinic. Neurological disorders have been subdivided into two groups, in line with the convention of disease classification on the basis of an origin in either the peripheral or CNS, but there is increasing recognition that such subdivision can be artificial and is not always helpful. Prior to considering individual central and peripheral diseases, some general issues of anatomy and pathology are discussed.

### Central spinal pain: some anatomical and pathological considerations

How spinal, and indeed cerebral, lesions affecting somatosensory pathways cause central pain is unclear. Most theories invoke either excitation of damaged sensory pathways, or diminution of inhibitory processes, or perhaps both. There are tracts in the dorsal and ventral segments of the spinal cord that mediate transmission of excitatory and inhibitory influences to and from the brain.

Pain transmission reaches the brain mainly via two types of ascending spinal pathways:

- 1 *Spino-parabrachial pathway*: this originates in lamina I within the superficial dorsal horn and projects to the parabrachial region of the brainstem, peri-aqueductal grey matter and more rostral structures including hypothalamus and amygdala. The pathway appears mainly concerned with the affective component of pain.
- 2 *Classic spinothalamic pathway*: this ascends in the anterolateral quadrant of the spinal cord, terminates in the more posterolateral thalamus and projects to the sensory cortex. It is implicated in discrimination and localisation of pain.

Increasingly recognised as distinct entities, these ascending pathways mediate distinct sensory and affective components inherent in pain. There is also an ascending pathway running close to the central canal of the cord, thought to be the main transmission path for visceral and urogenital pain.

There are major descending pathways from the sensory cortex, thalamus, hypothalamus and brainstem to the spinal cord. Some of these pathways inhibit spinal nociceptive processes. Evidence in humans for central inhibition:

- Drugs with enhancing effects on noradrenaline and serotonin, neurotransmitters thought to inhibit pain and present in descending inhibitory pathways, may alleviate pain. Conversely, drugs and toxins such as reserpine, p-chlorophenylalanine and strychnine that block serotonin and GABA can produce pain.
  - Stimulation of cerebral and spinal targets thought to be implicated in inhibitory processes can alleviate pain. This phenomenon is discussed further in the section on management of neuropathic pain.
- Recently, the importance of descending excitatory pathways has been recognised, the key relay station being the rostroventromedial medulla, the output from which contributes to hyperalgesia. The evidence that excitation of the CNS can cause pain in humans:
- Pain can occur in an epileptic attack, including post-stroke epilepsy.
  - Therapeutic stimulation of parts of the somatosensory CNS can inadvertently cause pain.
  - Abnormal neural activity coinciding with pain has been recorded – for example, in the thalamus, midbrain and spinal cord in some patients with on-going central pain.
  - Anticonvulsants and local anaesthetics can alleviate central pain.

Apart from excitation and inhibition, numerous other factors, including effects resulting from cortical and thalamic plasticity and changes in affective processing of pain, are of major importance.

### Pain in individual disorders of the central nervous system

#### Multiple sclerosis

Pain in MS (Chapter 11) was until relatively recently considered rare and received little attention in standard neurology textbooks. It is now clear that pain in this condition is common and frequently severe; it probably occurs in 50% or more of cases and may be reported as the dominant symptom. Neuropathic pain can be extremely severe even in cases where other manifestations of the condition are mild.

MS provides a striking example of the diversity of pain presentation and mechanisms that may exist within a single disease diagnosis, summarised in Table 23.1; pain may be neuropathic or

**Table 23.1** Acute and chronic pain in multiple sclerosis.

Acute	Chronic
<1 month	>1 month
Trigeminal neuralgia	Dysaesthetic lower extremity pain
Lhermitte's phenomenon	Back, joint and musculoskeletal leg pains
Paroxysmal neuralgic burning extremity pain	Painful leg spasms
Optic neuritis Painful tonic spasms	Visceral pain
Treatment: often responds to carbamazepine or phenytoin	Treatment: those used for neuropathic pain (including, rarely, intrathecal drugs, e.g. baclofen); standard treatments for back pain when present; antispastic agents for leg spasms
Mechanisms: in paroxysmal symptoms, ?ephaptic transmission at site of demyelination	Mechanisms of central pain: uncertain – spinothalamic tract fibre loss ± posterior column involvement probably implicated

nociceptive, and within each of these categories much variety is seen. However, there are a number of recognisable common presentations.

### Neuropathic paroxysmal pain

MS is the most common cause of secondary trigeminal neuralgia (Chapter 13) and occurs in 1–5% of cases. The presentation may be indistinguishable from that of classic trigeminal neuralgia but may be atypical. Trigeminal neuralgia can occasionally be the presenting symptom in MS; suspicion of this is aroused by the development of trigeminal neuralgia in an unusually young patient or, if symptoms are bilateral, spread beyond the territory of the fifth cranial nerve or are accompanied by an obvious somatosensory deficit (which is usually very subtle or clinically absent in the classical condition). Lhermitte's phenomenon consists of spreading electrical sensations down the back and into the lower limbs provoked by neck flexion and attributable to a demyelinating plaque in the cervical cord; it may be described as painful, although not invariably so. In addition to these two well-recognised presentations, paroxysmal pain may occur at almost any site, reflecting the location of the CNS lesions, and may be spontaneous or evoked by tactile or other stimuli.

### Neuropathic non-paroxysmal pain

This is perhaps the most common type of pain in MS and the presentation is usually consistent with a myelopathic origin, although lesions rostral to the cord can also produce pain, sometimes mimicking the picture of central post-stroke pain. It most commonly involves the lower limbs and trunk, but upper limb involvement also occurs. The pain may be of typical neuropathic character;

**Table 23.2** Pain in Parkinson's disease.

Musculoskeletal factors: shoulder stiffness, spinal deformity including scoliosis and camptocormia (bent spine), arthritis, contractures
Limb rigidity and stiffness
Dystonia, dyskinesia, akathisia
Restless legs and sleep-related pains
Visceral pains: abdominal pain. This is sometimes (but not necessarily) related to constipation. Also: non-cardiac chest pain
Central neuropathic pain

an additional common complaint is of feelings of pressure or constriction, like wearing an over-tightened corset or an undersized boot. Feelings of unpleasant intense cold, particularly of the distal lower limbs, are also commonly reported.

### Nociceptive pain

This also takes a number of forms. Painful spasticity is a characteristic feature especially in the advanced stages of more severe disease. Management of spasticity is covered elsewhere (Chapter 18). Musculoskeletal pain in general may be more troublesome and more difficult to manage – although not necessarily more common – than in the general population, because the motor problems of weakness, spasticity and consequent poor posture can limit the effectiveness of physical therapies normally employed to manage pain of this type.

### Parkinson's disease

Parkinson's disease (Chapter 6) provides a further example of a condition in which pain has traditionally received little attention, but in which it is very common (probably in excess of 50% of established cases). A range of non-motor symptoms, including pain, are increasingly recognised as common and distressing in patients with this disease. As in the case of MS, various characteristic types of pain are seen, reflecting different mechanisms, although central pain of Parkinson's disease remains poorly understood (Table 23.2).

### Neuropathic (central) pain

The presumed central pain of Parkinson's disease comprises a variety of types, including burning and stabbing, and may be accompanied by other sensory phenomena including tingling, itching, tense feelings and restlessness. These symptoms can precede the onset of the motor symptoms, sometimes by several years. Pain is often bilateral but can sometimes be more marked on one side, either ipsilateral or contralateral to the predominant motor features. Of interest because of its midline distribution, pain can involve the mouth, throat or genital regions, suggesting in some instances a link with the burning mouth syndrome and vulvodynia (see Burning mouth syndrome and Vulvodynia).

The diurnal relationship between pain and any relief with levodopa or dopaminergic medication often seems unclear. Although levodopa has occasionally been used as an analgesic drug in other conditions, it is rare that pain experienced by a patient with Parkinson's disease can be switched off simply by antiparkinsonian drugs. While pain resulting from stiffness often improves when the stiffness improves, any temporal relationship between dystonia, dopaminergic deficiency and drug administration needs to be

evaluated on an individual basis, but is unpredictable. Pain from focal dystonia, as might affect the hallux or produce a clenched fist, sometimes responds to botulinum toxin injections.

The mechanisms of central pain in Parkinson's disease are poorly understood. Compared with controls, these patients have lower pain thresholds to heat, especially in their affected limbs, and regardless of whether the patients are 'on' or 'off'. This is the opposite of the raised thresholds sometimes seen in central post-stroke pain (CPSP), suggesting there could be different mechanisms involved. Dopamine has analgesic properties and is present in descending spinal as well as ascending pathways. Furthermore, there are inhibitory pathways that project from the basal ganglia and brainstem to the spinal cord in which enkephalins, substance P, noradrenaline, serotonin and other neurotransmitters implicated in endogenous pain modulation are present.

It is therefore not surprising that degeneration of these extrapyramidal pathways in the brain and spinal cord could give rise to central pain, and conversely that pallidal deep brain stimulation might reduce pain. Mechanisms underlying the pain of such co-morbidities such as osteoarthritis, spinal deformity and muscle stiffness are of course entirely different; nociceptive musculoskeletal pain is common in patients with Parkinson's disease, who are also susceptible to osteoporosis with the attendant risk of crush fractures.

### Dystonia/dyskinesia pain

Following diagnosis, Parkinson's disease is no longer seen in its unmodified state beyond the early stages as it is virtually always treated with levodopa or other dopaminergic therapy. This ultimately leads to alternating states of dyskinesia and bradykinesia ('on-off' fluctuations). Involuntary movements may be very pronounced during the 'on' phase in advanced cases, giving rise to mechanically induced nociceptive musculoskeletal pain.

Pain is also associated with other extrapyramidal and related degenerative disorders. In pure autonomic failure and multiple system atrophy (Chapter 24), intense discomfort known as 'coat-hanger' pain can occur. This pain around the shoulders and upper arms could be caused by ischaemia in suboccipital and paracervical muscles. The ischaemia is associated with increasing degrees of postural hypotension, and thus the pain occurs when the patient is upright, particularly in the mornings and after meals, and is relieved by lying flat.

Amongst various often ill-defined sensory symptoms, pain is an important feature of various dystonias and tics, in particular Tourette's syndrome and spasmodic torticollis – in which there is evidence of central pain in addition to pain related to musculoskeletal components. Other combinations of pain and involuntary movements are encountered in the syndrome of painful legs and moving toes, complex regional pain syndromes (CRPS), and stump and phantom phenomena.

### Central post-stroke pain

Neuropathic pain following a stroke is common and appears to occur with equal frequency, and similar characteristics, whether the stroke is infarctive or haemorrhagic. The term 'thalamic pain' is often used for central pain following a stroke, doubtless because of the coining of the term 'thalamic syndrome' (Table 23.3) in the definitive 1906 paper by Déjerine and Roussy. However, central pain following vascular brain damage can result from injury from many structures other than the thalamus, and the term 'central post-stroke pain' (CPSP) is more appropriate.

**Table 23.3** Classic features of central post-stroke pain (the thalamic syndrome).

A mild, rapidly improving hemiplegia without contractures
Persistent superficial hemi-anaesthesia or hyperaesthesia, with impaired deep sensation
Mild hemi-ataxia and astereognosis
Choreo-athetotic movements on the paralysed side
Sharp, enduring, paroxysmal, often intolerable pain on the hemiplegic side that does not respond to any analgesic treatment

**Table 23.4** Clinical features of central pain.

Often very difficult for the patient to describe
Can be on-going, triggered, or a combination; superficial, deep, or a combination
Most often has a burning quality
May not disturb sleep
Patients may not appear to be in pain
May be in an odd distribution (e.g. a quadrant of the body; corner of mouth; ipsilateral mouth and hand – the cheiro-oral syndrome)
Onset may be delayed by weeks, months or years
Usually persistent, but influenced by factors such as movement, emotion, temperature change

**Table 23.5** Clinical findings in central pain.

Pain is experienced within the area of the sensory deficit or a smaller area
The sensory deficit, if selective, is most typically thermal or for pain, and sometimes only detectable by quantitative sensory testing
There may be various spontaneous or evoked sensory phenomena (e.g. allodynia), typically seen with neuropathic pain
Rarely, central pain occurs in the absence of detectable sensory impairment; conversely, pain can occur in an anaesthetic area (anaesthesia dolorosa)
There may be variable accompanying motor and autonomic features

Not all pain following a stroke is central and the pain should fulfil certain criteria in order to make the diagnosis of CPSP:

- The pain should be located within an area of the body corresponding to the somatosensory lesion of the CNS.
- The history should be suggestive of a stroke and the onset of the pain should occur at, or after, the stroke.
- There should be confirmation of a CNS lesion by imaging and/or negative or positive somatosensory signs.
- Other causes of pain, such as nociceptive or peripheral neuropathic pain, should be excluded if possible; however, it is of course the case that other forms of pain may coexist with pain of central origin.

Central pain in general exhibits some characteristic clinical features and findings (Tables 23.4 and 23.5).

Approximately 10% of patients suffering a stroke will develop CPSP, making this the most common cause of central pain of

supraspinal origin. The stroke may be of any degree of severity in terms of motor deficit (and in Déjerine and Roussy's original series of cases, weakness was minor in all); injury to the somatosensory pathways appears essential to the development of CPSP, but this can also be quite subtle. The pain is restricted generally to the area of sensory loss, but by no means has to be co-extensive with it; it can involve half of the body, or be restricted to a single digit. The likelihood of pain developing post-stroke appears to depend on location; it is particularly common (25%) following infarction in the posterior inferior cerebellar artery territory, producing lateral medullary (Wallenberg's) syndrome with ipsilateral facial sensory deficit and contralateral loss in the limbs and trunk.

There is usually some delay in the onset of CPSP following the stroke, and this can range from days to years, although in the latter case it is always possible that a more recent and silent cerebrovascular event may be responsible for the emergence of pain. In most cases, the pain develops in the few weeks after the stroke. Burning is the most frequently reported pain quality, and tactile/cold allodynia is common. Kinaesthetic allodynia, in which pain is mediated via the nerves of joint position sense, is rare but virtually pathognomonic of central pain.

### Spinal cord injury

Over two-thirds of patients with spinal cord injury have chronic pain and in one-third this is severe. Severing the cord has no therapeutic benefit; central pain can occur in the presence of a functionally complete cord lesion and abnormal spontaneous firing in dorsal horn neurones has been recorded immediately above a lesion at L1 in a paraplegic patient. However, incomplete cord lesions and gun-shot injuries cause pain more frequently than other cord injuries.

Pain following spinal cord injury can arise from a variety of mechanisms (Table 23.6) and it is important to attempt to identify those mechanisms in the individual case in order to manage the pain appropriately. It is usually easier to deal with nociceptive (musculoskeletal) than neuropathic pain; for example, attention to abnormal spinal posture or management of a frozen shoulder is more likely to be rewarding than treating central neuropathic pain.

The central pain associated with spinal cord trauma has similar characteristics to the pain associated with other lesions of the spinal

cord, not only including MS, but also expanding or compressive lesions such as tumours and syringomyelia, and vascular damage. Management of pain from spinal cord lesions is similar to that for other central pains. Surgery rarely has a part to play; the main exception is pain from post-traumatic syringomyelia (see Siringomyelia), which occasionally responds to decompression. Pain at the level of injury has been reported to respond to dorsal root entry zone (DREZ) lesioning, in which afferent impulses are interrupted as they enter the dorsal horn, but this procedure is now seldom performed as results are generally poor and unwanted neurological sequelae are common. Spinal cord stimulation can be helpful in patients with partial lesions but is of no value if the lesion is complete.

### Syringomyelia

In syringomyelia, a cystic cavity (syrinx) develops in the spinal cord, usually fairly centrally situated, but separate from the central canal. The general features and causes of syringomyelia are described in Chapter 16. Dissociated sensory loss typically occurs as the result of relatively selective damage to spino-thalamic tract fibres with sparing of the dorsal columns. Recurrent painless injury of the affected body parts, often the upper limb extremities, frequently occurs. However, although normal pain transmission is impaired, pathological central pain is very common, occurring in the majority of cases sometimes as the presenting symptom. The anatomical distribution of the pain typically reflects that of the somatosensory loss, commonly involving the upper limbs and trunk, but may be more extensive, affecting the lower limbs and perineum.

### Phantom pain

It has long been recognised that whenever a body part is removed, a sensation of the missing part can persist (the phantom sensation) and sometimes there will be pain in that missing part (phantom pain). The phenomenon of phantom limb pain was recognised by Ambroise Paré in the sixteenth century, but the term was probably first used by Silas Weir Mitchell in the nineteenth century. Phantom pain most commonly develops in a missing limb, or part of a limb, but phantom teeth, breasts, eyes, genitalia and various viscera have been described.

Phantom pain can occur in a body part that has been denervated but not amputated; for instance, the body below a completely or partially transected spinal cord, or an arm following a brachial plexus avulsion injury. Phantom pains, and other phantom sensations, are liable to seem especially bizarre to the lay-person, and because patients may therefore suspect they will be disbelieved or thought insane, phantom sensations including pain are almost certainly under-reported.

Phantom pain in a limb needs to be distinguished from stump pain. In the latter, pain is in the region of the stump, where neuromas (although not necessarily painful) are commonly present, with other tissue abnormalities including scarring and musculoskeletal changes. In any individual case of post-amputation pain, there can therefore be a combination of neuropathic and nociceptive pains. Local measures are appropriate in some cases to address problems of poorly fashioned skin flaps or local infections; sometimes surgery is needed, but it is very rarely indicated for pain control itself. Surgery for a neuroma is seldom required unless there are particular circumstances, such as the neuroma being situated where pain is induced by pressure from wearing a prosthesis. This is because removing the neuroma frequently results in the formation of another neuroma more proximally.

**Table 23.6** Pain following spinal cord injury.

Musculoskeletal pains, including spinal pain from instability and deformity, shoulder disorders, muscle spasm, secondary overuse, and pressure syndromes
Segmental pain, sometimes with a band of hyperaesthesia, at the level of injury: central (from the spinal cord) ± peripheral (from nerve roots, including cauda equina damage)
Spinal cord pain below the level of injury: central pain, sometimes with persistent dysaesthesia. Like central post-stroke pain, onset may be delayed months or years. Spinothalamic dysfunction is probably a necessary but not a sufficient factor. Particular conditions include the central cord syndrome and post-traumatic syringomyelia
Deep visceral pain, which may be a form of central pain. There may be associated autonomic dysreflexia
Phantom pain below the level of injury
?Complex regional pain syndrome

Phantom pain has characteristic features:

- It occurs unpredictably in those with missing body parts, particularly when the missing part is distal.
- It is felt in, or within, the area of the missing part.
- The pain varies from the mild to the intolerable. Suicide has occasionally been reported.

The pain may have various qualities (e.g. burning, aching, crushing and gnawing); it can be continuous or intermittent, sometimes with brief paroxysms; and can be influenced by stimulation of other parts of the body, visceral influences such as micturition, and psychological factors. It may be associated with cramps, spasms, painful postures and distortions within the phantom. It is worse if the patient perceives they have no ability to move the phantom, although paradoxically pain may prevent this feeling of being able to move. Pain prior to amputation is sometimes a risk factor for the development of phantom pain, and in such cases the phantom pain may resemble the pre-amputation pain.

With time, the area of the phantom sometimes shrinks, particularly its proximal part, and this feature can also affect phantom pain. This 'telescoping' can give rise to curious phantom phenomena; for instance, a phantom hand may be felt tucked up near the shoulder with nothing intervening. Other forms of distortion of the phantom are common, such as the fingers or thumb being enlarged and twisted into an abnormal and painful posture.

Phantom pain may develop instantaneously, or soon after removal of the part, or may develop months or years later. It is often very long-lasting, but sudden resolution rarely occurs spontaneously, and even more rarely after a stroke affecting the phantom area represented in the brain. Phantom sensations and pain occur regardless of the cause of loss of the body part (i.e. whether from trauma, surgical removal or disease). Usually, loss of a body part will have been instantaneous or rapid, but the same phantom phenomena have been described in the slow loss that occurs with leprosy.

Phantom phenomena, including pain, are relatively rarely experienced in congenital absence of a limb, or after amputation of a body part in childhood, although childhood phantom pain may be more common than previously thought.

Some very curious temporal painful phantom phenomena have been reported. Phantom lower limbs felt after thoracic spinal cord transection disappeared when cord compression from a cervical disc developed, only to return when the disc was removed. Conversely and paradoxically, phantom pain in a paraplegic became manifest following spinal anaesthesia. The author has recently encountered a case in which a phantom lower limb, which had spontaneously remitted, re-emerged following the implantation of a spinal cord stimulator.

Unfortunately, treatment of phantom pain remains extremely disappointing. Over 60 types of treatment have been reported, ranging from drugs to neurosurgical and other invasive treatments. Although the use of opioids is being explored further, currently treatment is usually ineffective. For those patients in whom amputation is therapeutic and elective, pre-emptive analgesia has not convincingly been shown to prevent the development of phantom pain, although this perhaps reflects inadequacy of the techniques employed to block the afferent barrage completely. It is hoped that recent studies on neural plasticity will lead to new approaches.

When a body part loses its sensory innervation, changes in somatosensory cortical and thalamic representation take place. Changes can be very rapid; for example, even a local anaesthetic

ring block of a finger results in cortical changes within a few minutes. The area of brain from which input has been deprived is physiologically 'invaded' by innervation from adjacent areas. Such phenomena have been studied extensively in humans, and shifts in cortical representation may be more extensive in the presence of pain, normalise with treatment of the pain and account for peculiar referred patterns of sensation, for instance a touch on the face being felt in the phantom limb of amputees. The specific role of pain in these phenomena remains to be clarified.

In order to try to modify these neuroplastic changes, graded motor imagery techniques have been tried, as has the mirror box, particularly for patients with a phantom upper limb. In this ingenious technique, a mirror is placed in front of the patient, at right angles to the chest, such that the patient sees the reflection of the intact limb producing a simulation of the missing limb. The patient is asked to mimic the position of the phantom limb with the intact limb, and then to look into the mirror on the side of the intact limb. By attempting symmetrical movements of the two limbs, the patient can feel the phantom limb move. Intriguingly, the ability to exert apparent control over the phantom limb can result in pain relief. Beneficial results have been reported with these techniques, but pain relief is unpredictable and often transient. Further studies are needed.

### Painful legs and moving toes syndrome

On the borderland between a central and peripheral neurological disorder and with movement-related and sensory components, the clinical features are summarised in the title: there is pain in the distal lower limbs accompanied by spontaneous movements of the toes, foot or lower leg. The pain varies from being a mild discomfort to a very severe intractable pain; rarely, instances of suicide have occurred.

The pain is often difficult to describe and can be burning, crushing, cramping or twisting. The movements are usually slow and irregular with sinuous fanning and clawing of the toes. The number of toes affected is very variable. Sometimes, the movements can briefly be stopped with effort, but break through again when concentration is relaxed. In some patients, pain precedes the onset of the movements; in others, vice versa. The condition can start unilaterally, although it tends to become bilateral, if sometimes asymmetrical. A similar phenomenon, 'painful arm and moving fingers', has also been described.

The cause is unknown, but the disorder has been described in association with lumbar root lesions in degenerative spine disease, peripheral neuropathy and peripheral limb trauma. Rarely, other involuntary movements are seen, which, as with the upper limb syndrome, suggests there is a central rather than peripheral cause in some patients – a distinction that might possibly be clarified in future from neurophysiological studies. The increasing recognition of movement abnormalities in CRPS suggests that painful legs and moving toes share common pathophysiological mechanisms with that condition, but without the objective signs of vasomotor or sudomotor instability.

Treatment is usually ineffective, for both the movements and the pain. For the pain, drugs including anticonvulsants such as gabapentin, antispasticity agents, benzodiazepines, phenothiazines, dopaminergic drugs and beta-blockers have not proven effective in the long term. There have been reports of sodium channel blocking agents such as carbamazepine being effective, possibly through blocking of ephaptic transmission across damaged axons. Epidural opiates and local anaesthetics have been tried, and while initially

**Table 23.7** Painful legs and moving toes and restless legs syndromes.

Painful legs and moving toes	Restless legs syndrome
Spontaneous movements of toes and feet	Irresistible desire to move legs around
Present throughout day	Worse in evening and night, sometimes associated with periodic limb movements during sleep
No known family history	Often positive family history
Involuntary irregular, fanning, sinuous, dystonic movements affecting toes in particular	No spontaneous involuntary movements
Pain deep, diffuse, of various sorts	Pains of various sorts, also dysaesthesia, discomfort
Underlying causes sometimes seen, including peripheral neuropathy and radiculopathy, infections, and trauma; rarely, central causes	Underlying causes occasionally seen, including peripheral neuropathy and radiculopathy, iron deficiency anaemia, pregnancy, renal failure
Rarely responds to dopaminergic drugs	May respond to levodopa and dopaminergic drugs, benzodiazepines, opioids, anticonvulsants

lumbar sympathetic blockade was thought promising, this has not proved beneficial in most patients. The main disorder with which painful legs and moving toes is confused is the restless legs syndrome, although the distinction can usually be made with ease (Table 23.7).

### Epilepsy

Pain can be a feature of an epileptic attack, as first noted by Gowers in 1901. Although rare, some studies have reported that about 2% of patients with epilepsy have painful seizures, but this figure is probably an overestimate resulting from selection bias. The pains have been divided into three categories:

- 1 Unilateral pain in the face, arm, leg or trunk:** seizures tend to originate from the hemisphere contralateral to the pain, usually in the Rolandic area. Parietal, or occasionally centro-parietal or other lesions can be responsible, but sometimes no obvious structural lesion is detectable. Pain can be caused by direct excitatory involvement of the primary sensory area or spread there from elsewhere. Ictal depression of inhibitory processes could provide an alternative explanation.
- 2 Headache:** distinct from the common post-ictal headache, headache and other head pains, sometimes with a migrainous element, may be part of the seizure. Temporal lobe involvement may be more common in these patients although localising value is often poor. Increased cerebral blood flow occurs during a seizure, and it is thought that vascular factors could contribute to these pains.

- 3 Abdominal pain,** rather than nausea, is a very rare feature of an epileptic attack and may be associated with temporal or frontal lobe seizures.

The treatment is that of the seizure disorder.

### Fibromyalgia

Fibromyalgia syndrome (FMS) was originally described in the 1800s and has been known by a number of titles including muscular rheumatism and interstitial fibrositis. These labels imply that the condition is primarily a rheumatological disorder, an impression strengthened by the presence of myofascial tender points at characteristic locations. However, there are no diagnostic abnormalities of muscle in the condition, although there is possible evidence of non-specific changes related to microcirculation alteration giving rise to reduced oxygen delivery, and the widespread hyperalgesia of FMS appears likely to indicate a state of diffuse central sensitisation.

There is no evidence of either an inflammatory process or autoimmune disorder, but in addition to widespread pain there are a number of associated features, in particular poor sleep and daytime fatigue, and often coexistence of other painful conditions such as headache, irritable bowel syndrome and temporo-mandibular pain.

Many treatments have been tried, including drugs such as amitriptyline and newer antidepressants such as duloxetine, pregabalin and intravenous lidocaine, acupuncture, exercise and other physical measures, and behavioural techniques. Their efficacy is variable and unpredictable and a multi-disciplinary approach is probably best.

### Peripheral pain: anatomical and pathological considerations (Chapter 2)

Pain from the periphery is conveyed to the CNS by primary afferent nociceptors – sensory neurones that are activated by noxious mechanical, thermal and chemical stimuli. These neurones contain thinly myelinated, faster conducting A $\delta$  fibres and unmyelinated, slower conducting C fibres; the former mediate brief, acute, sharp ‘first’ pain, and the latter the delayed, more diffuse, dull ‘second’ pain. The majority of A $\delta$  and C fibres are polymodal (i.e. they react to a variety of noxious stimuli), and these fibres use numerous signal transduction mechanisms in order to convert noxious environmental stimuli into electrochemical signals. C fibres have been further tentatively subdivided into:

- Fibres that, amongst other properties, express P2X3 purine receptors (one type of ATP-responsive channel) and receptors for glial cell line-derived neurotrophic factor (GDNF). These fibres are sensitive to GDNF, terminate deep in the substantia gelatinosa of the spinal cord, and may be important in mediating neuropathic pain.
- Fibres that contain peptides including substance P and calcitonin gene-related peptide (CGRP), and express the high affinity NGF receptor TrkA. These fibres are sensitive to NGF, terminate more superficially in the dorsal horn of the spinal cord and mediate plasma extravasation and vasodilatation – also called neurogenic inflammation. This inflammation, whether resulting from tissue damage or from release of peptides and neurotransmitters from the sensory nerve endings themselves, sensitises nociceptor endings. This results in peripheral sensitisation. These fibres are an important component of visceral afferents and have a more diffuse pattern of innervation than those fibres innervating skin. They also appear to regulate the behavioural sensitivity to pain through projections to deep central brain structures in the brainstem, hypothalamus and amygdala.

Both groups of C fibres respond to noxious stimulation and express the vanilloid (capsaicin) TRPV1 receptor which transduces noxious chemical and heat (>43°C) stimuli. Noxious cold (<15°C) is mediated by the menthol and a variety of other cold receptors. Chemicals such as bradykinin, serotonin, lipids and low pH stimulate other specific receptors. Mechanical stimuli are transduced by yet other receptors, less well characterised.

Some noxious stimuli affect ion channels and alter neuronal excitability directly; others involve metabotropic receptors and act through second-messenger processes. Several voltage-gated sodium, potassium and calcium ion channels are also expressed in sensory nerves, some specifically in C fibres, and a number of these are likely to be involved in transmission of nociceptive information. However, the selective properties of nociceptors change after damage or disease. For example, there are silent or 'sleeping' nociceptors that acquire mechanical sensitivity only during inflammation.

There are many ways in which these peripheral phenomena and their central sequelae can generate pain:

- **Ectopic discharges.** Discharges from damaged but also adjacent non-damaged neurones, the latter perhaps implicating Schwann cells, generate various pain-producing substances. These ectopic discharges not only generate spontaneous sensations, but also lead to changes in excitability of neurones in the CNS. The mechanisms responsible are likely to relate to changes in specific ion channels. Substances that block neuronal activity (e.g. local anaesthetics, mexiletine, some tricyclic antidepressants) which are sometimes effective for neuropathic pain work through effects on specific ion channels.
- **Changes in neuronal properties.** Genes expressed in primary sensory nerves are eventually responsible for transduction, conduction and synaptic transmission. Disorders affecting the sensory nerve result in changes in up- and down-regulation of these genes and their transcripts, and changes in the function and selectivity of the nerves. For example, the  $\alpha 2\delta$  calcium channel subunit is up-regulated after nerve injury, which may explain the efficacy of gabapentin in neuropathic pain.
- **Loss of sensory neurones.** After peripheral damage, atrophy occurs that affects the whole of the sensory neurone. This loss particularly affects C fibres, and the resulting imbalance can contribute to abnormal sensations, as in some patients with post-herpetic neuralgia in whom areas of severe sensory loss occur. The central ends of C fibres atrophy in the dorsal horn; whether adjacent A $\beta$  fibre terminals sprout into that area remains controversial, but innocuous mechanical stimuli become perceived as pain (mechanical allodynia). This is an example of central sensitisation.
- **Central sensitisation** after lesions of peripheral sensory nerves occur in the spinal cord and also at higher levels. Central sensitisation is associated with various features: enlargement of the area in the periphery where stimuli activate neurones; sub-threshold stimuli now reach threshold; increased response to supra-threshold stimuli; and pain from activity in non-nociceptive fibres. Some of these phenomena account for pain that spreads beyond the affected nerve territory, exaggeration and prolonged pain after peripheral stimulation, and other features including allodynia, hyperpathia and related sensory disturbances.
- **Disinhibition** can also be important, contrasting with these excitatory processes. Normally, GABA and glycine mediate inhibition

of pain-sub-serving processes. Blocking these substances can cause pain. Nerve injury can result in impaired GABA inhibition in the spinal cord.

- **Microglia and other glial cells** are intimately involved in the neuro-immune responses that follow neurological lesions of the CNS and which can generate pain. There are also peripheral immune responses that are associated with peripheral nerve damage and a number of painful peripheral nerve disorders.

## Pain in individual disorders of the peripheral nervous system

### Painful peripheral neuropathies

It is puzzling why some patients with a specific neuropathy develop pain, while others do not. Furthermore, pain in some neuropathies can result from several different aetiologies. For example, in diabetic neuropathy there are vascular, inflammatory and metabolic factors. In HIV neuropathy, there are direct effects of the virus, nutritional factors, vasculitis, toxicity from antiretroviral agents, and co-infection. Painful neuropathies, a few examples of which are singled out later, can be roughly classified into causative groups:

- **Inflammatory and vascular disorders** – diabetes, collagen vascular disease and vasculitis, polyarteritis nodosa, Guillain-Barré syndrome and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP). Many of these disorders cause mononeuritis multiplex, and to what extent vasa nervorum and nervi vasorum and sympathetic nerve fibres are implicated is uncertain. Changes in the neurochemical milieu surrounding damaged nerve endings, some of which follow leakage from damaged blood vessels, can be important.
- **Infective** – Lyme disease, HIV, leprosy and varicella zoster.
- **Infiltration of nerves** – sarcoid and tumours, particularly lymphoma.
- **Metabolic factors** – diabetes, alcohol, nutritional and vitamin deficiency states (especially thiamine and vitamin B<sub>12</sub> deficiency), peripheral ischaemia and paraneoplastic states.
- **Toxic and drug-induced causes** – chemotherapeutic drugs (e.g. vincristine, cisplatin, taxols – especially docetaxol), thalidomide, antiretrovirals, nitrofurantoin, gold, isoniazid, disulfiram; toxic agents – arsenic, thallium.
- **Trauma**, including iatrogenic lesions after surgery.
- **Hereditary peripheral neuropathies** (see Absence of pain).

Many disorders span more than one category; for example, diabetes features in both the vascular and metabolic categories, and the pain of HIV-associated neuropathy appears in both the infective and chemotherapeutic categories.

### Burning feet, and the small-diameter fibre neuropathies

Although autonomic and later large fibre involvement sometimes occur, burning pain, typically distal and affecting the feet, is often caused by a small fibre sensory neuropathy. While routine testing of nerve conduction is typically normal, there may be abnormalities of thermal thresholds. However, the latter is a psychophysical test requiring patient cooperation, and abnormalities do not prove that the neuropathy and hence the pain arises peripherally. Sometimes a small fibre neuropathy is only detectable on skin biopsy. It is striking how many of the painful neuropathies are accompanied by autonomic involvement, presumably because small-diameter fibres are those subserving both efferent autonomic and afferent sensory

modalities. Causes of these small-fibre neuropathies include the following:

- Diabetes mellitus, which deserves particular mention because this may only be revealed by a glucose tolerance test. Thus, in an otherwise obscure case of peripheral neuropathy with burning pain, diabetes needs to be carefully excluded.
- Connective tissue diseases such as Sjögren's disease and monoclonal gammopathy.
- Acquired amyloidosis.
- Genetic causes, which perhaps account for an otherwise cryptogenic burning feet syndrome more frequently than usually suspected.

As with so many other painful conditions, non-neurological causes need to be borne in mind, and with pain in the feet, even when burning, disorders such as plantar fasciitis need to be considered.

### Erythromelalgia

First recognised and named in 1872 by Weir Mitchell, a physician during the American Civil War and author of *Injuries of Nerves and Their Consequences*, this term comprises a group of symptoms that appear to have variable combinations of vascular and neuropathic features. The characteristic features are episodes of heat, redness and pain in the extremities, predominantly the legs, worse and prolonged in the heat, and with improvement in the cold such that, for relief, patients sometimes immerse their feet in cold water to an extent that skin maceration and its complications develop. The episodic features and heat triggering differentiate erythromelalgia from small fibre neuropathies, CRPS and vascular insufficiency.

Erythromelalgia can be divided into:

- 1 Primary:
  - Sporadic
  - Hereditary (childhood onset, autosomal dominant).
- 2 Secondary, to thrombocythaemia and less commonly polycythaemia, collagen vascular disease, diabetes, peripheral neuropathy, drugs (e.g. calcium-channel blockers, pergolide, bromocriptine), following freezing and non-freezing cold injury, and rare toxic causes.

Whether the clinical features are caused by vascular factors, a small fibre neuropathy or a combination, the various components have a final common pathway in which there are abnormalities of microvascular perfusion of the skin, with a combination of skin hyper-perfusion together with hypoxia.

Neurological investigations have variously shown evidence of abnormalities in both afferent C fibres and efferent post-ganglionic sympathetic fibres in a number of patients, but the precise relationship between such abnormalities and the vasomotor changes remains unclear. There is evidence suggesting that, by different mechanisms depending on the cause, there is sensitisation of polymodal C nociceptors, with abnormally low thresholds and prolonged after-discharges, and involvement of mechano-insensitive fibres. The axon reflex results in vascular leakage and vasodilatation. The hereditary form results from a gain-of-function mutation in the *SCN9A* gene encoding the  $Na_v1.7$  voltage-gated sodium channel. Recently, the very rare paroxysmal extreme pain disorder (familial rectal pain syndrome) has been shown to be a channelopathy resulting from a disorder affecting the same gene. How any of these mechanisms give rise to the episodic nature of the clinical features remains obscure.

### Treatment

- Remove the offending drug: the condition often resolves.
- Low-dose aspirin when due to thrombocythaemia: often effective.

- Epidural analgesics and other symptomatic measures: rarely effective.
- High dose topical capsaicin to damage C fibres: experimental and unlicensed.
- In the hereditary condition, consider drugs with inhibitory action at voltage-gated sodium channels (intravenous local anaesthetics, class I anti-arrhythmics and antiepileptics such as carbamazepine).
- Avoid damage from cold immersion.

### Neuropathy in diabetes mellitus (Chapter 10)

Pain occurs in over 10% of patients with type I and one-third of patients with type II diabetic peripheral neuropathy, but what characterises those patients with pain is unknown, even when their nerves are studied by microneurography. However, in a small study the glucose metabolite methylglyoxal has been shown to be a predictor of pain and appears associated with a gain-of-function in  $Na_v1.8$  channels. The classification shown in Table 23.8 is both arbitrary and a simplification, but illustrates the variety of types of painful neuropathies encountered. Individual patients often have more than one type of nerve involvement. In painful neuropathies of acute onset, vascular and inflammatory factors are particularly important and pain is more likely to be reversible; by comparison, metabolic factors probably predominate in those neuropathies of gradual onset, in which pain is often persistent.

Some of these diabetic neuropathies merit particular mention. Acute painful neuropathy, associated with rapid weight loss, has a good prognosis over months. 'Insulin neuropathy', a neuropathy that develops as insulin is introduced, again has a good prognosis. Both conditions are uncommon. About 50% of diabetic third cranial nerve palsies are painful. Pain presumably arises from involvement of associated trigeminal afferents and resolves over days or a few weeks. Truncal involvement can mimic acute cardiac or abdominal disorders, and shingles without a rash. Pain resolves over months. Lumbosacral radiculoplexopathy (diabetic amyotrophy; femoral neuropathy) is typically seen in late-onset diabetes in men over 60 years. There is severe aching thigh pain, worse at night. Gradual resolution occurs over months. The differential diagnosis includes lumbar root compression, pelvic malignancy, CIDP and vasculitis. A similarly painful plexopathy affecting the upper limb has been described.

**Table 23.8** Varieties of painful diabetic neuropathy.

	Acute onset	Chronic onset
Symmetrical	Acute distal sensory neuropathy 'Insulin neuropathy'	Peripheral polyneuropathy, particularly with small-fibre involvement Associated with CIDP
Focal and multifocal	Cranial neuropathy – IIIrd nerve palsy Truncal neuropathy Lumbosacral radiculoplexopathy Isolated (compression) peripheral neuropathy	Lumbosacral radiculoplexopathy Isolated (compression) peripheral neuropathy Associated with asymmetric CIDP

CIDP, chronic inflammatory demyelinating polyradiculoneuropathy.

The most common and most intractable painful neuropathy is a distal polyneuropathy, often worse at night or with stress. Most information on treatment is derived from studies on this group of patients, in whom pain has a severe and long-lasting impact.

The painful diabetic foot can be caused by neuropathic or neuroischaemic factors. Infection, including osteomyelitis, needs to be excluded, and meticulous foot care is essential.

Treatment, usually with drugs, is as for any other painful peripheral neuropathy. Optimal control of blood sugar should always be attempted, but glycaemic control in late-onset diabetes does not appear to be a predictor of painful neuropathy.

### Shingles and post-herpetic neuralgia: shingles

Shingles results from reactivation of the varicella-zoster virus (VZV) that has remained latent in a trigeminal or dorsal root ganglion following primary infection in the form of chickenpox, usually decades earlier. VZV, which is both epithelial and neurotrophic, causes a painful segmental neuropathy with skin changes that typically include small blisters from which the virus can be isolated. Although the clinical diagnosis of shingles is nearly always straightforward from its appearance, blisters with local pain and sensory disturbances are sometimes caused by herpes simplex rather than zoster infections. Definitive distinction can be made from viral identification in the blister fluid. Rarely, shingles can occur in the absence of a rash (*zoster sine herpete*). However, without viral confirmation during the initial stages, shingles remains a clinical diagnosis – suspected when there is segmental pain associated with concomitant sensory changes.

Reactivation is more likely when there is reduced cellular immunity as occurs with increasing age, immunosuppressive disorders and treatments, and in those with certain human leukocyte antigen (HLA) tissue types; it seems to occur less frequently in black people. In immunocompetent patients it is very rare that shingles signals an underlying malignancy or other predisposing factor. Investigation for an underlying cause is rarely necessary in isolated shingles. Both herpes simplex, and less commonly herpes zoster (in about 6% of cases), can recur. VZV is found in both small and large fibre sensory cell bodies in the dorsal root and trigeminal ganglia (i.e. it is not confined to nociceptive fibres), and it may cause pain through involvement of spinal NMDA receptors and possibly other mechanisms.

The pain of acute shingles can range from the trivial to the excruciating. Treatment during the acute stage is symptomatic with analgesics; sometimes strong opioids are required. Three practical questions then arise in respect of the pain.

First, what predicts the development of post-herpetic neuralgia? The incidence of post-herpetic neuralgia increases with increasing patient age. As a rule of thumb, the percentage affected is that of the age so 50% of patients aged 50 will develop this complication and 90% at age 90. This prediction is now considered a pessimistic over-estimate, but nevertheless old age is undoubtedly the most important factor. In addition, female sex, the presence of virus in peripheral blood, severity of rash, severity of the acute shingles pain, prodromal pain and possibly a specific HLA haplotype are also thought to be risk factors. Reducing the viral load with antiviral agents is the rationale for their use during the acute phase to diminish the likelihood of post-herpetic neuralgia.

Secondly, are antiviral drugs always indicated? These should be given if there is ocular involvement – when urgent referral for

ophthalmic assessment is essential – and in the immuno-compromised. While there is little firm evidence, meta-analyses suggest that there may be less prolonged pain and possibly a reduction in the incidence of post-herpetic neuralgia following early use of antiviral drugs, including valaciclovir and famciclovir. These two drugs have better bioavailability than aciclovir with oral administration and also have the advantage of being taken three rather than five times daily. The largest study of aciclovir failed to demonstrate a reduction in the incidence of post-herpetic neuralgia. There are ongoing studies with brivudin, which can be given once daily, but it is not currently licensed in the United Kingdom. Brivudine can give rise to a serious and sometimes fatal interaction with 5-fluorouracil, so co-administration is contraindicated.

Thirdly, are there other measures that will prevent the development of post-herpetic neuralgia? Corticosteroids are ineffective. There is only one small study suggesting that early treatment with amitriptyline reduces the occurrence of post-herpetic neuralgia; large, appropriately controlled trials are needed. Furthermore, it is inevitably difficult to decide whether to recommend prophylactic drugs to prevent an uncertain but sometimes severe complication that might never occur, particularly in an elderly patient in whom drug-induced side effects are common. Neither sympathetic blockade nor a single injection of steroids with local anaesthetic is beneficial, and although prolonged somatic nerve blocks using an epidural catheter have been reported as being helpful, these are rarely a realistic prophylactic approach. Recent, impressive evidence suggests that a live attenuated vaccine reduces the incidence and morbidity of herpes zoster and also the incidence of post-herpetic neuralgia. The role of this vaccine as a preventative public health measure to protect a population as a whole remains to be clarified.

### Post-herpetic neuralgia

Defining the time when pain from acute shingles becomes the chronic pain of post-herpetic neuralgia is arbitrary. The most generally applied point is 3 months after the rash. Pain and other sensory disturbances range from the trivial to the most severe. Severe post-herpetic neuralgia is a common reason for referral for pain management.

Post-herpetic neuralgia can comprise any form or multiple forms of pain, on-going or evoked, with or without itch, but two characteristic phenotypes are recognised although it should be emphasised that they represent opposite ends of a continuous spectrum. In one type, there is marked somatosensory deficit of the affected dermatome, and while paroxysmal pain can occur in addition to background pain, this is not usually stimulus-evoked. In the other type, sensory loss is much less pronounced, but allodynia and hyperalgesia can be severe. This heterogeneity relates to the different ways in which the virus damages nerves, the underlying pain-related processes being subserved by combinations of sensitisation and de-afferentation that give rise to various forms of sensory disturbance including sensory loss.

Skin biopsies suggest that patients with neuralgia have fewer cutaneous nerve endings than pain-free patients, but, in addition, a variety of neurochemical changes occur in the affected skin. The spinal cord is also affected. Focal atrophy of the dorsal horn sometimes occurs, together with surprisingly long-lasting chronic inflammatory changes which have been detected even 2 years after the shingles.

Acknowledging the numerous mechanisms that mediate the different forms of pain, treatment nevertheless remains as empirical as it is for most other similar pains. Systematic studies provide

evidence of benefit for tricyclic antidepressants, gabapentin and pregabalin, and opioids including morphine, oxycodone and tramadol. Topical treatments are most likely to be of benefit in those cases in which cutaneous hypersensitivity phenomena dominate the clinical picture and include lidocaine patches, now licensed in the United Kingdom; aspirin in ether, benzydamine and capsaicin have also been used. While capsaicin is licensed, it produces a burning sensation and is often poorly tolerated; great care is needed to avoid contact with the eyes. A high-concentration (8%) topical capsaicin patch has become available recently. Prior application of local anaesthetic is required to reduce the otherwise frequently intolerable burning pain caused by applying capsaicin at this concentration.

Just as in the management of epilepsy, there is no reason why combinations of drugs should not be tried (e.g. nortriptyline and gabapentin), especially as their modes of action are different and lower doses of each can be used.

Despite reports of numerous other treatments, ranging from transcutaneous electrical nerve stimulation to invasive procedures, the long-term benefit of these other techniques has not yet been established. One of the more recent claims has been for pain relief from intrathecal methylprednisolone, which in one study was reported to provide excellent pain relief over follow-up of 2 years, without reported complications, but subsequent studies have failed to confirm the benefits of this treatment.

### Guillain–Barré syndrome

Pain commonly affects patients with this condition and can sometimes be the first symptom, and a particularly prominent one. Pain affects mainly the low back, buttocks and backs of the thighs and although it often seems muscular in character – reminiscent of the pain seen in acute poliomyelitis, as well as in some of the inflammatory myopathies – there is evidence that gabapentin is an effective treatment, implying neurogenic mechanisms, and pain can be severe even in cases that are mild with respect to motor dysfunction. It has been postulated that the pain could be a consequence of radicular inflammation.

The pain is often under-recognised and can be difficult to manage in those severe cases in which the patient, although cognitively intact, is paralysed and ventilator-dependent. Opioids, particularly in the early stages, are sometimes required. Although complete, or near-complete, recovery has widely been considered the rule in this condition, recent data suggest that many patients experience pain years after the onset of symptoms, and that this correlates with persisting sensory (but not motor) deficits. (For a fuller account of Guillain–Barré syndrome see Chapter 10.)

### Neuralgic amyotrophy (brachial neuritis)

This condition (Chapter 10) is almost always extremely painful. Characteristically, the patient experiences acute pain around the shoulder girdle, followed days or a few weeks later by weakness, often producing winging of the scapula, and there may be patchy areas of sensory loss. There is histological evidence for sensory as well as motor nerve involvement. The characteristics of the pain are its severity, its diffuse and nagging quality, and sometimes the worsening with limb movement. The pain almost invariably seriously affects sleep. It will usually subside over some days or weeks and strong analgesics may be required in the initial stages, but there is no specific treatment available. Steroids are unhelpful.

### Painful inherited neuropathies

The inherited neuropathies (Chapter 10) associated with pain are rare. However, they have a particular importance because in some the underlying mechanisms are beginning to be clarified. Examples of these neuropathies include the following.

- *Hereditary sensory and autonomic neuropathy (HSAN) type I.* In most families there are *SPTLC1* gene mutations, and patients present with sensory symptoms including lightning pains during their teens or young adult life.
- *Fabry disease.* The paroxysmal painful symptoms, which date back to childhood, bear some resemblance to erythromelalgia. How the abnormal sphingomyelin accumulation in the nerves, and any vascular component, generate the pains is unclear. Pain may be improved after prolonged treatment with agalsidase alfa – a form of enzyme replacement therapy.
- *Familial amyloid neuropathies.*
- *Tangier disease.*
- *Primary erythromelalgia* (see Erythromelalgia).

### Iatrogenic painful peripheral nerve lesions

In contrast to the expected pain that often follows accidental injury to a peripheral nerve, painful peripheral nerve lesions following surgery are often under-recognised. For example, post-surgical neuralgia persisting after 1 year has been reported in 41–61% of patients after thoracotomy, 27% of patients after mastectomy and 28% of patients after saphenous vein surgery. Intriguingly, pain after caesarean section almost never occurs although in almost all other circumstances cases of chronic pain following surgery, if sought, will be found. While management follows along conventional lines, in certain instances nerve repair may be followed by satisfactory resolution of pain. A striking example is repair of the spinal accessory nerve, occasionally damaged during lymph node exploration in the posterior triangle of the neck. This example is also of interest in that it indicates an afferent component in a nerve considered to be solely motor.

### Complex regional pain syndrome

This topic is one of the most confused and controversial in the entire field of pain medicine. There is no universally accepted unifying theory on the cause of CRPS. The development of reliable accepted diagnostic criteria has been challenging. There is no definitive diagnostic investigation. Perhaps because of this, there is a tendency for the label of CRPS to be applied indiscriminately to any ‘funny-sounding pain in a funny-looking limb’ or quite simply to pain in one part of the body that is unexplained. Nevertheless, there is a highly characteristic clinical picture in the most florid cases, and so this section begins with an account of a typical severe case.

A previously healthy young woman sustains an ankle sprain while jogging, with the expected local pain and swelling. The ankle is bandaged and the joint immobilised. However, over time the pain does not settle as anticipated, but persists and gradually increases. Oedema also persists and is accompanied initially by erythema and later by mottled pallor and coldness; local excessive sweating develops as well as thickening of the toe nails and coarsening of the hair of the distal limb. In addition to background pain, tactile and cold allodynia emerge and become increasingly severe. The foot adopts a posture of fixed plantar flexion and inversion. Two years after the original injury, the patient has a cold, blue, immobile and functionally useless leg and foot which she cannot bear to have touched. She perceives the limb as alien and malign and requests amputation.

The term 'complex regional pain syndrome' was proposed in 1995 following an IASP consensus conference, to replace the terms 'reflex sympathetic dystrophy' (RSD) and 'causalgia'. The old term RSD was clearly unsatisfactory, as the condition is not the result of a reflex, is not demonstrably caused by an abnormality of the sympathetic nervous system and is not invariably associated with dystrophic changes. The term 'causalgia' was first used by Weir Mitchell, applied to the characteristic pain and physical signs in soldiers who sustained nerve injuries during the American Civil War.

It is of some interest to examine the historical background to the belief, widely held until relatively recently, that the sympathetic nervous system was crucially involved in the development of these conditions. In 1916, Leriche reported the case of a patient with upper limb causalgia whose symptoms improved following surgical sympathectomy, performed for brachial artery thrombosis. This led him to perform sympathectomy on subsequent patients with causalgia, again with reported symptomatic improvement. Later, local anaesthetic sympathetic blocks became commonly used and, later still, intravenous regional sympathetic block with guanethidine and other agents, but without critical analysis of their effectiveness. Only recently has sympathetic block come under closer scrutiny in the form of systematic review which suggests that intravenous regional sympathetic block probably has no specific therapeutic effect, and that the data on ganglionic blockade are too poor to permit any robust conclusions.

The current diagnostic criteria for CRPS are shown in Table 23.9. Recent guidelines for the diagnosis, treatment and referral of CRPS in adults have been published by the Royal College of Physicians. Although the condition continues often to be sub-classified into type I (without a demonstrable major nerve injury) and type II (with a major nerve injury), the distinction appears to have no practical utility in guiding therapy, nor does it contribute to the understanding of the condition. It is also unclear what constitutes a 'major' nerve injury, or how the pathogenesis might differ in a 'minor' nerve injury. CRPS can also occur following a number of non-traumatic precipitants, shown in Table 23.10.

The features of CRPS fall into four more or less distinct domains: sensory changes, vasomotor changes, sudomotor changes and oedema, and movement disorders and dystrophy.

Sensory changes include a number of abnormalities in addition to pain. The pain itself can be of various qualities with tearing, burning, stinging and squeezing most frequently reported; tactile and cold allodynia occur in about one-quarter of cases, and hyperalgesia and spontaneous pain in a substantial majority. Somatosensory deficit is also frequently found if sought, to pinprick and touch. In addition to these features, there are often abnormalities that indicate central mechanisms, such as neglect of the affected part (reminiscent of the neglect observed in patients with parietal lobe lesions) and feelings of the affected extremity being swollen or enlarged, even when the patient can see objectively that it is not.

Vasomotor changes characteristically evolve over time. Early vasomotor instability can produce cutaneous vasodilatation resulting in 'warm CRPS' as well as vasoconstriction ('cold CRPS'). These states can alternate. Late in the course of the condition the cold state is usual. In the advanced case, local tissue atrophy and disuse contribute to reduced regional blood flow, independent of any sympathetically mediated effect. Microneuronography studies, and catecholamine assays in venous blood of affected parts, indicate that local sympathetic outflow is reduced, not increased, in patients with CRPS. The apparent excessive sympathetic activity in these

**Table 23.9** Diagnostic criteria for complex regional pain syndrome ('Budapest criteria').

Category		Sign	Symptom
A–D must apply:			
A The patient has continuing pain which is disproportionate to any inciting event			
B The patient has at least one sign in two or more of the categories			
C The patient reports at least one symptom in three or more of the categories			
D No other diagnosis can better explain the signs and symptoms			
1 'Sensory'	Allodynia (to light touch and/or temperature sensation and/or deep somatic pressure and/or joint movement) and/or hyperalgesia (to pinprick)	<input type="checkbox"/>	<input type="checkbox"/>
2 'Vasomotor'	Temperature asymmetry and/or skin colour changes and/or skin colour asymmetry	<input type="checkbox"/>	<input type="checkbox"/>
3 'Sudomotor/oedema'	Oedema and/or sweating changes and/or sweating asymmetry	<input type="checkbox"/>	<input type="checkbox"/>
4 'Motor/trophic'	Decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair/nail/skin)	<input type="checkbox"/>	<input type="checkbox"/>

**Table 23.10** Non-traumatic causes of complex regional pain syndrome (CRPS) type I.

Disorders of the peripheral nervous system (e.g. herpes zoster)
Disorders of the central nervous system (e.g. stroke, multiple sclerosis, spinal trauma, cerebral tumour, brain injury)
Immobilisation
Systemic illness (e.g. after myocardial infarct and cardiac surgery), lung disease
Pregnancy
Electric shock
Drugs (e.g. phenobarbital, isoniazid)
Idiopathic

patients can be explained by the development of increased sensitivity to the local effects of catecholamines.

Sudomotor changes and oedema frequently occur but are seldom quantified in clinical practice. They usually resolve with improvement of other features of CRPS; there is no specific treatment.

**Figure 23.2** Complex regional pain syndrome (CRPS) showing dystrophic, vasomotor and oedematous changes in the left hand.

The dystrophic changes observed locally in CRPS have long been recognised, but a variety of disorders of movement also occur (Figure 23.2). Some of the dystrophic changes are explicable purely on the basis of disuse. The skin in the affected territory is typically thin and often shiny in appearance; the digits often taper towards their tips and the nails are thickened, brittle and ridged. Local hair growth exhibits loss or coarsening. Osteoporosis not surprisingly occurs, but in some cases appears disproportionately severe to be accounted for by disuse. Movement disorders are often present. Paucity of volitional movement of the affected part is almost universal, but in addition tremor and dystonia are sometimes seen.

The degree of prominence of the manifestations of the features of these four domains suggests that they are independent of one another. For example, in one case pain may be extremely severe but vasomotor changes trivial, whereas in another the reverse occurs. Some additional features associated with CRPS are listed in Table 23.11.

CRPS varies greatly in its severity; mild cases often resolve spontaneously, and fortunately few progress to resemble the case described at the beginning of this section. However, in order to prevent more severe cases developing, active management should be initiated early. In the absence of any specific treatment, the focus should be on combining effective pain relief with functional restoration. Although debate continues regarding whether CRPS can be defined as a neuropathic pain condition, it shares many features with conditions that are unequivocally neuropathic and therefore use of pharmacotherapy of demonstrated efficacy in neuropathic pain seems appropriate. Mediators of inflammation account for many of the features of CRPS, and corticosteroid therapy has been advocated. Sympathetic block can be effective in

**Table 23.11** Various clinical features seen in complex regional pain syndromes (CRPS).

Skin erythematous, cyanosed, pale or blotchy	Excessive, reduced or absent sweating
Swelling or atrophy of skin	Inappropriate warmth or coldness
Excess or loss of hair	Loss of skin wrinkles or glossiness
Nails ridged, curved, thin, brittle or clubbed	Subcutaneous atrophy or thickening
Dupuytren's and other contractures	Joint stiffness, acute or chronic arthritis
Muscle wasting and weakness	Osteoporosis – spotty, localized or widespread
Involuntary movements – tremor, dystonia, spasms	Detrusor and urinary dysfunction
A syndrome comprising 'neglect' and other similar disturbances	Hemi-sensory impairment outside the painful area
Hyperacusis	Alterations in visuospatial perception

After Schott (1999) with permission from Oxford University Press.

some cases, but is not supported by case-control studies. Physical therapies and psychological interventions both have a major role in rehabilitation. In severe cases, spinal cord stimulation can be effective.

### Pain associated with benign orthopaedic conditions

Glomus tumour and osteoid osteoma deserve mention here because patients may present to neurology clinics, and because they can be cured by appropriate treatment.

#### Glomus tumour

These uncommon benign tumours of bone, entirely unrelated to glomus jugulare tumours in the neck, are really hamartomas of the normal glomus body. The glomus body is an innervated arterio-venous anastomotic structure which has a temperature regulating function. The afferent arterioles are tortuous, associated with glomus (endothelial) cells, and innervated by myelinated and unmyelinated fibres. Some 50% of glomus tumours affect the hand, often subungually, where they may appear as a little blue nodule. Such an appearance is not diagnostic of a glomus tumour; the differential diagnosis includes melanomas, neuromas and neurofibromas. Glomus tumours occur anywhere over the body, including within bone, but they are usually subcutaneous. The key clinical triad comprises:

- 1 Severe and continuous pain
- 2 Extreme cold sensitivity (for instance, worsening pain by immersing the hand in cold water)
- 3 Extreme tenderness (for instance, even the slightest contact of the nodule with the end of an orange stick induces quite exquisite pain).

Diagnosis is often straightforward when tumours are visible, but otherwise can be difficult. Plain radiographs can reveal bony

erosion; otherwise detection requires ultrasound, MRI or angiography. Surgical removal is usually immediately curative.

### Osteoid osteoma

This bony disorder occasionally presents to the neurologist as a cause of unexplained pain, usually in a limb. The cardinal features are the often severe and sometimes localised pain, usually worse at night, and characteristically extremely good response to anti-inflammatory drugs. The good response only lasts for the duration of action of these drugs. The reason for this responsiveness is that the fine nerve terminals in this benign tumour of bone are exposed to prostaglandins present in the tumour. The abnormal bony tissue sometimes shows as a focal radiolucent or radio-opaque nidus, often with surrounding cortical thickening. On isotope bone scanning it produces a dramatic focal hot spot. CT scanning can also be useful. Gratifyingly, excision of the tumour is curative and immediate pain relief occurs.

### Motor neurone disease

Although not typically classified within neuropathies, pain has been reported in 64% of 42 patients with motor neurone disease (MND) and in 57% of 124 patients admitted to a hospice. Pain is variously described as aching, cramping, burning, shock-like, or is indescribable. In some patients with MND pain can be a dominant symptom, especially when weakness is not advanced.

The cause of this pain is ill-understood, although musculoskeletal factors and skin pressure (only rarely with pressure sores) are likely to operate. Central mechanisms may also be important. Just as with Parkinson's disease, pain may be one of the subjective sensory symptoms that can occur even long before serious disability develops, and in occasional patients with MND there is objective evidence of sensory involvement both clinically and on investigation. In many patients with MND it is likely that the pain is caused by a combination of musculoskeletal and neuropathic factors, which may be partially or completely alleviated by medication, in particular opiates, especially in the later stages of the disease.

### Painful peripheral viscerosomatic disorders

Some disorders referred to a neurologist appear to involve the interface between cutaneous and visceral innervations. These neuropathic disorders include the burning mouth syndrome and vulvodynia.

#### Burning mouth syndrome

Contrasting with the severe, usually unilateral, paroxysmal stabbing pains of glossopharyngeal neuralgia, sometimes accompanied by syncope, the burning mouth syndrome embraces various types of persistent and unpleasant sensations within the mouth and includes terms such as glossodynia. Women are affected more than men, and the mean age is 50–60 years. The clinical features comprise a burning sensation that is usually diffuse and bilateral, and any area within the mouth can be affected including the tongue.

The pain is usually constant but can fluctuate in severity during the day. Influencing factors in some patients include eating (making symptoms either better or worse), stress and previous dental procedures. There may be associated dryness of the mouth and loss or altered taste appreciation. The condition is usually long-lasting, although spontaneous improvement or recovery has been reported.

Treatment remains empirical and includes drugs used for neuropathic pain, and cognitive behavioural and other psychological therapies that also help the depression and other psychological disturbances that often coexist.

Although routine oral and sensory examination is normal, quantitative sensory testing suggests abnormality of small fibre function. There is also a reduction of epithelial nerve fibres, suggesting a trigeminal small fibre neuropathy. In some patients, abnormalities of the blink reflex suggest more central involvement affecting the trigeminal system. Thus, at present the burning mouth syndrome appears to be a neuropathic disorder of unknown but probably various causes. These involve both peripheral and central components, and there is some suggestion of nigro-striatal system involvement in the latter. There is some limited evidence that zinc deficiency could be responsible for some cases and that correcting this can be therapeutic.

#### Vulvodynia

Different from many causes of perineal pain, vulvodynia comprises vulval pain associated with painful burning sensations, mechanical allodynia and hyperalgesia. Sometimes there is no spontaneous pain, allodynia only being provoked by touch and pressure. The disorder is likely to be multi-factorial and either primary or secondary to vulval or vaginal inflammatory or infective causes. While surgical excision of the affected tissue has sometimes been advocated, conservative treatment with topical local anaesthetic cream, or oral amitriptyline, gabapentin or pregabalin is generally more appropriate.

The syndrome is probably another example of a neuropathic pain disorder, in turn related to reduced sensory thresholds to a variety of sensory stimuli. These abnormalities are likely to result from factors including increased innervation secondary to nerve sprouting or neural hyperplasia, and sensitisation of thermoreceptors and nociceptors within the vaginal mucosa. The increased innervation in vulvodynia tissues is associated with increased expression of TRPV1 (vanilloid or capsaicin) receptors, a finding that might account for both the sensory disturbances and mild erythema sometimes seen. Some of the clinical and pathological features also occur in interstitial cystitis and related conditions.

#### Visceral pain

Visceral pain, mainly transmitted to the CNS through afferents running within sympathetic nerves, has characteristic features (Table 23.12). These features, clearly different from those encountered in typical somatic pain, can be explained by various factors:

- Different molecular mechanisms that selectively transduce the various different peripheral chemical and mechanical stimuli, including ischaemia or distension, all which affect viscera.
- The contribution of processes that sensitise visceral afferents.
- The important contribution of silent afferents, which only become active in the presence of inflammation.

**Table 23.12** Characteristics of visceral pain.

Only evoked from some viscera (e.g. not from the liver)
Not always linked to injury
Diffuse and poorly localised
Referred to other sites
Accompanied by motor and autonomic responses

- Viscero-somatic convergence in the spinal cord, thalamus and cortex.
- Central spinal processes that result in amplification and persistence of afferent impulses from the damaged viscera.
- Ascending transmission of pain, via dorsal column and other non-spinothalamic pathways in the spinal cord, to specific brain-stem nuclei, amygdala and hypothalamus – regions implicated more in affective than discriminative aspects of pain.

Patients with visceral pain caused by acute painful cardiac, gastrointestinal or urogenital disorders rarely present to the neurologist. However, other aspects of visceral pain have important practical significance. Examples include odd distributions of pain (e.g. ear pain from carcinoma of the lung), involvement of the viscera in shingles and perhaps post-herpetic neuralgia, and possibly various chronic painful conditions such as the irritable bowel syndrome, non-ischæmic cardiac pain, fibromyalgia, chronic pelvic pain and headache. Some patients have a number of these disorders at the same or different times. In these individuals particularly, underlying mechanisms include abnormal sensitisation of peripheral or spinal neurones or aberrant central processing of visceral sensation, so that stimuli usually innocuous to other people are perceived as painful.

## Plexopathies

The dorsal root ganglia and proximal roots of peripheral sensory nerves can be affected by conditions that result in pain, and, depending on their location, sometimes affect the spinal cord as well. Causes commonly presenting to the neurologist include infection (e.g. shingles and post-herpetic neuralgia), inflammation (e.g. arachnoiditis) and compression (e.g. tumours and discs). However, more peripherally, it is painful plexus lesions that sometimes prove particularly difficult to diagnose and manage. Amongst the various painful conditions, including the thoracic outlet syndrome affecting the upper limb, the three most serious disorders resulting in painful plexopathies are:

- 1 Trauma
- 2 Malignancy
- 3 Following irradiation.

### Traumatic brachial plexus lesions

The most common cause of traumatic brachial plexus lesions is a traction injury, most typically following a motor cycle accident, in which there has been stretching or avulsion of the brachial plexus and sometimes the extradural and intradural nerve roots. Paradoxically, the introduction of crash helmets has made these injuries more frequently seen in clinical practice, because without head protection the patient was more likely to be killed. Traumatic plexus lesions are also frequently seen during warfare and usually result from missile injuries. Of interest from the developmental viewpoint is that lesions sustained in infancy are rarely painful.

Pain following trauma often develops immediately, but can develop or increase in severity in the months following the initial trauma. The pain affects the limb in the distribution of the affected roots or plexus but is sometimes more widespread. It is often burning and very severe, dominating the patient's life. Despite attempts at treatment, the prognosis for improvement in the pain is very poor. Pain can persist indefinitely. Spinal cord stimulation is sometimes effective in partial plexus lesions, but in cases of complete brachial plexus avulsion it is of no value; deep brain stimulation may have a role in such cases.

Recently, studies of nerve repair following brachial plexus injuries have shown there is a correlation and temporal association

between a reduction in de-afferentation pain and return of motor function, with the former preceding the latter. Such surgery, itself requiring exceptional surgical skills, has led to much interest in processes underlying recovery and pain relief, including the contribution of NGF and other growth factors.

### Malignant and radiation-induced plexopathies

Metastatic disease or a primary tumour can infiltrate the cervical, but more commonly the brachial or lumbosacral plexus, causing severe and unremitting pain. Particularly if at the outset there are few or no neurological signs pointing to neural involvement, discovering the cause of the pain can be very difficult. Nevertheless, pain is often the presenting symptom, for example occurring in 75% of patients with brachial plexopathy resulting from cancer. It is caused by malignant infiltration of the nerves themselves or of surrounding blood vessels and connective tissue. Involvement of adjacent structures such as bone also causes pain. On other occasions pain will develop in a patient known to have, or have had, malignant disease, in which case a malignant cause will be suspected early.

Usually, plexus involvement will become obvious when there are motor and sensory signs. When the lower trunk of the brachial plexus is involved, and Horner's syndrome accompanies the pain, a relatively proximal cause around T1 should be suspected, because it signifies involvement of the sympathetic trunk or ganglia (Pancoast's syndrome). Generally, pain is a major feature of malignant plexopathies; the absence of pain should lead to review of the diagnosis. Imaging will be the first step in evaluation.

Treatment of the pain will generally be managed by the oncologist or palliative care physician. This is because treatment is largely symptomatic and palliative, sometimes with radiotherapy, and a multi-disciplinary approach is required.

A particularly challenging problem is to decide whether, in a patient with known malignant disease and who has had radiotherapy, the pain is caused by the radiotherapy or to tumour recurrence. The distinction between malignant and radiation plexopathies is often very difficult. Some features that are helpful, although not diagnostic, are shown in Table 23.13.

Frequently, neither the clinical features nor the results of imaging studies allow a definite distinction to be made in an individual patient who has previously received radiotherapy. Treatment of pain from radiation-induced plexopathies is unfortunately extremely limited and the outlook for pain relief is poor.

## Management

Management of chronic pain per se is often difficult but pain in neurological disease presents particular challenges. Much, although by no means all, pain in neurological disease is neuropathic, and this is generally more resistant to treatment than nociceptive pain. Improving pain-contingent disability is often a major objective of cognitive behavioural pain management, but many neurological conditions limit the capacity for improving physical functioning and in some cases cognition is also impaired.

An essential first step in effective management is the evaluation of the nature of the pain (or pains) in the patient. Primary diagnosis is important, but usually does not of itself inform the clinician of the cause of the pain. However, a knowledge of the types of pain characteristically encountered in individual disorders focuses attention on the likely differential diagnosis regarding pain. An example is

**Table 23.13** Pain due to malignant plexopathy and radiation-induced plexopathy.

Presentation	Neoplastic	Radiation
	Pain	Paraesthesias, weakness
Pain	Early, severe	Later in course
<b>Plexus involvement</b>		
Brachial	Often lower plexus	Usually whole plexus
Lumbosacral	Lower, usually unilateral	Commonly bilateral
Horner's syndrome (brachial plexopathy)	Common	Unusual
Local tissue necrosis	Not present	Common
Rectal mass (lumbosacral plexopathy)	Common	Absent
Myokymia	Unusual	Present
Nerve enhancement (MRI)	Present	Usually absent
PET scan	Positive	Usually absent

the patient with hemiplegia following a stroke who complains of pain in the shoulder territory of the affected side. This may represent CPSP – but it may also have a local nociceptive origin. Nociceptive shoulder pain is well recognised in cases of stroke and is usually far more amenable to effective treatment than CPSP. It is also possible for both mechanisms of pain to coexist in the same patient. Another example is the patient with MS with back pain and pain in a lower limb. The lower limb pain might be the result of demyelinating myelopathy – but it could also be coincidentally caused by lumbar spinal nerve root compression, which might respond to quite different treatment. In the assessment of the patient with pain, the question ‘What is the diagnosis?’ should be swiftly followed by the question, ‘What is causing this pain/these pains in this patient?’

## Management of neuropathic pain

### Systemic drug treatments

It is an interesting (if frustrating) observation that in neuropathic pain, none of the drug treatments available are effective in all cases, or even in a clear majority of cases. This is in marked contrast to most nociceptive pain. Even severe nociceptive pain, such as that encountered acutely following major surgery, will respond to treatment with a potent opioid analgesic provided that a sufficient dose is given, in almost every case. However, in neuropathic pain, not only can opioids be completely ineffective, but other types of drugs with clear evidence of efficacy derived from clinical trials (such as tricyclic antidepressants) can be highly effective in one patient and completely ineffective in another patient with the same

neurological diagnosis and near-identical clinical presentation. Many drugs used to treat neuropathic pain give rise to troublesome side effects and are poorly tolerated, limiting their practical utility, but this is a separate issue from their simply not working.

The reasons for this marked variability in response to drugs are poorly understood, and there are usually no reliable indicators in any individual patient's presentation (or diagnosis, with a few exceptions) to suggest whether their pain will respond to a member of a particular drug group well, partially or not at all. Part of the explanation probably lies in genetically determined differences in drug metabolism between subjects, and genetic polymorphism in respect of the metabolism of some drugs has been clearly demonstrated. However, this cannot explain the wide variations in response to gabapentin and pregabalin, which are not metabolised. It seems likelier that most of the variability between patients' responses to drugs is attributable to differences in the activation and/or expression of nociception-inducing receptors and the neurotransmitters and neuromodulators acting on them. Whatever the prime reason, the clinical reality is that pharmacological treatment of neuropathic pain involves a considerable element of ‘trial and error’. Pharmacological treatments with evidence of efficacy in neuropathic pain, together with ratings of evidence levels, are shown in Table 23.14. A recent meta-analysis of pharmacotherapy for neuropathic pain indicated that even those drugs with good quality evidence of efficacy were effective only in a minority of patients (number needed to treat for over 50% pain relief approximately four for tricyclic antidepressants, six for serotonin and noradrenaline re-uptake inhibitors and seven for gabapentin and pregabalin).

### Opioids and other analgesics

While clearly and reliably effective in acute nociceptive pain, drugs in this group have tended traditionally to be dismissed as ineffective in neuropathic pain. However, there is evidence that opioids can be effective in treating neuropathic pain, at least in the short to medium term, in some cases, as well as tramadol, combined tramadol/paracetamol and the novel analgesic tapentadol. Conditions studied have largely been painful diabetic neuropathy and postherpetic neuralgia.

In the past two decades, the use of potent opioids in the treatment of chronic non-malignant pain has increased dramatically in many countries including the United States and the United Kingdom. However, the practice of prescribing these drugs long-term for patients with non-cancer pain is currently under scrutiny as evidence of lack of long-term effectiveness is emerging, as well as increasing problem opioid use (especially prescription opioids), accompanied by a rising rate of fatalities attributable to opioids, particularly in the United States. Recent guidelines on appropriate opioid prescribing have been published.

### Antidepressants

The tricyclic antidepressant (TCA) group of drugs have long been established as effective treatments in neuropathic pain, for both peripheral and central disorders. These drugs have complex actions which include central serotonin and noradrenaline reuptake inhibition and inhibition of voltage-gated sodium channels (all of which may contribute to their analgesic effects), and antimuscarinic activity which probably does not contribute to analgesia but is responsible for many of the unwanted effects. The noradrenergic action of TCAs may be more important than the serotonergic action so far as analgesic effect is concerned, as the serotonin-specific re-uptake inhibitors (SSRIs) seem relatively ineffective.

**Table 23.14** Pharmacological treatments with evidence of efficacy in neuropathic pain, together with ratings of evidence levels.

Classification of evidence for drug treatments in commonly studied neuropathic pain conditions and recommendations for use. Treatments are presented in alphabetical order. Only drugs used at repeated dosages are shown here (with the exception of treatments with long lasting effects such as capsaicin patches). Drugs marked with an asterisk were found effective in single class II or III studies and are generally not recommended. Drugs marked with two asterisks are not yet available for use.

Aetiology	Level A rating for efficacy	Level B rating for efficacy	Level C rating for efficacy	Level A/B rating for inefficacy or discrepant results	Recommendations for first line	Recommendations for second or third line
Diabetic NP	Duloxetine Gabapentin-morphine TCA Gabapentin Nicotine agonist** Nitrate derivatives ** Oxycodone Pregabalin TCA Tramadol alone or with paracetamol Venlafaxine ER	Botulinum toxin* Dextromethorphan Gabapentin/venlafaxine* Levodopa*	Carbamazepine Phenytoin	Capsaicin cream Lacosamide Lamotrigine Memantine Mexiletine Mianserin NK1 antagonist** Oxcarbazepine SSRI Topical clonidine Topiramate Valproate Zonisamide	Duloxetine Gabapentin Pregabalin TCA Venlafaxine ER	Opioids Tramadol
PHN	Capsaicin 8% patch Gabapentin Gabapentin ER** Lidocaine plasters Opioids (morphine, oxycodone, methadone) Pregabalin TCA	Capsaicin cream Valproate*		Benzydamine (topical) Dextromethorphan Fluphenazine Memantine COX-2 inhibitor Tramadol	Gabapentin Pregabalin TCA Lidocaine plasters	Capsaicin Opioids
Classical trigeminal neuralgia	Carbamazepine	Oxcarbazepine	Baclofen* Lamotrigine* Pimozide* Tizanidine*		Carbamazepine Oxcarbazepine	Surgery
Central pain	Cannabinoids (oro-mucosal, oral) (MS) Pregabalin (SCI)	Lamotrigine (CPSP) TCA (SCI, CPSP) Tramadol (SCI)* Opioids		Carbamazepine Gabapentin Lamotrigine (SCI) Levetiracetam Mexiletine S-ketamine iontophoresis Valproate	Gabapentin Pregabalin TCA	Cannabinoids (MS) Lamotrigine Opioids Tramadol (SCI)

CPSP, central post-stroke pain; ER, extended release; MS, multiple sclerosis; PHN, post-herpetic neuralgia; SCI, spinal cord injury; TCA, tricyclic antidepressants; SSRI, selective serotonin reuptake inhibitor.

Although undoubtedly effective in treating neuropathic pain, the TCAs possess several drawbacks. The antimuscarinic actions produce the familiar side-effects of dry mouth, blurred vision, constipation and a tendency to urinary retention. They are variably sedating, with amitriptyline, dosulepin and trimipramine being

more sedating and imipramine and nortriptyline less so. In some circumstances the sedative action is useful if the patient suffers from disturbed sleep, but these drugs are long-acting and even if given as a single evening dose (as is usually the case), unwanted sedation is frequently present in the morning and can persist

throughout the day. TCAs are highly protein-bound, resulting in potential for drug interactions with other protein-bound compounds, and they are cardiotoxic in overdose.

The newer selective serotonin and noradrenaline re-uptake inhibitors (SNRIs), duloxetine and venlafaxine, both show evidence of efficacy for treating neuropathic pain and appear comparable to TCAs in terms of efficacy but better tolerated, without the sedative and antimuscarinic actions and safer in overdosage.

### Antiepileptics

This group of compounds is more diverse in the mode of action of individual drugs than the antidepressants, which all exert their effects through central actions of monoamines. An account of the individual characteristics of these drugs is given in Chapter 7, and the following section highlights issues relevant to their use in the treatment of pain.

The properties responsible for the analgesic effects of the antiepileptics are not fully understood but are probably mainly attributable to two broad categories of action:

- 1 Use-dependent block of sodium channels (phenytoin, carbamazepine and oxcarbazepine, lamotrigine, lacosamide)
- 2 Inhibitory action at the  $\alpha 2\delta$ -1 subunit of pre-synaptic calcium channels (gabapentin, pregabalin).

It is often suggested that the antiepileptic drugs show a degree of selectivity of action on paroxysmal neuropathic pain, whereas burning continuous pain is more likely to respond to the antidepressants. Recent evidence suggests that there is some correlation between neuropathic pain phenotype (and hence putative pain-generator mechanisms) and response to oxcarbazepine.

Carbamazepine and oxcarbazepine remain the first line drugs for the treatment of trigeminal neuralgia (Chapter 13). Current evidence suggests that there is little to choose between them in terms of efficacy, with approximately 50% of patients becoming pain-free on titrating the dose to optimal level. Both drugs rarely cause serious adverse reactions including Stevens–Johnson syndrome, but less severe side effects of a dose-dependent nature are common, including nausea, dizziness, somnolence and fatigue, impaired concentration and memory, and headache. Oxcarbazepine appears on the whole to be better tolerated although it has a greater tendency to cause hyponatraemia. Evidence of benefit from these drugs in the management of other causes of neuropathic pain (e.g. painful diabetic neuropathy) is weak.

Gabapentin and pregabalin (sometimes referred to collectively as ‘gabanoids’) have both been demonstrated in systematic reviews to be effective in a range of neuropathic pain conditions. They both exert their action at the  $\alpha 2\delta$  type 1 subunit of pre-synaptic, voltage-dependent calcium channels. Their adverse effects are similar, including those listed for carbamazepine and oxcarbazepine, and in addition oedema, weight gain and dry mouth. However, serious adverse effects are uncommon, and the absence of either metabolism (both drugs are excreted unchanged by the kidneys) or plasma protein binding limits their capacity for adverse drug interactions, which is reassuring if they are being considered in the context of combination therapy.

Pregabalin exhibits linear pharmacokinetics whereas the kinetics of gabapentin are more complex; in practice this means that there is less inter-subject dose variability with pregabalin than with gabapentin, and titration to optimum dosage can generally be achieved more rapidly. Pregabalin also has the longer half-life, and is typically administered twice daily in contrast to the three or four times daily dose regime required for gabapentin.

Lamotrigine was reported in early studies as showing evidence of benefit in a range of neuropathic pain conditions, central as well as peripheral, but more recent evidence has tended to quell some of the earlier optimism. The usual dose-dependent side effects occur (although cognitive impairment seems relatively uncommon) but it can give rise to Stevens–Johnson syndrome, and slow and cautious up-titration is therefore recommended to minimise the risk of this, which creates the practical disadvantage that it can take months to attain a dose at the higher end of the therapeutic range. Its use should probably be reserved for cases of severe neuropathic pain resistant to antidepressants and the gabanoids.

Lacosamide, one of the newer antiepileptics, has randomised controlled trial evidence of benefit in painful diabetic polyneuropathy. It is generally well tolerated but may give rise to abnormalities of cardiac conduction and is contraindicated in patients with second or third degree heart block.

Other antiepileptics have been tried although the evidence to support their use is generally weak, and they should probably be used as third line drugs in cases where the first and second line options have proved ineffective. As with the TCAs, adverse effects often limit the practical usefulness of antiepileptic drugs in the treatment of pain.

### Local anaesthetics and related compounds

There is good evidence that drugs with inhibitory actions at voltage-gated sodium channels are effective treatments for neuropathic pain. Inhibition of ectopic neuronal activity by systemically administered local anaesthetics and antiarrhythmics such as mexiletine has been demonstrated at multiple sites in the peripheral and central nervous systems, including peripheral neuromas, the dorsal root ganglia, dorsal horn, rostroventromedial medulla and peri-aqueductal grey matter. Rather more surprisingly, it appears that a single administration of a dose of intravenous local anaesthetic can produce analgesic effects lasting much longer than predicted on the basis of the drug’s kinetics, for example several weeks. This observation accords with the author’s experience and in his unit intravenous lidocaine infusion is a frequently employed intervention used to treat neuropathic pain, with some success.

While cardiac antiarrhythmic drugs such as mexiletine are usually less dramatically effective in the treatment of neuropathic pain than the local anaesthetics, they have the advantage of being effective when administered by the orogastric route (the local anaesthetics when taken by mouth are almost completely excluded from the systemic circulation by hepatic first-pass metabolism).

### NMDA receptor antagonists

NMDA receptor antagonists, particularly ketamine, have been clearly demonstrated to be effective in treating neuropathic pain, with evidence to support their use in the treatment of both central and peripheral pain. Ketamine can cause several undesirable effects in addition to sedation, notably dysphoria, hallucinations and other transient psychotic effects; it is also in recent years increasingly being abused as a recreational drug. However, it may, in common with IV lidocaine, induce remissions of pain that long outlast its anticipated effect, and current evidence suggests that if used in relatively low dosage and with dose intervals of a week or more, it is safe. It is the author’s practice to assess the response to ketamine initially with an intravenous infusion of 150  $\mu\text{g}/\text{kg}$  over 30 minutes;

if effective and well tolerated, it can be administered subsequently via a number of routes, including sublingual.

### Cannabinoids

Cannabinoids can relieve both neuropathic pain and painful spasticity. There are currently two preparations available in the United Kingdom; nabilone (synthetic tetrahydrocannabinol; THC) which is presented as a capsule, and an oromucosal spray (Sativex) consisting of a mixture of THC and cannabidiol. Neuropathic pain appears more responsive to cannabinoids than nociceptive pain, and both central and peripheral pain respond to treatment. The licenced indication for the oromucosal spray is at present limited to treatment of severe spasticity in MS. Major side-effects are uncommon, although anxiety concerning risk of abuse and addiction is undoubtedly a factor in restricting its use.

### Topical agents

There is evidence supporting the use of 5% lidocaine patches, licensed in the United Kingdom for the treatment of post-herpetic neuralgia. Capsaicin cream, licensed for treatment of post-herpetic and diabetic neuropathic pains, may be useful, but side effects including burning and stinging at the site of application often occur, and great care has to be taken to avoid contact with the eyes. Recently, a high concentration (8%) capsaicin preparation, in the form of a self-adhesive patch, has become available for the treatment of post-herpetic neuralgia. It is liable to produce burning pain on initial application unless topical local anaesthetic is applied first; it should be administered by a clinician familiar with its use.

### Botulinum toxin

Botulinum toxin has pain-relieving properties in addition to those resulting from treatment of muscle spasm and abnormal posture. Pain relief can occur well before, and outlast, improvement in these musculoskeletal abnormalities. There have been anecdotal reports, and some small placebo-controlled studies, of pain relief in various other disorders including post-herpetic neuralgia and trigeminal neuralgia, diabetic neuropathy, migraine and chronic facial pain. Botulinum toxin does not seem to improve acute pain, and the role of this toxin in relief of pain is uncertain. There is experimental evidence that, apart from effects on acetylcholine, the toxin blocks release of substance P, release of glutamate and other neurotransmitters involved in nociceptive sensory processing.

### Intrathecal drugs

Several drugs have been used intrathecally for pain management. These include baclofen especially for central pain, clonidine, opioids and, most recently, ziconotide. Phenol has also been used, but as a neurolytic agent. The evidence base is poor, benefit unpredictable, and this form of treatment should only be carried out in specialised pain management units.

### Neuro-ablative and neuro-stimulation procedures

#### Neuro-ablative procedures

Over the past century, except in the treatment of trigeminal neuralgia, there has been a steady decline in neurosurgical and other procedures designed to interrupt pain pathways, particularly in those whose pain has a non-malignant cause. Apart from the risks of the procedure itself and in particular of causing damage affecting other neurological functions, even successful procedures can result in painful sensory loss (termed 'anaesthesia dolorosa' after somatic nerve lesioning, and 'sympathalgia' after sympathectomy).

Furthermore, paradoxically pain will often return, sometimes after a long interval, although obviously this is less important in management of those painful malignant conditions in which life expectancy is short. These sequelae are caused by a variety of often poorly understood adaptive central phenomena.

Certain destructive procedures are still occasionally performed, for instance dorsal root entry zone (DREZ) lesions for treatment of pain from spinal cord injury or brachial plexus lesions. Here too the evidence base for their efficacy is poor, and there is a substantial risk of ipsilateral lower limb weakness. The same reservations apply to destructive chemical procedures. The use of phenol and other neurolytic chemicals applied around nerve roots or intrathecally is rarely undertaken, apart from treating spasticity and its accompanying pain. Phenol applied peripherally can induce further pain (phenol neuritis).

#### Neuro-stimulation procedures

Every part of the somatosensory nervous system has been stimulated to try to relieve pain, but apart from transcutaneous electric nerve stimulation (TENS), these techniques are complex and only carried out in specialised centres. Much of the rationale for stimulation procedures is based on the seminal paper by Melzack and Wall (1965) which led to the gate control theory of pain. This paper, which reported physiological experiments on dorsal root potentials in rats, gave rise to the novel concept that stimulation of large diameter afferent fibres might inhibit (gate) the activity of small diameter, pain subserving fibres in the dorsal horn of the spinal cord, and possibly elsewhere. Although the subject of heated controversy, the paper led to the development of various techniques that provide innocuous neural stimulation, with the aim of alleviating pain.

*Transcutaneous electrical nerve stimulation* TENS involves applying electrodes to the skin with an interposed gel or other appropriate contacting substance. The electrodes are usually placed either side of the painful area, and are attached via wires to a small battery-operated stimulation unit. Impulses can be of variable frequency and intensity, the parameters usually being selected by the patient so as to cause non-painful tingling sensations. Stimulation can be continuous, intermittent or in bursts, and applied for minutes, hours or days. Side effects are infrequent and minor, usually comprising skin irritation beneath the electrodes. Contraindications include open or infected skin, pregnancy (other than in labour), and the presence of a pacemaker. TENS has no effect and can cause burns if applied to anaesthetic skin. Benefit is unpredictable, and may only develop some time after stimulation. Some pains are transiently worsened, particularly if there is tactile allodynia. Controlled trials are obviously difficult, but the technique is simple, safe and cheap, and patients can obtain devices over the counter.

The mechanism of action includes segmental inhibition at the dorsal horn, distinct from painful counter-irritation (pain inhibiting another pain) in which there is diffuse noxious inhibitory control through ascending and descending pathways. As a historical footnote, TENS was originally used as a screening tool for spinal cord stimulation (see Spinal cord stimulation), and only after some years was it introduced as a treatment in its own right.

*Peripheral nerve stimulation* Open implanting of stimulating electrodes around a peripheral nerve to obtain pain relief is rarely undertaken now. However, there is a growing trend in some specialist centres of using dorsal root ganglion stimulation for patients with appropriately anatomically restricted pain. There has also been

increasing use of (and increasing literature on) the technique of pulsed radiofrequency stimulation since it was first described in 1998. Essentially, this entails a modification of the much older technique of radiofrequency lesioning. Radiofrequency thermocoagulation denervation remains an established treatment for trigeminal neuralgia (Chapter 13) but is seldom used for other indications, for the reasons stated earlier. However, if a radiofrequency current is applied to a nerve target in short bursts with a long recovery period (typically 20 ms stimulation time per 500 ms), the local tissues do not heat above 42°C. No neurolysis occurs and the treatment should be considered a form of stimulation analgesia, although the physiological basis for the pain relief is unclear.

Occipital nerve stimulation has also rapidly become established in specialist centres in the treatment of some forms of intractable headache (Chapter 12).

**Spinal cord stimulation** Spinal cord stimulation (SCS; formerly known as dorsal column stimulation) was originally devised and trialed on the basis of Melzack and Wall's gate control theory of pain. An array of electrodes is implanted in the posterior epidural space, percutaneously or at open operation, so as to stimulate the spinal cord by means of electrical stimuli provided by a pulse generator. The aim is to stimulate the dorsal columns and the electrode array is placed so as to overlie them, but this stimulation is probably not its only mode of action. However, technically successful stimulation is generally deemed to require the production of paraesthesia in the painful territory (but with the proviso below).

Over the four and a half decades since its introduction, it has become clear that some types of pain respond better than others to this technique. Well-established indications include CRPS, neuropathic pain secondary to peripheral nerve damage or radicular lumbar or cervical spinal pain (often in the context of a poor outcome from decompressive surgery), and post irradiation and partial traumatic brachial plexus lesions. In general, neuropathic pains in which the lesion is in the periphery respond better than myelopathic pains, and – as would be expected – severe dorsal column damage in the territory of the attempted stimulation renders the technique ineffective. Pain arising rostral to the cord is generally completely unresponsive. There is growing use of SCS for a range of visceral pains, and a substantial body of literature supports its use in treatment-resistant angina pectoris.

Curiously, the results of conventional frequency SCS are very poor in all pains of nociceptive type. However, recently a modification of this treatment has been introduced that utilises much higher frequencies and early results indicate that this may be effective for nociceptive as well as neuropathic pain. This ultra-high frequency SCS does not induce paraesthesia, which may increase patient acceptability. More clinical data are required before this new form of SCS is established in terms of the indications for its use.

Up-to-date recommendations for best clinical practice, details of conditions that respond, contraindications, technical details and a literature review are well set out in a consensus document from the British Pain Society and the Society of British Neurological Surgeons.

**Deep brain stimulation** This highly specialised technique originated from two startling discoveries: in humans, stimulation of the fornix and septal regions during psychosurgery produced analgesia, and, in rats, stimulation of the central midbrain grey matter allowed them to be operated on without an anaesthetic. The three areas most frequently targeted include the peri-aqueductal grey

matter, peri-ventricular grey matter and the somatosensory nuclei of the thalamus. While experimental pain relief has been attributed predominantly to stimulation of endogenous opioid systems at the first two sites, and stimulation of inhibitory pathways at the third, the underlying mechanisms in humans remain unclear. Debate continues on many aspects, including the indications for deep brain stimulation (probably patients with constant, burning or aching neuropathic pain unresponsive to other measures), appropriate targets and stimulation parameters.

**Motor cortex stimulation** This counter-intuitive procedure involves the extradural placement of electrodes over the motor cortex. Pain relief is thought to be subserved by effects on descending inhibition, in turn mediated by sensory nerves present in the motor cortex. Recently, repetitive transcranial magnetic stimulation over the motor cortex has been reported to provide analgesia in patients with central pain and trigeminal neuralgia, an effect that might usefully predict benefit from long-term motor cortex stimulation.

### Other physical methods of treatment

Many treatment modalities are used, including different forms of physiotherapy for nociceptive pains, and treatment is usually carried out by physiotherapists, occupational therapists and other allied therapists such as osteopaths and chiropractors. TENS is one such procedure and has been discussed earlier. Another technique often used for musculoskeletal and other pains, and a form of peripheral stimulation, is acupuncture.

### Acupuncture

Acupuncture, the insertion of needles into the body for pain relief, has been used for 5000 years. Various techniques are employed:

- Needle stimulation of local points in painful areas, such as for treatment of tennis elbow.
- Needle stimulation of distant points, sometimes multiple and sometimes situated along classic Chinese acupuncture lines. However, the importance of classic acupuncture points is doubtful.
- Needle(s) are simply inserted, repetitively rotated or stimulated electrically, and inserted to different depths.
- Treatment is often given for about 30 minutes, but the optimum duration is unclear.

Acupuncture has been used in treatment of acute and numerous chronic painful and other disorders. It is most commonly and perhaps most effectively used for musculoskeletal rather than neuropathic pain. Contraindications include local skin lesions, anticoagulation and pregnancy. Side effects are infrequent, but infection, bleeding, syncope, paraesthesia and, depending on the site and depth of needle insertion, pneumothorax and other internal complications very rarely occur. Attempts have been made to undertake controlled trials of efficacy using specially adapted needles, but in practice acupuncture is usually given on a trial and error basis.

Despite its potential for placebo effects, acupuncture provides a form of powerful peripheral stimulation. The physiological basis underpinning acupuncture is complex, and includes effects mediated by release of endogenous opioids, as demonstrated by the fact that acupuncture analgesia can be reversed by naloxone. Acupuncture also induces both segmental and supraspinal descending inhibitory effects.

Acupuncture carried out for prolonged periods and at a stimulus intensity sufficient to cause pain raises the pain threshold and can

induce analgesia. This acupuncture-induced analgesia, different from treatment of pain, has been used in selected cases as a method for allowing surgery to take place without general anaesthesia.

### Psychological approaches to management of chronic pain

The psychological components of pain are extraordinarily complex, but the tendency to assume that pain intensity correlates with perceived pain severity can easily be disproved. Rather than being closely linked to sensory dysfunction, from the psychological perspective it is the affective, cognitive, behavioural and social aspects for the patient as well as the family that are crucial. As consistently shown by functional imaging, magneto-encephalography and other investigative tools, non-sensory brain changes occur alongside the sensory phenomena that characterise acute and chronic pains. Structures, particularly including the anterior cingulate, prefrontal cortex and insula, are implicated in encoding pain affect. It is thus increasingly recognised that any firm division between psychological and somatosensory aspects of pain is probably meaningless.

Currently, normal psychological aspects of pain are thought to comprise four concepts: attention, catastrophising, avoidance and depression. The neurophysiological bases underlying these are starting to be investigated. Building on these concepts and coinciding with the decrease in invasive procedures, there has been a rapid increase in the use of psychological strategies for management of pain.

Patient management falls to pain psychologists, the majority of whom work as members of a multi-disciplinary pain management team. It is important for the patient to accept that pain psychologists are concerned with management and not cure of the pain. Individual psychologists tend to have expertise in one or more specific therapeutic approaches, and while it is difficult to compare different forms of psychological intervention, cognitive behavioural therapy is one of the most widely used techniques that meta-analyses have shown to be effective.

Psychiatric treatment is sometimes also required. It is usually unwise to attribute chronic pain to a psychological cause, and patients with significant depression will need appropriate treatment and when necessary referral to a psychiatrist. Malingering presenting as chronic pain is well recognised but rare.

### The placebo phenomenon

The placebo phenomenon in treating pain encapsulates the concept that individuals receiving a pharmacologically inert substance, or other inherently inactive 'sham' therapy, but believing that they are receiving an effective analgesic treatment experience reduced pain. Although it is often stated that one-third of the population are 'placebo responders', this figure can generally be traced to a single paper by Beecher who cited a number of studies in which the average rate of placebo response was indeed around 30% but with huge departures from the average across the studies quoted. Subsequent studies have indicated rates of placebo response ranging from 0 to 100% and it is clear that there is no 'fixed fraction' of placebo responders. Moreover, there is experimental evidence that individuals can be converted from non-responders to responders through conditioning. Cultural, experiential, experimental and numerous other factors are relevant. It is often thought that pain relief following a sham treatment can only induce psychological change, but there is compelling evidence that placebo effects can have measurable, and sometimes substantial, physiological effects. This evidence, from acute pain studies, includes findings that:

- Placebo ultrasound can reduce swelling and trismus as well as pain, and reduce C reactive protein levels, after wisdom tooth extraction.
- Naloxone can in some cases reverse placebo analgesia, suggesting endogenous opioid mechanisms are important, although naloxone can also produce hyperalgesia that can offset the placebo effect.
- Placebo analgesia is associated with changed patterns of cerebral blood flow similar to those seen with opioids.
- Functional MRI evidence suggests that placebo decreases activity in pain-sub-serving brain regions; conversely, during anticipation of pain, brain activity increases in the prefrontal cortex.
- Placebo analgesic effects, including physiological phenomena, are seen following technically abortive surgery when the patient is under general anaesthesia and therefore unaware.
- Placebo is a phenomenon also seen in treatment of other, non-painful and chronic, disorders including Parkinson's disease, Alzheimer's disease and depression.

The placebo phenomenon is proving to be an intriguing and important phenomenon in pain and other conditions, and the mechanisms are likely to include those subserving expectancy and conditioning. It should be noted that nocebo responses, in which an inert treatment induces an adverse response (e.g. nausea following a saline injection believed to be an opioid), are also well recognised.

Although pain relief by means of placebo would appear to be an ideal outcome, there are major ethical considerations when using placebo in clinical practice and in clinical trials. The issue is controversial, but the prevailing consensus is that patients should not receive placebo without consent, even if that consent includes placebo being one of a number of treatment options offered.

### Insensitivity to pain

In these conditions, stimuli that would normally be painful are not transmitted to the brain. This lack of pain input may be congenital and occurs in some rare hereditary small fibre neuropathies, notably, but not exclusively, HSAN type IV (Chapter 10). Patients with this autosomal recessive neuropathy develop serious painless injuries amongst other defects, and have absence of unmyelinated peripheral axons, small sensory neurones in the dorsal root ganglia, and Lissauer's tracts. The mechanisms for the lack of pain perception may relate to mutations in the *TrkA* gene that encodes the high affinity receptor for NGF, which in turn is crucial for development of nociceptive and sympathetic neurones.

Acquired causes include occasional cases of diabetes, syphilitic tabes dorsalis, and lesions interrupting second-order central crossing spino-thalamic fibres as seen in syringomyelia. As a result of the lack of protective innervation, patients can develop painless scars, burns and ulcers, inadvertently bite their tongue and otherwise self-mutilate, and have disorganised (Charcot) joints and osteomyelitis. Such injuries need to be contrasted with the self-mutilation that can occur in association with anaesthesia dolorosa, in which the positive sensory disturbances (possibly including itch) give rise to constant scratching and damage, the human equivalent of autotomy in animals.

### Congenital insensitivity to pain

In congenital indifference to pain (also known as asymbolia for pain, congenital pure analgesia and congenital indifference to pain), patients appear to have absent pain recognition which dates from birth. They do not react to painful stimuli anywhere over the body,

but other sensory modalities and reflexes seem to be normal. They sustain painless injuries including skin lesions and fractures dating from childhood. Autosomal dominant and recessive families have been reported. In some patients insular damage perhaps leading to sensori-limbic disconnection has been reported, but in most patients no consistent pathological abnormalities have been found in either the peripheral or central nervous system. The cause of these very rare disorders remains unknown, although the clinical features recall those patients with other conditions in which medial pain-sub-serving circuits may well be implicated – for example, patients with frontotemporal dementia, and patients who in previous decades had a frontal lobotomy for treatment of intractable pain. However, it is now evident that, in some patients, their supposed indifference to pain is caused by impaired function of the voltage-gated sodium channel gene *SCN9A*, encoding the Na<sub>v</sub> 1.7 sodium channel, and is in reality a channelopathy-associated insensitivity to pain.

### Transient indifference to pain

It has long been observed that in certain acute situations of severe tissue injury in which pain would be expected, quite paradoxically pain may not be experienced at all. Classic studies came from Beecher who described this in battle-injured soldiers in the Second World War, but the same phenomenon has been documented in other wartime situations and in occasional patients with very severe injuries admitted to a hospital A&E department.

Early in the history of the recognition of this condition in warfare, it was assumed by some that the absence of pain was in some way induced by relief at having escaped alive from a potentially lethal combat situation, but there is no evidence to bear this out; recipients of these injuries are generally distressed rather than elated. Moreover, the analgesia is localised to the site of injury; the soldier who reports no pain from his shattered leg may complain of pain from clumsy venous cannulation in the arm.

The mechanisms of this form of analgesia are thought to include cortical and spinal inhibitory processes. It is always short lived (hours). Presumably the response has evolved because it confers selective advantage, and it can be seen to have potential survival value, enabling an animal to run from a predator on a broken leg. Perhaps having a similar basis is the impaired pain perception in those patients with parasomnias who sustain injuries during sleep-related violence. Pain appreciation is also impaired as a result of the transient effects of drugs such as opiates.

### Conclusions

Pain in disorders of the nervous system is common, and diverse in its pathophysiological mechanisms and clinical manifestations. It is widely underestimated in its prevalence and severity. It can be very difficult to treat effectively, but in practice is often inadequately treated even when effective therapies are available. Effective management depends on accurate diagnosis, not only of the primary neurological condition, but of the putative mechanisms of generation of the pain – or pains – in the individual patient. The optimal management of the more challenging cases frequently requires the input of a multi-specialist team comprising (amongst others) psychologists and physical therapists as well as physicians.

In recent years, understanding of the mechanisms that give rise to pathological pain have advanced greatly. However, it remains the case that the advances in our knowledge have not been matched by advances in effective treatment.

### Acknowledgement

The author wishes to acknowledge his indebtedness to his retired friend and colleague Dr G.D. Schott, much of whose contribution to the first edition of this textbook has been retained in this chapter, and also his grateful thanks to Dr M.S. Chong for the generosity of his time spent reading the manuscript and his helpful comments and advice.

# Autonomic Aspects of Neurology

Christopher Mathias<sup>1</sup>, Gordon Ingle<sup>2</sup> and Valeria Iodice<sup>2</sup>

<sup>1</sup>UCL Institute of Neurology

<sup>2</sup>National Hospital for Neurology & Neurosurgery

The last three decades have seen major advances in awareness and recognition of autonomic disorders, and in the investigation and treatment of a variety of diseases that cause or contribute to autonomic dysfunction; these have been a result of many factors. Many clinicians consulted by patients with symptoms that cannot be readily explained now consider autonomic disorders as a possible cause. Advances in non-invasive technology have resulted in more accurate and reproducible methods of investigation, thus aiding diagnosis, understanding pathophysiological mechanisms and enabling targeted therapy for autonomic dysfunction. Collaboration between specialties within neurology, such as with movement disorders groups and with other medical disciplines such as diabetology, cardiology and, more recently, rheumatology, has been helpful in understanding autonomic involvement in common neurological and medical diseases. Advances in basic science have enabled neurological repair (e.g. in the spinal cord) and have refocused attention on the many autonomic abnormalities that occur in patients with spinal cord injuries. Finally, new autonomic disorders have been described, examples being dopamine beta hydroxylase deficiency (DBH), immune disorders affecting autonomic ganglia and the postural tachycardia syndrome (PoTS), and in the latter its close association with the joint hypermobility (Ehlers–Danlos III) syndrome.

Autonomic investigation units began to be established in the United Kingdom during the 1970s. Their scope of activity varied, depending much upon research funding. Established units have seen exponential growth in clinical service and research activity, which have advanced greatly the recognition, investigation and management of autonomic disorders. Activities now encompass a wide range of disorders, from autonomic failure syndromes to common disorders such as parkinsonian syndromes, hyperhidrosis, autonomic mediated syncope (AMS) and, in the last few years, PoTS. This chapter summarises the usual diagnostic approach and the range of tests and treatments available.

## Classification of autonomic dysfunction

The autonomic nervous system has cranio-sacral parasympathetic and thoraco-lumbar sympathetic pathways (Figure 24.1) and supplies every organ in the body. The system influences target organ function locally and also operates more centrally (i.e. it controls vital functions

such as arterial blood pressure and body temperature). Specific neurotransmitters in each pathway influence ganglionic and post-ganglionic activity (Figure 24.2 and Figure 24.3). Thus, autonomic diseases may occur with lesions or dysfunction at different sites of the neural axis, in the brain, spinal cord or periphery.

Autonomic disorders may be classified in a variety of ways. One approach is to divide them into localised and generalised disorders. Localised disorders affect an organ or region of the body but they may be part of generalised disease, such as gustatory sweating in diabetes mellitus (Table 24.1). Generalised disorders often affect systems, such as those involved in blood pressure control and thermoregulation. They can be primary when the cause is unclear, or secondary when associated with a specific disease or its complications (Table 24.2a).

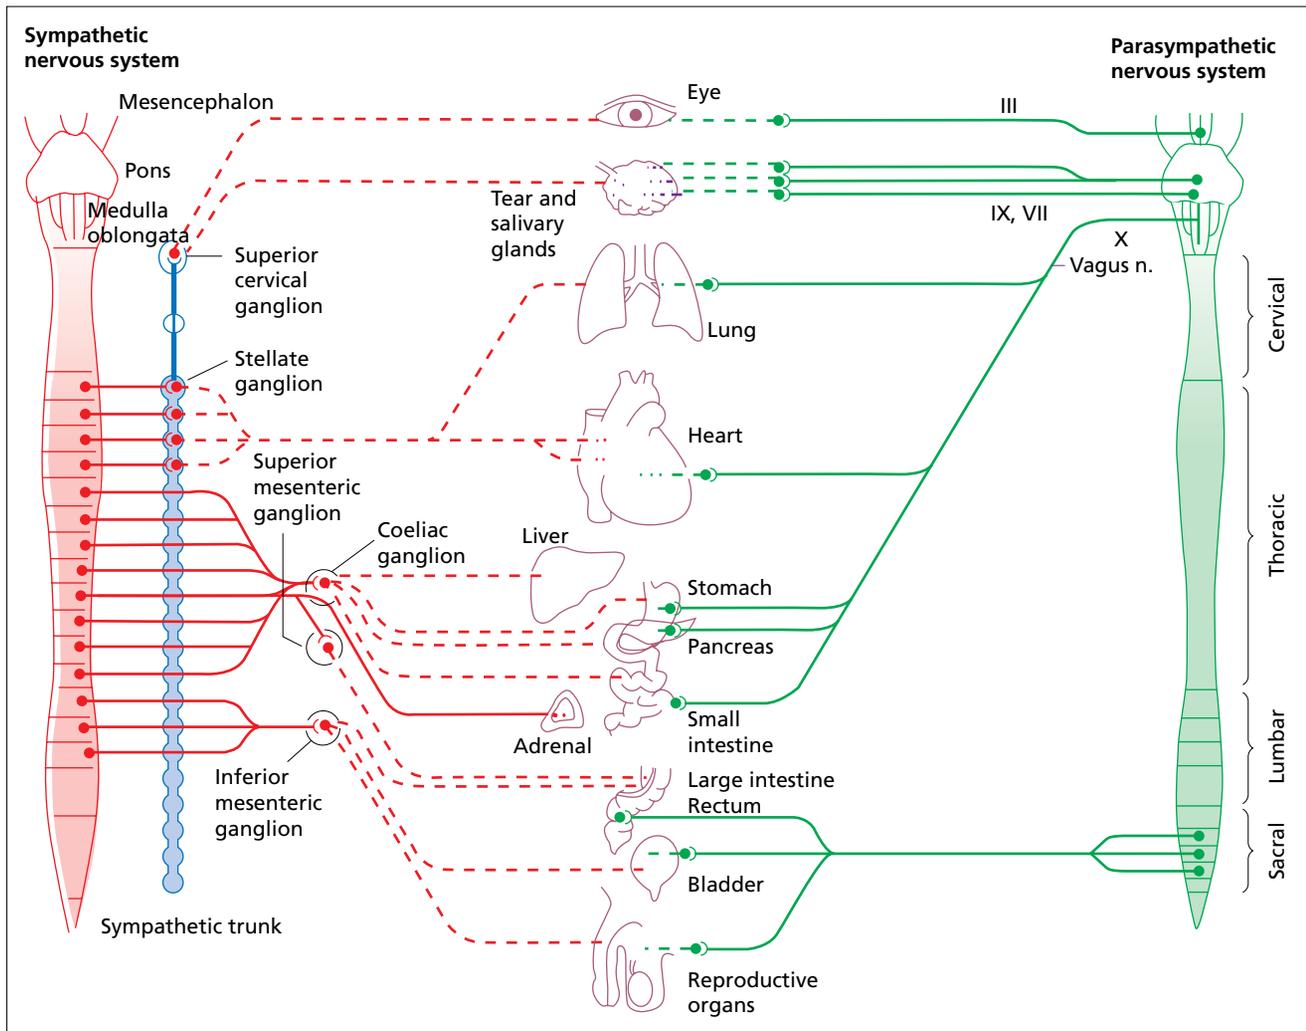

Damage to the autonomic nervous system often causes irreversible abnormalities. This contrasts with intermittent autonomic dysfunction, the common transient abnormalities that generate so much morbidity (Table 24.2b). These conditions include AMS, PoTS and essential hyperhidrosis. Drugs are a common cause of autonomic dysfunction, either because of their pharmacological effects or because of autonomic nerve damage (Table 24.3). Classification of disorders causing damage to the autonomic nervous system may also be considered under prognosis, based on natural history and/or possible interventional measures (Table 24.4).

## Clinical features

Clinical features of autonomic disease cover a wide spectrum (Table 24.5) and result from underactivity or overactivity. The history is of particular importance in consideration and recognition of autonomic disease and in distinguishing dysfunction from other disorders. In brief:

- Sympathetic adrenergic failure causes orthostatic (postural) hypotension and ejaculatory failure in the male.
- Sympathetic cholinergic failure causes anhidrosis.
- Parasympathetic failure causes dilated pupils, fixed heart rate, sluggish urinary bladder, atonic large bowel and, in the male, erectile failure.

The extent of dysfunction is dependent on the degree of autonomic damage. With autonomic hyperactivity, the reverse occurs. In some disorders, particularly in AMS, there may be a combination of

**Figure 24.1** Cranio-sacral parasympathetic and thoraco-lumbar sympathetic outflow. Source: Janig 1987. Reproduced with permission of Springer Science+Business Media.

over-activity and under-activity, with bradycardia caused by increased parasympathetic activity and hypotension brought about by withdrawal of sympathetic activity.

Autonomic disease may occur in any age group. At birth it is seen in the rare condition familial dysautonomia (Riley–Day syndrome), in teenage years in the common disorder vasovagal syncope and between the ages of 30 to 50 in familial amyloid polyneuropathy (FAP). Neurodegenerative disorders affecting the autonomic nervous system often occur after the age of 50 years.

The majority of autonomic diseases are sporadic. However, genetically transmitted disorders include the Riley–Day syndrome and FAP. There often is a family history in vasovagal syncope, especially in those presenting below the age of 20 years. Drug-induced autonomic disease is caused by impaired metabolism or the production of toxic metabolites, as with perhexiline maleate neuropathy. A detailed history relating to drug usage, chemical and toxin exposure is always necessary (Table 24.3).

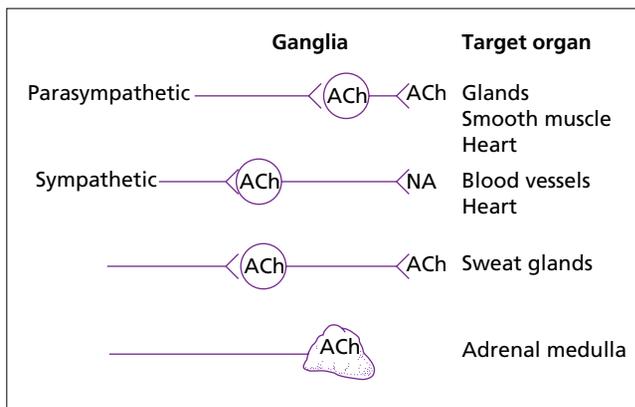

Autonomic involvement, even if it affects only a single organ or system (Table 24.5), may be an important feature of an underlying disease. For example, Horner’s syndrome, with mainly cosmetic effects, can be the harbinger of underlying non-autonomic disease

(such as apical tuberculosis or lung neoplasm in Pancoast’s syndrome). The usually benign Holmes–Adie pupil sometimes occurs in isolation, or with absent tendon reflexes and other autonomic features, such as an afferent baroreceptor defect causing orthostatic hypotension and labile hypertension, sweating abnormalities and a dry cough (Holmes–Adie syndrome). In generalised disorders such as multiple system atrophy (MSA), a single system is sometimes involved initially. Thus, erectile failure in the male, and constipation or urinary bladder dysfunction in either gender, can pre-date other autonomic or neurological features. The clinical features are now considered under each major system.

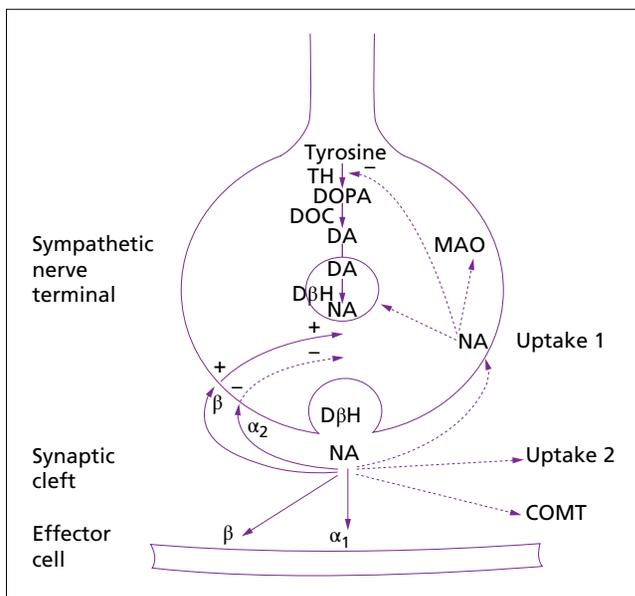

## Cardiovascular system

### Orthostatic hypotension

Symptoms of orthostatic hypotension are often the reason for requesting medical advice and can provide initial clues to underlying autonomic disease. Orthostatic or postural hypotension is defined as a fall in blood pressure of 20 mmHg systolic or 10 mmHg diastolic on sitting, standing or during 60° head-up tilt (Figures 24.4 and 24.5). In neurogenic orthostatic hypotension, levels of plasma noradrenaline do not rise when upright, as occurs in

**Figure 24.2** Outline of the major transmitters at autonomic ganglia and post-ganglionic sites on target organs supplied by the sympathetic and parasympathetic efferent pathways. The acetylcholine receptor at all ganglia is of the nicotinic subtype. Ganglionic blockers such as hexamethonium thus prevent both parasympathetic and sympathetic activation. However, atropine acts only on the muscarinic (ACh-m) receptor at post-ganglionic parasympathetic and sympathetic cholinergic sites. The co-transmitters along with the primary transmitters are also indicated (ACh, acetylcholine; NA, noradrenaline). Source: Adapted from Mathias 1998 with permission of Elsevier.

**Figure 24.3** Formation of noradrenaline (NA) from tyrosine within a sympathetic nerve terminal (DA, dopamine; DβH, dopamine beta hydroxylase; DDC, dopadecarboxylase; DOPA, dihydroxyphenylalanine; TH, tyrosine hydroxylase). NA in granules is released by a process of exocytosis into the synaptic cleft, following which it acts on various alpha or beta adrenoceptors, either pre- or post-synaptically. NA is subject to various processes which involve uptake 1 into the nerve terminal, following which it is either incorporated into granules, exerts negative feedback on TH or is metabolised by monoamine oxidase (MAO). Some is taken up into non-neuronal tissues (uptake 2), some metabolised by catechol-O-methyltransferase (COMT), while the rest spills over into the circulation. Source: Mathias 2004. Reproduced with permission of Elsevier.

**Table 24.1** Examples of localised autonomic disorders.

Horner's syndrome
Holmes–Adie pupil
Crocodile tears (Bogorad's syndrome)
Gustatory sweating (Frey's syndrome)
Reflex sympathetic dystrophy
Idiopathic palmar or axillary hyperhidrosis
Chagas' disease ( <i>Trypanosoma cruzi</i> )*
Surgical procedures†
Sympathectomy (regional)
Vagotomy and gastric drainage procedures in 'dumping' syndrome
Organ denervation following transplantation (heart, lungs)

\*Listed here because the disease targets specifically intrinsic cholinergic plexuses in the heart and gut.

†Surgery also may cause other localised disorders, such as Frey's syndrome after parotid surgery.

**Table 24.2** (a) Outline classification of autonomic disorders.

### Primary

#### Acute/subacute dysautonomias

- Pure pan-dysautonomia
- Pan-dysautonomia with neurological features
- Pure cholinergic dysautonomia

#### Chronic autonomic failure syndromes

- Pure autonomic failure
- Multiple system atrophy (Shy–Drager syndrome)
- Autonomic failure with Parkinson's disease

### Secondary

#### Congenital

- Nerve growth factor deficiency

#### Hereditary

- Autosomal dominant trait
- Familial amyloid neuropathy

#### Autosomal recessive trait

- Familial dysautonomia – Riley–Day syndrome
- Dopamine β hydroxylase deficiency

#### Metabolic diseases

- Diabetes mellitus
- Chronic renal failure
- Chronic liver disease
- Alcohol-induced

#### Inflammatory

- Guillain–Barré syndrome
- Transverse myelitis

normal subjects (Figure 24.6), the lack of rise reflecting impaired sympathetic activity. Hypoperfusion of organs, especially above heart level such as the brain, cause the malaise, nausea, dizziness and visual disturbances that often precede loss of consciousness (Table 24.6).

The fall in blood pressure and associated symptoms during postural change often varies within the same individual. If blood pressure falls precipitously, syncope tends to occur instantly and is likely to cause injury. Occasionally, seizures occur as a result of cerebral hypoxia in syncope. With time and frequent exposure to orthostatic hypotension, some come to tolerate a low cerebral perfusion pressure with few or even no symptoms, presumably because of improved cerebrovascular autoregulation.

A variety of symptoms result from hypoperfusion elsewhere. Neck pain in a coat-hanger distribution (suboccipital and shoulder regions) differs from other types of neck pain by developing when upright. It is relieved by sitting or lying flat, when the blood pressure recovers. The pain probably is caused by reduced perfusion of neck muscles that need to be tonically active to maintain upright head posture. Using arm muscles especially when upright can increase cerebral symptoms of orthostatic hypotension by a subclavian steal-like mechanism further reducing brainstem blood flow. Central chest pain, suggestive of angina pectoris,

abnormalities (e.g. in high spinal cord lesions). The reverse – polyuria – occurs when supine, especially at night when blood pressure is restored or even elevated. In the elderly, falls occur even without other symptoms of orthostatic hypotension. Other less specific symptoms include weakness, tiredness and fatigue.

A key component in the history is the relationship between symptoms and head-up postural change. Symptoms may be more prominent with rapid head-up change (e.g. getting out of bed in the morning) and on rising after a large meal, excessive alcohol or exercise (Figures 24.7 and 24.8). A variety of factors influence orthostatic hypotension and should be sought in the history (Table 24.7). Many patients recognise the association with head-up postural change and either sit down, lie flat, stoop or assume curious postures, such as squatting. These positions can prevent the fall in blood pressure or even elevate blood pressure. Orthostatic hypotension is often worsened by drugs that have vasodilator effects used to treat associated disease (levodopa or insulin), alleviate symptoms (nitrates) or reverse organ failure (sildenafil).

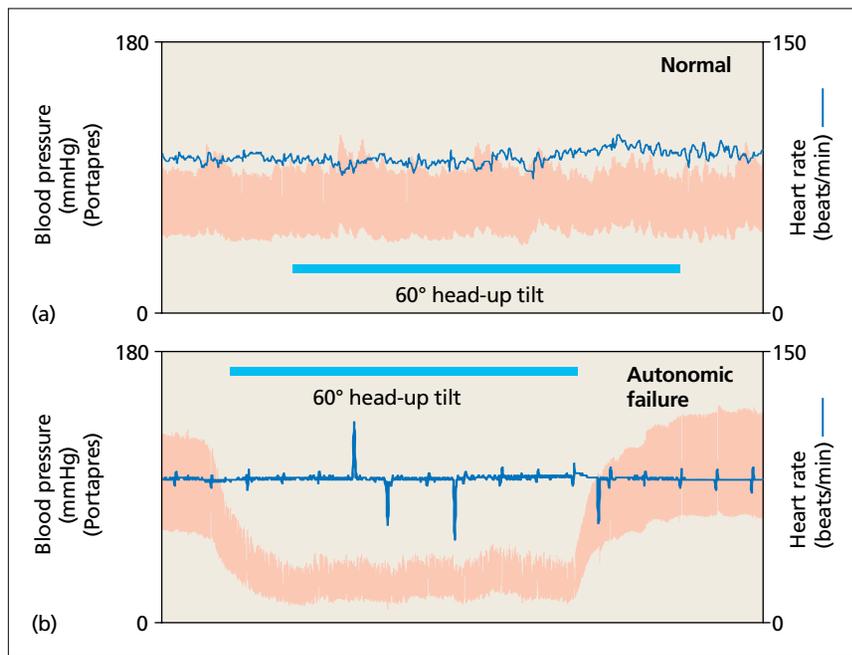

### Syncope without orthostatic hypotension

Syncope has many causes (autonomic, cardiac, neurogenic and metabolic). In AMS orthostatic hypotension is not present but there is transient hypotension and bradycardia, often with a provoking factor. There are three major forms: vasovagal syncope, carotid sinus hypersensitivity and situational syncope. Blood pressure falls because of sympathetic withdrawal while heart rate falls because of increased vagal activity. This is more likely to occur when upright. There are usually no autonomic abnormalities detected between attacks. The history of the syncopal attack and its recovery often separates AMS from other neurological diseases, such as epilepsy. Recovery on lying flat usually is rapid, as this restores blood pressure and cerebral perfusion. Tongue biting normally does not occur. In some, convulsions result from hypoxia, especially if the subject is not laid flat and blood pressure recovery is delayed. Urinary incontinence can occasionally occur.

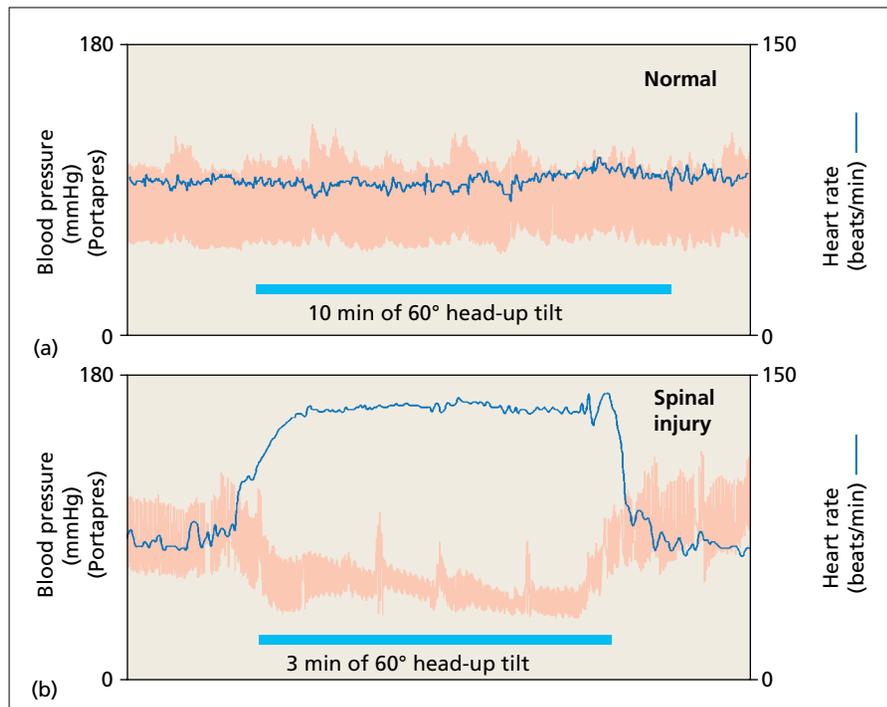

In vasovagal syncope (common faints or emotional syncope) provoking factors include fear, pain, the sight of blood and medical procedures, especially involving needles. Nausea and other gastrointestinal upsets, probably through activation of visceral afferents, may be causative. Palpitations and sweating occur in the pre-syncopal phase. In those with an adequate warning, sitting or lying flat prevents syncope. The reverse, prolonged standing or assumption of the upright position on a tilt table, may provoke a response; the latter is the basis for the laboratory investigation. Tilt table testing is usually for 10 minutes, with a provocative stimulus such as venepuncture; sometimes prolonged tilt testing for 45 minutes is needed. It is important to determine the underlying mechanism contributing to syncope as this influences the management of vasovagal syncope (Figures 24.9, 24.10 and 24.11).

In the elderly, carotid sinus hypersensitivity is increasingly recognised as a cause of falls (Figure 24.12). There may be a classic history of syncope induced while shaving, turning the head or buttoning the collar, when carotid afferents are stimulated. However, this history may not be obtained. Falls and syncope that remain unexplained should arouse suspicion of this disorder.

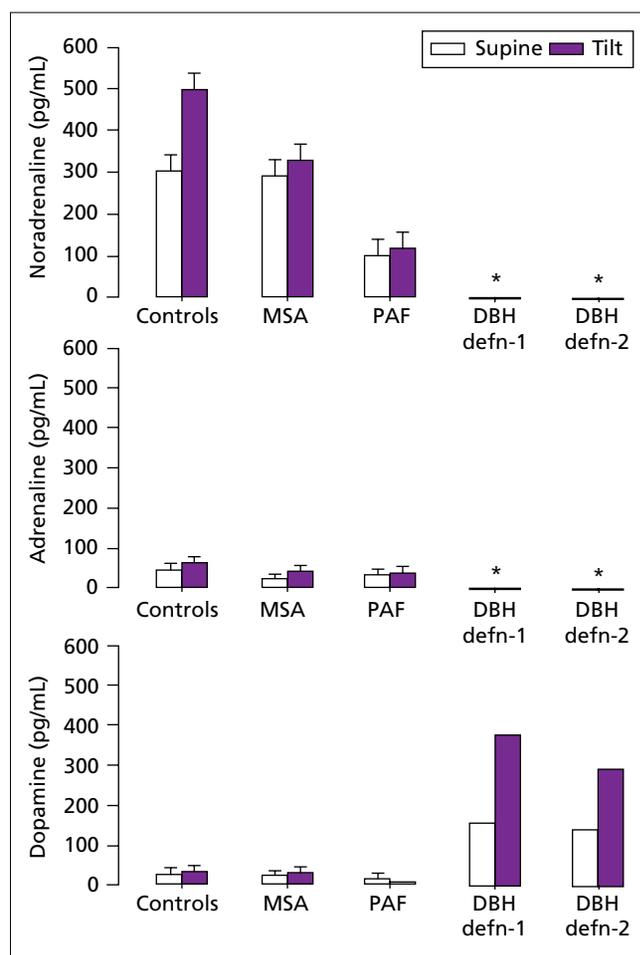

In situational syncope, various factors predispose the individual to syncope: induction of a Valsalva manoeuvre and hyperventilation. This occurs in weight-lifters, trumpet-blowers, in mess tricks

**Figure 24.4** Blood pressure and heart rate before, during and after head-up tilt in (a) a normal subject, and (b) a patient with autonomic failure. In the normal subject there is no fall in blood pressure during head-up tilt, unlike a subject with autonomic failure in whom blood pressure falls promptly and remains low with a blood pressure overshoot on return to the horizontal. In this subject there is only a minimal change in heart rate despite the marked blood pressure fall. In both subjects continuous blood pressure and heart rate was recorded with the Finometer. Source: Mathias 2006. Reproduced with permission of Elsevier.

**Figure 24.5** (a,b) Blood pressure and heart rate measured continuously with the Finometer in a patient with a high cervical spinal cord lesion. There is a fall in blood pressure because of impairment of the sympathetic outflow disrupted in the cervical spine. Heart rate rises because of withdrawal of vagal activity in response to the rise in pressure. Source: Mathias 2006. Reproduced with permission of Elsevier.

**Figure 24.6** Plasma noradrenaline, adrenaline and dopamine levels (measured by high pressure liquid chromatography) in normal subjects (controls), patients with multiple system atrophy (MSA), pure autonomic failure (PAF) and two individual patients with dopamine  $\beta$ -hydroxylase (DBH) deficiency while supine and after head-up tilt to 45° for 10 minutes. The asterisk indicates levels below the detection limits for the assay, which are less than 5 pg/mL for noradrenaline and adrenaline and less than 20 pg/mL for dopamine. Bars indicate  $\pm$  standard error of mean (SEM). Source: Mathias and Bannister 2013. Reproduced with permission of Oxford University Press.

(deliberate manoeuvres) and following paroxysms of coughing. In micturition syncope, hypotension results probably from a combination of vasodilatation caused by warmth and/or alcohol and straining during micturition (which raises intrathoracic pressure and induces a Valsalva manoeuvre), compounded by release of the pressor stimulus arising from a distended bladder while standing upright. Swallowing-induced syncope sometimes occurs with glossopharyngeal neuralgia.

#### Orthostatic intolerance with posturally induced tachycardia

When orthostatic intolerance occurs without orthostatic hypotension, but with a substantial rise in heart rate (of over 30 beats/minute), the term postural tachycardia syndrome (PoTS) is used

Falls

**Figure 24.7** Changes in BP before and after a standard meal in a group of normal subjects (stippled area) and in a patient with autonomic failure (IR), while in the supine and horizontal position. Bars indicate  $\pm$  standard error of mean (SEM). In the normal subjects there is no change in BP. In the patient with autonomic failure there is a marked fall in BP soon after food ingestion, with levels falling to around 80/50 mmHg and remaining low for 3 hours, even in the supine position. Source: Mathias and Bannister 2013. Reproduced with permission of Oxford University Press.

**Figure 24.8** Systolic and diastolic blood pressure in two patients with autonomic failure before, during and after bicycle exercise performed with the patient in the supine position at different workloads, ranging from 25 to 100W. In the patient on the left there is a marked fall in blood pressure on initiating exercise; she had to crawl upstairs because of severe exercise-induced hypotension. In the patient on the right, there are minor changes in blood pressure during exercise, but a marked decrease soon after stopping exercise. This patient was usually asymptomatic while walking, but developed postural symptoms when he stopped walking and stood still. It is likely that the decrease in blood pressure post-exercise was a result of vasodilatation in exercising skeletal muscle, not opposed by the calf muscle pump. Source: Mathias 1994. Reproduced with permission of Elsevier.

**Table 24.7** Factors influencing orthostatic hypotension.

Speed of positional change
Time of day (worse in the morning)
Prolonged recumbency
Warm environment (hot weather, central heating, hot bath)
Raising intrathoracic pressure – micturition, defaecation or coughing
Food and alcohol ingestion
Water ingestion*
Physical exertion
Physical manoeuvres and positions (bending forward, abdominal compression, leg crossing, squatting, activating calf muscle pump)*
Drugs with vasoactive properties (including dopaminergic agents)

\*This raises blood pressure in autonomic failure.

†These manoeuvres usually reduce the postural fall in blood pressure, unlike the others.

(Figure 24.13). It predominantly affects women below the age of 50 years. Symptoms include marked dizziness on postural change or modest exertion; syncope may occur. There are usually no features of generalised autonomic failure. Associated disorders include the joint hypermobility syndrome (Ehlers–Danlos III; Figures 24.14 and 24.15), chronic fatigue syndrome, mitral valve prolapse and hyperventilation. A relationship to disorders described in wartime, such as da Costa's syndrome and soldier's heart, now often grouped with chronic fatigue syndrome, when dizziness and syncope on effort is accompanied by exhaustion, dyspnoea, headache, palpitations and pain over the heart, seems probable.

### Hypertension

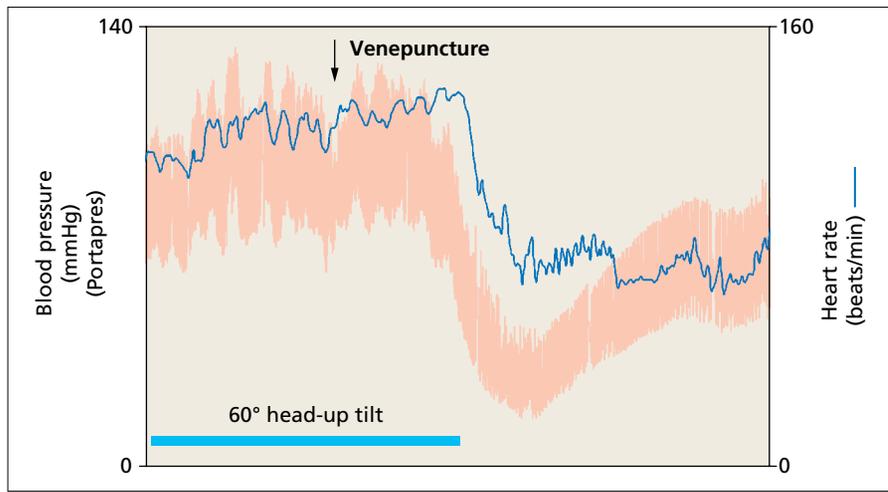

Unlike hypotension, hypertension typically causes few symptoms other than headaches – and these only occasionally. In high spinal cord lesions, severe paroxysmal hypertension can develop as part of autonomic dysreflexia, when an uninhibited increase in spinal sympathetic activity is caused by contraction of the urinary bladder, irritation of the large bowel, noxious cutaneous stimulation or skeletal muscle spasms. This can cause hypertension, a throbbing pounding headache, palpitations with bradycardia and sweating/flushing over the face and neck. The limbs tend to be cold as a result of peripheral vasoconstriction. In tetanus, hypertension in ventilated patients can be precipitated by muscle spasms or tracheal suction. Intermittent hypertension can occur in Guillain–Barré syndrome, porphyria, posterior fossa tumours and pheochromocytoma (Figure 24.16), often without any evident precipitating cause.

Sustained hypertension resulting from increased sympathetic activity may occur in subarachnoid haemorrhage. Hypertension in the supine position can complicate orthostatic hypotension in pure autonomic failure (PAF). The mechanisms include impaired baroreflex activity, adrenoceptor supersensitivity, an increase in central blood volume because of a shift from the periphery and the effects of drugs used to prevent orthostatic hypotension.

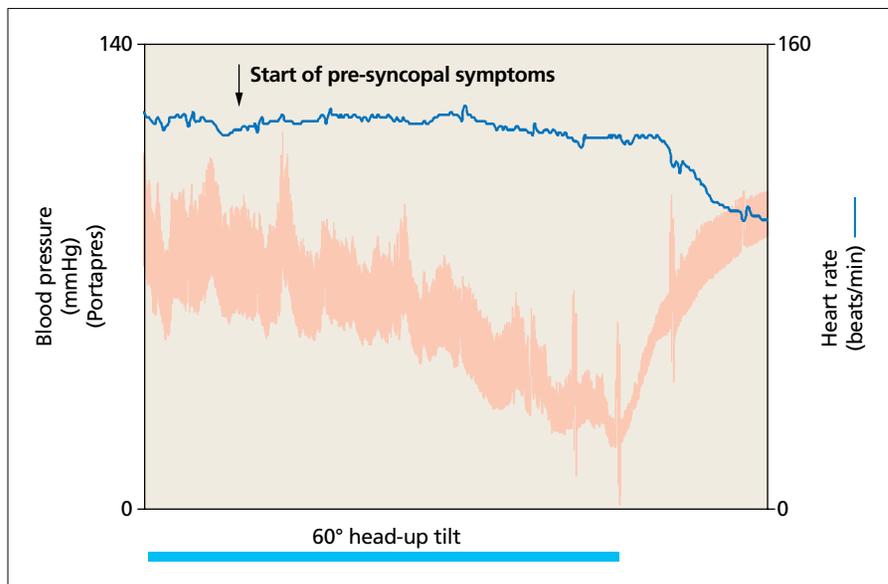

### Heart rate disturbances

Bradycardia, along with hypertension, sometimes occurs in cerebral tumours with or without raised intracranial pressure and during autonomic dysreflexia in high spinal cord injuries. In the latter, the afferent and vagal efferent components of the baroreflex arc are intact, and the heart slows in an attempt to control the rise in blood pressure. In pheochromocytoma, bradycardia with escape rhythms and atrioventricular dissociation occurs in response to a rapid rise in blood pressure.

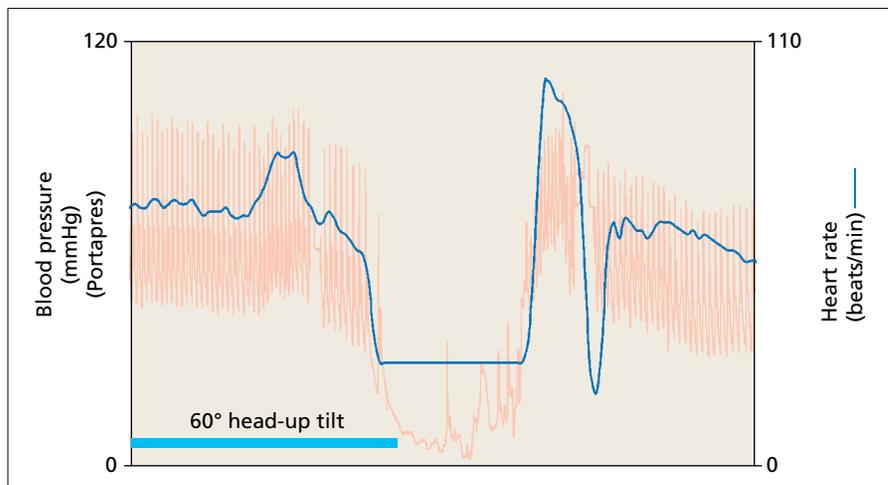

Severe bradycardia can occur in artificially ventilated high cervical cord injuries with diaphragmatic paralysis. The patients' intact vagal nerves are sensitive to hypoxia and stimuli such as

**Figure 24.12** Continuous blood pressure and heart rate measured non-invasively (by Portapres) in a patient with falls of unknown aetiology. Left carotid sinus massage caused a fall in both heart rate and blood pressure. The findings indicate the mixed (cardio-inhibitory and vasodepressor) form of carotid sinus hypersensitivity. Source: Mathias 2013. Reproduced with permission of Oxford University Press.

**Figure 24.13** Blood pressure and heart rate measured continuously before, during and after 60° head-up tilt by the Finometer in (a) a normal subject, and (b) in subject with the postural tachycardia syndrome (PoTS). Source: Mathias *et al.* 2012. Reproduced with permission of Macmillan.

tracheal suction can readily induce bradycardia and even cardiac arrest. The inability to increase sympathetic activity is likely to contribute. Similar responses also occur in tetraplegic patients during general anaesthesia, especially when muscle paralysis followed by intubation is performed without atropine.

In neurally mediated syncope, severe bradycardia occurs in conjunction with hypotension. Syncope can even occur when the heart rate is preserved by a cardiac demand pacemaker, because sympathetic withdrawal alone can cause substantial vasodilatation resulting in hypotension.

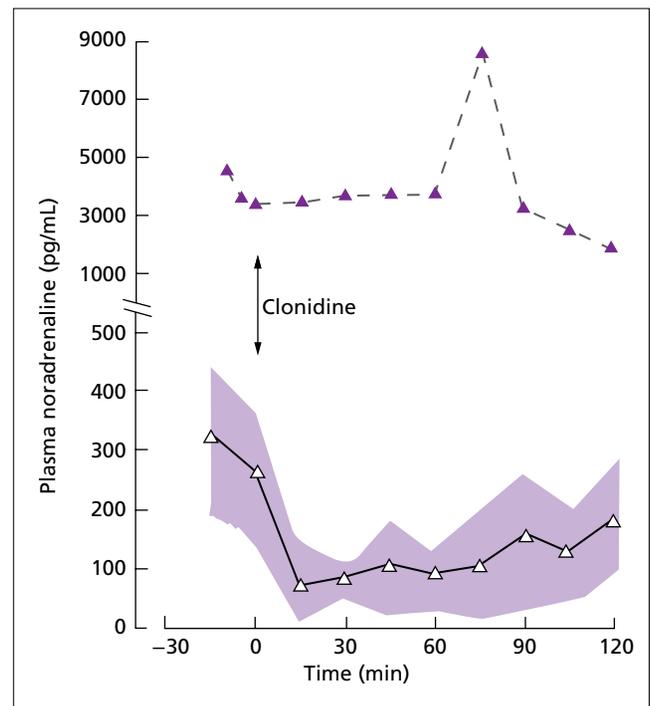

**Figures 24.14** Clinical signs of joint hypermobility in a patient with PoTS and joint hypermobility syndrome/Ehlers-Danlos syndrome type III (also known as EDS hypermobility type). Source: Mathias *et al.* 2012. Reproduced with permission of Macmillan.

**Figure 23.15** Clinical signs of joint hypermobility in a patient with PoTS and joint hypermobility syndrome/Ehlers-Danlos syndrome type III (also known as EDS hypermobility type). Source: Mathias *et al.* 2012. Reproduced with permission of Macmillan.

In diabetes mellitus, the presence of a cardiac vagal neuropathy can result in higher resting heart rate and impaired sinus arrhythmia and abnormalities on other tests of cardiac parasympathetic function (Figure 24.17). Disorders of cardiac conduction are common in Chagas' disease (South American trypanosomiasis) and sometimes in amyloidosis.

In PoTS, tachycardia is usually associated with head-up postural change and exertion. Tachycardia resulting from increased sympathetic discharge occurs along with hypertension in the Guillain-Barré syndrome and in tetanus. In phaeochromocytoma, tachycardia results from catecholamine release and  $\beta$ -adrenoceptor stimulation.

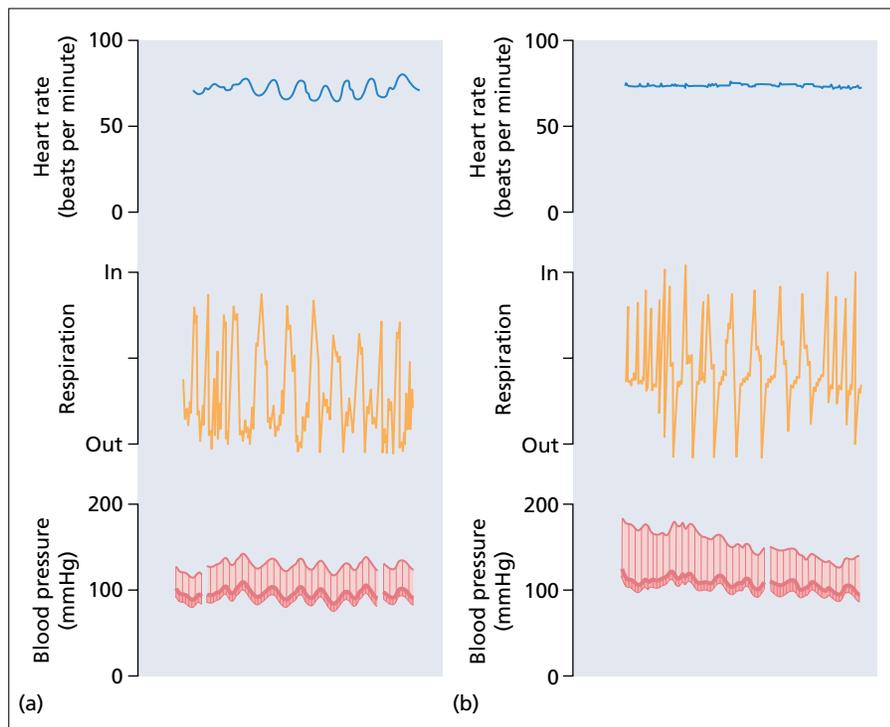

**Figure 24.16** Plasma noradrenaline levels in a patient with a phaeochromocytoma (black triangles) and in a group of patients with essential hypertension (open triangles) before and after intravenous clonidine, indicated by an arrow ( $2 \mu\text{g}/\text{kg}$  over 10 minutes). Plasma noradrenaline levels fall rapidly in the essential hypertensives after clonidine and remain low over the period of observation. The stippled area indicates the  $\pm$  standard error of mean (SEM). Plasma noradrenaline levels are considerably higher in the phaeochromocytoma patient and are not affected by clonidine. Source: Mathias and Bannister 2013. Reproduced with permission of Oxford University Press.

### Facial and peripheral vascular changes

When blood pressure falls in postural hypotension or neurally mediated syncope, there is usually facial pallor with an ashen appearance. Restoration of colour follows promptly on assuming the supine position when blood pressure rises. Facial pallor can also occur during an attack in phaeochromocytoma but usually is accompanied by sweating, headache and hypertension. In long-standing tetraplegia, hypertension during autonomic dysreflexia is often accompanied by flushing and sweating over the face and neck. The precise mechanisms are unknown.

In Harlequin syndrome there is vasodilatation and anhidrosis on one side of the face caused by sympathetic impairment, with sparing of the pupil. The lesion spares the first thoracic segment (from which oculomotor fibres often leave) but affects sympathetic fibres of the second and third thoracic roots.

Raynaud's phenomenon can be seen in both PAF and MSA, for reasons that are unknown. In the latter, cold purplish blue hands and feet can be particularly troublesome. Livedo reticularis can accompany sympathetic over-activity, as in phaeochromocytoma. In erythromelalgia there is limb discomfort with vascular changes. The precise reasons for the cutaneous, vascular and sudomotor changes in reflex sympathetic dystrophy (chronic region pain disorder) remain debatable.

**Figure 24.17** The effect of deep breathing on heart rate and blood pressure in (a) a normal subject, and (b) a patient with autonomic failure of the sort seen in diabetes. There is no sinus arrhythmia in the patient, despite a fall in blood pressure. Respiratory changes are indicated in the middle panel. Source: Mathias and Bannister 2013. Reproduced with permission of Oxford University Press.

### Sudomotor system

The eccrine glands concerned with temperature regulation are innervated by sympathetic cholinergic fibres, unlike apocrine glands on palms and soles which are influenced by circulating substances, predominantly catecholamines. Anhidrosis or hypohidrosis is common in PAF and differences in sweating may first be noticed during exposure to warm temperatures. Occasionally, hyperhidrosis in segmental areas can be a disconcerting symptom, as a compensatory response to diminished sudomotor activity elsewhere. Anhidrosis may be congenital and occur without any other deficit. It can be an integral component of certain hereditary sensory and autonomic neuropathies, such as congenital insensitivity to pain with anhidrosis (HSAN type IV; Chapter 23).

Localised or generalised anhidrosis, sometimes with compensatory hyperhidrosis, can be associated with the Holmes–Adie pupil. This association is known as Ross’s syndrome. In spinal cord injuries, there is often a band of hyperhidrosis above the lesion with anhidrosis below. During autonomic dysreflexia in high spinal lesions sweating occurs mainly over the face and neck. Facial and truncal hyperhidrosis can occur in Parkinson’s disease. Hyperhidrosis is seen intermittently in pheochromocytoma and accompany hypertension in tetanus.

Localised hyperhidrosis over the face and neck caused by food (gustatory sweating) can be socially distressing. It occurs in diabetes mellitus, following Bell’s palsy and after parotid surgery, as a result of aberrant connections between nerve fibres supplying the salivary and sweat glands. Minimally invasive endoscopic techniques for sympathectomy often are successful in reducing axillary and palmar hyperhidrosis, but some develop troublesome compensatory hyperhidrosis over innervated areas of the trunk and lower limbs. The mechanisms are unclear.

Hypothermia can occur in hypothalamic disorders and in the elderly, in whom degenerative hypothalamic lesions are sometimes postulated. In high spinal injuries, especially in the early phases, the absence of ‘shivering thermogenesis’ and inability to vasoconstrict and thus prevent heat loss can readily result in hypothermia. Hypothermia can be missed if oral temperature only is recorded without a low-reading thermometer. Measurement of core tympanic or rectal temperature is essential.

Hyperpyrexia may be a problem with anhidrosis, with exposure to high ambient temperatures. Heat also increases vasodilatation and can enhance orthostatic hypotension leading to collapse.

### Alimentary system

Reduced salivation and a dry mouth (xerostomia) occur in autonomic disease, especially in pure cholinergic dysautonomia. It can cause dysphagia, prominent when eating dry food. The lower two-thirds of the oesophagus contains smooth muscle that is autonomically innervated. Diseases affecting these pathways often cause dysphagia. Dysphagia is unusual in PAF, but often occurs in the later stages of MSA, where the problem is usually in the oropharyngeal region and can result in tracheal aspiration. The oesophagus is involved in Chagas’ disease, with achalasia and mega-oesophagus causing vomiting. Gastric stasis in diabetes mellitus can cause abdominal distension and vomiting of undigested food.

Constipation is common in PAF but diarrhoea can also occur as result of overflow. Diarrhoea, especially at night, can be a distressing problem in diabetes mellitus. Reasons postulated include incomplete digestion, altered bowel flora and abnormal motility, but the cause remains poorly understood. Gastro-intestinal disturbances (reflux, abdominal bloating, low transit and constipation) previously classed as the irritable bowel

syndrome are being increasingly recognised in association with PoTS and Ehlers–Danlos III.

### Kidneys and urinary tract

Nocturnal polyuria is a frequent symptom in PAF. The causes include restitution of blood pressure sometimes to elevated levels while supine, redistribution of blood from the peripheral into the central compartment, and alteration in release of hormones that influence salt and water handling (such as renin, aldosterone and atrial natriuretic peptide). In MSA, where there is additional autonomic impairment of bladder and sphincter control, nocturia can be particularly troublesome. By day, the low level of blood pressure when upright is likely to cause oliguria.

Autonomic disease can cause urinary frequency, urgency, incontinence or retention. Loss of sacral parasympathetic function, as in the early phase of spinal cord injury, causes an atonic bladder with urinary retention, whereas recovery of isolated spinal cord function results in a neurogenic bladder. Dyssynergia, with detrusor contraction but without sphincter relaxation, causes autonomic dysreflexia. Ureteric reflux predisposes to renal damage, especially in the presence of infection. In PAF, urinary symptoms initially may be attributed in older men to prostatic hypertrophy and in women to pelvic muscle weakness, especially in those who are multiparous. In MSA, surgery in suspected prostate enlargement usually is of no benefit. The use of drugs with anticholinergic effects sometimes unmasks urinary bladder dysfunction in autonomic failure.

Infection is common when bladder dysfunction causes urinary stasis. Some patients, such as those with spinal injuries, are prone to urinary calculi, especially when immobility increases calcium excretion. In PoTS and joint hypermobility syndrome (Ehlers–Danlos III), female patients have a greater tendency to recurrent urinary tract infections, sometime difficult to eradicate when there is interstitial cystitis. Whether laxity of the bladder wall contributes is unclear.

### Sexual function

In the male, failure of erection, dependent partly on the parasympathetic system, can cause impotence. Ejaculation is controlled by the sympathetic system. Retrograde ejaculation can occur, especially if there are urinary sphincter abnormalities. Dissociating the effects of increasing age, systemic illness and depression from definable organic causes of impotence can be difficult and the effect of concomitant drug therapy needs consideration (Chapter 25). The 5-HT uptake inhibitor, fluoxetine, prolongs ejaculation. Other drugs normally not considered to have autonomic side effects, such as thiazides used in hypertension, can diminish sexual potency.

Priapism resulting from abnormal spinal reflexes sometimes occurs in patients with spinal cord lesions. In women, autonomic impairment does not appear directly to affect sexual function, although this has been inadequately studied.

### Eyes and lacrimal glands

The non-striated component of the levator palpebrae superioris (Müller's muscle) is innervated by sympathetic fibres and a mild ptosis is part of Horner's syndrome. If sympathetic lesions are bilateral, as in high spinal cord transection, Horner's syndrome is difficult to detect. A variety of pupillary abnormalities occur with autonomic involvement; both the miosis of Horner's syndrome and dilated myotonic pupils in Holmes–Adie syndrome. Symptoms directly relating to ocular function can be minimal in such disorders. Night vision is impaired in sympathetic denervation. There is reduced tolerance to sunlight when pupils are dilated following

parasympathetic failure. The ciliary muscle is innervated by parasympathetic nerves; blurred vision caused by cycloplegia may follow disease or anticholinergic drugs. The latter can also raise intra-ocular pressure and cause glaucoma.

Impaired tear production can occur in PAF, sometimes as part of a presumed sicca or Sjögren's syndrome, along with diminished salivary secretion. Excessive and inappropriate lacrimation occurs in crocodile tears syndrome (gusto-lacrimal reflex).

### Respiratory system

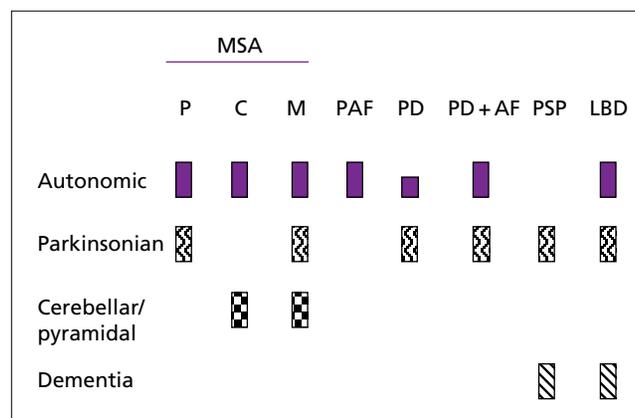

Involuntary inspiratory sighs, stridor and snoring of recent onset are more frequent in MSA than in Parkinson's disease. Stridor results from weakness of the crico-arytenoid muscles, the main laryngeal abductors. Nocturnal apnoea, which occurs in the later stages of the disorder, is caused by involvement of brainstem respiratory centres.

Abnormal responses following activation of reflexes from the respiratory tract, such as during tracheal suction, can cause profound cardiovascular disturbances. Thus, for example, severe hypertension and tachycardia can occur in tetanus, and bradycardia and cardiac arrest with high cervical cord transection.

### Additional features of neurological conditions: MSA and Parkinson's disease

In the parkinsonian form of MSA, bradykinesia and rigidity with minimal tremor are more likely than in idiopathic Parkinson's disease (Figure 24.18). This causes difficulties in mobility, especially turning in bed and changing direction. Facial expression is affected to a lesser degree in MSA than in idiopathic Parkinson's disease. In MSA there often is a response to antiparkinsonian agents in the early stages but drug side effects, such as orthostatic hypotension, are likely to occur as the disease progresses. In Parkinson's disease with autonomic failure, extrapyramidal features have often been present for a long period and usually remain responsive to levodopa therapy.

In the non-parkinsonian forms of MSA, cerebellar features predominate with an ataxic gait, intention tremor, scanning speech and

**Figure 24.18** The major clinical features in parkinsonian syndromes and allied disorders with autonomic failure. These include the three major neurological forms of multiple system atrophy (MSA); the parkinsonian form (MSA-P, also called striatonigral degeneration), the cerebellar form (MSA-C, also called olivopontocerebellar atrophy) and the multiple or mixed form (MSA-M, which has features of both other forms), pure autonomic failure (PAF), idiopathic Parkinson's disease (IPD), Parkinson's disease with autonomic failure (PD + AF), progressive supranuclear palsy (PSP) and diffuse Lewy body disease (LBD). After Mathias (1997, 2005).

nystagmus. Ataxia can be difficult to separate from or perhaps be compounded by unsteadiness caused by orthostatic hypotension. There also may be pyramidal involvement with increased tone, exaggerated tendon reflexes and extensor plantar responses. In the mixed form of MSA, a varying combination of extrapyramidal, cerebellar and pyramidal features is seen. Sensory deficits are uncommon in MSA. Patients with secondary autonomic failure have neurological features that are a part of, or a complication of, a primary disease. In diabetes mellitus, a sensorimotor neuropathy often coexists with, or precedes the autonomic neuropathy.

### Psychological and psychiatric disturbances

Dementia is unusual in PAF. Most patients with MSA are not clinically depressed, despite their disabilities and the probable deficit in central catecholamine levels. Overall, they tend to have a normal affective state, especially when comparisons are made with Parkinson's disease. In PAF there is no psychological disorder, but the absent autonomic responses can result in subtle emotional deficits. They appear less emotional than normal subjects and, when compared with similarly disabled patients with Parkinson's disease without autonomic failure, are less anxious. Cognitive function may transiently be affected when blood pressure falls below critical cerebral perfusion pressure limits. Whether this affects certain tasks (e.g. involving attention) rather than others, is unclear.

Anxiety and tremulousness may occur in phaeochromocytoma. Psychological factors contribute to vasovagal syncope (hence the term 'emotional syncope') and also to essential hyperhidrosis. Whether this is the cause, or result, of the autonomic condition can be difficult to determine. Anxiety is frequently observed in PoTS and joint hypermobility syndrome (Ehlers–Danlos III), especially in those with multiple morbidities who have been undiagnosed for many years with symptoms attributed to psychological factors. Psychiatric disturbances can also complicate conditions associated with autonomic dysfunction such as porphyria.

### Clinical examination

A detailed physical examination is essential and, with the symptoms elicited, provides important clinical pointers towards autonomic disease. Features on general examination include dryness of skin, hyperhidrosis or cold hands in Raynaud's disease, and pupillary changes. Measurement of blood pressure, both lying and standing (or sitting), is needed to determine if orthostatic hypotension is present, as is recording the pulse rate changes in patients with PoTS. The extent and distribution of the neurological abnormalities provide important clues to underlying central or peripheral autonomic disorders. Examination of other systems, as in hepatic disease, diabetes and joint hypermobility syndrome (Ehlers–Danlos III), is necessary along with urine testing for glucose and protein.

The combination of a detailed history and physical examination is crucial in determining if autonomic disease is present, in ascertaining the probable underlying diagnosis and also for interpreting the results of autonomic tests in the context of the associated disorder.

### Investigations

The aims of investigations in autonomic dysfunction are twofold. The first relates to diagnosis. The second is to understand the pathophysiological basis of disturbed autonomic function, as this often forms the basis of treatment strategies and their evaluation. An outline of investigations is provided in Table 24.8.

## Management

The management of autonomic dysfunction encompasses a number of aspects. Of immediate and practical importance is alleviation of symptoms. The ideal is to rectify the autonomic deficit and cure the underlying disorder but this rarely is achieved. Autonomic

disease often involves various systems. Basic principles in relation to management of the major clinical features are provided here. Specific aspects vary in different diseases and always should be directed to the needs of the individual patient.

## Cardiovascular system

### Orthostatic hypotension

Orthostatic hypotension causes few symptoms in some but can cause considerable distress in others. It can contribute to disability and even death because of the potential risk of substantial injury. Treatment may be needed even in those who are asymptomatic, as they are at risk in situations such as fluid depletion or treatment with vasodilator drugs when there may be marked falls in blood pressure.

No single drug or treatment can effectively replace the actions of the sympathetic nervous system in different situations. A multi-pronged approach, combining non-pharmacological and pharmacological measures, is usually needed (Table 24.9).

The doctor and patient should be aware of the limitations of treatment and associated deficits (such as cerebellar features in MSA) can limit mobility in some patients, despite effective treatment of orthostatic hypotension.

Increasing patient awareness of factors that lower blood pressure is important. Rapid postural change, especially in the morning when getting out of bed, must be avoided because the supine blood

pressure often is lowest at this time. Prolonged bed rest and recumbency through factors that include decompensation can contribute to orthostatic intolerance even in healthy individuals and can considerably worsen orthostatic hypotension in autonomic failure. Head-up tilt at night is beneficial and reduces salt and water loss by stimulating the renin–angiotensin–aldosterone system. Straining during micturition and defaecation lowers blood pressure further by inducing a Valsalva manoeuvre. In toilets in small enclosed areas (e.g. in aircraft), the severe hypotension induced can be dangerous because of the inability to fall to the floor and thereby recover blood pressure and consciousness. In hot weather, because of impairment of thermoregulatory mechanisms, the rise in body temperature will increase cutaneous vasodilatation and worsen orthostatic hypotension. Ingestion of alcohol or large meals, especially those with a high carbohydrate content, causes splanchnic vasodilatation and postprandial hypotension which can aggravate orthostatic hypotension. Various physical manoeuvres, such as leg crossing, squatting, sitting in the knee–chest position and abdominal compression, reduce orthostatic hypotension (Figure 24.19). Drugs needed for associated symptoms (such as dopaminergic drugs) or to improve quality of life (sildenafil for erectile failure) lower blood pressure further.

Lower limb elastic compression stockings, abdominal binders and positive-gravity suits reduce venous pooling during standing. Each has its limitations and increases susceptibility to orthostatic hypotension when not in use. Water ingestion (250–500 mL) raises blood pressure substantially in PAF by mechanisms that remain unclear (Figures 24.20 and 24.21). The ensuing diuresis can be troublesome, especially in MSA with associated urinary bladder disturbances.

Drugs that act in a variety of ways to raise blood pressure are often needed in association with non-pharmacological measures in moderate to severe orthostatic hypotension (Table 24.10). A valuable first line drug is fludrocortisone in a dosage of 50–100 µg at night or twice daily. It acts by retaining salt and water and increasing the sensitivity of blood vessels to pressor substances. In some patients ankle oedema, and with higher doses hypokalaemia, are unwanted effects.

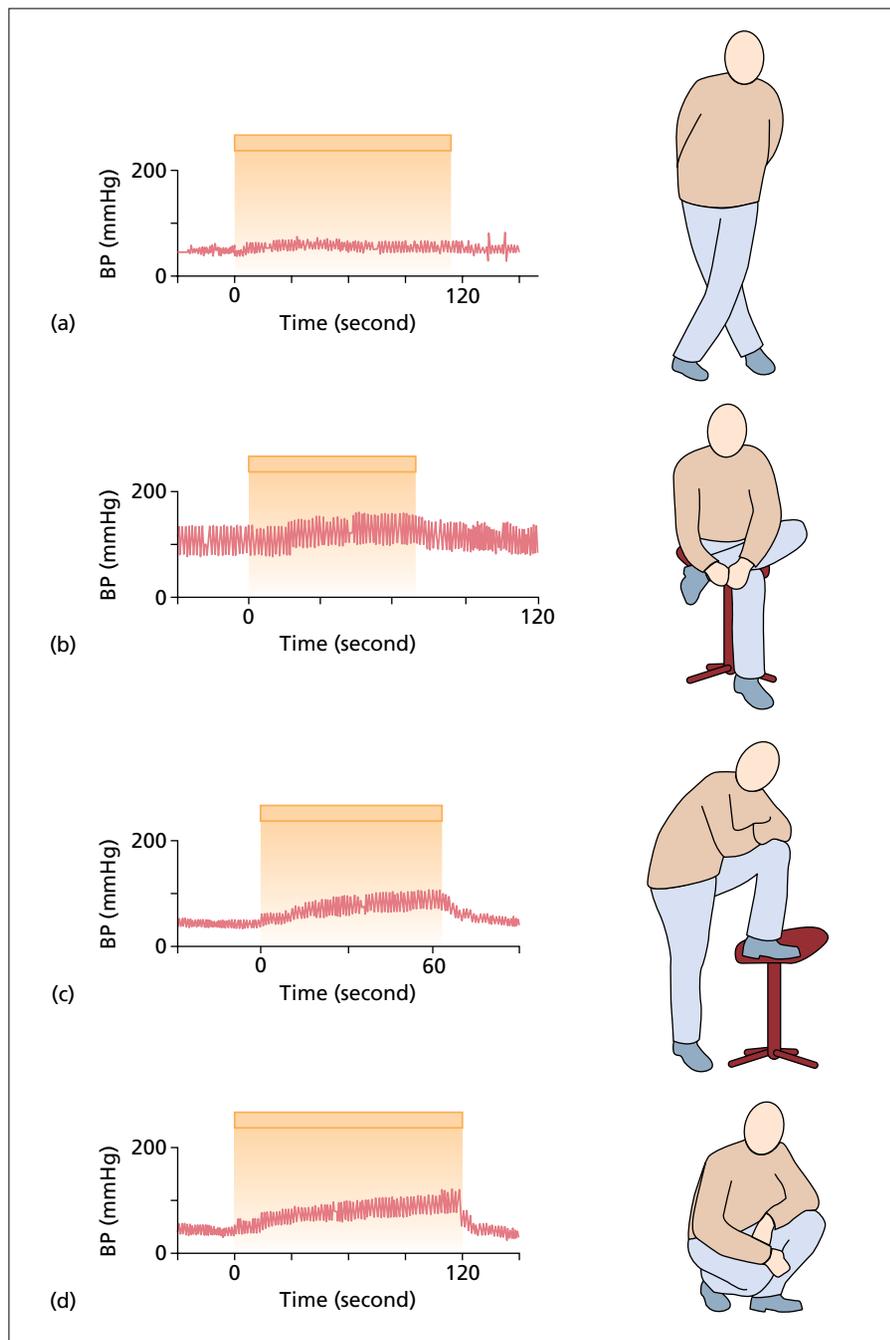

The second line drugs include those that mimic actions of noradrenaline. Ephedrine (15 mg three times daily to a maximum of 45 mg three times daily), which acts both directly and indirectly, raises blood pressure in central and incomplete autonomic lesions, including MSA. In peripheral sympathetic lesions, such as PAF, it can have minimal effects. Tachycardia, tremor and insomnia limit use of higher doses. In peripheral lesions, where ephedrine may not be effective, midodrine (2.5 µg to a maximum of 10 µg three times daily) is used. It is converted to the active metabolite, desglymidodrine, which acts on α-adrenoceptors. Side effects include a tingling scalp, goose pimples and, in the male, urinary retention. The ergot alkaloid, dihydro-ergotamine, acts predominantly on venous capacitance vessels, but its effects are limited by its poor absorption necessitating high oral doses (5–10 mg three times daily).

In dopamine beta-hydroxylase (DβH) deficiency, a rare genetic disorder, there is an absence of plasma noradrenaline and adrenaline with increased plasma dopamine levels, resulting in severe orthostatic hypotension (Figure 24.22). Symptoms noted during infancy include hypotension, hypotonia and hypothermia. Children with DβH deficiency cannot exercise fully because their blood pressure falls, causing syncope. Symptoms usually worsen during the first two decades and severe orthostatic hypotension becomes prominent in adulthood. DβH deficiency is caused by changes in *DBH* gene expression and is inherited as an autosomal recessive disorder. Restoration of plasma noradrenaline is achieved by treatment with the precursor of noradrenaline, L-threo-3–4-dihydroxyphenylserine

**Table 24.9** Approaches to management of orthostatic hypotension (e.g. in chronic autonomic failure).

<b>Non-pharmacological measures</b>
<b>To be avoided</b>
Sudden head-up postural change (especially on waking)
Prolonged recumbency
Straining during micturition and defaecation
High environmental temperature (including hot baths)
Severe exertion
Large meals (especially with refined carbohydrate)
Alcohol
Drugs with vasodepressor properties
<b>To be introduced</b>
Head-up tilt during sleep
Small frequent meals
High salt intake
Judicious exercise (including swimming)
Body positions and manoeuvres
<b>To be considered</b>
Elastic stockings
Abdominal binders
Water ingestion
<b>Pharmacological measures</b>
Starter drug (fludrocortisone)
Sympathomimetics (ephedrine, midodrine, L-DOPS)
Specific targeting (octreotide, desmopressin, erythropoietin)

L-DOPS, L-dehydroxyphenylserine.

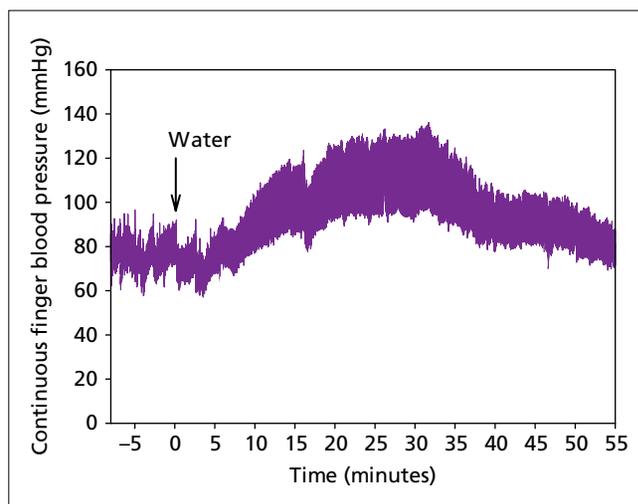

**Figure 24.19** (a–d) Physical counter-manoeuvres using isometric contractions of the lower limbs and abdominal compression. The effects of leg crossing in standing and sitting positions, placing a foot on a chair and squatting, on blood pressure in a 54-year-old male patient with PAF and incapacitating OH. The patient was standing (sitting) quietly prior to the manoeuvres. Bars indicate the duration of the manoeuvres. Source: Smit *et al.* 1997. Reproduced with permission from John Wiley & Sons.

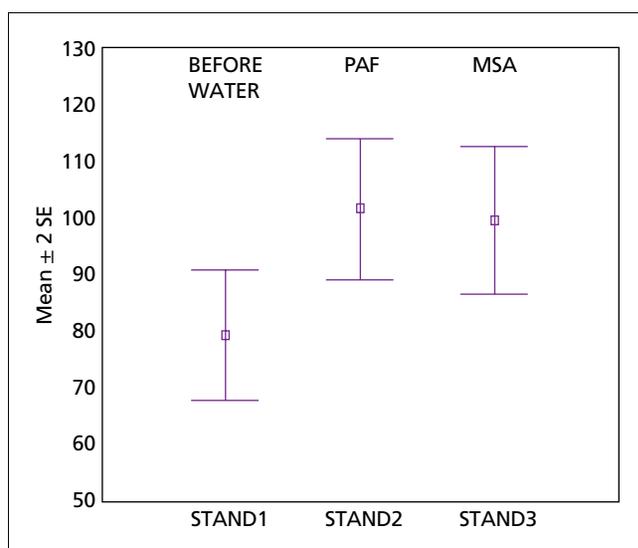

(DOPS), which has a structure similar to noradrenaline but with a carboxyl group. It can be given by mouth and is converted from the inert form to noradrenaline by the enzyme dopa decarboxylase, thus bypassing the DBH deficiency. It thus replaces the deficient neurotransmitter and has been remarkably effective in this condition (Figure 24.23). DOPS can benefit other patient groups with PAF.

Specific targeting of pathophysiological mechanisms should be introduced when the combination of fludrocortisone and sympathomimetics is not effective. Nocturnal polyuria often worsens

morning orthostatic hypotension. The vasopressin-2 receptor agonist, desmopressin, orally at night (e.g. 5–40 µg intranasally) is a potent antidiuretic with minimal direct pressor activity. In MSA with nocturia also caused by bladder disturbances, desmopressin can be of considerable benefit in allowing less disturbed rest. Smaller doses are needed in PAF patients who appear more sensitive than those with MSA. Plasma sodium should be measured at intervals to exclude hyponatraemia. Water intoxication can be reversed by stopping the drug, and withholding water.

**Figure 24.20** Changes in blood pressure before and after 500 mL distilled water ingested at time '0' in a patient with pure autonomic failure. Blood pressure is measured continuously using the Portapres II. Source: Cariga and Mathias 2001. Reproduced with permission of Portland Press and the Biochemical Society.

**Figure 24.21** Standing blood pressure in seven pure autonomic failure (PAF) and seven multiple system atrophy (MSA) patients before and 15 and 30 minutes after ingestion of 500 mL water. Source: Young and Mathias 2004. Reproduced with permission of BMJ.

In postprandial hypotension, large meals should be avoided; instead small meals with low carbohydrate content should be eaten at frequent intervals. Drinking coffee after meals can help as caffeine blocks vasodilatory adenosine receptors. A dose of 250 mg (present in two cups of typical espresso) can be used although tolerance sometimes develops. The somatostatin analogue, octreotide (25 or 50 µg, ideally 30 minutes before food) prevents postprandial hypotension by inhibiting release of a variety of vasodilatory gastrointestinal peptides. It also reduces postural and exercise-induced hypotension. Side effects include abdominal colic and loose stools which respond to spasmolytics (Buscopan) and opiates (codeine

**Table 24.10** Outline of mechanisms by which drugs reduce postural hypotension.

#### Reducing salt loss/plasma volume expansion

Mineralocorticoids (fludrocortisone)

#### Reducing nocturnal polyuria

V<sub>2</sub>-receptor agonists (desmopressin)

#### Vasoconstriction

##### Sympathetic

On resistance vessels (ephedrine, midodrine, phenylephrine, noradrenaline, clonidine, tyramine with monoamine oxidase inhibitors, yohimbine, L-dihydroxyphenylserine)

On capacitance vessels (dihydroergotamine)

##### Non-sympathomimetic

V<sub>1</sub>-receptor agents (terlipressin)

#### Increasing acetylcholine

Acetylcholine esterase inhibitors (pyridostigmine)

#### Preventing vasodilatation

Prostaglandin synthetase inhibitors (indometacin, flurbiprofen)

Dopamine receptor blockade (metoclopramide, domperidone)

Beta<sub>2</sub>-adrenoceptor blockade (propranolol)

#### Preventing postprandial hypotension

Adenosine receptor blockade (caffeine)

Peptide release inhibitors (somatostatin analogue: octreotide)

#### Increasing cardiac output

Beta-blockers with intrinsic sympathomimetic activity (pindolol, xamoterol)

Dopamine agonists (ibopamine)

#### Increasing red cell mass

Erythropoietin

phosphate and loperamide). Octreotide does not appear to enhance supine nocturnal hypertension.

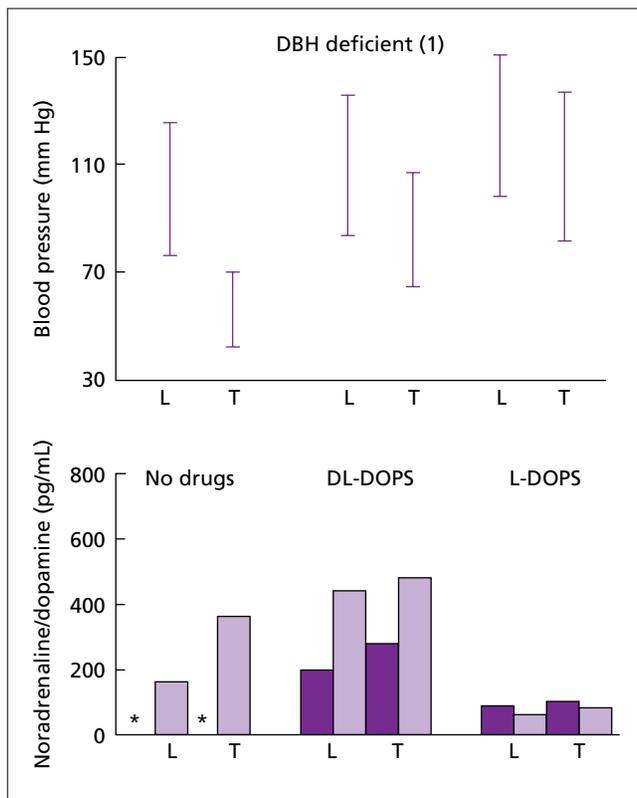

Anaemia worsens symptoms of orthostatic hypotension and can occur in PAF and with renal impairment, in diabetes mellitus and in systemic amyloidosis. Erythropoietin (given subcutaneously) stimulates red cell production, raises red cell mass and haemoglobin levels. This reduces orthostatic hypotension and its symptoms in such situations.

Difficulties in the management of orthostatic hypotension have resulted in an array of drugs that have been reported to provide benefit in individual cases or in certain disorders (Tables 24.11 and 24.12). As with all drugs they should be used cautiously. Some have serious side effects such as cardiac failure with pindolol, and gastric ulceration and haemorrhage with indometacin. The use of a noradrenaline pump in extreme cases has been used with benefit.

Drugs should be used to reduce the side effects of therapy that is essential for associated disease. When levodopa is used to treat parkinsonism, higher doses of dopa-decarboxylase inhibitors should be used. The dopamine antagonists metoclopramide and domperidone also reduce the peripheral effects of dopamine.

#### Supine hypertension

Supine hypertension occurs frequently in PAF and can be worsened by drug treatment. It is unclear if certain drugs, such as higher doses of fludrocortisone, are more likely to cause it. Supine

**Figure 24.22** Blood pressure (systolic and diastolic) while lying (L) and during head-up tilt (T) in one of two siblings with dopamine beta hydroxylase (D $\beta$ H) deficiency (1) before, during and after treatment with DL-DOPS (racemic mixture; DOPS, dihydroxyphenylserine) and L-DOPS (laevo form). The laevo form causes a greater rise in blood pressure and a greater reduction in postural hypotension than the racemic mixture. (From Mathias *et al.* 1990, with permission.)

hypertension increases symptoms of cerebral ischaemia during postural change through an unfavourable resetting of cerebral autoregulatory mechanisms. Head-up tilt especially at night is probably the most practical method to prevent nocturnal supine hypertension. Omission of the evening dose of vasopressor agents, a pre-bedtime snack or alcohol to induce postprandial hypotension, and sometimes even use of short-acting antihypertensive drugs should be considered.

The long-term possible effects of supine hypertension include cardiac hypertrophy and damage to subcortical cerebral vessels. This can occur in PAF; these patients have a good prognosis and drugs can be used over many years. The benefits of treating orthostatic hypotension effectively, thus reducing the likelihood of trauma and improving their quality of life, should be weighed against the long-term risks.

### Autonomic mediated syncope

Management is dependent on the cause, provoking factors, disability caused and whether the episodes are of the cardio-inhibitory, vasodepressor or mixed type. Vasovagal syncope usually carries an excellent prognosis. Once the diagnosis is confirmed, an important component is positive reassurance. Advice on non-pharmacological measures includes ensuring salt repletion, an adequate fluid intake and techniques to enhance sympathetic activity and prevent pooling.

These include the use of isometric hand exercise and activation of the calf muscle pump. If necessary, subjects should lie flat with their legs upright or with their head between the knees. Each subject should decide on which methods to use effectively in different situations. This is of particular value when there is a window of warning before the loss of consciousness. In vasodepressor syncope, low-dose fludrocortisone and sympathomimetics can be used if needed. Ephedrine is contraindicated if tachycardia is a problem; midodrine is the alternative. In those with a predominant cardio-inhibitory component, a demand pacemaker needs consideration especially when there is minimal warning before fainting. Cognitive behavioural psychotherapy is helpful if there is coexisting phobia, panic attack or anxiety disorder. 5-HT and noradrenaline uptake inhibitors such as fluoxetine, sertraline and venlafaxine have also been used.

In carotid sinus hypersensitivity, a cardiac demand pacemaker often is needed in the cardio-inhibitory and mixed forms. When the vasodepressor component is present and persists following pacemaker insertion, vasopressor agents including midodrine should be considered. Caution should be exercised as these patients often are elderly and sometimes have vascular disease and prostatic hypertrophy which increase the tendency to side-effects. In unilateral hypersensitivity, carotid sinus denervation is sometimes carried out.

In situational syncope, management should be directed towards the underlying cause and pathophysiological basis. In micturition syncope, occurring mainly in males, advice is needed to avoid contributing factors (e.g. alcohol). The bladder should be emptied while sitting rather than standing, especially if the patient has to pass urine during the night.

### Postural tachycardia syndrome

Patients with postural tachycardia syndrome often need a combination of measures. Tachycardia is often associated with a low supine level of blood pressure, and a substantial number also have vasovagal syncope. Treatment is similar to the vasodepressor form of vasovagal syncope, with non-pharmacological measures and if needed drugs such as fludrocortisone and sympathomimetics. Ephedrine is contraindicated. Midodrine does not cause tachycardia and is the sympathomimetic of choice. Beta-adrenoceptor blockers, especially cardioselective ones such as bisoprolol, have a role. In those with blood pressure lability or more sustained elevations there is a role for the central sympatholytic drug, clonidine. A selective sinus node blocker, ivabradine, has also been used to reduce tachycardia.

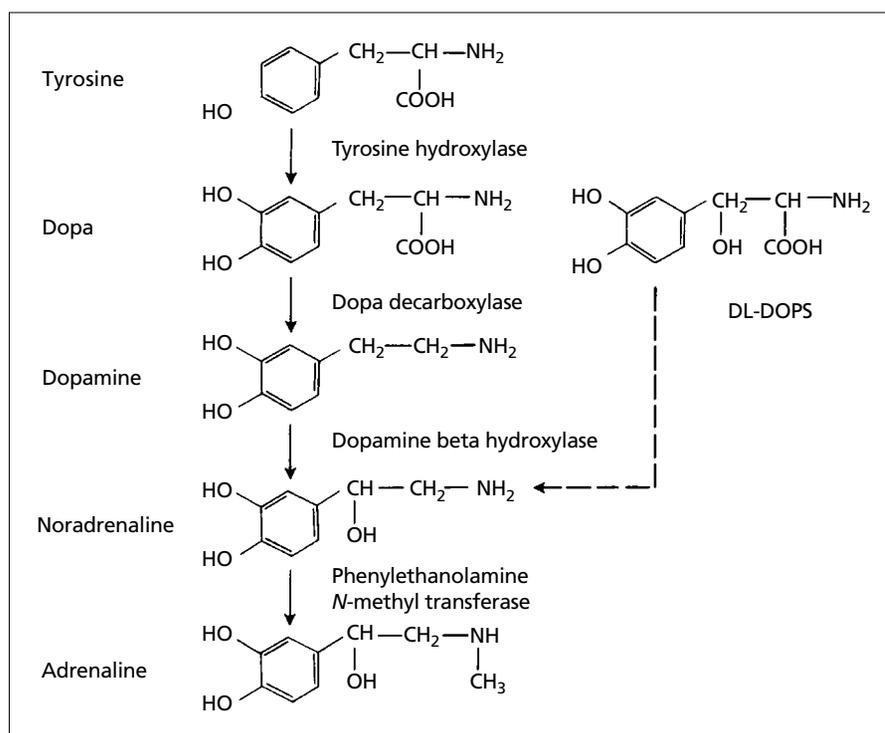

### Hypertension

Hypertension resulting from increased sympathetic nervous activity in the Guillain-Barré syndrome and following subarachnoid haemorrhage often responds to propranolol and sympatholytic agents. In high spinal cord injuries, determining and rectifying the provoking cause of autonomic dysreflexia is crucial, as the key is prevention. A range of drugs, based on knowledge of the pathophysiological mechanisms, can be used to prevent or reduce hypertension in such patients (Table 24.11).

### Sudomotor disorders

#### Anhidrosis

The ensuing problems include dry skin, hyperthermia and vasomotor collapse in hot weather. Dry skin is helped by suitable emollients. Prevention of hyperthermia is important by avoiding exposure to heat and ensuring a suitable micro-environment, ideally by air conditioning. Mechanisms to aid heat loss include tepid sponging to aid evaporation, fans to enhance convection loss and

**Figure 24.23** Biosynthetic pathway in the formation of adrenaline and noradrenaline. The structure of DL-DOPS is indicated on the right. It is converted directly to noradrenaline by dopa decarboxylase, thus bypassing dopamine  $\beta$ -hydroxylase.

**Table 24.11** Drugs used for reducing hypertension in autonomic dysreflexia.

Afferent		Topical lidocaine
Spinal cord		Clonidine*
		Reserpine*
		Spinal anaesthetics
Efferent	Sympathetic ganglia	Hexamethonium
	Sympathetic nerve terminals	Guanethidine
	Alpha-adrenoceptors	Phenoxybenzamine
Target organs	Blood vessels	Glyceryl trinitrate
		Nifedipine

\*Clonidine and reserpine have multiple effects, some of which are peripheral.

the ingestion of cool drinks. In severe hyperpyrexia, immersion in a cold bath may be needed.

### Hyperhidrosis

Management depends upon the underlying cause, the sites involved and the functional and emotional disability. In hyperhidrosis over the palms and soles, local application of astringents containing glutaraldehyde and antiperspirants containing aluminium salts reduces sweating as does iontophoresis (a local treatment that works by introducing an ionised substance through intact skin by the application of direct current). Low-dose oral pharmacotherapy includes anticholinergics (propranolol 15 mg three times daily)

**Table 24.12** Management strategy in autonomic failure.

#### Specific

For orthostatic hypotension and bladder, bowel, sexual dysfunction: non-pharmacological and pharmacological therapy

For respiratory abnormalities: consider tracheotomy

For oropharyngeal dysphagia: consider percutaneous endoscopic gastrostomy (PEG)

For depression: drug treatment

#### General education

Of patients and partners, relatives, carers, medical practitioners, supportive therapists, to include physiotherapists, occupational therapists, speech therapists and dietitians

#### Autonomic nurse specialist or autonomic liaison nurse

To link, coordinate and streamline specialist care with the patient, carers and community

and centrally acting sympatholytics (clonidine 25–50 µg three times daily). Side effects include a dry mouth. Glaucoma should be excluded prior to use of anticholinergics. Clonidine can reduce facial flushing. Topical anticholinergic cream (hyoscine hydrobromide or glycopyrrolate) may be helpful over small areas. Botulinum toxin is successful in hyperhidrosis affecting the axillae, palms and face. Injections may need to be repeated.

When these measures fail, surgical intervention using percutaneous endoscopic transthoracic sympathectomy, with ablation of prevertebral sympathetic ganglia from T2 to T4 should be considered. Ablation of T1/T2 is also used in facial flushing. In some, compensatory hyperhidrosis below the anhidrotic region can be extremely troublesome.

### Alimentary system

Xerostomia is helped by artificial saliva. Excessive salivation responds to botulinum injection. Achalasia of the oesophagus may require dilatation, botulinum injection or surgery. In MSA with oropharyngeal dysphagia, advice should be provided on the type and consistency of food; severe dysfunction increases the risk of tracheal aspiration and a feeding percutaneous gastrostomy is sometimes needed.

The dopamine antagonists metoclopramide and domperidone increase gastric emptying in gastroparesis, as does the macrolide erythromycin which stimulates motilin receptors. Peptic ulceration occurs in the early stages after high spinal cord injury and prophylaxis includes H<sub>2</sub> antagonists (cimetidine and ranitidine) and proton-pump inhibitors (omeprazole).

In diarrhoea caused by bacterial overgrowth, as in the blind loop syndrome, broad-spectrum antibiotics (neomycin or tetracycline) may be the initial step before using codeine phosphate or other opiate-based anti-diarrhoeal agents. Octreotide, the somatostatin analogue, can reduce diarrhoea in amyloidosis and diabetic autonomic neuropathy. Aperients and laxatives, together with a high-fibre diet, are needed in constipation.

### Urinary tract

In outflow tract obstruction, procedures which include prostatectomy, transurethral resection or sphincterotomy are sometimes needed. Surgical procedures often induce or worsen incontinence in MSA. Bladder dysfunction is helped by drugs that influence detrusor muscle activity (anticholinergics) or sphincter malfunction (alpha-adrenergic blockers). Intermittent or in-dwelling catheterisation may be necessary. Nocturia in PAF is often helped by intranasal or oral desmopressin given in the evening.

### Sexual function and the reproductive system

Erectile failure in men can be treated by suction devices, an implanted prosthesis or drugs. The latter can be given locally (intracavernosal or urethral) or orally (sildenafil). Sildenafil and allied drugs have the potential through vasodilatation to lower blood pressure substantially, especially in patients with orthostatic hypotension. In DβH deficiency, difficulty in ejaculation is improved by treatment with DOPS. Pregnant women with high spinal injuries can develop severe hypertension with cardiac dysrhythmias and eclampsia during uterine contractions and delivery. Spinal anaesthesia, which reduces spinal sympathetic discharge, often permits a normal delivery.

### Respiratory system

A tracheostomy is sometimes necessary in severe inspiratory stridor resulting from laryngeal abductor paresis, especially when oxygen desaturation occurs at night. With periodic apnoea, timed or triggered bi-level positive airway pressure ventilation may be

useful. In high spinal cord lesions on artificial ventilation particular care should be taken during tracheal suction and toilet to avoid bradycardia and even cardiac arrest. In ventilated tetanus patients, the reverse – tachycardia and hypertension – may occur.

### Eye and lacrimal glands

In alachryma, tear substitutes such as hypromellose eye drops are needed. Cycloplegia can be reduced by local cholinomimetics such as pilocarpine. Patients should be made aware of night blindness in sympathetic denervation and of a low threshold to sunlight in parasympathetic denervation.

## Treatment in MSA and Parkinson's disease

In the parkinsonian forms of MSA, levodopa is sometimes of benefit in the early stages. However, it can cause or enhance orthostatic hypotension and should be used with higher doses of dopa decarboxylase inhibitors. The monoamine oxidase-B inhibitor, selegiline, has been used in combination with levodopa but may also worsen orthostatic hypotension. It can cause hypotension also in Parkinson's disease by mechanisms that include the central effects of its metabolites, methyl-amphetamine. Amantadine can provide motor benefit without lowering blood pressure. Dopaminergic agonists may be effective but it is unclear if they worsen orthostatic hypotension. With time there is often refractoriness to anti-parkinsonian drugs in MSA. There is no effective pharmacotherapy for cerebellar deficits in MSA. Supportive therapy using disability aids should be provided.

The management of autonomic dysfunction needs to consider local organ dysfunction, the underlying or associated disease and integrative components often needing specialist care (Table 24.12).

Of particular importance, especially in generalised disorders, is the need for a holistic approach which includes the management of the autonomic deficits and the underlying disorder. Management should involve not only the patient, but the family, carers and community.

Jalesh Panicker

National Hospital for Neurology &amp; Neurosurgery

Urogenital dysfunction is common in neurological disease and has a significant impact on patients' health and quality of life. The investigations and management of disorders of urogenital function were formerly regarded as the preserve of urologists. However, as specialists in neurology increasingly enquire about urogenital symptoms, and become aware of the range of effective non-surgical treatments, they are taking a more active interest in urology – a specialty that focuses on bladder and sexual dysfunction viewed from the neurological perspective.

This chapter covers the neural control of lower urinary tract and sexual functions, followed by a description of the effects of neurological disease at different levels of the nervous system, and the essentials a neurologist should be aware of when managing these conditions.

### The lower urinary tract and its neurological control

The lower urinary tract (bladder and urethra) has essentially two functions: storage and periodic elimination of urine. This requires the synergistic activity of smooth and striated muscles of the bladder, bladder neck and urethra. This coordination is mediated by complex neural circuits located in the brain, spinal cord and peripheral ganglia.

The lower urinary tract differs from other visceral organs in many ways. Micturition is under voluntary control and depends upon learned behaviours. This reflects the critical role that the central nervous system (CNS) has in controlling lower urinary tract functions but renders the lower urinary tract susceptible to dysfunction whenever there is neurological disease. However, many of the other visceral organs are regulated involuntarily and can maintain a level of functioning even after damage to the extrinsic innervation. The pattern of activation of the lower urinary tract is unusual in that it has only two modes of operation, and therefore the neural circuits involved in regulating micturition have a phasic or switch-like activity. This is in contrast to the tonic pattern of activity that regulates the cardiovascular system.

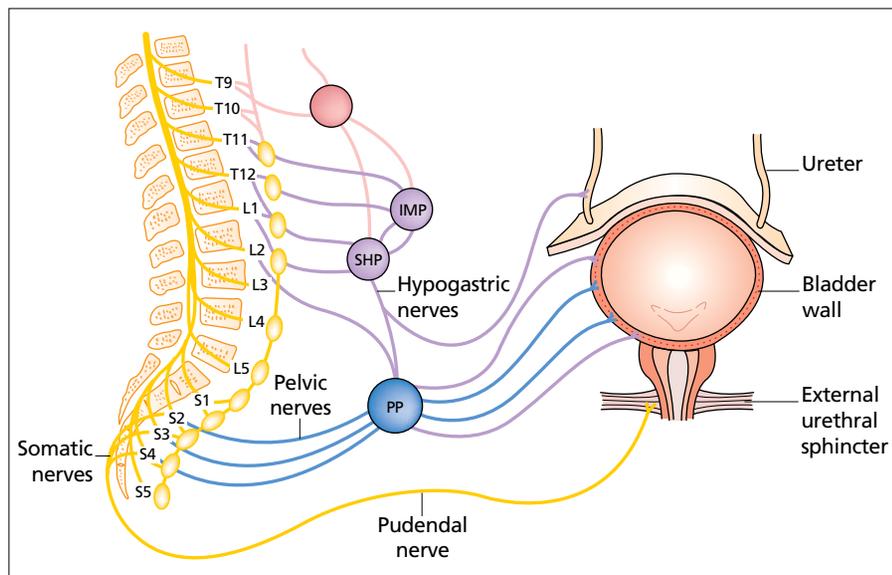

The bladder is in the *storage phase* for 98% of the time. The frequency of micturition in a person with a bladder capacity of 400–600 mL is once every 3–4 hours and switching to a *voiding phase* is initiated by a conscious decision which is determined by the perceived state of

bladder fullness and an assessment of the social appropriateness of voiding. To effect storage and voiding, connections between the pons and the sacral spinal cord must be intact, as must the peripheral innervation that originates from the most caudal segments of the cord. During the storage phase, the pressure within the bladder outlet is raised to maintain continence, and this is mediated through sympathetic and pudendal nerve activation of the internal and external urethral sphincters, respectively. Inhibition of the parasympathetic outflow prevents detrusor contractions. Throughout the storage phase, our perception of bladder fullness enables us to make the necessary planned strategies to achieve the next appropriately located void before reaching an uncomfortable degree of bladder distension or the sensation of 'severe urge to void'.

Whereas the voluntary control of micturition originates from the cerebral cortex, the switch is operated from the brainstem via neurones that run to the sacral cord segments S2–S3, where they synapse on neurones innervating the lower urinary tract. In recent years, functional brain imaging has contributed greatly to our understanding of the central input into lower urinary tract control and a consistent finding of all these studies is activation of the peri-aqueductal grey matter during bladder filling. This is in keeping with experimental studies in the cat, and it is thought that the peri-aqueductal grey matter serves as a central relay centre for afferent activity from the pelvic organs and is an interface between the afferent and efferent limbs of bladder control circuits, 'informing' the pontine micturition centre, in the dorsal tegmentum of the pons, about the degree of bladder fullness. The peri-aqueductal grey matter has multiple connections with higher centres such as the thalamus, insula, cingulate and prefrontal cortices. Activation of the insula is consistent with what is known about regions of activation involved in interoceptive awareness of visceral sensations.

The prefrontal cortex, the seat of planning complex cognitive behaviours and of appropriate social behaviours, is activated on bladder filling and it is likely that this region of the brain is involved in the conscious and social control of bladder function. It has been proposed that the task of the prefrontal cortex is to make a decision as to whether or not micturition should take place at a particular place or time.

With the decision to void, activation is seen in the prefrontal cortex, insula, hypothalamus and peri-aqueductal grey matter and the pontine micturition centre. The pontine micturition centre is

**Figure 25.1** Innervation of the lower urinary tract. IMP, inferior mesenteric plexus; PP, pelvic plexus; SHP, superior hypogastric plexus. Source: <http://www.deckerpublishing.com/SlideMenuLinks/permissionsIntroPage.aspx>

no longer tonically inhibited and the pattern of reciprocal activation–inhibition of the sphincter–detrusor reverses. Voiding is achieved by relaxation of the urethral sphincter and pelvic floor muscles, and parasympathetic mediated contraction of the detrusor muscle, resulting in effective bladder emptying. Intact neural circuitry between the pontine micturition centre and bladder ensures coordinated activity between the detrusor and sphincter muscles. Figure 25.1 depicts the peripheral innervation of the bladder.

### Lower urinary tract dysfunction following neurological disease

Both central and peripheral lesions of the nervous system can result in characteristic patterns of bladder dysfunction which depend upon the level of the lesion in the nervous system. The patterns of lower urinary tract dysfunction and findings during commonly performed tests are outlined in Table 25.1.

#### Cortical disease

When the lesion is above the level of the pons, inhibitory control of the pontine micturition centre is lost and this results in involuntary spontaneous or induced contractions of the detrusor muscle (detrusor overactivity), which can be identified during the filling phase of cystometry. The importance of the anterior regions of the frontal lobes in bladder control was established by Andrew and Nathan. A series of patients was reported with disturbed bladder control from various frontal lobe pathologies including tumours, damage following rupture of an intracranial aneurysm, penetrating brain wounds or leukotomy. The typical clinical picture was of a patient with severe urgency and frequency of micturition and urge incontinence, who is both socially aware and embarrassed by their incontinence. Only if frontal lobe pathology is more extensive, causing loss of social inhibition, do patients become unconcerned about their loss of bladder control.

Urinary retention has occasionally been described in patients with brain lesions. In the series by Andrew and Nathan (1964) two of the patients were in urinary retention at some stage and there

have been a small number of case histories of patients with right frontal lobe pathology with urinary retention.

#### Cerebrovascular disease

Incontinence following stroke is not a straightforward problem. Cystometric studies in patients following stroke generally conclude that detrusor overactivity is the most common urodynamic abnormality, although patients with haemorrhagic stroke more often develop urinary retention as a result of detrusor underactivity. There does not appear to be any definite lateralisation of lesions causing detrusor overactivity, although possibly the pathology is more often right-sided, nor are there any specific locations; however, anteriorly situated damage is more likely to result in incontinence. At admission, approximately 50% of patients with stroke will have incontinence, but the prevalence declines over the following 6 months to approximately 5%. Long-term incontinence is commonly caused by detrusor overactivity and is seen in patients with severe neurological deficits (aphasia particularly) and a high level of persistent disability.

Increasingly, cerebral small vessel disease is being recognised as a cause of incontinence. Sakakibara *et al.* first observed a correlation between the extent of white matter changes and incidence of detrusor overactivity. Kuchel *et al.* analysed the location of white matter changes and urinary dysfunction in community-dwelling elderly individuals and demonstrated the presence of white matter change in the right frontal and right inferior frontal regions to predict incontinence severity. In a functional imaging study involving a paradigm of repeated bladder filling and emptying, regional activations and deactivations became more prominent with increasing global white matter change and the main effect activations and deactivations were superimposed with the anterior thalamic radiation. The results of a study by Tadic *et al.* indicated that the white matter changes, particularly the anterior portion that includes the anterior thalamic radiation, were related to an overactive bladder in cognitively intact, elderly women.

Another approach to looking at stroke and urinary incontinence has been epidemiological. Following a stroke, the presence of

**Table 25.1** The pattern of lower urinary tract dysfunction differs according to the site of neurological lesion.

	Suprapontine lesion (e.g. stroke, Parkinson's disease)	Infrapontine suprasacral lesion (e.g. myelopathy)	Infrapontine lesion (e.g. conus medullaris, cauda equina, peripheral nerve)
History/ bladder diary	Urgency, frequency, urgency incontinence	Urgency, frequency, urgency incontinence, hesitancy, retention	Hesitancy, retention
Post-void residual urine	No PVR	± Elevated PVR	PVR >100 mL
Uroflowmetry	Normal flow	Interrupted flow	Poor/absent flow

**Table 25.2** Incontinence in the patient with dementia may be multi-factorial.

Neurogenic detrusor overactivity
Specific cognitive deficits – memory impairment, visuo-spatial disorientation, dysphasia, compulsive behaviour, apraxia, amotivation, social disinhibition
Urological causes – bladder outlet obstruction (e.g. prostate enlargement, stress incontinence)
Functional incontinence – impaired mobility
Medications – antidepressants, cholinesterase inhibitors
The ageing bladder – ‘detrusor hyperactivity with impaired contractile function’

urinary incontinence within 7 days appears to be the most powerful prognostic indicator for poor survival and eventual functional dependence, more so than a depressed level of consciousness in this period. The explanation for this is not known but it has been suggested that either incontinence is the result of a severe general rather than specific loss of function reflecting the severity of brain damage, or that those who remain incontinent are less motivated, both to recover continence and more general functions.

## Dementia

Urinary incontinence in dementia is a major socio-economic problem of ever-increasing proportions and incontinence is also common in the frail elderly and has many causes. In a large group of elderly patients who were institutionalised because of their general frailty, the same underlying pathophysiologies were found in those with cognitive impairment as those without. Although detrusor overactivity was the most common cause of incontinence in 40% there were other causes and in nearly one-third incontinence was related to disorders of the urethral outlet (i.e. potentially surgically correctable conditions). There are several causes for incontinence in the individual with dementia which should be considered during the evaluation; these are listed in Table 25.2.

There is also evidence of a specific disorder of the detrusor muscle characterised by ultra-structural changes of smooth muscle and axonal degeneration that has an increasing incidence in the elderly. This is thought to result in detrusor overactivity and incomplete

emptying; detrusor hyperactivity with impaired contractile function (DHIC). It seems highly likely that with loss of general ‘coping abilities’ because of cognitive impairment, DHIC becomes a prominent cause of incontinence.

The relationship of symptoms to cerebral pathology is unclear. Frontal lobe pathology would be expected to cause detrusor overactivity and there is some evidence that this is a contributing factor. One of the differences between symptoms in those with and those without dementia is that urgency preceding episodes of incontinence is more frequently reported by those without.

In a study of patients with cognitive decline, incontinence was associated with severe Alzheimer's disease but preceded cognitive impairment in diffuse Lewy body disease. A cross-sectional study by Ransmayr *et al.* suggests that urgency and urge incontinence, indicative of detrusor overactivity, is more common in dementia with Lewy bodies than in Alzheimer's disease.

Since the advent of cholinesterase inhibitors to treat symptoms in mild to moderate Alzheimer's disease, it is not uncommon to find a patient on such a treatment who has also been prescribed an antimuscarinic to treat their urinary urgency. No systematic study has yet been published that looks at interactions of these medications, but on theoretical grounds it would seem sensible to use an antimuscarinic to treat the bladder that does not cross the blood-brain barrier, such as tolterodine or trospium chloride, or possibly an antimuscarinic that is relatively more selective for the M3 rather than the M1 receptor such as darifenacin (Table 25.6).

Low-pressure hydrocephalus, a much less common cause of dementia, has incontinence as a cardinal feature. Improvement in cystometric function has been demonstrated within hours of lumbar puncture in patients with this disorder.

## Parkinson's disease

Non-motor symptoms in Parkinson's disease (PD) are thought to be the consequence of widespread dopaminergic and non-dopaminergic neurodegeneration. The resulting ‘vegetative symptoms’ have a very negative impact on the patient and their carer as the condition advances.

Nocturia is the most common non-motor symptom. How common bladder symptoms are in patients with clearly defined idiopathic PD is uncertain. Studies report prevalence figures between 38 and 71% but some early studies of prevalence were based on

patients presenting in urology clinics, in elderly patient populations or were published before the diagnosis of multiple system atrophy (MSA) was recognised as often as it is today. In the most recent study of patients with PD diagnosed according to modern criteria, and using validated questionnaires, the prevalence of urinary symptoms was found to be 27–39%, considerably higher than in healthy controls. A clear correlation with the neurological disability and stage of disease suggests a relationship between dopaminergic degeneration and symptoms of urinary dysfunction.

Typically, PD patients with bladder dysfunction have advanced disease and describe how the bladder symptoms came on many years after treatment for PD started. Cystometry commonly shows a reduced capacity and detrusor overactivity, usually with complete emptying, although sometimes an apparently obstructed voiding picture may be seen. It has been suggested that there may be an impaired relaxation of the urethral sphincter ('pseudo-dyssynergia') which could be reduced by subcutaneous apomorphine. The most common complaint is of nocturia and urinary urgency, and urgency incontinence can occur if poor mobility compounds the bladder disorder. A particular difficulty arises because symptoms of outflow obstruction can also occur in males with PD, making the distinction between neurogenic and bladder outflow obstruction resulting from benign prostatic enlargement difficult. The reputation for a poor outcome following prostatic surgery in men with PD is probably because of the inclusion of some patients with MSA in studies of 'Parkinson's disease and the bladder'. If there is convincing evidence of prostatic occlusion and obstructed voiding on cystometry, a prostatectomy should be considered.

The commonly accepted hypothesis to explain bladder symptoms in PD is that degeneration of dopaminergic neurones leads to loss of the substantia nigra tonically D1-mediated inhibition of the pontine micturition centre. Detrusor overactivity has been demonstrated in experimentally induced parkinsonism in marmosets, and selective dopamine D1 receptor agonists alleviated the abnormality. In rats, dopaminergic neurones originating in the ventral tegmental area (VTA) control the micturition reflex biphasically, with a facilitatory effect from low-dose stimulation of dopamine D2 receptors, while high-dose stimulation of the dopamine D1 receptors has an inhibitory effect on micturition. Patients with PD and bladder symptoms have less uptake of dopamine transporter tracer (DAT scan) in the striatum than patients with PD but without bladder dysfunction, indicating a correlation between urinary dysfunction and degeneration of the nigrostriatal dopaminergic cells. Furthermore, recent studies have shown that the presence of bladder symptoms is related to the decrease in the total number of dopaminergic neurones in the striatum and that relative degeneration of the caudate correlates with severity of symptoms.

The effect of antiparkinsonian medication on bladder function is complex and studies of the effect of levodopa or apomorphine on bladder behaviour have produced conflicting results. In one study of patients with more advanced disease showing 'on-off' phenomena, detrusor overactivity lessened with levodopa in some patients and worsened in others. A recent study suggests that in advanced PD, levodopa exacerbates detrusor overactivity in the filling phase, but also improves bladder emptying through increased detrusor contractility, so that the post-micturition residual volumes diminish. The effects of medication on bladder control are complex and it has been suggested that the effect of dopamine occurs through cortical mechanisms, by improvement in the ability to separate and integrate sensory input.

### Multiple system atrophy

MSA selectively involves neural components specifically involved in the innervation of the urogenital tract; bladder control may therefore be affected early in the course of the disease, often before symptoms and signs of postural hypotension. Corticotrophin-releasing factor staining cells in the pontine region have been shown to undergo selective atrophy and it has been postulated that these cells are in the region of the pontine micturition centre. Axons of the intermediolateral cell column conveying autonomic innervation to the sacral segments are known to atrophy, as do the cells in Onuf's nucleus which innervate the sphincters. Single-photon emission computed tomography (SPECT) studies have shown reduced cerebellar vermis activation during urinary storage and micturition in MSA.

The functional effects of these deficits include detrusor overactivity, incomplete emptying, an open bladder neck in men and sphincter weakness, all compounding to produce early and severe incontinence. Incomplete emptying commonly occurs (unlike the situation in PD), although the symptoms are predominantly those of incontinence. Very occasionally, a complete failure to void (i.e. retention) can be a presenting feature in both men and women. Bladder dysfunction may change during the course of MSA, with a progressive reduction in the degree of detrusor overactivity and increasingly high post-micturition residual volume. This is a situation that is highly amenable to treatment and many patients with MSA can regain bladder control for several years before their general neurological disability becomes overwhelming.

There are characteristic differences in the pattern of urogenital dysfunction between PD and MSA (Table 25.3). The diagnostic role of sphincter electromyography (EMG) to identify re-innervation, secondary to the loss of anterior horn cells in Onuf's nucleus in MSA (Figure 25.2), has been contentious. In a retrospective post-mortem study, a very high proportion of patients who were subsequently shown to have died of MSA had an abnormal sphincter EMG – often early in the course of their disease – but sufficient EMG data were lacking on patients who had alternative diagnoses, including PD, for the specificity of the test to be calculated. Some groups have shown sphincter EMG abnormalities in patients with long-standing PD. The author is a proponent of the value of sphincter EMG if found to be highly abnormal in a patient with early parkinsonism or in patients with a cerebellar syndrome of late onset. The test is method-sensitive and centres that carry out individual motor unit analysis by manual methods seem to find it more valuable than those that use an automated analysis technique.

Bladder symptoms in other parkinsonian syndromes are generally less prominent and are rarely as severe, or occur at a stage of the disease when a neurological diagnosis is clearly evident.

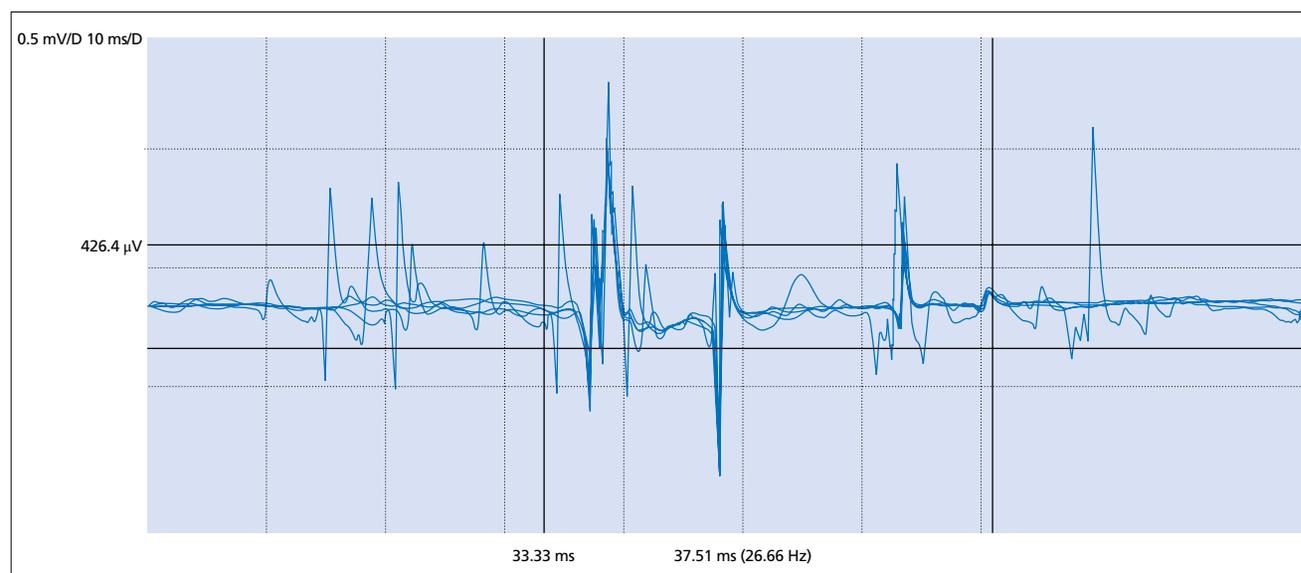

### Brainstem lesions

The location of the micturition centre in the pons means that occasionally pathology affecting the dorsal tegmentum can result in disturbances of micturition, most commonly difficulties voiding. Voiding difficulty is a rare but recognised symptom of a posterior fossa tumour in children and has been reported in series of patients with brainstem pathologies including strokes. An analysis of urinary symptoms of 39 patients who had brainstem strokes showed that lesions that resulted in disturbance of micturition were usually dorsally situated. There have also been a number of sporadic case reports describing urinary retention resulting from brainstem lesions. The proximity in the dorsal pons of the medial longitudinal fasciculus to the pontine micturition centre means that an

**Table 25.3** Differences in urogenital dysfunction between multiple system atrophy (MSA) and Parkinson's disease (PD).

	MSA	PD
Time of onset of urogenital dysfunction	Often precedes other neurological deficits	Usually follows other neurological deficits
Bladder dysfunction	Early and severe incontinence. Overactive bladder symptoms initially, progresses to urinary retention	Less severe incontinence Overactive bladder symptoms, nocturnal polyuria
Post void residual	Elevated	Usually normal
Urodynamics	Detrusor overactivity, acontractile detrusor In men, the finding of an open bladder neck may be relevant (video-urodynamics)	Detrusor overactivity
Sphincter EMG	Early signs of re-innervation (prolonged duration motor units mean >10 ms)	Usually normal, especially in the early stages
Sexual dysfunction	ED (often first manifestation)	ED, sometimes sexual compulsive behaviour as part of an impulse control disorder

ED, erectile dysfunction; EMG, electromyogram.

**Figure 25.2** Concentric needle electromyogram (EMG) recording from the external anal sphincter (gain 0.5 mV, sweep speed 10 ms per division). The duration of the weighted motor unit potential (MUP) is 37.5 ms (normal <10 ms). Abnormally prolonged MUPs suggest re-innervation and may be seen in multiple system atrophy; however, this finding should be interpreted within the clinical context.

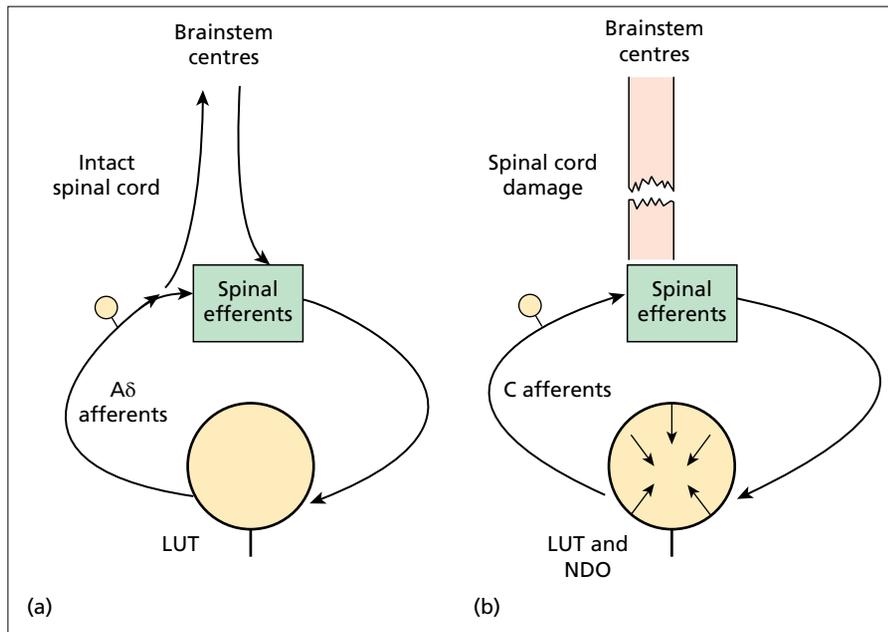

internuclear ophthalmoplegia is highly likely in patients with pontine pathology causing a voiding disorder.

### Spinal cord disease

Following acute spinal cord injury (SCI), the bladder may become acontractile during the stage of spinal shock. Over the course of weeks, reflex detrusor contractions gradually develop in response to low volumes of filling. Neurophysiological studies of recovery in the cat reveal that formerly quiescent C fibres emerge as the major afferent from the bladder and activation of this aberrant C fibre mediated spinal reflex drives detrusor overactivity (Figure 25.3). It is assumed that the same pathophysiology occurs in humans, and the improvement in detrusor overactivity following intravesical

instillation of C fibre neurotoxins, capsaicin and resiniferatoxin, supports this view. The same spinal lesion that causes the emergence of the C fibre reflex often causes upper motor neurone symptoms and signs in the lower limbs, and urge incontinence is particularly likely to affect patients with spastic paraparesis and detrusor overactivity. This is the basis of a valuable clinical point: when considering whether or not a patient has a neurogenic bladder resulting from spinal cord involvement, an absence of neurological signs in the legs makes such a diagnosis unlikely.

Spinal pathways that connect the pontine micturition centre to the sacral cord are responsible for a coordinated reciprocal activity of the detrusor and sphincter muscles. Following disconnection from the pons, the synergistic activity between sphincter and the

**Figure 25.3** C fibres and the emergence of detrusor overactivity following spinal cord damage. (a) In health, thinly myelinated A $\delta$  fibres have a lower threshold for activation and are responsible for conveying sensations of bladder filling. Whereas, unmyelinated C fibres have a greater threshold for activation and are thought to be quiescent. (b) Following spinal cord damage, C fibres become sensitised and are mechanosensitive at lower bladder volumes. A segmental spinal reflex emerges that is mediated by C fibres afferents nerves and results in involuntary detrusor contractions, the basis for neurogenic detrusor overactivity. LUT, lower urinary tract; NDO, neurogenic detrusor overactivity. Source: Panicker and Seth 2013. Reproduced with permission of Wiley.

detrusor is lost; the result is that the sphincter tends to contract when the detrusor is contracting, resulting in a condition known as detrusor–sphincter dyssynergia (DSD). This, together with poor neural drive on the detrusor muscle during attempts to void, means that there is likely to be incomplete bladder emptying and high detrusor pressures. Incomplete bladder emptying can in turn exacerbate the symptoms caused by detrusor overactivity. Although the neurological process of voiding may have been as equally severely disrupted by spinal cord disease as the process of storage, voiding difficulties and incomplete bladder emptying may not be evident and often it is only on direct questioning that a patient will admit to difficulty initiating micturition, an interrupted stream or a sensation of incomplete emptying. Table 25.4 summarises the pathophysiological consequences of a spinal cord lesion on the lower urinary tract.

Following SCI, detrusor overactivity, loss of compliance (the expansile property of the bladder) and DSD can be of such severity as to cause ureteric reflux, hydronephrosis and eventual upper renal tract damage. Before the introduction of modern treatments, renal failure was a common cause of death following SCI. The bladder problems of those with SCI must therefore be managed in such a way as to lessen the possibility of upper tract disease as well as provide the patient with adequate bladder control for a fully rehabilitated life. These patients need to remain under the care of a urologist who can regularly monitor the upper urinary tract and it may be better for the patients, who are often young and have no progressive disease, to undergo definitive surgery on their lower urinary tract with a view to protecting the upper tracts and restoring continence. It was in patients with complete spinal cord transection that the ‘Brindley stimulator’, which applied electrical stimulation directly to each of the sacral roots, S2, 3 or 4 was implanted, with

**Table 25.4** The possible pathophysiological consequences of spinal lesions on lower urinary tract functions.

Dysfunction	Symptoms
Detrusor overactivity: involuntary detrusor contractions at low filling volumes	Urgency Frequency Urge urinary incontinence
Detrusor–sphincter dyssynergia: concomitant contraction of the sphincter muscles when the detrusor is contracting during voiding	Interrupted stream Incomplete bladder emptying
Detrusor underactivity: impaired detrusor contractions during voiding	Poor stream Incomplete bladder emptying
Loss of central connections	Impaired initiation of voluntary voiding Inability to suppress urgency

considerable clinical improvement, but at the cost of sectioning of the dorsal roots.

### Multiple sclerosis

The pathophysiological consequences of multiple sclerosis (MS) affecting the spinal cord are similar to those of SCI, but the medical context of increasing disability is such that the patient’s

management must be quite different. In patients with MS there is a strong association between bladder symptoms and the presence of clinical spinal cord involvement including paraparesis (i.e. any upper motor neurone signs in the lower limbs). Furthermore, bladder symptoms become increasingly resistant to treatment as lower limb mobility deteriorates.

The most common urinary symptom is urgency and all series of urodynamic studies of patients with MS have shown that this is caused by underlying detrusor overactivity. However, patients may also volunteer or admit on direct questioning to difficulty with voiding such as hesitancy of micturition and an interrupted urinary stream. Evidence of incomplete emptying is commonly based on the patient's observation that having passed urine once, they are able to do so again within 5–10 minutes, rather than a reported sensation of continued fullness.

Unlike the bladder dysfunction that follows SCI, MS and other progressive neurological diseases very rarely cause upper urinary tract involvement. The reason for this is not known, but it means that in such diseases the emphasis of management needs to be on symptomatic relief.

### Other (non-traumatic) spinal cord diseases

A consistent feature of transverse myelitis is that although there may be an excellent clinical recovery from a tetraplegia of such severity that at its nadir artificial ventilation was necessary, bladder dysfunction is often the major residual neurological sequel. The explanation for this is not known but it may relate to the emergence of spinal segmental reflexes (Figure 25.3) during the period of 'spinal shock' which then persist as a dominant functional mechanism. This observation must inevitably cause a certain degree of pessimism about the prospect of restoration of bladder function if 'spinal repair' becomes a reality. Bladder dysfunction is common following acute disseminated encephalomyelitis (ADEM) and correlates with neurological deficits, especially in the lower limbs.

Detrusor overactivity occurs as an early feature and may even be a presenting symptom in patients with tropical spastic paraparesis caused by infection by human T-lymphotropic virus type 1 (HTLV-1).

Neurosyphilis, once a common cause of bladder dysfunction, is now rarely seen but tabes dorsalis classically resulted in an areflexic hyposensitive bladder because of involvement of the dorsal columns and roots, although a variety of abnormal urodynamic findings have been described.

Arteriovenous (AV) malformations of the spinal cord may be difficult to recognise clinically but commonly cause bladder disturbance as a prominent early feature. Although the majority of AV malformations occur in the thoraco-lumbar region, alterations to cord blood flow and subsequent conus ischaemia mean that the patient may present with what appears to be a conus or cauda equina lesion. Symptoms of voiding difficulty are common at an early stage followed by urinary retention.

A combination of upper and lower motor neurone signs in the legs together with urinary symptoms is characteristic of spinal dysraphism and a tethered cord. Typically, asymmetric wasting of the calves and intrinsic muscles of the feet occurs, but the prominent bladder symptoms and possibly extensor plantar responses suggest a diagnosis of a conus lesion rather than peripheral neuropathy or previous poliomyelitis. Although the majority of cases present in childhood, it is a condition that should be considered even in adults with the appropriate clinical features. Urodynamic studies show a mixed picture of detrusor overactivity and incomplete bladder

emptying, and although an improvement in bladder function following a de-tethering procedure has been claimed, the operation is usually carried out to treat pain or prevent progression of neurological deficit.

### Sacral and infrasacral lesions

Following damage to the conus medullaris, cauda equina or peripheral nerves voiding dysfunction predominates, caused by poorly sustained detrusor contractions and/or non-relaxing urethral sphincters.

### Conus or cauda equina lesions

Damage to the cauda equina and S2–4 roots leaves the detrusor 'decentralised' but not 'denervated' because the post-ganglionic parasympathetic innervation is unaffected. This may explain why the bladder dysfunction following a cauda equina lesion is unpredictable and even detrusor overactivity has been described. Loss of voluntary control is usually a symptom and there are sometimes pronounced defects of anal sphincter control with incontinence for flatus or liquid stools in addition to an inability to evacuate the bowel without digital assistance. Loss of control over bladder, bowel and loss of sexual function is particularly difficult for patients to bear psychologically when they are otherwise ambulant and mobile.

Although there are a number of series reporting the urodynamic changes that can occur following a cauda equina lesion, there have been only limited analyses of the effect a cauda equina lesion can have on quality of life. However, the levels of compensation awarded in medico-legal cases reflect the fact that the loss of control of the pelvic organs resulting from a cauda equina injury is catastrophic.

### Diabetic neuropathy

Bladder involvement was once considered an uncommon complication of diabetes but the greater use of techniques for studying bladder function have shown that the condition is often asymptomatic and discovered incidentally. Bladder dysfunction in isolation does not occur and other symptoms and signs of generalised neuropathy must be present in affected patients. The onset of the disorder is insidious, with progressive loss of bladder sensation and impairment of bladder emptying over years, eventually culminating in chronic low-pressure urinary retention. It seems likely that there is involvement of both the vesical sensory afferent fibres causing reduced awareness of bladder filling and also of parasympathetic efferent fibres to the detrusor decreasing the ability of the bladder to contract.

### Other neuropathies

About one-quarter of patients with Guillain-Barré syndrome have bladder symptoms. These usually occur in patients with more severe neuropathy and appear after limb weakness is established. Both detrusor areflexia and bladder overactivity have been described.

Recessively inherited type II congenital sensory neuropathy and familial dysautonomias with involvement of small nerve fibres have bladder dysfunction amongst their associated disabilities.

### Pelvic nerve injury

The peripheral innervation of the pelvic organs can be damaged by extirpative pelvic surgery such as resection of rectal carcinoma, radical prostatectomy or radical hysterectomy. The dissection necessary in the surgery of rectal cancer is likely to damage the parasympathetic innervation to the bladder and genitalia as the

pelvic nerves take a medio-lateral course through the pelvis either side of the rectum and the apex of the prostate. The nerves are either removed together with the fascia that covers the lower rectum or can be damaged by a traction injury as the rectum is mobilised prior to excision.

Urinary incontinence following a radical prostatectomy or a radical hysterectomy that includes the upper part of the vagina is probably also caused by damage to the parasympathetic innervation of the detrusor. In the case of a radical prostatectomy, there can be additional direct damage to the innervation of the striated urethral sphincter.

### Myotonic dystrophy

Although myotonic EMG activity has not been found in the sphincter or pelvic floor of patients with myotonic dystrophy, bladder symptoms can be quite prominent and difficult to treat, presumably because of involvement of bladder smooth muscle. With advancing disease resulting from involvement of the internal anal sphincter, faecal incontinence can become a problem.

### Urinary retention

Although a failure of storage and detrusor overactivity leading to urinary incontinence is the most common bladder dysfunction seen with neurological disease, failure to empty and urinary retention also occur. When referred a patient in retention where the cause is not known, examination can reveal findings that betray a neurological lesion. Examining the sacral dermatomes for loss of sensation perianally and over the perineum ('saddle' area) can be helpful, although 10% of patients with a long-standing cauda equina syndrome have no peri-anal sensory loss. The examination should include assessing the tone and strength of voluntary contractions of the anal sphincter muscle, as well as assessing polysynaptic reflexes with centres in the sacral spinal segments (anal and bulbocavernosus reflexes). Innervation of the lower bowel and genitalia is shared through the second, third and fourth sacral spinal segments, and therefore patients in urinary retention because of a lesion of the cauda equina or conus lesion often report bowel and sexual dysfunction. However, if a urologist has referred a man or, more commonly, a young woman with urinary retention and there is no evidence of neurological disease on clinical examination, it is unlikely that imaging or other neurological investigations will be abnormal. Table 25.5 lists the differential diagnoses to consider in a patient presenting with urinary retention once a structural urological lesion has been excluded.

### Urinary retention in women

Women with unexplained non-neurogenic urinary retention were, until quite recently, often thought to have a psychogenic cause for their complaint and indeed this is still a common medical misconception. However, in 1985 an EMG abnormality of the striated urethral sphincter was described which, it was hypothesised, impairs urethral relaxation resulting in obstructed voiding and incomplete bladder emptying or complete retention. It was observed that many of the young women also had a history or clinical features of polycystic ovaries and over the years this condition has become known as Fowler's syndrome. Although an association with polycystic ovaries is often found this is not essential for the diagnosis, whereas exclusion of underlying urological or neurological pathology is. The syndrome is characterised by painless urinary retention, with a bladder capacity in excess of 1 L, and often difficulty in removing any catheter used for self-catheterisation. Anecdotally, many of

these women have had a clinical incident that triggered the onset of their symptoms, such as a surgical procedure under general anaesthesia, a urinary tract infection or childbirth. The pathophysiology remains to be fully elucidated but it has been postulated that the disorder is brought about by a hormonally sensitive channelopathy of the striated urethral sphincter causing the muscle to be in a state of involuntary continuous contraction. The constant contraction of the sphincter has an inhibitory effect on the detrusor. Investigations demonstrate a raised resting urethral pressure and abnormal urethral sphincter EMG characterised by complex repetitive discharges and decelerating bursts, and sometimes an increased sphincter volume on ultrasound.

The cause for urinary retention often remains elusive even after extensive investigations. A prospective study of 61 women in urinary retention referred to the uro-neurology department over 1 year revealed that only in 40% was a probable aetiology identified, the most common being Fowler's syndrome. Interestingly, nearly 40% of women in the study had been receiving treatment with opiates for various pain syndromes. Based on this, a more recent hypothesis is that Fowler's syndrome is the result of spinal cord intoxication by enkephalins. These have the effect of suppressing sensations from the bladder and inducing detrusor areflexia. In fact, the bladder of a woman with Fowler's syndrome shares many characteristics with that of someone who has developed urinary retention as a result of taking opiates.

There is also an uncommon condition in men where painless urinary retention is not associated with constipation, and sexual function is preserved, but in whom extensive investigation fails to reveal

any underlying abnormality. It has been speculated that this disorder is caused by some abnormality of the intrinsic afferent innervation, possibly loss of the 'myofibroblast' or interstitial cell, thought to be an integral part of the bladder stretch sensing mechanism. This condition might make up a proportion of the women with unexplained urinary retention.

## Management of lower urinary tract dysfunction

From the foregoing sections it will be evident that the most common bladder problem caused by neurological disease is a failure of storage and therefore incontinence. Because the bladder has such a limited repertoire of behaviour, incontinence can be the end product of several different pathophysiologies, but chief amongst these are either a failure of inhibition of the pontine micturition centre because of a suprapontine cortical lesion, or the emergence of an abnormal segmental spinal reflex as a result of disconnection between the sacral cord and the pons.

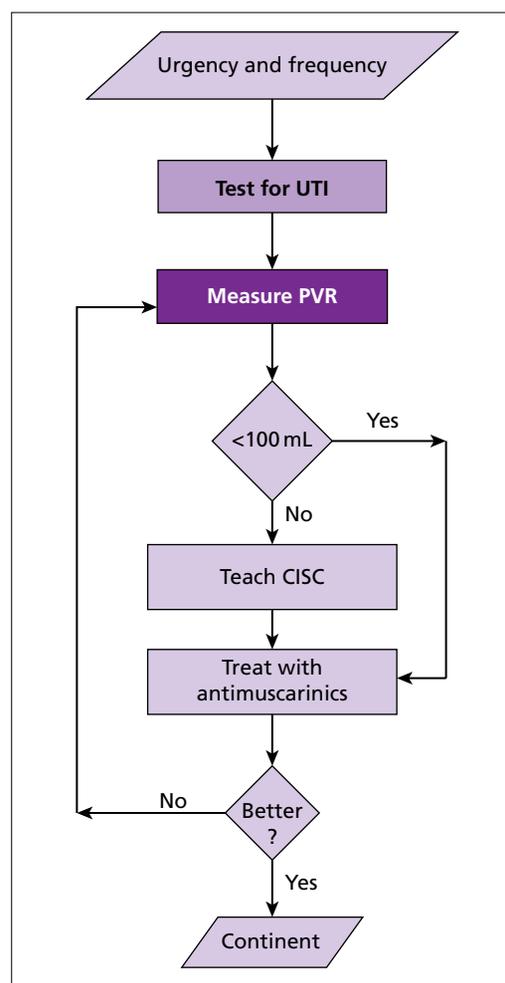

Non-pharmacological measures are generally helpful in the early stages when bladder symptoms are mild. A fluid intake of around 1–2L a day is suggested, although this should be individualised. Caffeine reduction may reduce urgency and frequency, especially in patients who drink coffee or tea in excess. Bladder retraining, whereby patients void by the clock and voluntarily 'hold on' for increasingly longer periods, aims to restore the normal pattern of micturition.

Figure 25.4 shows a simple algorithm based on the two main interventions directed at the dual problems of detrusor overactivity and incomplete emptying that has proved to be a convenient low-cost effective management scheme. Urodynamic testing should be selectively employed to supplement clinical assessment in determining management of neurogenic lower urinary tract dysfunction. There is a hierarchy of treatment that may need to be employed as urinary incontinence worsens (e.g. with deteriorating spinal function in MS). The first line treatment is antimuscarinics, and if necessary then in combination with intermittent self-catheterisation. If these measures are insufficient, detrusor injection of botulinum toxin would then be considered. These various treatments and interventions are described next.

## Management of storage dysfunction

### Antimuscarinics (anticholinergics)

Antimuscarinic medications are the first line treatment for overactive bladder symptoms and their use is associated with better patient-reported cure and/or improvement and significant reduction of maximum detrusor pressures in patients with neurological disease. The premise for treatment of detrusor overactivity with an antimuscarinic agent was that this blocked the parasympathetic innervation effect on the M2/M3 receptors of the detrusor muscle. However, it is now being recognised that there may be a more complex mode of action during the storage phase, and mediated through a muscarinic afferent mechanism, thus explaining the observed effects of increased bladder capacity and reduction of urinary urgency with treatment. Not all the antimuscarinics currently available have been systematically investigated and their use is often by inference of efficacy. Dual therapy (combinations of oxybutynin, tolterodine and trospium) has been shown to be effective and well tolerated in a few patients. There are now a number of such agents available (Table 25.6), and the long-acting extended-life (XL) formulations of these medications have the

**Figure 25.4** Algorithm for management of neurogenic incontinence. CISC, clean intermittent self-catheterisation; PVR, post void residual; UTI, urinary tract infection. Source: Fowler *et al.* 2009.

significant advantage of only needing to be taken once a day to provide 24-hour cover.

Side effects associated with all of these agents are common, a dry mouth in particular reduces patient compliance. These drugs can also block central muscarinic M1 receptors and cause impairment in cognition and consciousness in susceptible individuals. In the cognitively impaired, antimuscarinics should be prescribed with a warning for carers to be vigilant about possible deterioration in cognitive function or the onset of confusion. In the absence of positive evidence it seems sensible at this time to recommend the use of antimuscarinics that do not cross the blood–brain barrier (i.e. trospium chloride, or darifenacin, a selective blocker of the M3 receptor which is not known to be involved in cognition).

### Desmopressin

Desmopressin, a synthetic analogue of arginine vasopressin, temporarily reduces urine production and volume determined detrusor overactivity by promoting water reabsorption at the distal and collecting tubules of the kidney. It is useful for the treatment of urinary frequency or nocturia in patients with MS, providing symptom relief for up to 6 hours. It is also helpful in managing nocturnal polyuria, which is sometimes seen in patients with PD and various

**Table 25.6** Antimuscarinic medications available in the United Kingdom.

Generic name	Trade name	Dose (mg)	Frequency
Darifenacin	Emselex	7.5–15	o.d.
Fesoterodine	Toviaz	4–8	o.d.
Oxybutynin	Ditropan, Cystrin	2.5–20	b.d. – q.d.s.
Oxybutynin modified release	Lyrinel XL	5–20	o.d.

Trospium modified release	Regurin XL	60	o.d.

b.d., twice daily; o.d., once daily; q.d.s., four times daily; t.d.s., three times daily.

neurological conditions associated with dysautonomia. However, it should be prescribed with caution in patients over the age of 65 years or with dependent leg oedema, and should not be used more than once in 24 hours for fear of hyponatraemia or congestive heart failure.

### Botulinum toxin

The most significant recent development in the treatment of neurogenic bladder dysfunction has been the use of botulinum toxin A (BTX-A), injected into multiple sites of the detrusor muscle. The treatment was introduced on the theoretical basis that botulinum toxin would temporarily block the presynaptic release of acetylcholine from the parasympathetic innervated muscles and produce a paralysis of the detrusor smooth muscle; however, it is now known that it has a more complex action that is likely to involve the intrinsic afferent innervation as well.

The toxin is cystoscopically injected into the bladder wall, resulting in significant improvement in cystometric capacity, detrusor pressures and bladder compliance. This is accompanied by an improvement in storage symptoms – reduced frequency, urgency, nocturia and incontinence episodes – and quality of life. Pivotal Phase III studies of onabotulinumtoxinA have shown clear benefit in managing neurogenic detrusor overactivity; however, no clinically relevant benefit in efficacy or duration was seen between dosages of 300 and 200 U, whereas the likelihood of developing urinary retention requiring self-catheterisation was dose dependent. Based upon these studies, onabotulinumtoxinA is now licensed for use in

neurogenic detrusor overactivity in several countries. The beneficial effects last between 8 and 11 months, at which point the patient is eligible for further injections. Despite its success, patients must be counselled about a risk of performing clean intermittent self-catheterisation (CISC), because of the resultant voiding dysfunction and raised post void residual volume. Therefore patients being considered for this should be shown how to perform CISC so that they can demonstrate the ability and willingness to do this should it become necessary.

### Neuromodulation

Tibial nerve stimulation is effective in treating patients with overactive bladder symptoms. The mechanism of action is unclear, but is thought to involve rebalancing the inhibitory and excitatory impulses travelling to the bladder. Tibial nerve stimulation therefore inhibits bladder activity by modulation of sacral and lumbar afferent nerves. Studies that examined the effect of percutaneous tibial nerve stimulation in a cohort of patients with MS showed improved urodynamic parameters as well as improvement in overactive bladder symptoms. Transcutaneous tibial nerve stimulation has also been shown to be successful in patients with MS. Additional studies are required to demonstrate long-term efficacy of tibial nerve stimulation in neurological patients.

Sacral neuromodulation can be used to treat detrusor overactivity and urgency incontinence, as well as non-obstructive chronic urinary retention. This is a surgical procedure, which takes place over two stages, to introduce a stimulating electrode in the sacral extradural space. The first stage is a test phase, where the stimulating lead is inserted through the S3 foramen and is connected to an external stimulator. Over the subsequent weeks, the patient is assessed to see if the stimulation has been beneficial by reducing symptoms documented by bladder diaries and measured residual volumes. If there has been significant benefit, the patient is eligible for a second stage which involves the implantation of a more permanent small subcutaneous stimulator connected to the stimulating lead. The continuous stimulations are maintained at a level that is subsensory for the patient, who remains unaware of its ongoing action.

Sacral neuromodulation has been tried in small numbers of patients with MS with limited success but, being a progressive neurological condition, it may lose its efficacy as the disease progresses. Moreover, currently available implants are not MRI compatible and therefore it is likely that the procedure would be an option only in patients whose MS has a benign indolent course and who report bladder symptoms that are not responsive to less invasive treatments. A systematic review of sacral neuromodulation for neurogenic lower urinary tract dysfunction concluded that the number of patients investigated so far is low, and there is a lack of randomised controlled trials, which would be needed before further guidance can be issued. Interestingly, it has been shown that in patients with SCI, early sacral neuromodulation prevented the development of neurogenic detrusor overactivity and high detrusor pressures compared with control patients who did not receive early intervention.

In patients with Fowler's syndrome the mainstay of treatment had been indefinite intermittent or in-dwelling catheterisation, but sacral neuromodulation has been shown to restore voiding in these women, probably by resetting brainstem functions. Sacral neuromodulation was first described as a treatment for urinary retention in the mid-1990s. At the time, it had been introduced for the management of bladder dysfunction, paradoxically for both intractable incontinence and retention. Of an initial cohort of 60 women with Fowler's syndrome who underwent a successful initial test

procedure, percutaneous nerve evaluation (PNE) and subsequently underwent implant with a permanent sacral electrode, 70% were voiding spontaneously when followed up after a mean interval of 7 years.

### Management of voiding dysfunction

Prior to prescribing an antimuscarinic for patients complaining predominantly of symptoms of detrusor overactivity, it is important to measure their post-void residual urine volume, particularly if the patient's symptoms suggest there is incomplete voiding. This can be performed with 'in-out' catheterisation or alternatively using a small hand-held ultrasound device (bladder scanner) which many specialist nurse continence advisers now have access to. The importance of recognising incomplete emptying is that any residual volume in the bladder can trigger volume-determined reflex detrusor contractions, exacerbating the clinical situation through worsening of the symptoms of frequency, urgency and urgency incontinence. If a symptomatic patient has a residual volume of over 100 mL, CISS is advocated.

A specialist nurse or continence adviser is the most suitable person to instruct the patient, or if necessary their carer, how to carry out intermittent catheterisation. Women find the procedure more difficult initially and often require a mirror to help locate the urethral orifice but, once learnt, even blind or partially sighted patients can become proficient. Many void a variable amount before passing the catheter, but after commencing antimuscarinic medication effective voiding may be so compromised that the patient relies mostly on intermittent self-catheterisation. Frequency of catheterisation will best be determined by the patient, but initially they should be advised to perform the procedure three or four times a day. Contact and support by the specialist nurse, particularly in the early stages of learning the technique, increases the patient's confidence and careful follow-up ensures compliance to a prescribed regimen. Asymptomatic bacteriuria is a common finding in those using intermittent self-catheterisation and is not an indication for antibiotic treatment.

Catheter technology has advanced significantly in recent years. Various innovative features have been incorporated into the design, although mostly of single-use catheters, with consequent increases in cost. The new catheters are manufactured from various materials, and of differing lengths and diameters. The continence adviser or specialist nurse can advise on the types of catheter available and put the patient in touch with suppliers.

Catheter choice depends on factors such as ease of use and storage, discomfort and minimisation of damage on insertion and the risk of urinary tract infection. Trauma and discomfort are reduced by using gel on the catheter, although many of those that are now available are hydrophilic coated so that on contact with water they develop a highly lubricated surface; some now come packed 'pre-wetted'. Convenience of use has improved as they are now disposable and can be secreted in a pocket or small bag. Those for use in women have been compacted into a tube similar in size to a lipstick container.

Unfortunately, there are few other effective methods for improving bladder emptying. There have been studies demonstrating that alpha blockers can reduce residual volumes in patients with MS, but the clinical impression is that alpha blockers are not effective in individual patients, possibly because incomplete bladder emptying is thought to be the result of a combination of poorly sustained and ill-coordinated detrusor contractions, or of an inappropriate contraction of the striated urethral sphincter.

The application of a suprapubic vibrating stimulus improves bladder emptying, and has benefited some patients. In patients with reflex detrusor overactivity, the vibrating stimulus might help to initiate micturition and possibly improve bladder emptying by triggering a detrusor contraction. Several devices are commercially available for suprapubic vibration, including small hand-held battery-operated vibrators.

## Sexual functions and its neurological control

### Physiology

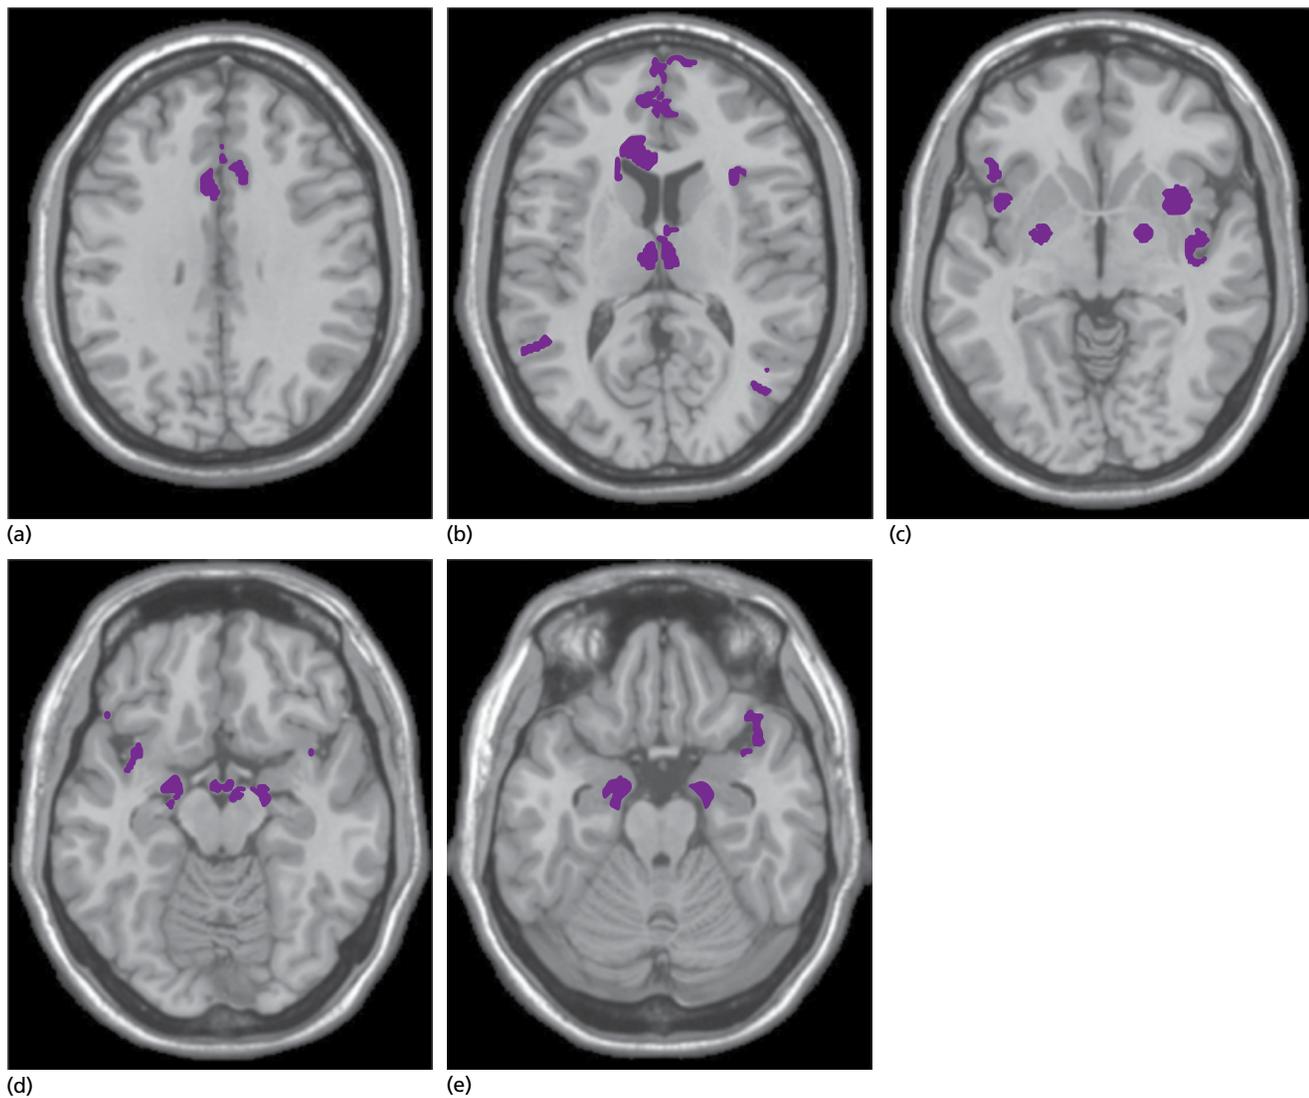

Human sexual function depends on the integrity of the nervous system at many levels: higher centres determine the cognitive and emotional aspects of sexuality, hormonal levels drive libido and desire through the hypothalamus, and the ability to effect a sexual response depends on spinal autonomic reflexes. Malfunction of some aspect of this highly distributed system is therefore common in neurological disease.

Functional imaging techniques have been applied to examine brain responses on sexual arousal. Figure 25.5 shows a meta-analysis of four studies that used erotic visual stimulation compared with erotically neutral viewing in healthy subjects of both genders. Activation of the prefrontal cortex, the anterior cingulate, occipito-temporal cortex, thalamus, amygdala, hypothalamus, insula and claustrum is seen, those regions being part of the limbic and paralimbic system long known to be important in mediating sexual motivation. The hypothalamus has been linked to most aspects of sexual behaviour in both humans and animals. A study of brain activation during penile stimulation by the subjects' female partners showed strong activation predominantly on the right side of the insula and secondary somatosensory cortex and de-activation of the amygdala but no activation of the hypothalamus. The same group reported brain activation during male ejaculation and showed prominent activity in the dopamine-rich mesodiencephalic junction-ventral tegmentum, an area that was also seen to be activated with the 'rush' experienced by heroin and cocaine addicts who describe an orgasmic-like sensation with heroin use.

Animal and human studies following SCI have pointed to the existence of two independent pathways for the male erectile response: a psychogenic pathway mediated by the thoraco-lumbar sympathetic outflow (T12-L2) and a sacral spinal reflex pathway, whereby genital stimulation results in a short-lived erection. In neurological health these two responses appear to fuse to produce an erection adequate for intercourse. Comparable pathways mediate vaginal lubrication, the female sexual response being analogous to penile erection.

Erection results from increased blood flow into the corpus cavernosum, a response mediated by the efferent parasympathetic pathway originating in the intermediolateral aspect of the sacral cord (S2-S4) travelling in the pelvic nerve (nervi erigentes). The preganglionic neurotransmitter in these fibres is acetylcholine but the post-ganglionic nerve fibres, which terminate either on the vascular smooth muscle of the corporeal arterioles on the non-vascular smooth muscle of trabecular tissue surrounding the corporeal lacunae, release nitric oxide (NO).

In women, sexual arousal results in an increased vaginal blood flow, erection of the cavernous tissue of the clitoris and the outer part of the vagina. As in men, the erectile response of these tissues is NO dependent; neuronal NO synthetase has been detected in both the body and glans of the clitoris. Nerve fibres containing

**Figure 25.5** Meta-analysis of functional magnetic resonance studies that showed responses to erotic visual stimulation.

vasoactive intestinal polypeptide (VIP), calcitonin gene-related peptide (CGRP) and substance P (SP) have also been described in human clitoral tissue. Normal vaginal lubrication, which is dependent both on intact innervation and normal oestrogen levels, is also NO mediated.

Detumescence after orgasm is mediated by noradrenaline in the sympathetic system and in the absence of sexual arousal it maintains the penis in the flaccid state. In men, orgasm and ejaculation are not the same process. Ejaculation involves emission of semen from the vas deferens and seminal vesicles into the posterior urethra, and closure of the bladder neck, under sympathetic control, whereas orgasm involves contraction of the pelvic floor muscles under somatic nerve control from the perineal branch of the pudendal nerve. In neurological disease the two processes can be separately affected.

During female orgasm there can be a series of synchronous contractions of the sphincter and vaginal muscles, with associated sensory changes which are generally described as being intensely pleasurable pelvic events.

### **Sexual dysfunction following neurological disease**

Sexual dysfunction is a significant, but often underestimated, symptom in patients with neurological disease.

#### **Traumatic brain injury**

Sexual dysfunction, usually reduced sexual desire, is common following traumatic brain injury particularly if there has been substantial cognitive damage. Both the extent and the location of damage determine the outcome. Damage to prefrontal areas can result either in erotic apathy or conversely disinhibition with inappropriate sexually demanding behaviour. Similar problems can be seen following encephalitis. Partner dissatisfaction plays an important part in influencing sexual activity following traumatic brain injury.

The importance of hypothalamic and pituitary damage following head injury and resulting hypopituitarism has recently been recognised, and full endocrine evaluation some months after a significant brain injury is often appropriate.

## Stroke

Although pre-existing sexual dysfunction resulting from diseases such as hypertension, diabetes and myocardial infarction can mean that there is less impact of stroke on sexual behaviour, the frequency and spectrum of sexual problems can be comparable to those seen following traumatic brain injury.

## Epilepsy

Temporal lobe disease causing epilepsy is particularly likely to have sexual manifestations. Sexual auras can occur as part of complex partial seizures and genital automatisms were observed in 11% of patients undergoing diagnostic video-telemetry. Although various sexual behaviours and occasionally hypersexuality have been described in patients with temporal lobe epilepsy (TLE), the picture most commonly seen is that of a profound failure of arousal.

There is sufficient evidence from studies that have compared sexual dysfunction in patients with generalised epilepsy and those with TLE to suggest that the deficit is a result of a specific temporo-limbic involvement rather than a consequence of epilepsy, psychosocial factors or antiepileptic medication. The problem is usually that of a low or even absent libido – something that is a presenting complaint either because of its effect on sexual relationships formed prior to the onset of the disorder or because lack of sexual motivation prevents the formation of adult relationships. In a study that looked at changes in sexuality following epilepsy surgery, extratemporal resections usually resulted in no change whereas temporal lobe resection resulted more commonly in a change in sexuality.

## Parkinson's disease

Whether or not specific genital dysfunction is a feature of PD is not entirely resolved. Using questionnaire surveys, several studies have shown that dissatisfaction with the quality of sexual experiences in men with PD is more likely than in control subjects. A survey of young patients with PD and their partners revealed a high level of dissatisfaction, with the most severely affected couples being those in which the patient was male and who complained of erectile dysfunction (ED) and premature ejaculation. Although ED, premature ejaculation in men and difficulty in arousal and reaching orgasm in women with PD may be significant problems, unless age and disability matched groups are compared it is difficult to know how specific these complaints are to PD. Early studies that found a high incidence of ED in men with PD may not have excluded MSA. A study that compared a group of married men with PD with a group with arthritis found a similar pattern of sexual functioning in the two groups, suggesting that although sexual dysfunction was common in PD, it was not more so than in men with a chronic illness that does not involve the nervous system. Age, severity of disease and depression, as well as testosterone levels, seem to be major determinants of sexual dysfunction, as they are in other neurological diseases.

Sexual compulsive behaviour may occur in patients with PD in the setting of an impulse control disorder (ICD). In a recent large multicentric cross-sectional study of patients with PD, the overall incidence of ICDs was found to be 13.6%. The most common syndromic presentations were compulsive buying (5.7%), pathological gambling (5.0%), binge-eating disorder (4.3%) and compulsive sexual behaviour (3.5%). Nearly one-quarter of patients have more than one impulse disorder and 3.9% had three or more.

There is experimental and clinical evidence that dopaminergic mechanisms are involved both in determining libido and inducing

penile erection. In animal studies, the medial preoptic area of the hypothalamus has been shown to regulate sexual drive and selective stimulation of D2 dopaminergic receptors in this region increases sexual activity in rats. The pro-erectile effect of sublingual apomorphine was exploited as a licensed worldwide treatment for ED in 2001. Although some men with PD being treated with apomorphine had been taking advantage of this effect, no large-scale study of its effect in men with PD or MSA was carried out and since its licensing other therapies have been shown to be more effective.

Men with PD respond satisfactorily to treatment with sildenafil citrate and recently a small but positive response in sexual well-being was reported in men, but not women, after deep brain stimulation of the subthalamic nucleus.

## Multiple system atrophy

ED may be a prodromal symptom of MSA. Initially, erectile response becomes intermittent and over the course of months or years erectile failure becomes complete. This can certainly pre-date the onset of recognised neurological features by several years. This was previously thought to be part of the symptom complex of autonomic failure, but the occurrence of this complaint is clearly separate from postural hypotension; it has been speculated that there is some more central, possibly dopamine-dependent, underlying process. Initially, libido remains intact and men treated with phosphodiesterase inhibitors who already have postural hypotension appear to be at particular risk of exacerbation. It is not clear whether ejaculation is equally affected and little information exists about whether or not sexual function in women is equally seriously disrupted.

## Spinal cord injury

The earliest reports of human neurogenic sexual dysfunction were large series of war veterans who had sustained SCI. These early studies showed that the level and completeness of a lesion determined the extent of preserved erectile and ejaculatory capacity of a paraplegic man and it was from these observations that the concept of there being both spinal reflex and psychogenic pathways for erection originated. Following a complete cervical lesion, psychogenic erections were lost but spontaneous or reflex erections remained intact. In low lesions, particularly if the cauda equina was involved, there was poor or absent erectile capacity, because the thoracolumbar sympathetic outflow originates between T12 and L2 and it is through this pathway that psychogenic erectile responses are mediated. Occasionally, men with low lumbar cord lesions but intact sacral roots find that they are still able to obtain psychogenically driven erectile responses.

Ejaculation also depends on spinal cord integrity. Studies of men who have undergone bilateral anterolateral cordotomies for relief of pain and who have lost orgasmic sensation suggest that 'erotically coloured' sensation is conveyed in spinal pathways that travel in close proximity to the spinothalamic tracts. Anorgasmia has been described following an anterior cord syndrome where patients have been demonstrated to have loss of small myelinated nerve fibre function while large fibre dorsal column functions were spared. Preserved ejaculation function following a spinal cord lesion is unusual and it was found that only 4% of men following SCI were still able to ejaculate, a matter of the greatest concern to paraplegic young men who wish to father children.

Much less is known about sexual dysfunction in women with SCI but it seems that all aspects of genital neurology are affected; the women have little or no genital sensation, experience poor vaginal

lubrication and have difficulty in reaching orgasm. As with erectile function in men, the analogous process of vaginal lubrication appears in health to be determined by psychogenic and reflex pathways and thus the level and completeness of an SCI determines what responses are preserved. A sensory level above T11–L2, the segmental origin of the thoraco-lumbar sympathetic outflow, was found to be associated with a failure to achieve psychogenic lubrication. By contrast, reflex genital vasocongestion in response to manual stimulation occurred despite a lack of subjective arousal, whereas women with cauda equina damage cannot usually achieve reflex lubrication. In women with preservation of sensory function in T11–L2, the psychogenic genital vasocongestion response is maintained. This suggests that the sympathetic outflow in the female is as important as it is in the male. Women with complete or incomplete suprasacral injury can achieve reflex genital response by manual stimulation but not when there is involvement of the sacral roots. Failure to reach orgasm is common in women with SCI and correlates poorly with the type of injury. Although their ability to reach orgasm is diminished, the written descriptions of the experience of orgasm in women with SCI were indistinguishable from those without, although they took much longer to achieve orgasm. It has been hypothesised that this preserved responsiveness is mediated through intact vagal innervation of the cervix.

### Multiple sclerosis

The evidence points to spinal cord involvement as the major cause of ED in MS. Cord involvement in MS can initially result in a partial deficit so that ED is variable, with preserved nocturnal penile erections and erections on morning waking. It is only in the last 10–20 years that neurological teaching has recognised the error of the dictum that ‘if a man can get an erection at any time, impotence is likely to be psychogenic’. The experience of men with SCI obviously belied that statement, but early studies put the incidence of ‘organic impotence’ in men with MS as low as 4%. Now it known to be a common problem, with estimates that it affects 50–75% of men with MS, depending on the severity of disability of the group studied.

A study that analysed the type of sexual dysfunction that affected men with MS who were still ambulant found that ED was the most common complaint (63%), followed by ejaculatory dysfunction and/or orgasmic dysfunction (50%) and reduced libido (40%). Other non-specific effects of MS also have adverse effects on sexual function, including fatigue, depression, spasticity and anxiety about incontinence. Prior to the advent of the oral erectogenic medications, men with MS were being successfully treated with intracavernosal injection therapy. Subsequently, a multicentre placebo controlled trial demonstrated an excellent response to sildenafil citrate by men with MS. Orgasmic capacity was also increased, a fact that was attributed to the men being able to sustain an erection for longer. Although many men are helped through that mechanism, a significant number continue to have difficulty with ejaculation for which there is no effective medication, although yohimbine can be tried. Probably the best recourse is to a vibrating sex aid.

Women with MS appear to report sexual dysfunction less frequently than men, but nevertheless it is a problem that is thought to affect more than 50%, the incidence increasing with increasing disability. A questionnaire survey of 133 women with mild disability found that although half reported voiding symptoms, 70% still enjoyed sexual intercourse, felt aroused and could experience orgasm. These figures are consistent with other questionnaire surveys that show that approximately one-third of women with MS experience loss of orgasm, reduced libido or decreased lubrication.

Sensory dysfunction in the genital area was experienced by 62% of women with advanced MS. The nature of the sensory dysfunction is usually loss of sensation but, occasionally, particularly early in the course of the disease, dysaesthesia can make genital contact with their partner unbearable. Loss of orgasmic capacity is the complaint for which women seek treatment. Following the success of sildenafil citrate in the treatment of sexual function with men with MS, 19 women were recruited to a double-blind placebo controlled trial. A questionnaire was used to measure sexual response and although there was a significant improvement in the lubrication and some improvement in sensation, there was no overall change in orgasmic response to sildenafil compared with placebo. The responses to the ‘global efficacy question’ reflect limited overall subjective improvement following sildenafil. This was disappointing although perhaps not surprising. Despite the absence of specific treatment, the opportunity to discuss problems with a health care professional was found to be beneficial.

### Lesions of the sympathetic thoraco-lumbar outflow

The fibres that travel from the thoraco-lumbar sympathetic pathway emerge from spinal levels T10–L2 and course through the retro-peritoneal space to the bifurcation of the aorta, from where they enter the pelvic plexus. Loss of sympathetic innervation of the genitalia causes disorders of ejaculation with either failure of emission or retrograde ejaculation, although the ability to experience the sensation of orgasm can be retained. The sympathetic thoraco-lumbar fibres are particularly likely to be injured by the procedure of retro-peritoneal lymph node dissection and complaints of loss of ejaculation are common after such surgery.

### Conus or cauda equina lesions

The cauda equina contains the sacral parasympathetic outflow together with the somatic efferent and afferent fibres. A lesion of the cauda equina therefore results in sensory loss as well as a parasympathetic defect and both men and women complain of perineal sensory loss and loss of erotic genital sensation – for which there is no effective treatment. In men ED is also a complaint.

A recent detailed study of 36 men with long-standing cauda equina damage of various aetiologies used a self-administered questionnaire to gauge sexual dysfunction and found severe dysfunction in 35%, moderate in 24% and slight sexual dysfunction in the remainder, with only one man highly confident of achieving and maintaining an erection. Orgasmic function was slightly more impaired than erectile function and sexual desire slightly less. The patients’ age, but not findings on clinical neurological, even perineal sensation or EMG of the anal sphincter, correlated with sexual dysfunction. There had been very little recovery of function since onset and only five men had received medical attention for their problem.

### Peripheral neuropathies

Diabetes is the most common cause of ED. Surveys of andrology clinics have found 20–31% of men attending to be diabetic. The prevalence of ED increases with age and duration of diabetes and the problem is known to be associated with severe retinopathy, a history of peripheral neuropathy, amputation, cardiovascular disease, raised glycosylated haemoglobin, use of antihypertensives and higher body mass index. A large population study of men with younger onset diabetes found 20% to have ED. Whether the pathogenesis of ED in diabetics is caused mainly by neuropathy or whether there is a significant microvascular contribution or the two processes are co-dependent is not yet resolved, but at a cellular

level the evidence suggests there is a depletion of neurotransmitters. Age-matched studies of women with and without diabetes suggest that diabetic women are also affected by specific disorders of sexual function including decreased vaginal lubrication and capacity for orgasm.

Guillain-Barré syndrome (GBS) does not appear specifically to affect the innervation involved in sexual function over and above the extent to which it causes general disability. In about 25%, bladder symptoms appear after onset of weakness, but it is unknown if these are the patients who on recovery are likely to have sexual dysfunction. GBS patient support groups report anecdotally of sexual dysfunction in both genders as part of general disability.

**Table 25.7** Factors that influence sexual functions in patients with neurological disease.

<b>Primary</b>	Neurological lesions interfering with the sexual response and/or sexual feelings
<b>Secondary</b>	Fatigue Difficulties in attention and concentration Bladder/bowel incontinence Physical immobility: muscle weakness, leg spasms Dysaesthesia/allodynia Other factors: incoordination, tremor, pain
<b>Tertiary</b>	Depression, anxiety Anger, guilt and fear Altered self-image, low self-esteem Relationship with the partner, change in family role
<b>Others</b>	Medications: antidepressants, baclofen, gabapentin Use of urethral indwelling catheter

By contrast, neuropathies that involve selectively the small and unmyelinated nerve fibres, such as amyloid and some other rare inherited neuropathies, have urogenital symptoms as prominent features. Amyloid neuropathy, either familial or secondary, has a marked effect on urogenital function and symptoms are common. ED can be an early symptom of autonomic involvement.

### Management of sexual dysfunction

There are several factors that influence sexual functions in patients with neurological disease (Table 25.7) and these should be individually addressed. Measures such as pelvic floor exercises or electrical stimulation feedback with cognitive therapy, which can improve symptoms in the neurologically intact, have not been found to be as effective in those with neurogenic sexual dysfunction. In men with neurogenic ED, corporeal injections of first papaverine and then alprostadil were the mainstay of treatment until the advent of sildenafil citrate, the type 5 phosphodiesterase inhibitor (PDE-5), in 1998.

Normal erectile function is dependent on the smooth-muscle relaxing effects of NO which is mediated by the cyclic nucleotide signalling pathway. Down-regulation of this pathway is central to the pathophysiology of many forms of ED. Hence, selective inhibition of PDE-5 which catalyses the degradation of cyclic guanosine monophosphate (cGMP) promotes erectile responses to sexual stimulation. The efficacy of sildenafil citrate transformed the treatment of ED, not only by providing an effective well-tolerated oral therapy, but also by introducing open discussion about the problem. The advent of vardenafil, which has the highest *in vitro* potency, may improve responsiveness, and tadalafil, which has a prolonged half-life of 18 hours, is enabling couples to have sexual activity with less planning (Table 25.8). ED will affect the female partner, and in an ideal world it is recommended that evaluation of the woman should be addressed within the context of the couple in a sexual medicine clinic.

Female sexual dysfunction is less satisfactorily treated. Growing realisation of the problem has resulted in the problem being better addressed and strategies considered (Table 25.8).

**Table 25.8** Sexual dysfunction in men and women with neurological disease and potential treatment strategies.

Dysfunction	Symptoms	Potential management strategies
Sexual interest/desire	Diminished or absent feelings of sexual interest or motivation; rarely hypersexuality	Relationship counselling, psychotherapy ?Hormonal replacement
Sexual arousal	Poor/absent erections (males) (erectile dysfunction)	Treatment for erectile dysfunction – PDE5 inhibitors, Vacuum constriction devices, Intracavernous/ intraurethral prostaglandin therapy Vaginal lubricants
	Diminished/absent feelings of sexual excitement and sexual pleasure (sexual arousal dysfunction) and/or vulval swelling or vaginal lubrication (genital arousal dysfunction) (females)	?Sildenafil
Orgasm/ejaculation	Delayed or absent ejaculation (males)	?Yohimbine, midodrine
	Reduced or absent orgasms (males and females)	Therapy: sensate focus techniques, sex therapy, cognitive-behavioural therapy Sex aids
Pain	Dyspareunia (females)	Anaesthetic gels, pain modulation

PDE5, phosphodiesterase 5.

# Systemic Conditions and Neurology

David Werring<sup>1</sup>, Robin Howard<sup>2</sup> and Simon Shorvon<sup>1</sup>

<sup>1</sup>UCL Institute of Neurology

<sup>2</sup>National Hospital for Neurology & Neurosurgery

Neurology has developed somewhat separately from the body of general medicine. However, the subjects remain inextricably linked, because diseases of all body systems can profoundly influence the nervous system. About one in five acute medical admissions to district general hospitals in the United Kingdom are caused by neurological illness. General physicians often lack first-hand experience in managing patients with neurological symptoms; neurologists can make important contributions to optimising management, often assisting with accurate diagnosis, appropriate investigation and treatment. Effective communication between neurologists and general physicians is thus critical.

In this context, a working knowledge of the neurological aspects of general medical conditions is invaluable and this chapter aims to summarise neurological manifestations of disorders of other body systems, outlining some basic elements of pathophysiology, diagnosis and management. It is intended neither to be exhaustive, nor a comprehensive and detailed guide to treatment. Rather, we aim to give a broad overview of the range of neurological disease encountered in general medicine.

## Aortic and cardiac disorders

The neurological consequences of aortic or cardiac disorders can be devastating. Ischaemic stroke and transient ischaemic attack (TIA) – the main clinical result of embolism from the heart or great vessels – are briefly considered here but also dealt with in detail in Chapter 5. An understanding of the effects of vascular disease of the great vessels and spinal cord requires an understanding of basic vascular anatomy, outlined here.

### Aortic pathology

#### Anatomy

The whole body, including the nervous system, is supplied by the aorta. Disease processes affecting the aorta and surgical instrumentation can therefore cause damage to the brain, spinal cord and peripheral nervous system. The neurological syndrome caused depends more on the part of the aorta affected, rather than the nature of the pathology.

### Blood supply

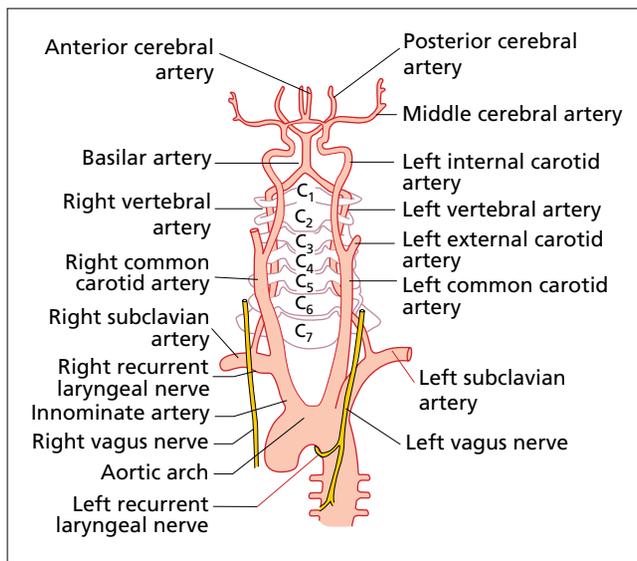

**Cerebral** The aorta leaves the heart to become the aortic arch; the great vessels supply the brain, brainstem and cervical spinal cord (Figure 26.1). From the heart, the order in which these vessels arise is as follows: innominate (brachiocephalic) artery – continuing as the right subclavian artery and giving rise to the right common carotid; then the left common carotid, and finally the left subclavian artery. Each vertebral artery arises from the subclavian of that side.

**Spinal** The anterior spinal artery is formed from paired branches arising from the vertebral arteries which descend at the level of the medulla. The anterior spinal artery is joined by radiculo-medullary arteries at various segmental levels. The upper and mid-thoracic anterior spinal artery is generally supplied by a small feeding vessel. The anterior spinal artery at the level of the lumbar enlargement is supplied by a single large vessel, the great anterior medullary artery of Adamkiewicz (Albert Adamkiewicz, 1850–1921, professor of general and experimental pathology, Cracow). This artery usually runs alongside a nerve root on the left side, usually between T9 and L2. The posterior spinal arteries are also formed from the intracranial vertebral arteries rostrally but after their origin become mixed with a posterior pial arterial plexus joined at various levels by posterior radiculo-medullary vessels (Figure 26.2).

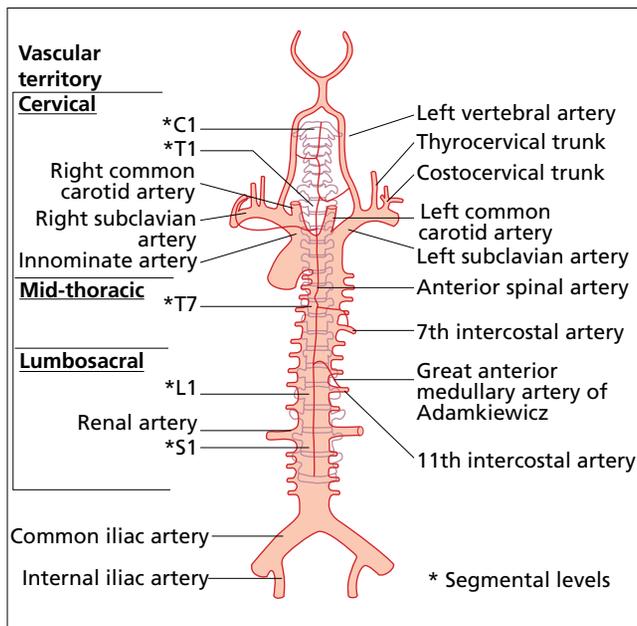

### Cerebral ischaemia resulting from aortic disease

Aortic disease, such as atherosclerosis, aortitis or aneurysm, can cause cerebral ischaemia (i.e. stroke, TIA and hypoperfusion syndromes). Aortic atheroma is an increasingly recognised source of embolic material to the brain and, although difficult to detect by non-invasive imaging, it can be well visualised by trans-oesophageal echocardiography. Neurological syndromes caused by aortic disease are often indistinguishable from those produced by emboli from other sources.

Steal syndromes can result from occlusive disease of the innominate or subclavian vessels proximal to the origin of a vertebral artery. The left side is three times more likely to be affected than the right, probably because the different vertebral–subclavian angle, predisposes to atheroma. The word steal describes reverse flow, usually in a vertebral artery, typically exacerbated by exercising the ipsilateral arm, thus increasing blood flow to the arm and metabolic

**Figure 26.1** Vessels arising from the aorta. Source: Aminoff 1992. Reproduced with permission of Elsevier.

**Figure 26.2** Blood supply of the spinal cord. Source: Aminoff 1992. Reproduced with permission of Elsevier.

demand or, less commonly, neck movement. Non-invasive imaging of these phenomena suggests that in the vast majority of cases such a steal is asymptomatic, but surgical or endovascular intervention may be considered if symptoms are troublesome. The term subclavian steal syndrome should only be used if symptoms are present; these are usually of posterior circulation ischaemia including vertigo, visual disturbances and ataxia.

#### Spinal cord ischaemia resulting from aortic disease

The most common spinal cord ischaemic lesion is an anterior spinal artery syndrome, characterised by loss of spinothalamic sensation (pain and temperature), paralysis (usually bilateral) below the level

**Figure 26.3** Spinal cord infarction. A 60-year-old woman presented with sudden radicular low back pain radiating around the umbilicus with sudden leg weakness and numbness. This progressed over a several hours with loss of sphincter function. T2 coronal MRI shows abnormal high signal in the central portion of the lower dorsal cord (arrow).

of the lesion with preserved dorsal column function (vibration and joint position) and loss of sphincter control. This develops abruptly or evolve over several hours. Clinically, at the onset radicular thoracic pain occurs and is often severe. The cervical spinal cord has a more robust vascular supply than the thoracic and lumbar regions, from collateral feeders, so that cervical cord infarction is uncommon. Very rarely, dissection of the extracranial vertebral arteries can cause cervical cord ischaemia with brachial diplegia and neck pain. The mid to lower thoracic region is selectively vulnerable to ischaemia, and this is the authors' experience, although not confirmed in all studies. Atherosclerosis and thrombo-embolism in the anterior spinal artery is rare; infarction in this territory is often a result of aortic disease or surgery. However, no cause is identified in more than 50% of cases. The diagnosis of spinal infarction is clinical, but magnetic resonance imaging (MRI) shows signal abnormalities in the cord in the majority (Figure 26.3). Diseases of the aorta including atherosclerotic occlusive disease, aortitis, dissection, aneurysms or coarctation can cause spinal cord ischaemia. In order to produce cord ischaemia, the pathological process generally must involve the suprarenal aorta, because the most important radiculomedullary arteries that feed the cord usually originate above this level.

Although the spinal cord syndrome caused will generally be similar regardless of the underlying pathology, patients with dissection of the thoracic aorta present classically with searing interscapular pain, shock and asymmetric arm pulses. The dissection commonly causes ischaemia of the mid-thoracic spinal cord, producing a thoracic sensory level. Cardiac or aortic surgery requiring clamping of the aorta for over half an hour, and aortic angiography, can also cause an anterior spinal artery syndrome. The likelihood of spinal infarction is up to 1 in 10 following a surgical procedure involving the suprarenal aorta, but is rare following infra-renal procedures. In some post-instrumentation cases the mechanism is a cholesterol embolus arising from an atheromatous aorta. Spinal cord ischaemia can result from endovascular stent graft repairs of thoracic and thoraco-abdominal aortic aneurysm. Peri-operative cerebrospinal fluid (CSF) drainage, with augmentation of systemic

blood pressure, sometimes has a beneficial role in reducing the risk of paraplegia in patients undergoing surgical or endovascular procedures involving the aorta.

Inflammation of the aorta can cause neurological symptoms directly or indirectly via the development of aneurysms, aortic stenosis or atherosclerosis. Syphilitic aortitis was common prior to the introduction of penicillin but is now rare. It typically affects the thoracic aorta, causing aneurysmal dilatation and cerebral embolism. Atherosclerosis, by contrast, causes aneurysmal dilatation of the abdominal aorta. Takayasu's disease is a large vessel vasculitis that can cause aortitis, typically in female patients under 30 years of age. This rare condition has a pre-pulseless phase with systemic symptoms of fever, weight loss, arthralgia, myalgia, night sweats and chest pain. This develops into the pulseless phase, in which there is occlusion of the major vessels of the aortic arch with aortic regurgitation, aneurysm formation and hypertension. Cerebral ischaemia is uncommon.

### Neurological complications of cardiac surgery

Cardiac surgery, particularly coronary artery bypass grafting (CABG) is one of the most common thoracic operations performed in developed countries. Early neurological sequelae include acute stroke (1–5% of patients), delirium and confusion. Later on, an encephalopathy can become apparent. The mechanisms underlying these complications include particulate microemboli and hypoperfusion during surgery and postoperative atrial fibrillation. Embolism is the most common mechanism of postoperative stroke, accounting for some 60% of cases. Pre-existing symptomatic cerebrovascular disease is a strong risk factor for postoperative stroke. Carotid stenosis (asymptomatic or symptomatic) may be identified, leading to the question of intervention. Although carotid stenosis is associated with an increased risk of postoperative stroke, studies show that in most cases it is not directly causal; it is likely that the stenosis is simply one marker of generalised vascular disease. For this reason the management of asymptomatic carotid stenosis pre-operatively is controversial; randomised trials are needed to guide such management decisions. The available data do not support routine intervention in patients with asymptomatic carotid stenosis, but if the stenosis is high grade (>90% or occlusion) or bilateral, intervention may be considered. Generally, in symptomatic patients with carotid stenosis greater than 70% intervention prior to cardiac surgery is recommended. It is not known whether intervention on the carotid is best performed before or simultaneously with the cardiac surgery; some advocate a joint procedure to avoid two potential peri-operative stroke risks. Other complications of cardiac surgery include short- and long-term cognitive impairment, acute delirium and seizures. Cognitive abnormalities of executive function, memory, attention and processing speed occur in between 5–80% of patients in the first few post-operative weeks. The mechanisms underlying such deficits are unknown but it is speculated that changes in perfusion, oxygenation or microparticle embolisation during pump bypass are relevant. The natural history of early cognitive impairment is for resolution over months, but about 25% of patients have detectable long-term deficits on formal psychological testing.

### Neurological complications of acquired cardiac disease

#### Cardiac embolism

Ischaemic stroke is caused by large vessel atherosclerosis and thromboembolism, small vessel occlusion, cardiac embolism and a miscellany of many rarer causes including arterial dissection, haematological abnormalities and metabolic conditions. Cardiac embolism accounts for up to one-quarter of all ischaemic strokes. Clinical and radiological findings suggestive of cardio-embolism include abrupt and maximal

deficit at onset (rather than stepwise) and haemorrhagic transformation (because of rapid reperfusion) or multiple vascular territory infarcts on imaging, with an identified potential cardiac source on echocardiography. About 80% of cardiac emboli enter the anterior cerebral vessels; an anterior circulation branch occlusion and striato-capsular infarction is highly suggestive of a cardio-embolic source. Although cardio-embolism to the posterior circulation is less common, certain stroke syndromes are characteristic, including the 'top of the basilar syndrome' (reduced conscious level, visual field loss, limb sensory or motor symptoms) and unilateral posterior cerebral artery occlusion causing hemianopia. Of course, none of these features are specific, and it must be remembered that a definitive diagnosis of cardiac embolism can be difficult in the presence of coexisting large vessel athero-thrombotic or cerebral small vessel disease. Common sources of cardiac embolism are shown in Table 26.1.

### Rhythm disturbances

**Atrial fibrillation** Atrial fibrillation (AF; Chapter 5) is associated with a sixfold increase in stroke risk. There is a cumulative risk of stroke in patients with AF, which can be stratified according to the number of additional factors. Important factors increasing the stroke risk in patients with AF include age, history of previous stroke, hypertension and left ventricular dysfunction. The presence of one or more of these risk factors should lead to strong consideration of anticoagulant treatment, which reduces the risk of stroke by about 70%. Warfarin has recently been shown to be superior to aspirin in older patients as well as those under 75 years of age. In addition to warfarin, non-vitamin K oral anticoagulants (NOACs) are now available, including direct thrombin and factor Xa inhibitors. Large-scale randomised trials indicate that NOACs are as effective as warfarin but with an approximately 50% lower risk of intracranial haemorrhage. Long-term observational data on NOAC use in clinical practice will help more clearly establish their efficacy and safety.

**Sick sinus syndrome** Sick sinus syndrome is defined by sinus node dysfunction, often idiopathic and common in the older population. Patients are often asymptomatic, although syncope, palpitations or dizziness occur. Rhythm disturbances include sinus bradycardia,

**Table 26.1** Common sources of cardiac embolism.

<b>Rhythm disturbances</b>
Atrial fibrillation
Sick sinus syndrome
<b>Cardiomyopathy</b>
Congenital
Acquired – alcohol, recreational drugs (cocaine), amyloid, ischaemic heart disease
<b>Valve disease</b>
Endocarditis
Rheumatic heart disease
Mitral valve prolapse
Prosthetic valves
<b>Structural cardiac lesions</b>
Atrial myxoma
Ventricular aneurysm
Patent foramen ovale
Ventricular akinesia (e.g. following myocardial infarction)

sinus arrest, sino-atrial block and bradycardia–tachycardia syndrome. Cardio-embolic stroke occurs in up to 20% of patients, and is more common in those with tachyarrhythmias. Pacemakers do not definitively reduce the risk of stroke. If atrial fibrillation occurs, anticoagulation should be considered to reduce the risk of stroke.

### Cardiomyopathies

Primary cardiomyopathies (i.e. not caused by diseases such as ischaemic heart disease) are associated with arrhythmias and a tendency for stasis of blood within the heart, which can lead to left ventricular thrombus formation and embolism to the brain. Dilated or restrictive types are far more likely to be a cause of embolism than hypertrophic cardiomyopathies, in which cerebral embolism is rare. Primary cardiomyopathies have a genetic component, and family screening is usually indicated. Anticoagulation should be considered in those with a very low ejection fraction (e.g. <30%) because this may help prevent recurrent events.

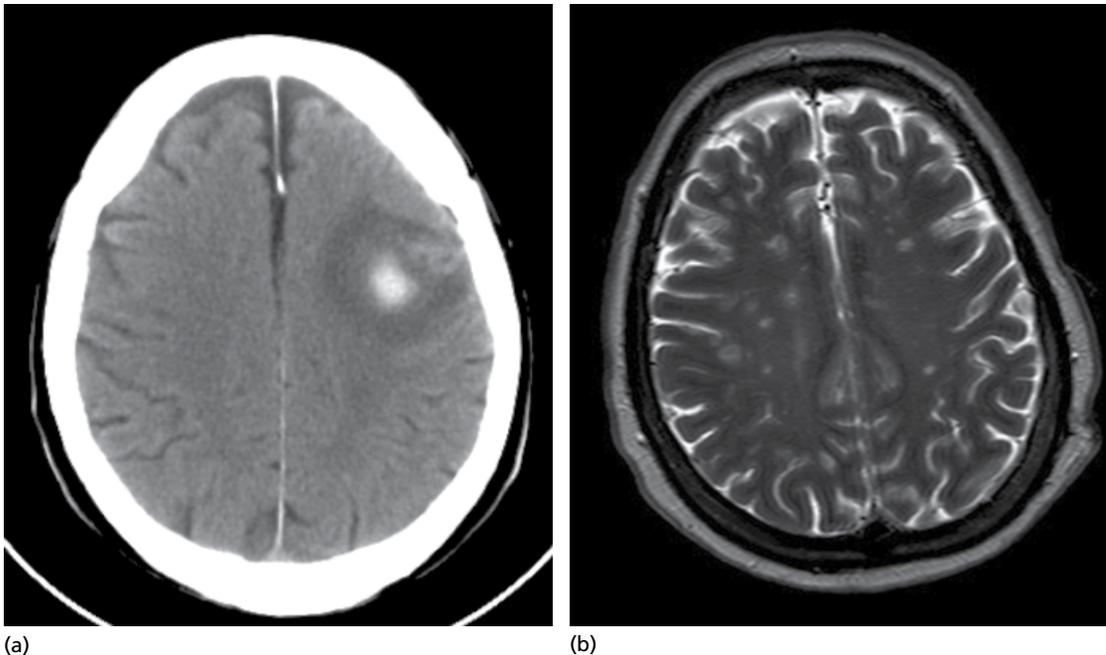

### Valve disease

Infective endocarditis (Chapter 9) is an important cause of embolism to the brain, which occurs in about one-fifth of patients. Usually, emboli occur during active infection, when the patient will usually be systemically unwell with fever, malaise and evidence of emboli to other organs such as the skin, eyes and kidneys. Patient groups at particular risk of endocarditis include those with immunosuppression, intravenous drug use, prosthetic heart valves or structural heart valve disease. Embolic material may cause infection or vasculitis of vessels where septic emboli impact, with or without the development of a mycotic aneurysm (often in the distal branches of the middle cerebral artery). Thus, in a high risk patient evidence of multiple cerebral emboli (or systemic emboli) should alert the physician to the possibility of infective endocarditis. The disease can also cause intracerebral haemorrhage (Figure 26.4). Anticoagulation is not recommended in native valve endocarditis

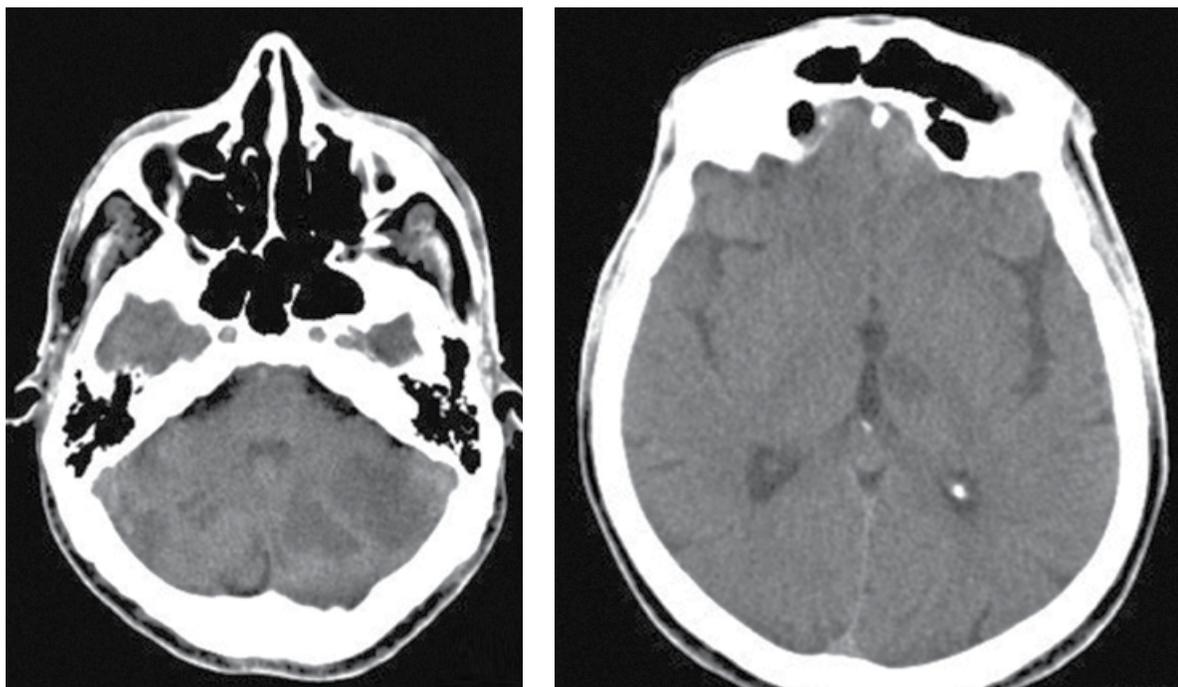

because of the high risk of haemorrhagic complications. However, in the case of prosthetic valve endocarditis anticoagulants may need to be continued, although it is probably safe to discontinue them for 1–2 weeks temporarily. Early cerebral angiography is generally advised in symptomatic haemorrhage to exclude mycotic aneurysm, which can be treated by endovascular methods. Conversely, angiography is probably not necessary in cases of asymptomatic unruptured mycotic aneurysms. Because endocarditis often remains undetected by blood cultures and even echocardiography, a high index of suspicion is needed in any patient with unexplained haemorrhagic or ischaemic stroke and a cardiac murmur. Cerebral microbleeds, small rounded lesions best seen on blood-sensitive MRI (e.g. T2\* gradient echo or susceptibility-weighted sequences), are common in infective endocarditis and may provide another diagnostic clue. Meningeal involvement is common in endocarditis, and CSF analysis, if safe following careful clinical and radiological assessment, will suggest the diagnosis if a markedly high polymorph count is found (>100 cells/mm<sup>3</sup>). Rheumatic fever can also cause valvular damage leading to embolism to the brain, particularly if the mitral valve is affected or atrial fibrillation develops during the illness. Sydenham's chorea is discussed in Chapter 6.

### Atrial myxoma

The diagnosis of atrial myxoma is challenging. A myriad of symptoms can occur, and this often leads to long delays in diagnosis and treatment. About 30% of atrial myxomas cause cerebral emboli – accounting for about 0.4% of all strokes and stroke is the most common neurological presentation (Figure 26.5). The majority of patients (up to 90%) present with constitutional symptoms of fatigue, fever, myalgia, arthralgia and weight loss. Cardiac symptoms are often present and include breathlessness in association with congestive failure and syncope. Investigations show elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), anaemia and thrombocytosis or thrombocytopenia. Chest X-ray shows left

**Figure 26.4** Bacterial endocarditis. (a) Left frontal intracerebral haemorrhage in a patient with bacterial endocarditis and sudden non-fluent dysphasia. Haemorrhage may have come from a ruptured mycotic aneurysm, although no aneurysm was detected on formal angiography in this case. (b) Scattered foci of high signal caused by disseminated septic emboli caused by endocarditis (T1 axial images).

**Figure 26.5** Axial CT brain scans from a patient with an atrial myxoma showing low attenuation in both cerebellar hemispheres and the left thalamus resulting from embolic material.

atrial or ventricular enlargement and occasionally intracardiac tumour calcification. Echocardiography is the investigation of choice, but transthoracic studies have a false negative rate of about 20%. For this reason, if clinical suspicion is high, transoesophageal echocardiography must be performed.

Stroke can result from embolic tumour fragments rather than fibrin thrombus, so anticoagulation may not be helpful and is probably best avoided, particularly as delayed cerebral aneurysm formation, often fusiform, in distal branches, can lead to cerebral haemorrhage. The treatment of atrial myxoma is optimisation of cardiac function and urgent surgical removal. Follow-up with transoesophageal echocardiography is recommended as recurrence can occur, especially within the first 2 years – but occasionally more than 10 years later.

## Endocrine conditions

### Thyroid disorders

Thyroid disorders can have a major impact on neurological function; they affect any part of the central nervous system (CNS), peripheral nerves or muscle, mainly via high or low levels of circulating T4 and T3 or immune-mediated damage. It is especially important to recognise neurological manifestations of thyroid disease, as the symptoms will usually respond to appropriate treatment.

### Hyperthyroidism

Hyperthyroidism is most often brought about by immune mechanisms (Graves' disease), but other causes include thyroiditis, multinodular goitre or, rarely, pituitary tumours. A myopathy is present to some extent in almost all patients with hyperthyroidism, although this may be asymptomatic. The onset is usually subacute, with proximal limb muscles typically affected, leading to difficulties ascending stairs, rising from a chair and raising the arms. Bulbar involvement is less common, although this may be a prominent feature in the rare

acute form of thyrotoxic myopathy. Pain is common. Clinical findings are of proximal wasting especially involving shoulder and pelvic girdle muscles including quadriceps with hyper-reflexia but usually normal tone. The investigation findings usually include a normal creatine kinase (CK), in contrast to the raised CK of hypothyroid myopathy; electromyographic (EMG) abnormalities are seen, such as polyphasic motor potentials and sometimes a decrement in compound muscle action potential (CMAP) on repetitive stimulation. Rarely, hyperthyroidism is associated with a form of hypokalaemic periodic paralysis, a condition seen particularly in South-East Asia (Chapter 10).

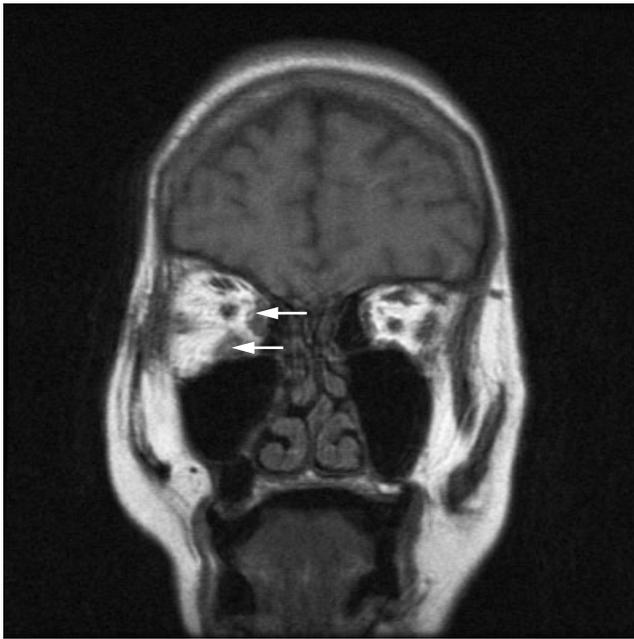

Thyroid disease is strongly associated with myasthenia gravis, probably because susceptible individuals are genetically predisposed to autoimmune disorders. About 10% of patients with myasthenia have a thyroid disorder, more commonly hyperthyroidism than hypothyroidism.

Hyperthyroidism can occasionally cause a dramatic upper motor neurone syndrome, particularly affecting the legs, with spasticity, weakness, clonus and extensor plantars. This can cause diagnostic confusion by mimicking spinal cord compression. A mixed upper and lower motor neurone picture can also be present causing an amyotrophic lateral sclerosis-like presentation.

Tremor is a near-invariable feature of hyperthyroidism, often most apparent in the outstretched arms. Myoclonus, chorea and even parkinsonism have also been described.

Peripheral neuropathy is an uncommon but described feature of hyperthyroidism. A flaccid paraparesis with areflexia rarely occurs (Basedow's paraplegia).

Thyroid eye disease is a common feature of Graves' disease, occurring in up to 70% of patients depending on criteria used. The features of Graves' ophthalmopathy are lid retraction, inflammation of orbital soft tissues, causing redness and swelling of the lids and conjunctivae, proptosis, extraocular muscle involvement causing ophthalmoplegia, corneal damage and, rarely, optic nerve compression.

**Figure 26.6** Graves' disease. Graves' disease with progressive diplopia and restriction of right eye movements. MRI shows enlarged inferior and medial recti on the right (arrows).

MRI or CT scanning are helpful in showing enlarged extraocular muscles, particularly the medial and inferior recti (Figure 26.6). Although usually both eyes are affected, some patients have markedly asymmetric involvement. Treatment includes steroids, botulinum toxin, radiotherapy or surgery.

Hyperthyroid encephalopathy is now rare, but can occur in untreated patients, after radio-iodine treatment, during intercurrent illness or following surgical procedures. Florid signs of thyrotoxicosis, confusion, agitation, fever, seizures and upper motor neurone signs may all be present. Mortality from this disorder remains high.

### Hypothyroidism

Hypothyroidism, resulting from immune-mediated mechanisms or following surgical or radiotherapy thyroid ablation, is an important treatable cause of neurological dysfunction affecting many parts of the nervous system.

An encephalopathy characterised by slowness, lethargy and impaired attention is commonly seen in hypothyroidism. In its most severe form, myxoedema coma, there is a substantial mortality if not recognised early and treated. Clinical features of myxoedema coma include hypothermia, depressed conscious level and usually a precipitating event such as sepsis or trauma. Early recognition and treatment with thyroid replacement (T4 and T3), antibiotics and steroids are often life-saving.

Hypothyroidism should be carefully excluded in all patients presenting with any dementing illness, because it is so readily amenable to treatment. Neuropsychiatric features can also occur, for example psychosis with paranoia and hallucinations (myxoedema madness).

Cerebellar ataxia is well described and does occur, if rarely, in hypothyroidism, involving gait and the limbs, but with normal eye movements. Muscular weakness is common in hypothyroidism and sometimes an early clinical feature; it occurs in some 80% of cases if carefully sought. Weakness (usually fairly mild) is accompanied by

depressed or slow-relaxing reflexes (pseudomyotonia), and typically involves the pelvic and shoulder girdles. Percussion of the muscle may cause a slow rippling effect termed myoedema. Pain during or following muscle activity is typical of hypothyroid myopathy, and all patients presenting with unexplained muscle pains, especially related to exertion, should be screened for hypothyroidism; early treatment prevents development of more severe symptoms. The CK level is usually raised, sometimes markedly so (<10 times normal). Treatment with thyroxine improves the weakness, usually promptly but in advanced cases it is sometimes over a year before the situation recovers fully.

Hypothyroidism also causes peripheral nerve problems. An entrapment neuropathy, most frequently carpal tunnel syndrome, is seen in some 10% of hypothyroid patients. A useful working rule is to check the thyroid function in all patients with suspected carpal tunnel syndrome. Treatment is restoration of the euthyroid state rather than surgical decompression. A polyneuropathy develops in up to two-thirds of hypothyroid patients, usually mild and mainly sensory.

### Neurological aspects of Hashimoto's thyroiditis

The possible relationship between thyroid antibodies and encephalopathy has been debated since the 1960s. The term Hashimoto's encephalopathy describes a subacute, sometimes relapsing encephalopathy, responding well to corticosteroids and associated with a high titre of antithyroid antibodies. The encephalopathy in such cases is not explained by thyroid status, which may be normal. The term Hashimoto's encephalopathy has been criticised as it implies that the antibodies are pathogenic in the development of encephalopathy, a link for which there is little convincing evidence. It has been suggested that the thyroid antibodies may be epiphenomena, and indeed they may be seen in encephalopathies known to have an alternative cause. It is therefore important to try to establish a definitive diagnosis for an encephalopathy associated with antithyroid antibodies. For example, the syndromes of encephalopathy with antibodies to voltage-gated potassium channels or *N*-methyl-D-aspartate (NMDA) receptors, or amyloid-beta related angitis, may also need to be considered. Sometimes, invasive tests including cerebral biopsy are needed to exclude treatable causes of encephalopathy.

### Diabetes mellitus

Diabetes mellitus can cause multiple effects on the nervous system. Rare congenital causes of diabetes that may be encountered by neurologists include mitochondrial cytopathies, particularly patients with sensorineural deafness but also those with MELAS or Kearns-Sayre syndrome (Chapter 10), Friedreich's ataxia and Wolfram's syndrome (type 1 diabetes, diabetes insipidus, optic atrophy and deafness [DIDMOAD]). The other main neurological conditions associated with diabetes are acute metabolic disturbances (related to hyperglycaemia or hypoglycaemia) and the diabetic neuropathies.

### Acute metabolic disturbances

Diabetic ketoacidosis occurs because of insufficient insulin levels in patients with type 1 diabetes, usually because of undertreatment with insulin or its omission, with or without an intercurrent illness such as sepsis. Drowsiness occurs but not usually coma. Very rarely, cerebral oedema can develop during treatment because of over-rapid correction of hyperosmolality, especially in children. This can cause death from raised intracranial pressure (ICP). Hyper-osmolar non-ketotic coma (HONK) occurs mainly in patients with type 2 diabetes and can lead to very high blood glucose with high sodium levels and therefore high osmolality. Reduced conscious level or

seizures also occur. Conversely, low blood glucose can result from excessive doses of oral hypoglycaemics or insulin. With a low blood sugar, there is often a warning prodrome, allowing the patient to react and correct the problem, but in some patients with type 1 diabetes the warning is absent, placing them at much greater risk of prolonged hypoglycaemia. Early warning symptoms include sweating, trembling, tingling hands and palpitations. Neurological features include confusion, dysarthria, altered behaviour and agitation, seizures and, albeit rarely, focal neurological features (e.g. hemiparesis or hemiplegia) that can mimic a TIA or stroke. If profound hypoglycaemia is unrecognised coma and permanent hypoglycaemic brain injury can occur.

### Diabetic neuropathies

The neuropathies caused by diabetes are covered in detail in Chapter 10. The most common is a distal sensorimotor neuropathy, affecting over 50% of patients with long-standing disease. Rarer variants include diabetic autonomic neuropathy, acute painful neuropathy, cranial neuropathy (especially oculomotor), thoraco-abdominal neuropathy and painful proximal neuropathy (diabetic amyotrophy).

### Pituitary disorders

Pituitary tumours are discussed in Chapter 21. Pituitary neoplasms either produce an excess of hormone secretion (in about two-thirds) or are non-functioning – sometimes causing deficiency by mass effects (in about one-third). Tumours secreting prolactin (prolactinomas) cause secondary amenorrhoea, galactorrhoea, infertility and impotence. Other clinical syndromes include acromegaly (resulting from growth hormone secretion) and Cushing's disease (resulting from adenocorticotrophic hormone [ACTH] secretion). Patients with pituitary tumours can present with visual disturbances, including visual failure, headaches, and endocrine features, or simply with an unexplained high serum prolactin level. Non-secreting tumours cause hypopituitarism, with secondary amenorrhoea, infertility or impotence, loss of secondary sexual characteristics or hypothyroidism.

Diabetes insipidus results from dysfunction of the posterior pituitary. Reduced secretion of arginine vasopressin and antidiuretic hormone cause symptoms of thirst, polyuria and polydipsia. The common causes are trauma, tumours, sarcoidosis and other granulomatous conditions, and infections.

Pituitary apoplexy (Sheehan's syndrome) is a dramatic clinical syndrome of severe headache, nausea, vomiting and often hypotensive collapse with sudden bilateral visual loss. The usual cause is haemorrhage into a pituitary macroadenoma.

### Inappropriate antidiuretic hormone secretion and cerebral salt wasting

Inappropriate antidiuretic hormone secretion (SIADH) and cerebral salt wasting are discussed in Chapter 20.

### Parathyroid disorders

In cases of hypoparathyroidism (or pseudohypoparathyroidism, a rare familial form with skeletal and developmental anomalies), the reduction in serum ionic calcium causes sensory disturbances, tetany, chorea or seizures (Table 26.2); basal ganglia or cerebellar calcification may also occur. Hyperparathyroidism resulting from parathyroid adenoma or hyperplasia causes muscle weakness, fatigability and amyotrophy with preserved reflexes, and has been reported on occasion to resemble motor neurone disease.

### Adrenal disorders

**Cushing's disease** Cushing's disease results from pituitary hypersecretion of ACTH and thus high plasma cortisol, most often from a pituitary microadenoma. Cushing's syndrome is the result of treatment with exogenous steroids or primary hyperadrenalism and ACTH levels are low. Clinically, the disease and the syndrome are indistinguishable, both being characterised by centripetal obesity, hypertension, hirsutism, abdominal striae, acne, menstrual irregularity, immunosuppression, myopathy and psychosis. Cushing's disease is usually caused by a microadenoma that typically does not cause visual symptoms.

### Addison's disease

Addison's is caused by adrenal insufficiency. In the past, tuberculosis was a common cause, but now an autoimmune mechanism is the cause in most cases. A rare cause is adrenoleukodystrophy, in which brain and spinal cord involvement results in other neurological features of varying severity (Chapter 19). The important features of Addison's disease are a tendency to faint, episodes of unexplained coma or episodes of stupor, weight loss, apathy and vomiting with pigmentation of the skin and mucous membranes. Addison's disease can be mistaken for 'ME'. The condition can be life-threatening, especially during intercurrent illnesses. The laboratory findings are of low serum sodium, high potassium and low serum cortisol and high ACTH. Primary adrenal failure (Addison's disease) needs to be differentiated from secondary causes of ACTH deficiency, both iatrogenic and resulting from pituitary failure.

**Phaeochromocytoma** Phaeochromocytoma is a neuroendocrine catecholamine secreting tumour of the adrenal medulla and is an important cause of hypertension, especially in younger people. Tumours are often multiple and sometimes extramedullary (paragangliomas). Other clinical features include panic, anxiety, palpitations, headaches and weight loss. Neurological features are rare, but can include those of accelerated hypertension, including intracranial haemorrhage and hypertensive encephalopathy.

### Electrolyte disturbances

Electrolyte abnormalities are extremely common in acute and outpatient practice; their effects range from being asymptomatic to causing profound disturbance of function in the central and peripheral nervous systems. As a general principle, the clinical severity of any electrolyte disturbance is greatest when the abnormality has developed rapidly. Treatment is aimed at not only correcting the electrolyte disturbance itself, but also identifying and treating the cause. The CNS effects of electrolyte imbalance, often including altered consciousness and seizures, are related to fluid shifts and brain volume changes. Serum hyperosmolality causes brain shrinkage, while hypo-osmolality causes brain swelling. Other mechanisms include disordered transmembrane potentials and neurotransmission. The clinical features of abnormalities in serum sodium, potassium, calcium and magnesium are summarised in Table 26.2 and are briefly discussed here.

### Sodium

Neurological effects of sodium disturbances are covered in detail in Chapter 20. SIADH is a consequence of a number of intracerebral pathologies including meningo-encephalitis or subarachnoid haemorrhage. Because the diagnosis can be made only when the serum is dilute and the urine inappropriately concentrated, osmolality

**Table 26.2** Causes and features of common electrolyte disturbances.

Electrolyte disturbance	Some causes	Neurological features
Hyponatraemia	SIADH Cerebral salt wasting Diuretic use Diarrhoea, vomiting Addison's disease Drug induced (e.g. carbamazepine, antidepressants, tobutamide) Liver disease Cardiac failure Psychogenic polydipsia	Coma Confusion Convulsions (<115 mmol/L)
Hypernatraemia	Diabetes insipidus HONK Diarrhoea Dehydration Sweating, inadequate water intake Cushing's syndrome, Conn's syndrome	Reduced conscious level Seizures Tremor Movement disorders
Hypokalaemia	Diarrhoea Vomiting Renal tubular disease Drug/toxin induced (e.g. alcohol, diuretics, antibiotics, theophylline, steroids, laxatives) Diabetic ketoacidosis	Generalised muscle weakness
Hyperkalaemia	Renal disease Addison's disease Drug induced Excessive intake Burns Metabolic acidosis	Generalised muscle weakness ECG changes Cardiac arrest
Hypocalcaemia	Hypoparathyroidism Vitamin D deficiency Chronic renal failure Pseudohypoparathyroidism Eating disorders Acute pancreatitis, septic shock Magnesium deficiency	Paraesthesias Tetany Seizures, chorea Encephalopathy Papilloedema and ICP Coma
Hypercalcaemia	Hyperparathyroidism Other endocrine diseases Osteolytic bone malignancy Immobility Sarcoidosis Drug induced Vitamin D intoxication Renal disease	Anorexia, abdominal pain Nausea Fatigue Reduced conscious level Constipation Myoclonus, rigidity Elevated CSF protein
Hypomagnesaemia	Rarely isolated – usually part of complex electrolyte derangement Calcium deficiency states	
Hypermagnesaemia	Renal disease Iatrogenic (e.g. treatment of eclamptic seizures)	

CSF, cerebrospinal fluid; ECG, electrocardiography; HONK, hyper-osmolar non-ketotic coma; ICP, intracerebral pressure; SIADH, syndrome of inappropriate antidiuretic hormone.

measurements are critical in the evaluation of hyponatraemia. The over-rapid correction of chronic hyponatraemia can cause the distinct syndrome of central pontine myelinolysis (Chapter 20); the fully developed syndrome of a quadriplegia with brainstem signs carries a high mortality. This syndrome is more common in high risk groups such as alcoholics.

Hyponatraemia can be a clue to the development of limbic encephalitis associated with antibodies against voltage-gated potassium channels. This syndrome is associated with SIADH and consequent hyponatraemia.

### Potassium

Patients with hyperkalaemia or hypokalaemia do not usually present to neurologists. However, both conditions are features of periodic paralysis (Chapters 3 and 10), and whatever the cause, the main neurological effect of low (or sometimes high) serum potassium is muscle weakness. Serum potassium must always be checked in anyone with weakness.

### Calcium and magnesium

Disturbances of calcium metabolism sometimes present to a neurologist and should be sought in patients with tetany, seizures or occasionally chorea. Tetany is the classic clinical manifestation of acute hypocalcaemia, reflecting neuromuscular irritability. Symptoms of tetany include tingling or numbness (peri-oral or in the hands and feet), muscle cramps and, when severe, carpopedal spasm, laryngospasm, seizures or generalised tonic muscle contractions. Less specific symptoms include fatigue, hyperirritability, anxiety and depression, and some patients, even with severe hypocalcaemia, have no neuromuscular symptoms. Key causes of hypocalcaemia are hypoparathyroidism, pseudohypoparathyroidism and vitamin D deficiency. Chronic hypocalcaemia can lead to calcification in the basal ganglia, usually found coincidentally on imaging. Treatment of severe symptomatic acute tetany (e.g. carpopedal spasm seizures) is with intravenous calcium. For milder symptoms of neuromuscular irritability (paresthesias), oral calcium supplementation may be sufficient. Vitamin D deficiency must be corrected.

Isolated hypomagnesaemia is uncommon. Clinical manifestations of hypomagnesaemia overlap with those of hypocalcaemia and include features of neuromuscular hyperexcitability (e.g. tetany, convulsions), weakness, apathy, delirium and coma. Encephalographic (ECG) changes include QRS complex widening, peaking of T waves and, with more severe hypomagnesaemia, PR prolongation and arrhythmias. Abnormalities of calcium metabolism, including hypocalcaemia and hypoparathyroidism, may be associated. Hypomagnesaemia may be a feature of eclamptic seizures and should be treated in this context.

## Haematological disorders

This section considers anaemias, haematological proliferative disorders, bleeding diatheses and coagulation disorders. Haematological disorders and stroke are discussed in Chapter 5 and are briefly mentioned here.

### Anaemias

Anaemias generally cause rather non-specific symptoms including fatigue, dizziness, impaired concentration, faintness and syncope, irritability and headache; a full blood count should always be performed to exclude anaemia as a cause of these symptoms, and those of chronic daily headache. Occasionally, severe anaemia (less than 8 g/dL) can cause focal neurological deficits, and TIAs (usually in the presence of a significant atherosclerotic stenosis in an

extracranial or intracranial vessel). Iron deficiency anaemia has been reported to be associated with idiopathic intracranial hypertension, with response to treatment of the anaemia. Iron deficiency is also associated with the restless leg syndrome (Chapters 6 and 20), sometimes with normal haemoglobin but a reduced serum ferritin level. Retinal haemorrhages are sometimes seen with very severe anaemias, especially with B<sub>12</sub> deficiency.

Vitamin B<sub>12</sub> deficiency, one cause of megaloblastic anaemia, is an important and potentially treatable cause of neurological symptoms and signs and discussed in detail elsewhere (Chapters 16 and 19). Vitamin B<sub>12</sub> deficiency can cause many different neurological syndromes: peripheral neuropathy with or without myelopathy (together known as subacute combined degeneration of the cord), encephalopathy, dementia, optic neuropathy and ophthalmoplegia. Folic acid can mask the anaemia without preventing the neurological sequelae. Before the discovery of vitamin B<sub>12</sub>, subacute combined degeneration of the cord was fatal. Treatment is with long-term hydrocobalamin injections. Measurement of serum homocysteine should be carried out if the serum vitamin B<sub>12</sub> level is non-diagnostic and there is clinical suspicion of deficiency. Nitrous oxide exposure and low serum copper are also rare causes of a syndrome resembling subacute combined degeneration of the cord.

Sickle cell disease causes neurological symptoms from intravascular sickling of erythrocytes via a number of mechanisms including large vessel arteriopathy, small perforating vessel occlusion, haemolysis, abnormal vasomotor tone and promotion of a hypercoagulable state. The incidence of stroke in sickle cell disease is much higher than in the general population. Sickling is exacerbated by low oxygen saturation and/or intercurrent illness. Small vessels can be occluded to cause subcortical infarction (usually not acutely symptomatic) while large vessels (especially the supraclinoid intracranial internal carotid and proximal middle cerebral arteries) can develop intimal proliferation causing stenosis and thrombo-embolism (often symptomatic). In patients with overt large artery stroke there is commonly distal collateral formation (secondary Moyamoya changes). Subacute or chronic symptoms include headaches, which may be migrainous, and cognitive impairment caused by the accumulation of ischaemic damage. Haemorrhagic complications of sickle cell disease can occur in adults, especially subarachnoid haemorrhage. Neurological symptoms have been found to occur in some 25% of patients with sickle cell disease, while up to one-third have imaging evidence of cerebrovascular disease. Migrainous headaches are common. Treatments available to prevent the neurological consequences of sickle cell disease include partial-exchange transfusion, hydroxyurea and bone marrow transplantation.

Thalassaemia is a rare cause of neurological symptoms. Haematopoiesis outside the marrow occurs in lymphoid tissue, spleen, liver and bone. Myelopathy has been described and attributed to haematopoietic tissue in the epidural space. Corticosteroids, radiotherapy, blood transfusions and surgical decompression have been used in this situation.

### Proliferative conditions

#### Leukaemias

Leukaemia can cause neurological symptoms by direct infiltration of nervous tissue or indirectly by haemorrhage related to low platelets, from infection resulting from impaired immunity, electrolyte disturbances or hyperviscosity.

Leukaemic cells enter the nervous system by haematogenous seeding, lymphatic spread or direct invasion by spread along the

meninges. Meningeal leukaemia is most commonly associated with acute lymphocytic leukaemia (ALL) and presents as a subacute meningitic syndrome with headache, drowsiness, neck stiffness, irritability and cranial neuropathy, especially affecting the optic, oculomotor, abducens, facial and vestibulocochlear nerves. Papilloedema is commonly seen. Raised CSF protein may impair CSF resorption leading to hydrocephalus. The CSF contains leukemic cells and usually a high protein, although repeated lumbar puncture may be needed to establish a diagnosis.

Solid leukaemic deposits may occur in any part of the CNS, although the brain is more commonly affected than the spine. Peripheral nerve involvement is unusual.

### Plasma cell dyscrasias

Plasma cell dyscrasias are conditions resulting from the proliferation of a single clone of immunoglobulin-secreting plasma cells (activated B cells). The antibodies secreted by the proliferating clone are classified into IgM, IgG and IgA types according to their heavy-chain class, from which are derived various terms including monoclonal gammopathy, M-protein and other paraproteins. All patients with neuropathy should be tested for a paraprotein.

The plasma cell dyscrasias include myeloma (multiple myeloma and osteosclerotic myeloma), Waldenstrom's macroglobulinaemia, monoclonal gammopathy of undetermined significance (MGUS), plasmacytoma and plasma cell leukaemia.

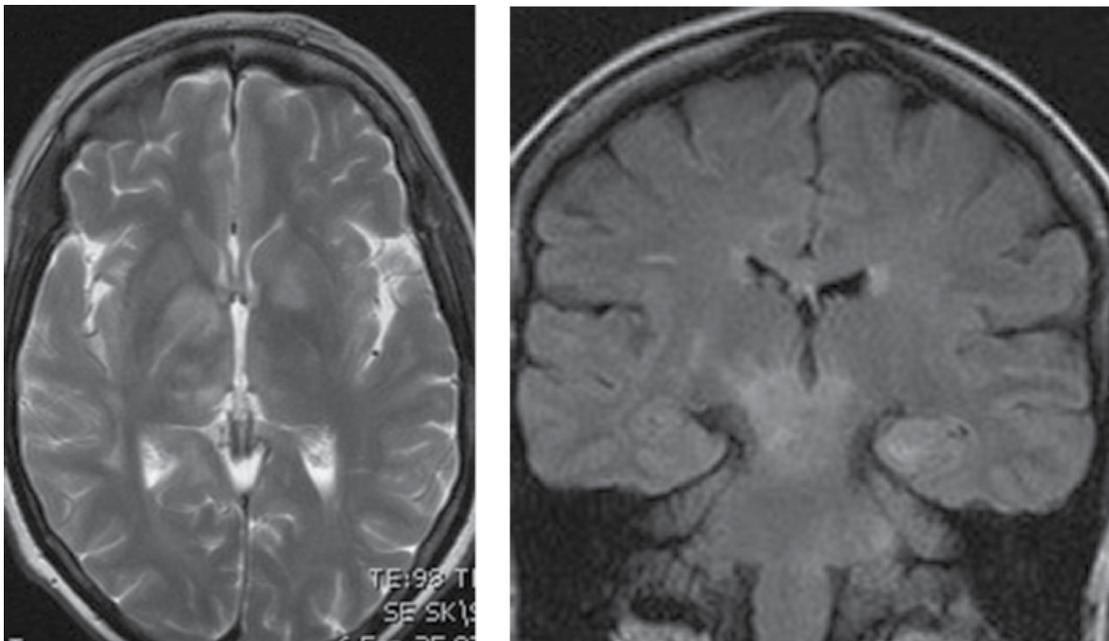

Multiple myeloma affects bones causing pain, fractures and sometimes compression of neural tissue. Myeloma involving the vertebrae is a common cause of spinal cord compression; the development of the paraparesis is usually preceded by back pain for several months. The cauda equina and nerve roots are sometimes compromised by direct infiltration. Meningeal involvement can also cause cranial neuropathies; occasionally such meningeal infiltration may be the only manifestation of myeloma. A peripheral neuropathy can result from a paraneoplastic mechanism, amyloid deposition compromising nerve blood supply or direct infiltration of nerves.

Waldenstrom's macroglobulinaemia is a syndrome secondary to lymphoplasmacytoid lymphoma, causing hyperviscosity associated with an IgM gammopathy; it involves the nervous system in about 25% of cases. A progressive sensori-motor neuropathy results from IgM antibody binding and/or lymphocytic infiltration. The hyperviscosity can cause focal neurological deficits including strokes and an encephalopathy with headache. Patients also have a bleeding tendency and may develop bruising, purpura and subarachnoid haemorrhage. The Bing-Neel syndrome describes CNS infiltration by neoplastic lymphoplasmacytoid and plasma cells with or without CSF hyperglobulinaemia. The increased blood viscosity caused by cellular infiltration impairs circulation through small vessels in the brain and the eye causing central venous thrombosis. The abnormal cells may involve the brain parenchyma, leptomeninges, dura and/or CSF. Patients present with a variety of neurological symptoms and signs including seizures, hearing loss, cognitive impairment, gait instability and lower limb weakness. It is important to distinguish the condition from CNS involvement resulting from hyperviscosity, vasculitis or malignant transformation. Treatment of the underlying lymphoma includes systemic or intrathecal chemotherapy and cranial irradiation.

MGUS is a benign condition, but some patients ultimately develop a malignant plasma cell dyscrasia; the paraprotein level should be monitored 6–12 monthly. A chronic inflammatory demyelinating peripheral neuropathy (CIDP) may be associated.

### Lymphomas

Lymphoma, both of Hodgkin's and non-Hodgkin's type, can affect the nervous system. Usually, patients will have evidence of lymphoma elsewhere and the disease spreads directly to CNS tissue (Figure 26.7). Spinal cord disease (solid tumours) and meningeal infiltration are common manifestations of lymphoma. Extradural deposits compromise the blood supply of the cord to cause an ischaemic myelopathy or exert a direct compressive effect. The cauda equina and lumbosacral roots can be infiltrated causing

**Figure 26.7** Metastatic intracerebral lymphoma. Axial T2 and coronal T1 MRI scans showing multiple hypointense intracranial lesions affecting both grey and white matter structures including the temporal lobes, brainstem and cerebellum.

painful radicular syndromes. Meningeal lymphoma can have a chronic clinical course, sometimes with spontaneous temporary remission. The hemispheres, cerebellum or brainstem may be infiltrated to cause focal signs and elevated ICP. A number of lymphoma-associated paraneoplastic syndromes have been described, including peripheral neuropathy, necrotising myelopathy, leukoencephalopathy and polymyositis.

Primary CNS lymphomas are rare, constituting only 1% of primary brain neoplasms (Figure 26.8). They are typically of B-cell origin and affect principally individuals with impaired immunity, including transplant recipients, patients with HIV and inherited immunodeficiency disorders. The tumours are usually ill-defined lesions in the cerebral hemispheres, ventricles, corpus callosum, basal ganglia and cerebellum. Lymphoma can respond dramatically but temporarily to corticosteroids in the early stages, which can cause diagnostic confusion. Lymphoma also presents with focal symptoms or encephalopathy and/or seizures and nodular enhancing lesions in the ventricular wall. Intravascular lymphoma is a rare subtype of large B-cell lymphoma that is characterised by the proliferation of lymphoma cells within the lumina of small blood vessels, particularly capillaries and post-capillary venules, without an obvious extravascular tumor mass or detectable circulating lymphoma cells in the peripheral blood (Figure 26.9).

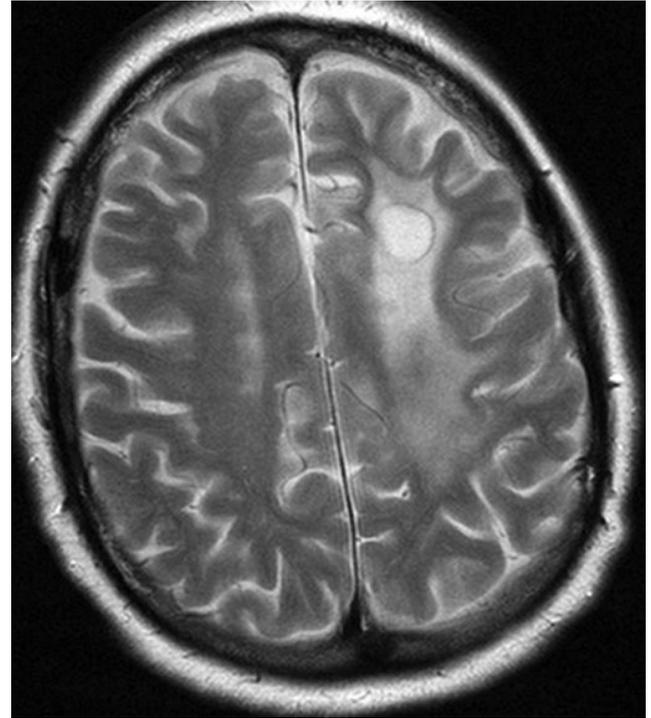

The differential diagnosis of cerebral lymphoma is wide and includes metastatic carcinoma, glioma, tuberculosis, toxoplasmosis, neuro-cysticercosis and sarcoidosis. A tissue diagnosis is usually essential. For a more detailed discussion of primary CNS lymphoma see Chapter 21.

#### Langerhans cell histiocytosis

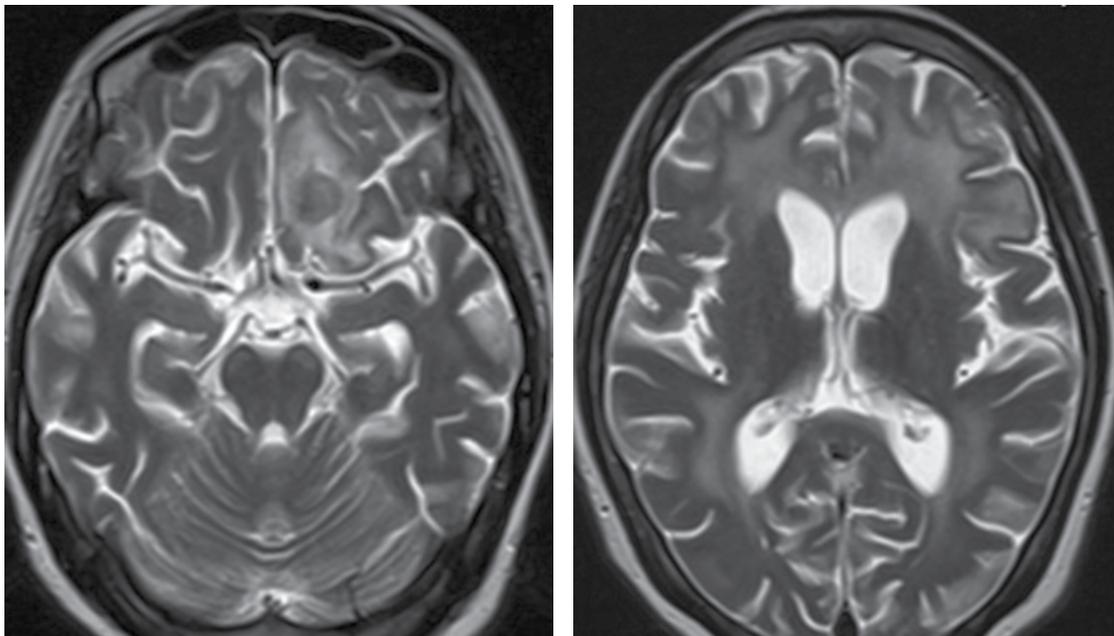

Langerhans cell histiocytosis (LCH) is a histiocytic cell disorder that occurs in all age groups. Histiocytes are derived from macrophages or dendritic cells in the skin and mucosa. LCH is characterised by single or multiple osteolytic bone lesions which may be

associated with extraskeletal lesions affecting multiple organs and the CNS.

The most frequent site of lytic bone lesions are the skull, particularly involving the calvaria, maxillofacial bones and the sella affecting the hypothalamus–pituitary axis. Patients with LCH present with localised bony pain, skull or facial swelling, hearing loss, seizures or

**Figure 26.9** Intravascular cerebral B-cell lymphoma. Axial T2 MRI showing extensive white matter high signal and haemorrhage.

**Figure 26.8** Intracerebral B-cell lymphoma. Left inferior frontal lesion with extensive, diffuse signal change in cerebral white matter and diffuse volume loss (MRI T2-weighted images).

cranial nerve palsies. Involvement of the CNS is particularly associated with the presence of bone lesions affecting the anterior or middle cranial fossa. There may be ataxia, cognitive dysfunction, hypopituitarism or diabetes insipidus. Mass lesions or granulomas develop in the parenchyma or choroid plexus leading to obstruction of CSF flow and hydrocephalus. Imaging shows lytic bone lesions or bilateral T2 high signal changes in the basal ganglia and cerebellum. Treatment is with varying chemotherapy regimens.

Related conditions include Erdheim–Chester disease which is a multisystem, infiltrative, histiocytic disorder in which granulomatous lesions affect the long bones, skull, pituitary and CNS in addition to multiple systemic organs. Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy) is a predominantly macrophage-related disorder associated with extensive lymphadenopathy involving mediastinum, axillary and inguinal sites as well as the head and neck.

### Polycythaemia

Polycythaemia is an increased red cell mass causing a raised haematocrit. It may be primary (polycythaemia vera) or secondary to another condition (e.g. chronic hypoxia). The symptoms of polycythaemia can be generalised and rather ill-defined (including poor concentration, feelings of cephalic fullness, tinnitus, paraesthesias) or acute focal vascular syndromes, either permanent or transient. These may be caused by arterial or venous events. Chorea is associated with polycythaemia vera (related to a mutation in the erythropoietin receptor gene, *JAK2*) and may respond to treatment of the polycythaemia. Polycythaemia vera can transform into other haematological malignancies (e.g. leukaemias, myelofibrosis). The mainstay of treatment of polycythaemia is repeated venesection.

### Thrombocythaemia

Thrombocythaemia (platelet count  $>800\ 000/\text{mm}^3$ ) is associated with an increased risk of thrombosis and haemorrhage within the CNS. It may be associated with leukaemia or myelodysplasia. Thrombosis can occur in arteries, veins or venous sinuses and is related to hyperviscosity. Haemorrhage can also occur (subdural, extradural, intracerebral, subarachnoid); the mechanism presumably involves abnormal platelet function. Treatment with hydroxyurea is usually recommended to prevent neurological symptoms.

### Bleeding disorders

#### Thrombotic thrombocytopenic purpura

Thrombotic thrombocytopenic purpura (TTP) is a rare disorder of early adulthood characterised by recurrent and widespread occlusion of small vessels. The pathophysiology involves micro-angiopathic haemolysis and formation of platelet micro-thrombi throughout the body including the CNS. TTP may be familial or acquired but in both cases endothelial cells secrete abnormally large von Willebrand factor multimers that are not degraded because of the lack of the cleavage enzyme ADAMTS-13. This allows the formation of platelet thrombi in small vessels. The clinical hallmarks are fevers, hepatic and renal disease and a low platelet count. Fragmented red cells on the blood film, elevated lactate dehydrogenase, bilirubin and reticulocyte count also point towards the diagnosis. Fluctuating neurological symptoms of altered consciousness level, seizures, headache or encephalopathy can be the presenting features in half of the patients and may be preceded by a provoking factor such as an intercurrent illness. The majority of patients will at some stage of the illness develop neurological symptoms. Low

platelets lead to haemorrhage including intracerebral haemorrhage. Ischaemic stroke from large or small vessel occlusion also occurs. The mainstay of treatment is plasma exchange. Antiplatelet agents or anticoagulants can be used although evidence for efficacy is lacking. Other immunomodulatory treatments have been used including ciclosporin. Rituximab is the subject of ongoing investigation.

Haemophilia, disseminated intravascular coagulation and von Willebrand's disease are also rare causes of intracerebral haemorrhage.

### Coagulation disorders

The antiphospholipid antibody syndrome (Chapter 5), although usually characterised by venous thromboses, is also an important rare cause of arterial cerebrovascular events, sometimes in association with skin rashes, migraine and recurrent miscarriage. Thrombophilias including protein C and S deficiency, antithrombin III deficiency, factor V Leiden and the *MTHFR* mutation are associated with cerebral venous thrombosis, but not strongly with arterial events. These disorders are also discussed in more detail in Chapters 5 and 19.

### Primary immunodeficiency

Primary immunodeficiency describes conditions caused by inherited defects of the immune system and can be divided into disorders affecting humoral immunity, cell-mediated immunity, phagocytic or complement function. Combined immunodeficiency is caused by mutations of the genes coding for the development and function of both T and B cells and the most severe form causes early death from overwhelming infection. Incomplete forms are milder and present in late childhood with recurrent or chronic respiratory tract infections (including bronchiectasis), chronic viral disease, opportunistic infection, chronic lymphoma, a family history of immunodeficiency or the new onset of autoimmune disease. T-cell disorders include ataxia-telangiectasia (see Neurocutaneous syndromes), Wiskott–Aldrich syndrome and X-linked lymphoproliferative disease.

Common variable immunodeficiency (CVID) is characterised by impaired B-cell differentiation with defective immunoglobulin production. The clinical manifestations are heterogeneous and include recurrent infections (including meningitis), chronic lung disease, autoimmune disorders, gastrointestinal disease and a heightened susceptibility to lymphoma. CVID is a collection of hypogammaglobulinaemia syndrome and is associated with multiple genetic defects. The condition is defined by reduced serum concentration of IgG, IgA and/or IgM with a poor response to immunisation in the absence of other immune deficiency states. Patients with CVID can develop diffuse infiltration with non-caseating granuloma affecting lymphoid or solid organs including the brain and the eyes. There is an increased risk of malignancy, and, in particular, non-Hodgkin's lymphoma which is usually extranodal, well differentiated and of B-cell origin and can lead to meningeal or parenchymatous involvement.

### Gastrointestinal disorders

#### Hepatic encephalopathy

In severe hepatic failure, toxins are not removed from portal blood and thus enter the systemic circulation. The toxins responsible for hepatic encephalopathy include ammonia, aromatic amino acids, mercaptans, short-chain fatty acids and endogenous benzodiazepines. The speed of onset of encephalopathy parallels

that of the underlying hepatic failure; this may vary from hours to very slow progression over months. Delirium typically fluctuates during the day and may be accompanied by euphoria and neurological signs including a flapping postural tremor of the hands (asterixis) and constructional apraxia. Hepatic foetor is the sickly sweet odour on the breath found in many cases. Untreated, delirium progresses to stupor and coma. Treatment is mainly aimed at reducing the nitrogen burden in the bowel – a low protein diet, regular large doses of lactulose and sometimes neomycin. Hepatic transplantation is sometimes required.

### **Vitamin deficiencies causing neurological disorders** (Chapter 19)

#### **Vitamin B<sub>1</sub> deficiency**

Vitamin B<sub>1</sub> (thiamine) deficiency causes Wernicke's encephalopathy, Korsakoff's syndrome and beri-beri (Chapter 19). Wernicke's encephalopathy is a subacute illness causing delirium, nystagmus – with or without ophthalmoplegia – and ataxia, typically of gait more than limbs. The syndrome is underdiagnosed and potentially treatable. Korsakoff's syndrome can follow Wernicke's encephalopathy and is characterised by a more restricted syndrome of anterograde and retrograde amnesia without delirium. Although classically a result of chronic alcoholism, Wernicke's encephalopathy and Korsakoff's syndrome are well known to result from other causes, such as intractable vomiting (e.g. anorexia nervosa, hyperemesis gravidarum). One of the three patients originally reported by Wernicke suffered from severe vomiting from pyloric stenosis induced by sulfuric acid poisoning.

The extent of recovery is influenced by the time to diagnosis and treatment with thiamine. Some of the eye signs and ataxia often resolve but a residual amnesic syndrome is common. In any patient with cognitive disturbance or delirium in the context of heavy alcohol use, prompt treatment with high dose intravenous B vitamins is recommended – it rarely causes harm.

#### **Vitamine B<sub>3</sub> (niacin) deficiency (Pellagra)**

Endemic niacin deficiency is rarely seen in developed countries, but is characterised by dementia, dermatitis and diarrhoea (the three D's). The most common cause of pellagra now is chronic alcoholism, which usually presents with acute and isolated delirium. There can also be generalised rigidity (sometimes cogwheeling), dysarthria and myoclonus.

#### **Vitamin D deficiency**

Proximal muscle weakness can develop as a result of vitamin D malabsorption. The symptoms usually start in the legs, affecting hip movements but with preservation of distal power, reflexes and sensation. EMG shows myopathic features with short duration polyphasic potentials. The degree of muscle weakness is not correlated with plasma calcium concentration and the underlying mechanism is unclear. Vitamin D treatment is generally helpful. Causes include lack of sunlight, chronic malabsorption syndromes, coeliac and Crohn's disease, renal and hepatic disease, cystic fibrosis. Genetic factors are important and people with dark skin are particularly susceptible, and some drug therapies – including the enzyme-inducing antiepileptic drugs – are associated with a decrease in vitamin D levels.

#### **Vitamin E deficiency**

Vitamin E deficiency results from cholestatic liver disease, fat malabsorption, abetalipoproteinaemia or as a familial absorption disorder. The clinical features include neuropathy, ataxia, ophthalmoplegia

and muscle weakness. A familial condition with poor conservation of plasma  $\alpha$ -tocopherol in very low density lipoproteins is characterised by ataxia, cerebellar signs, dysarthria, leg areflexia, impaired proprioception, bilateral extensor plantar responses, pes cavus and scoliosis. These signs are strikingly similar to those seen in Friedreich's ataxia (Chapter 17). All patients presenting with an unexplained spinocerebellar syndrome or tremor should have vitamin E concentrations measured, as the symptoms can respond to treatment.

### **Malabsorption**

Malabsorption is the result of gluten sensitivity or many other processes affecting the small bowel, including surgical resection.

#### **Coeliac disease**

Many neurological syndromes affecting the central and peripheral nervous systems have been reported in association with coeliac disease, including epilepsy, myoclonus, cerebellar atrophy and ataxia, multifocal leukoencephalopathy, dementia and peripheral neuropathies, both axonal and demyelinating. It is speculated that immunological mechanisms or trace vitamin deficiency underlie these associations. Substantial neurological features can occur in the absence of overt coeliac disease. Coeliac disease should certainly be considered in cryptogenic ataxias and neuropathies (Chapter 17).

#### **Inflammatory bowel disease**

Both ulcerative colitis and Crohn's disease are associated with thrombo-embolic complications including cerebral venous thrombosis and spinal cord ischaemia caused by arterial and venous thrombosis. Scattered white matter lesions are seen on T2-weighted MRI more frequently than in control subjects and patients receiving anti-tumour necrosis factor (anti-TNF) biological agents are at risk of developing progressive multifocal leukoencephalopathy and possibly lymphoma. Inflammatory bowel disease is associated with a sensory axonal and demyelinating polyneuropathy and also dermatomyositis.

### **Renal disease**

Renal diseases are relevant to neurologists in two main ways. First, certain diseases affect both the kidneys and the nervous system – these include the vasculitides and connective tissue diseases as well as serious conditions including genetic disorders (Fabry's disease, Wilson's disease, von Hippel-Lindau disease), infections and plasma cell dyscrasias. Secondly, renal failure, dialysis and renal transplantation can affect neurological function in a variety of ways.

### **Conditions affecting both renal and neurological function**

These conditions are mainly covered in other sections; the key features of some selected conditions are briefly summarised in Table 26.3. A neurologist should remember that renal disease in its early stages causes few or no symptoms and that renal function must therefore be screened when there is even a small degree of clinical suspicion. Vigilance is important; the consequences of progressive renal disease are severe and potentially avoidable. Routine biochemistry (urea and creatinine) are crude measures of renal impairment. If renal disease is questioned (e.g. a patient with a mononeuritis multiplex), urine microscopy for casts and detailed urinalysis, close monitoring of blood pressure and renal ultrasound should all be performed without delay.

**Table 26.3** Conditions affecting renal and neurological function.

Condition	Renal effects	Neurological effects
<b>Vasculitis</b>		
PAN	Proteinuria, granular casts, hypertension	Peripheral neuropathy, encephalopathy, stroke (infarction and SAH)
Eosinophilic granulomatosis with polyangiitis (EGPA)(previously Churg–Strauss syndrome)	Rarely involved	Mononeuritis multiplex encephalopathy, SAH
Granulomatosis with polyangiitis (GPA) (previously Wegener's granulomatosis)	Proteinuria, haematuria, red cell casts, renal failure	Cranial neuropathies, mononeuropathies, polyneuropathy, ischaemic stroke
<b>Connective tissue disorders</b>		
Rheumatoid disease	Glomerulonephritis (rare)	Polyneuropathy, mononeuropathies, cervical cord damage due to bony disease
SLE	Haematuria, proteinuria, nephritic syndrome, renal failure	Neuropsychiatric symptoms, encephalopathy, seizures, ischaemic stroke, chorea
Sjögren's syndrome	Tubular disorders	Dorsal roots ganglionopathy, neuropathy, cranial neuropathy (especially V), encephalopathy, MS-like symptoms
<b>Myeloproliferative disorders</b>		
Multiple myeloma	Proteinuria, Bence-Jones protein, nephrotic syndrome	Nerve root/cord compromise
MGUS	Rarely abnormal	Demyelinating sensory > motor peripheral neuropathy
Waldenström's macroglobulinaemia	Proteinuria, nephrotic syndrome	Sensorimotor neuropathy, encephalopathy, SAH, stroke, myelopathy
POEMS	Rarely, M protein in urine	Demyelinating neuropathy (sensory > motor) resembling CIDP (50%)

CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; MGUS, monoclonal gammopathy of undetermined significance; MS, multiple sclerosis; PAN, polyarteritis nodosa; POEMS, (syndrome of) polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes.

## Neurological consequences of renal disease and its treatment

### Uraemic encephalopathy (Chapter 20)

Neurological manifestations are usually associated with the rapid development of uraemia in acute renal failure. The onset is with subtle clouding of consciousness that may progress rapidly to apathy, irritability, confusion and disorientation. A coarse irregular tremor with asterixis can develop. Severe metabolic encephalopathy associated with uraemia is also associated with a progressive stimulus-sensitive multi-focal myoclonus and eventually the development of generalised tonic-clonic or focal motor seizures. Frank psychosis and agitation with hallucinations sometimes supervene before the development of uraemic coma, Cheyne–Stokes respiration and respiratory arrest. Uraemic encephalopathy is generally reversible with recovery from acute uraemia.

### Dialysis encephalopathy

Dialysis encephalopathy (dialysis dementia) is the rare but potentially fatal condition that previously complicated chronic dialysis and is still occasionally seen. Patients develop subacute progression of fluctuating symptoms in the early stages which either become fixed or progress. The condition is characterised by dysarthria, dysphasia and progressive metabolic encephalopathy with myoclonus and asterixis, culminating in generalised seizures and intellectual decline. The syndrome is caused by the aluminium content in gels and dialysate solution. Treatment with purified dialysate has led to the disappearance (almost) of this condition. Chronic haemodialysis can also lead to Wernicke's encephalopathy, sensorimotor axonal polyneuropathy and occasionally subdural haematoma.

### Dialysis disequilibrium syndrome

This is related to changing osmotic gradients between plasma and brain during rapid dialysis. Patients present with non-specific symptoms of nausea, visual blurring and headache prior to development of worsening mental confusion, clouding of consciousness, seizures and tremor. The symptoms are usually mild and can be alleviated with slow flow rates during dialysis and the addition of osmotically active solutes to the dialysate.

### Neuropathy associated with renal disease

Uraemic neuropathy is a distal axonal degeneration with secondary myelin loss. This occurs in the majority of patients with chronic renal failure; the severity is related to the extent and duration of renal failure. Onset is often with periodic limb movements or restless legs and established neuropathy is characterised by a distal paraesthetic sensory disturbance. The neuropathy is reversible with treatment of the renal failure.

## Neurological aspects of organ transplantation

Organ transplantation is now widely undertaken. Kidney, liver, heart, lung, pancreas and bone marrow are successfully transplanted with relatively low morbidity and mortality. The neurological complications of these procedures are related to the effects of the underlying organ failure, immunosuppression leading to secondary infection, allograft rejection, effects of drug treatment or consequences of the surgical procedure. The neurological complications vary with time following surgery.

### CNS infections

CNS infections develop in less than 10% of transplant recipients and in immunosuppressed patients; these can be severe and carry a high mortality. Infections in the immunosuppressed patient are discussed in Chapter 9 but a number of issues relate specifically to post-transplant patients. The risk of infection depends on the degree of immunosuppression, the intensity of exposure to potential pathogens and the time since transplantation. It is rare for opportunistic infection to develop within 1 month of surgery and commencing immunosuppression. During this period, infection is unrelated to the degree of immunosuppression, and is usually caused by the regular nosocomial organisms such as Gram-negative bacteria, staphylococci and *Candida*. Patients are predisposed to these infections, as is anyone critically ill, by contamination of vascular access or drainage catheters, prolonged intubation, stents or other foreign bodies and fluid collections. Rarely, active toxoplasmosis and viral infections can be passed with the graft.

More than 1 month after transplantation, as effective immunosuppression develops, the patient is at increased risk of infection with viruses: cytomegalovirus (CMV); Epstein–Barr virus (EBV); herpes simplex virus (HSV); varicella-zoster virus (VZV); human herpesvirus (HHV), and fungi (*Aspergillus* and *Candida*). Most patients with successful transplants are maintained on low-dose immunosuppression and are not at particularly high risk of late opportunistic infection.

More than 6 months after transplantation, infection can occur if the degree of immunosuppression has been increased because of recurrent or chronic allograft rejection. These patients are at particular risk of opportunistic infections listed above but also with other viruses (e.g. JC virus), fungi (*Aspergillus*, *Cryptococcus*, *Nocardia*, *Histoplasmosis*, *Mucor*), protozoa (toxoplasmosis) or bacteria (*Listeria monocytogenes*, *Pneumocystis carinii*, mycobacteria).

### Viral infection

The pattern of opportunistic viral infection following transplantation is highly variable. The most frequent pathogens are EBV, VZV, adenoviruses and herpes viruses HSV1 and HSV2; HHV6 is less common. CMV and EMV can cause severe encephalitis which can be difficult to diagnose. Reactivation of VZV can lead to cutaneous dissemination (chickenpox) and/or a generalised meningo-encephalitis, transverse myelitis and cranial neuropathy. Progressive multi-focal leukoencephalopathy (Chapter 9) is associated with JC virus infection and must be distinguished in the post-transplant encephalopathic patient from central pontine myelinolysis and posterior reversible leukoencephalopathy related to treatment.

### Bacterial infection

Bacterial infection in the transplant patient is less common than viral but can be caused by *Listeria monocytogenes* which causes meningo-encephalitis, often with a brainstem emphasis, multiple abscess formation or myelitis. Mycobacteria can cause pulmonary tuberculosis, TB meningitis or atypical TB CNS infection. Haemophilus or staphylococcal pneumonia and/or meningitis also occur in post-transplant patients. *Nocardia* infection is associated with cerebral abscess formation and often with pleural disease.

### Fungal infection

Fungal meningitis (Chapter 9) is most commonly caused by *Aspergillus* in the first 6 months, while typically *Cryptococcus* develops later than 6 months. *Aspergillus* species occur commonly in the environment. Primary infection is usually airborne and established in the lungs. Spread to the CNS occurs in some 50% of cases. This

carries an extremely poor prognosis because of the development of severe meningitis, focal aspergilloma brain abscesses and invasion of the cerebral vessels leading to intracerebral haematomas. The spinal cord can also be occasionally affected. Disseminated cryptococcosis involves the CSF and can cause severe chronic relapsing meningitis with raised ICP. There is a high mortality in transplant recipients. *Candida* meningitis is a rare post-transplant infection with chronic relapsing meningitis and/or brain abscess formation; this usually responds well to aggressive antifungal treatment. *Mucor* is an occasional CNS infection.

### Parasitic infection

*Toxoplasma gondii* is the most frequent protozoa to infect transplant recipients. The pattern of single or multiple enhancing cerebral abscesses is similar to that described in other immunosuppressive situations in Chapter 9. There may also be an acute encephalitis, occasionally with myocardial involvement. The CSF shows marked mononuclear pleocytosis with elevated protein, sometimes with depressed glucose. MRI shows characteristic ring enhancing abscesses, often in the basal ganglia.

## Neurological sequelae of transplantation

### Seizures

Seizures are relatively common in transplant recipients and have a number of causes. They commonly occur as a manifestation of drug toxicity (especially with ciclosporin and OKT3). Seizures can also be associated with drug withdrawal, metabolic derangements, hypoxic–ischaemic injury, cerebrovascular disease and sepsis. The initial management is correction of the underlying disturbance but in patients with ongoing impairment of consciousness it is essential to exclude non-convulsive status epilepticus. Status epilepticus should be treated conventionally, with benzodiazepines and a barbiturate or levetiracetam. However, titration of these drugs can be difficult because of renal and hepatic impairment, and hypoalbuminaemia. Isolated seizures following organ transplantation rarely lead to long-term epilepsy and therefore anticonvulsant medications are seldom required when the acute episode has resolved.

### Encephalopathy

Encephalopathy develops commonly following transplantation and varies from a mild confusional state to psychosis with obtundation and coma. In the acute postoperative situation it is often brought about by a surgical complication (e.g. hypoxic–ischaemic insult), the development of a metabolic encephalopathy, acute allograft rejection, isolated or multiple organ failure, sepsis, seizures or drug toxicity (particularly ciclosporin).

### Stroke

Stroke following transplantation is an important cause of morbidity and mortality. It is often related to the underlying disease process and in particular accelerated cerebrovascular atherosclerosis in diabetes mellitus. Stroke can also be a consequence of cardiogenic emboli and CNS infections that cause vasculopathy or vasculitis. Cardiac transplantation carries the complications of bypass – cardio-embolic stroke, air embolism and bacterial endocarditis.

Fungal CNS infections (particularly aspergillosis and mucormycosis) are associated with invasion and occlusion of the cerebral vessels resulting in haemorrhagic infarction.

Medication including ciclosporin and sirolimus and, to a lesser extent, tacrolimus can also lead to hypercholesterolaemia, potentially increasing the risk of vaso-occlusive events.

Intracerebral haemorrhage is usually seen in the setting of haemorrhagic transformation of an ischaemic stroke, resulting from coagulopathy or following CNS infection. Subdural haematoma can occur with thrombocytopenia, particularly following bone marrow transplantation. Subarachnoid haemorrhage is particularly associated with the increased incidence of berry aneurysms which may rupture following renal transplantation for polycystic disease. Cerebral venous thrombosis can occur as a consequence of a hypercoagulable state, dehydration or CNS infection.

### Medication

Complications of immunosuppressive drugs are also discussed in Chapters 19 and 21. The drugs most frequently causing neurotoxicity are ciclosporin, tacrolimus, steroids and OKT3.

Ciclosporin neurotoxicity occurs in some 25% of patients and includes tremor, headache and, less commonly, posterior reversible encephalopathy. The complications are lessened with oral administration and are usually reversible with discontinuation of the drug. Profound impairment in cognitive function has also been reported to be associated with tacrolimus and ciclosporin. OKT3 is a murine E monoclonal antibody used in the treatment of rejection and has been associated with aseptic meningitis, encephalopathy and seizures.

The combination of steroids with neuromuscular junction blocking agents can cause prolonged neuromuscular blockade or a critical illness myopathy.

### CNS malignancy

There is an increased incidence of CNS malignancy in allograft recipients who are immunosuppressed. Intracerebral B-cell lymphoma affecting the brain and spinal cord and glioblastoma multiforme are the most common CNS cancers. They may be associated with previous EBV infection.

### Neuro-ophthalmological problems

Cortical blindness, complex visual disturbances and hallucinations, not uncommon in all critically ill patients, can be caused by dose-related toxicity from tacrolimus or ciclosporin. This is often reversible.

### Movement disorders

Both ciclosporin and tacrolimus are associated with a high incidence of tremor. Occasionally, parkinsonism has been described in bone marrow transplant recipients. Rarely, chorea has occurred as a manifestation of rejection following cardiac transplantation. It is usually steroid responsive.

### Neuromuscular problems

Mononeuropathies follow surgery and anaesthesia and can occur as a consequence of positioning, traction or the mechanical complications of surgery. Phrenic nerve damage can follow cold plegia of the heart (induced hypothermia) during cardiac transplantation. Rarely, systemic infection may lead to a form of polymyositis.

Acute myopathy sometimes follows liver transplantation, particularly in those receiving intravenous steroids and neuromuscular blocking agents. In general, the prognosis for neuromuscular complications following most transplantation is good providing there is no major structural damage, but this is not true for graft versus host disease (GvHD, see Bone marrow transplantation).

### Complications related to specific allograft transplantation

#### Renal transplantation

Renal transplantation is now undertaken routinely but neurological complications remain relatively frequent. Uraemic encephalopathy can develop suddenly following acute tubular necrosis, acute

accelerated rejection or renal vein thrombosis. Spinal cord ischaemia occurs when the iliac artery is diverted for graft re-vascularisation; this is a particular risk when there is an anomalous vascular supply to the spinal cord from the internal iliac artery rather than the intercostals. There is an increased frequency of cerebrovascular disease related to the underlying vasculopathy and hypertension, particularly in the presence of diabetes or systemic lupus erythematosus (SLE). However, there is evidence that combined kidney and pancreas transplantation decreases the subsequent incidence of stroke in diabetic patients. Compressive neuropathies involving the femoral nerve are often related to haematoma formation. Rejection encephalopathy is extremely rare.

#### Liver transplantation

Liver transplantation carries a relatively high incidence of complications. These are related to the underlying hepatic disease including viral hepatitis, alcoholic liver disease, primary biliary cirrhosis, acute liver failure or toxic hepatic damage. Patients with hepatic encephalopathy have usually been critically ill and carry all the consequences of their underlying disorders following surgery. Delayed rejection or failing graft function may lead to recurrent encephalopathy or central pontine myelinolysis, impairment of coagulation and failure of synthetic and metabolic hepatic functions. Encephalopathy is also a common complication – associated with drug toxicity, metabolic derangement, hypoxic-ischaemic injury and sepsis. Coagulopathies can also lead to intracerebral or subarachnoid haemorrhage. The postoperative period is frequently complicated by the development of severe sepsis and critical care myopathy.

#### Cardiac transplantation

Cardiac transplantation complications are usually related to bypass. Cannulation of the diseased ascending aorta can dislodge atheromatous material leading to cerebral emboli and there is a risk of introducing air emboli when bypass is discontinued. There remains a significant instance of ischaemic and haemorrhagic stroke, ischaemic hypoxic brain injury, encephalopathy and peripheral nerve injury often affecting the lower brachial plexus because of stretching during chest wall retraction. The recurrent laryngeal nerve can also be damaged leading to vocal cord paralysis; phrenic nerve paralysis, from direct trauma or cold plegia, can cause diaphragmatic weakness.

#### Lung transplantation

Lung transplantation is often undertaken in combination with heart transplantation. Encephalopathy is usually a result of metabolic causes, drug toxicity or seizures. The cerebrovascular and neuromuscular complications are similar to those described earlier.

#### Bone marrow transplantation

Bone marrow transplantation is now widely undertaken both for the treatment of haematological malignancies but also as an adjunct in the treatment of other malignancies or autoimmune disorders. Neurological complications usually occur after allogeneic bone marrow transplant requiring immunosuppression. Following bone marrow infusion, pancytopenia can be present for 2–5 weeks before a significant response is mounted. During this critical period, overwhelming Gram-negative sepsis, severe bleeding from thrombocytopenia and disseminated intravascular coagulation are the most serious complications. Transplantation is combined with radiotherapy or intrathecal chemotherapy. There may be an associated posterior reversible leukoencephalopathy. However, the most serious complication is the development of GvHD.

Acute GvHD occurs in the first 100 days following transplantation and primarily affects the skin, liver and intestines. Chronic GvHD is a different entity and develops at any time later than 80 days following transplantation. The condition strongly resembles a vasculitic syndrome with scleroderma-like skin involvement, bronchiolitis, Sjögren's syndrome, polymyositis, myasthenia gravis and neuropathy.

Polymyositis develops up to 4–5 years after allogeneic bone marrow transplantation in association with GvHD. Seropositive myasthenia occurs sometimes with severe bulbar and respiratory muscle weakness. The use of neuromuscular blocking agents can lead to prolonged blockade and the development of critical illness myopathy. Acute demyelinating neuropathy has also been described in chronic GvHD. Reduction of immunosuppression usually results in improvement of the symptoms but there remains a high morbidity and mortality associated with the condition.

## Neurological involvement in systemic vasculitides and related disorders

Neurological involvement in systemic vasculitic disorders is common although, with the exception of giant cell arteritis (GCA) and isolated cerebral angiitis (ICA), it is rare for patients with this group of disorders to present solely with neurological symptoms. As such, many neurological episodes occur in patients who already have an established rheumatological or systemic vasculitis diagnosis and who may consequently be receiving some form of immunomodulatory therapy. Neurological symptoms presenting in such patients can be split into three broad aetiological groups, each requiring different therapeutic approaches. First, neurological symptoms or signs can develop with increased underlying systemic disease activity, needing prompt escalation of the immunomodulatory therapy. Secondly, the symptoms may be iatrogenic and related to side effects of disease modifying or other agents (e.g. a proximal myopathy associated with steroid therapy or reversible posterior leukoencephalopathy associated with immunomodulatory treatments). Thirdly, the symptoms can be caused by a separate and possibly associated disease process which requires attention on its own merits (e.g. ischaemic stroke in a patient with rheumatoid arthritis and diabetes).

Any part of the nervous system can be affected by the diseases described here, but the propensities vary across these conditions as do the causative mechanisms. For each disease mentioned, the different sites of neurological involvement are ranked depending on how commonly they occur. Many of the disease mechanisms, and thus related therapeutic considerations are shared across these conditions and are discussed first. Vasculitic disorders can be classified according to the predominant size and type of the vessel affected and/or whether there is associated granuloma. A further division is between vasculitides associated with the presence or absence of anti-neutrophil cytoplasmic antibodies (ANCA). The three ANCA associated forms of vasculitis are granulomatosis with polyangiitis (GPA; previously known as Wegener's granulomatosis); microscopic polyangiitis (MPA) and eosinophilic granulomatosis with polyangiitis (EGPA; previously known as Churg–Strauss; Table 26.4).

### Pathological mechanisms

Regardless of the lesion site within the neuraxis, the final common pathway of vasculitis is ischaemic damage to neural tissue, usually with permanent damage. Histological examination of tissue from both the central and peripheral nervous systems often reveals a

**Table 26.4** Classification of vasculitis.

#### Large vessel vasculitis

Giant cell arteritis (GCA)  
Takayasu's arteritis (TAK)

#### Medium-sized vessel vasculitis

Polyarteritis nodosa  
Kawasaki's disease

#### Small vessel vasculitis (SVV)

##### ANCA-associated vasculitis (AAV)

Granulomatosis with polyangiitis (Wegener's) (GPA)  
Eosinophil granulomatosis with polyangiitis (Churg–Strauss) (EGPA)  
Microscopic polyangiitis (MPA)

#### Immune complex vasculitides

Antiglomerular basement membrane disease  
IgA vasculitis (Henoch–Schönlein purpura)  
Vasculitis secondary to immune complex disease (SLE, dysproteinemias, cryoglobulinaemia, chronic infection)

#### Variable vessel vasculitis

Behçet's disease  
Cogan's syndrome

#### Single organ vasculitis

Central nervous system, peripheral nerve, cutaneous, testicular

#### Vasculitis associated with systemic disease

SLE, systemic lupus erythematosus.

necrotising arteritis affecting blood vessels with a transmural infiltrate initially consisting of a variety of reactive leukocytes, typically a mixture of polymorphs, lymphocytes and eosinophils. The proportions, subtypes and behaviour of these cells vary both within and across the different types of systemic vasculitides, with granulomas (a nodular aggregation of mononuclear inflammatory cells or modified macrophages usually surrounded by a rim of lymphocytes) more common in GPA and GCA. The cell populations at the lesion site also vary with the age of the lesion: neutrophils in the acute phase and intimal proliferation and fibrosis in the chronic phase. All these cellular responses conspire to reduce blood flow through the affected vessel. When individual nerves are involved the arteritis usually affects the pre-capillary arteries. In the CNS the calibre of blood vessel affected is associated with disease type, but overlap is common. A nosology based primarily on vessel size is desirable but problematic, especially as immunotherapy is not yet at the stage where different populations of inflammatory cells can be targeted.

With inflammatory and reactive stromal cells narrowing the arterial lumen, secondary thrombotic events can occur causing distal embolism to terminal portions of the arterial tree. However, in some systemic disorders the vasculopathy is primarily or even solely caused by thrombotic occlusion of arteries, capillaries or veins, in which case anticoagulation may be appropriate (see Systemic lupus erythematosus). Other causes of secondary vasculitis affecting the nervous system include:

- *Infections*: fungi, TB, other bacteria, spirochaetes, viruses including VZV, HIV.
- *Drugs*: amphetamine, cocaine.
- *Malignancy*: either via direct involvement such as in lymphoma or as part of a paraneoplastic vasculitis.

Isolated cerebral angiitis (ICA) is a rare but well-recognised disorder. The existence of its peripheral equivalent, an isolated peripheral nervous system vasculitis, is less certain because many vasculitic neuropathies are secondary to an underlying disease (e.g. Sjögren's syndrome).

Compressive spinal cord or root pathology can occur in any of the systemic disorders, especially as steroid-related osteopenia has a predilection for the vertebral bodies. However, this is most commonly seen in patients with rheumatoid arthritis (RA). Entrapment neuropathies can be caused by nodule formation in RA (typically ulnar or median nerve) or granulomas (typically cranial nerves).

Ophthalmoplegia occurs in approximately 5% of patients with GPA. The causes of this are varied and multifactorial:

- Contiguous extension of a granulomatous mass from a nasal or paranasal site into the orbit causing pseudotumour.
- Vasculitis of the extraocular muscles.
- Oculomotor palsy secondary to vasculitis.
- Granulomatous compression at some point along a cranial nerve.

Dedicated MRI scanning protocols with contrast can help to demonstrate the cause.

### Diagnosis and treatment of vasculitides involving the nervous system

Immunosuppressive therapies for vasculitis are relatively toxic, and the decision to administer them should be supported by a tissue diagnosis, if at all possible. When neurological symptoms and signs occur alongside multi-system disease activity, a diagnostic biopsy may well be from affected skin, kidney or lung. However, if the neurological syndrome occurs while disease remains quiescent in other organs then brain, nerve or muscle biopsy may be the only reasonable option.

Immunosuppressive treatment of neurological involvement in systemic disorders is unlikely to be based directly on prospective randomised trials; however, indirect evidence is available from controlled trials of patients with systemic vasculitis. Given that the underlying pathology is similar in non-neurological organs, extrapolation is reasonable. In general, the majority of vasculitic disorders can be reversed or controlled in some 90% of patients with a combination of high-dose oral corticosteroids and oral cyclophosphamide. Cyclophosphamide is usually given for 3 months with less toxic drugs such as azathioprine to sustain remission while steroid therapy is gradually reduced. Newer agents or non-pharmacological treatments such as plasma exchange are sometimes needed in resistant or persistently relapsing conditions. Many of the current immunosuppressive drugs and their associated side effect monitoring parameters are included in Table 26.5 and the newer biological agents are shown in Table 26.6.

### Polyarteritis nodosa and related conditions

Polyarteritis nodosa (PAN) is the prototype necrotising vasculitis. Medium-sized vessels are those usually affected and can be associated with aneurysm formation, seen on angiography. Middle-aged men are most commonly affected. Systemic symptoms include abdominal pain (from hepatic or other visceral infarcts), hypertension (from renal involvement, although glomerulonephritis is not a feature), fever and weight loss. Diagnosis is based on the clinical features and either positive angiography or biopsy of affected tissue (skin, kidney or nerve). The only serological marker clearly associated with PAN is hepatitis B infection (20–40% HbsAg-positive). PAN is considered to be an ANCA-negative syndrome.

**Table 26.5** Drug treatments for vasculitis.

Drug	Class/action	Side-effects	Monitor (prophylaxis)
<b>Acute, induction or rescue therapy</b>			
Methylprednisolone	Corticosteroid	Diabetes, neuropsychiatric, hypotension	Glucose, BP
Cyclophosphamide	Alkylating agent	Haemorrhagic cystitis, bone marrow suppression, neutropenia, sepsis	FBC (mesna for cystitis)
IVIg	Pooled antibodies from ~1000 human donors	As for any blood product, renal failure rarely	Check IgA levels before therapy, (absent IgA=absolute contraindication), U&E
<b>Long-term therapy</b>			
Prednisolone	Corticosteroid	Diabetes, osteopenia, adrenal suppression	DEXA scan (bisphosphonates for osteoprophylaxis)
Mycophenolate mofetil	Inhibitor of inosine monophosphate dehydrogenase	Bone marrow suppression, gastrointestinal intolerance, chronic viral infections	FBC; (ideally) monitor mycophenolic acid levels
Methotrexate	Folate antagonist/adenosine agonist	Pulmonary fibrosis, liver failure, bone marrow suppression	FBC, U&E, LFT (folate prophylaxis)
Azathioprine	Blocks purine synthesis	Bone marrow suppression, squamous-cell carcinoma, chronic viral infections, hypersensitivity	FBC + (ideally) check TMPT pre-Rx. (absent TMPT=absolute contraindication; reduced level=reduce dose)
Tacrolimus	Calcineurin inhibitor	Diabetes, hypertension	FBC, U&E, glucose, tacrolimus levels

FBC, full blood count; Ig, immunoglobulin; IVIg, intravenous immunoglobulin; LFT, liver function test; TMPT, thiopurine methyltransferase; TNF, tumour necrosis factor; U&E, urea and electrolytes.

**Table 26.6** Biological agents currently being used or studied.

	Drug	Adverse reaction
<b>Anti TNF therapies</b>		
TNF receptor fusion protein	Etanercept	Cytopenia, infection, liver dysfunction, injection site reactions
Monoclonal antibodies	Adalimumab SC Golimumab SC Certolizumab SC Infliximab IV	All as above
<b>B-cell depletion (monoclonal anti-CD20)</b>		
	Rituximab IV	Cytopenia, infection, liver dysfunction, infusion reactions
<b>IL-6 inhibitor</b>		
	Tocilizumab IV	Cytopenia, infection, liver dysfunction, infusion reactions, hypercholesterolaemia
<b>T-cell co-stimulatory molecule inhibitor</b>		
	Abatacept IV/SC	Cytopenia, infection, liver dysfunction, infusion reactions

IL, interleukin; IV, intravenous; SC, subcutaneous.

The most common neurological problem is a progressive mononeuritis multiplex which occurs in up to 50% of patients with PAN. In common with other causes of vasculitic mononeuritis this tends to present with a painful sensory or sensorimotor picture. More central involvement occurs in 25% of cases, in a variety of patterns – encephalopathy, seizures, stroke, aseptic meningitis, rarely an ischaemic myelopathy and sometimes cranial nerves palsies.

MPA is related to PAN and is also more commonly seen in males. Unlike PAN, the kidneys are most commonly affected and when the lungs are simultaneously involved it is one of the causes of ‘pulmonary–renal syndrome’, along with GPA, SLE, EGPA and Goodpasture’s syndromes. Other less specific features include arthralgia, purpuric rashes, myalgia and conjunctival haemorrhage. Like PAN, diagnosis rests primarily on the clinical syndrome with histological support from affected tissue (usually kidney, skin or lung). Angiography has less of a role in MPA because, as its name suggests, it tends to affect arterioles, capillaries or venules below the resolution of direct angiography. MPA, like GPA, is associated with circulating ANCA. There are two main ANCA staining patterns: peri-nuclear (pANCA) associated with the myeloperoxidase antigen, and cytoplasmic (cANCA), associated with the neutrophil enzyme proteinase 3. Both these forms are seen in microscopic polyangiitis (60–70% pANCA and 30–40% cANCA); combined they have a sensitivity of 90% with a specificity of 70%. ANCA can also be positive in patients with RA and SLE. The pattern of neurological involvement seen in MPA is similar to that of PAN.

Like MPA, EGPA affects the lungs and kidneys and also has an association with ANCA, albeit a weaker one. Unlike other systemic vasculitides, EGPA produces symptoms of asthma and is almost always associated with a peripheral eosinophilia ( $>1.5 \times 10^9 \text{ L}^{-1}$ ). Cardiac, gastrointestinal and skin involvement is also common. Histology of affected tissue usually shows three cardinal features: necrotising vasculitis, granulomas and infiltration by eosinophils. Typically, a vasculitic neuropathy is seen in EGPA and sometimes with GPA and MPA.

### Granulomatosis with polyangiitis (Wegener’s granulomatosis)

GPA is characterised by the triad of upper respiratory tract granuloma (typically affecting the nasal mucosa and/or inner ear), lower respiratory tract granuloma (typically pulmonary nodules) and a necrotising

glomerulonephritis. Non-specific generalised skin and joint symptoms akin to those described for MPA also occur. cANCA is usually found in this condition and has a specificity of 95% and a sensitivity of 80%. Some physicians use circulating levels as an indirect disease marker against which immunomodulatory therapy can be titrated.

The best data for neurological complications associated with GPA come from a large series from the Mayo Clinic, of over 300 cases. Patients rarely died of neurological complications, but one-third had neurological involvement at one or more sites in the nervous system at some point in their illness:

- Peripheral polyneuropathy 50%
- Cranial neuropathy, including hearing loss 20%
- Ophthalmoplegia 15%
- Stroke 12%
- Seizures 10%, and
- Cerebritis 5%.

Peripheral nerve involvement is heavily skewed towards mononeuritis multiplex (80% of neuropathy patients) with 10% having an insidious distal symmetrical polyneuropathy; a further 10% were unclassified. The most common nerve affected by mononeuritis multiplex is the common peroneal nerve, followed by the tibial, ulnar, median, radial and femoral nerves. Fifty per cent of those with cranial nerve involvement have optic nerve pathology, usually an arteritic anterior ischaemic optic neuropathy. Cranial nerves VI and VII were the next most commonly affected. Ophthalmoplegia can be the presenting symptom in GPA, and can be caused by several mechanisms. All call for an increase in immunomodulatory therapy. Acute or subacute hearing loss is associated with GPA; this is often because of a combination of conduction hearing loss (otitis media or otitis interna) and sensorineural loss (granuloma or vasculitic processes affecting the auditory nerve).

### Giant cell arteritis

GCA, widely known as temporal arteritis, is the most common primary vasculitis affecting those over 50 years. Typically, the extracranial branches of the aorta and the aorta itself are involved, with intracranial involvement much more rarely, probably because intracranial vessels lack the internal elastic lamina that appears to be the focus of the inflammatory response. Headache is the most common symptom, but can be absent. Other symptoms caused by involvement of extracranial arteries include jaw claudication and scalp tenderness. Constitutional symptoms are present in at least

one-third of cases as this condition overlaps with polymyalgia rheumatica (weight loss, fever and myalgia). Blindness is the most common serious neurological sequel and can present with either monocular (or bilateral) or homonymous visual loss (Chapter 14). The former is caused by arteritic involvement of the posterior ciliary arteries, leading to optic nerve head infarction which may be partial causing sector or altitudinal field defects. The latter is caused by thrombo-embolism of the posterior cerebral arteries, which are preferentially affected. Sequential ischaemic optic neuropathies or bilateral occipital infarction can lead to permanent blindness. Strokes affecting the MCA territory also occur, although they are rarer. Sometimes the arteritis is clinically apparent to palpation. Affected arteries feel thickened, pulseless and cord-like, such as the superficial temporal artery or other extracranial branches of the external carotid artery, the facial artery as it runs under the mandible, or the occipital arteries as they run over the inion. The ESR is almost always raised as is the CRP; anaemia is present in two-thirds of cases with a leukocytosis and raised transaminases in one-third. Temporal artery biopsy is the most specific finding but often a diagnosis will have to be made without this confirmation as skip lesions occur. The diagnostic yield drops with the interval following initiation of steroid therapy, although this fact should not delay initiating steroids; perusing a biopsy after the oft-quoted 2-week window of opportunity post-steroids is occasionally fruitful. Patients started on steroids are not completely protected from ischaemic events; there is good evidence for starting patients also on low-dose aspirin when GCA is suspected.

### Isolated cerebral angiitis

ICA or primary cerebral vasculitis is especially difficult to diagnose. Unlike most of the diseases mentioned earlier, there are neither extra diagnostic clues from involvement of non-neurological organ systems, nor specific serological nor CSF tests. ICA can present in a wide variety of ways with an acute or subacute, relapsing or even chronic time course. Three main patterns of presentation are proposed: an encephalopathic picture with accompanying headache, confusion and coma; isolated or multiple intracranial mass lesions with a mixture of focal and general CNS signs and raised ICP; an atypical MS-like syndrome with a relapsing–remitting course, optic nerve involvement, sometimes with stroke-like episodes and seizures (Figure 26.10).

Although brain MRI is usually abnormal in patients with ICA, there are no pathognomonic findings; intra-arterial cerebral angiograms have a disappointing specificity and sensitivity, of the order of 30%. This leaves brain biopsy as the diagnostic test of choice. Brain biopsy (including meninges) leads to a diagnosis in over 75% of cases, even when targeted at radiologically normal-looking brain tissue. However, about half of positive biopsies for presumed ICA show an alternative, unsuspected cause of the problem. Infection, lymphoma and multiple sclerosis (MS) are high on this list.

Treatment of ICA is not and may never be based on prospective placebo-controlled trials. However, as with treatment for the systemic vasculitides, more potent immunosuppression than can be provided by steroids alone is almost certainly warranted. A current reasonable therapy regimen would be: intravenous methylprednisolone 1 g/day for 3 days followed by 60 mg/day prednisolone tapering over months and eventually being superseded by a steroid-sparing agent such as azathioprine, with oral cyclophosphamide 2 mg/kg/day for 9–12 weeks, or pulsed intravenous cyclophosphamide 0.5 g/m<sup>2</sup> every 2 weeks for 3–6 months, starting after the 3 days of intravenous steroid.

### Rheumatoid arthritis

RA, also known as rheumatoid disease, is a multi-system disorder usually presenting with a symmetrical distal polyarthropathy. Stiffness of the joints is usually prominent, especially in the morning and the diagnosis is usually supported by the presence of rheumatoid nodules, positive rheumatoid factor in serum and characteristic juxta-articular changes on X-rays of affected joints. Inflammatory or vasculitic neurological complications also occur but are rare. More common are entrapment neuropathies and, most worrying, spinal cord or lower brainstem syndromes secondary to erosive skeletal involvement of the atlanto-axial, odontoid or other vertebral components. The cervical spine is most often affected by erosive disease but extradural pannus can cause compression at any spinal location, including the cauda equina (Chapter 16).

A group of rheumatological disorders overlap with RA, the mixed connective tissue diseases (MCTD) consisting of RA, scleroderma, Sjögren's syndrome, SLE and myositis. Patients with this disorder are often positive for the U1-RNP antibody which is associated with the main threat to life: pulmonary hypertension. Neurological manifestations are similar to those seen in RA or SLE; an inflammatory myopathy is present in up to 50% of cases. MCTD-associated myopathy is particularly responsive to steroids.

### Systemic lupus erythematosus

SLE is a multi-system disorder like RA, which commonly affects the joints and almost any other organ system, although the arthritis is less erosive than that seen in RA and mucocutaneous involvement more common. Antinuclear antibodies (ANA) are often present in SLE, but the test has a high false positive rate and detection of more specific antibodies to intracellular antigens is often required (e.g. double and single stranded DNA). Neurological complications of SLE usually occur within the CNS. In the largest unselected cohort to date, up to 50% had so-called neuropsychiatric lupus (NPSLE).

**Figure 26.10** Primary CNS vasculitis. Axial CT scan showing multiple confluent cerebral infarcts.

This proportion is closer to 30% if all those with headache alone are excluded, as they probably should be because headache is no more common in SLE patients than controls. Mood disorders, strokes and cognitive disorders occur in 10–15% of patients; seizures, frank psychosis and acute confusional states are less common, as are disorders of the nerve or muscle.

The exact mechanism(s) involved in NPSLE are still unclear. A key feature seems to be a primary vasculopathy not fulfilling criteria for a true 'vasculitis', with mild to moderate peri-vascular mononuclear cell infiltration (but not destructive fibrinoid necrosis) sometimes causing occlusion and small infarcts. Clinically, stroke has been reported to affect 19% of patients with SLE, making this potentially an important cause of stroke in younger individuals. Cohort studies confirm that those with SLE are at higher risk of stroke than an age-matched population. Other factors than the vasculopathy (e.g. accelerated atherosclerosis or hypertension), can be caused by long-term corticosteroid use.

Antibodies contribute to various components of NPSLE; for example, antiphospholipid antibodies are associated with stroke. Furthermore, anticardiolipin antibodies have been detected in 55% of patients with NPSLE compared to 20% with SLE alone. The therapeutic implication is that NPSLE should be treated with antithrombotic rather than immunosuppressive therapy. The indications for anticoagulation (e.g. with warfarin rather than aspirin) for secondary stroke prevention remains controversial. If stroke occurs and there are high levels of antiphospholipid antibodies, long-term anticoagulation with warfarin is generally recommended.

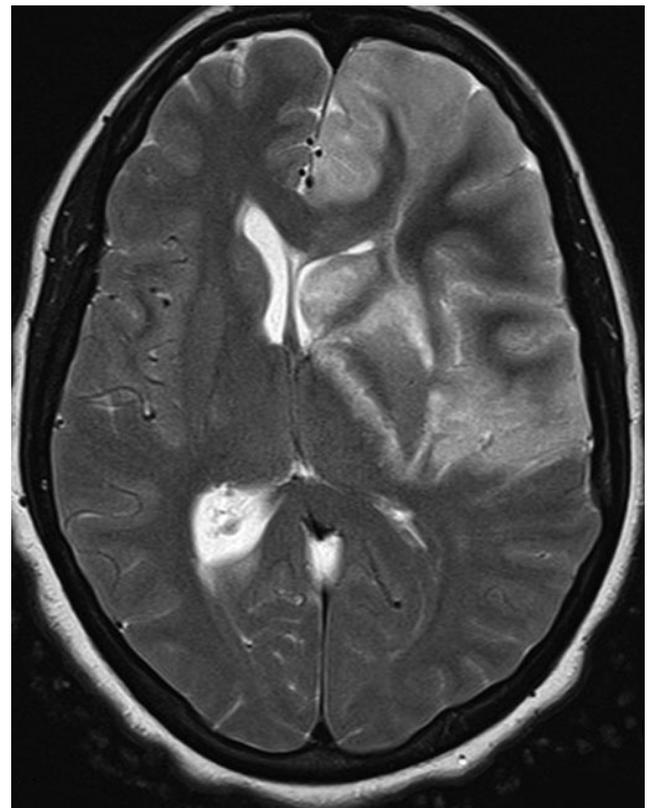

### Antiphospholipid syndrome

Antiphospholipid syndrome (APS) is characterised by thrombosis (venous and/or arterial or microvascular) and/or pregnancy loss in association with a heterogeneous group of antibodies known as antiphospholipid antibodies (aPL). Positive aPL consists of the presence of one or more of the following antibodies:

- Lupus anticoagulant (LA) which causes prolongation of *in vitro* phospholipid-dependent clotting assays
- Anticardiolipin antibodies (aCL)
- Anti- $\beta_2$  glycoprotein-1 ( $\beta_2$ -GPI) antibodies.

aPL are present in autoimmune disorders (including SLE, RA, systemic sclerosis, Behçet's syndrome and Sjögren's syndrome); and in association with lymphoproliferative disorders, drugs and infections. The presence of aPL in patients with SLE is approximately 30% and <40% of patients with SLE and aPL will develop APS. aPL is directly prothrombotic and accounts for <10% of cases of acute venous thrombo-embolism (VTE), usually affecting the deep veins of the lower limbs.

The most frequent site of arterial occlusion is the cerebral vasculature which may be thrombotic or embolic. Ischaemic stroke resulting from arterial thrombosis is the most common neurological manifestation in APS, and aPL have also been noted in the presence of Sneddon's syndrome. A wide range of neurological manifestations have been described in association with aPL: an MS-like syndrome, migraine, cognitive impairment, epilepsy, psychiatric disorders and visual disturbances. However, a causal relationship remains unproven. The conventional initial management of VTE in patients with APS involves standard therapy with low molecular weight heparin followed by indefinite oral anticoagulation using standard intensity (target INR 2.5). However, high-intensity anticoagulation (target INR 3.5) is recommended for patients with APS-related stroke.

**Figure 26.11** Catastrophic antiphospholipid syndrome. Axial MRI (T2-weighted) showing left anterior and middle cerebral artery infarction.

Catastrophic APS (CAPS) is a rare but potentially life-threatening condition characterised by sudden extensive microvascular thrombosis leading to multi-organ failure (Figure 26.11). CAPS carries a high mortality. Treatments have included anticoagulation, intravenous immunoglobulin and immunosuppressive therapy including high-dose corticosteroids, cyclophosphamide and rituximab.

### Sjögren's syndrome

Sjögren's syndrome is characterised by lymphocytic infiltrates and destruction of epithelial exocrine glands. The main symptoms are dry eyes (keratoconjunctivitis sicca) and dry mouth (xerostomia). Sjögren's syndrome is classified as primary (where dry eyes and dry mouth with systemic complications are more common), or secondary to other connective tissue disorders such as RA, SLE or overlap syndromes (mixed connective tissue diseases [MCTD]). Systemic involvement is characterised by chronic fatigue, arthralgia, oesophageal hypomotility, haematological disorders and, rarely, a cutaneous vasculitis, alopecia and vitiligo.

The primary syndrome usually affects females (9 : 1 female : male ratio), develops slowly and is associated with B-cell lymphoma in 5% of cases. Lymphocytic infiltration leads to cutaneous purpura, lymphocytic alveolitis/interstitial pneumonitis and malabsorption. There may also be renal tubular necrosis, nephritis and Raynaud's syndrome. Antinuclear antibodies, rheumatoid factor and various anti-extractable nuclear antigen antibodies (ENAs, specifically anti-Ro and anti-La antibodies) are associated with Sjögren's syndrome. Schirmer's test for objective evidence of dry eyes and minor salivary

gland biopsy showing focal lymphocytic sialadenitis (usually of the lip) also has a role in the most recent diagnostic criteria.

In Sjögren's syndrome, several different types of neuropathy have been described. The most common pattern (approximately 50%) is of an asymmetric, segmental or multi-focal sensory neuropathy starting with distal paraesthesia but often progressing to involve the trunk or face. A large proportion of these patients have an associated sensory ataxia, severe in some cases; they are likely to have high signal intensity in the posterior columns of the spinal cord on T2 MRI. In some subjects, ataxia is less prominent but neuropathic pain more so; the general progression of symptoms tends to be over months to years. A less common pattern of peripheral nerve involvement is one of a sensory and motor syndrome indistinguishable from mononeuritis multiplex seen in other connective tissue disorders; the progression tends to be acute or subacute rather than slowly progressive. Neuropathological studies suggest that the sensory–ataxic pattern is caused by a ganglioneuritis with lymphocytic infiltration of the dorsal root ganglia similar to that seen in the glandular tissues of the mouth. While a vasculitic pathology is more likely to underlie the mononeuritis multiplex type, overlap forms clearly occur.

Cranial neuropathies are also associated with Sjögren's syndrome and again tend to follow one of two patterns mirroring involvement of the peripheral nerves: either a sensory neuropathy affecting one or both trigeminal nerves with no motor features, or a cranial polyneuropathy that can affect any nerve with little discrimination between motor and sensory nerve populations. Hearing loss is sensorineural because of a lesion of the VIIIth nerve and this may develop suddenly or progressively. Autonomic features are often associated with Sjögren's syndrome neuropathies (60%): abnormalities of pupillary function (Holmes–Adie pupils), sweating and orthostatic hypotension are the most common manifestations; a pure autonomic neuropathy also occurs, but is much rarer. Many older patients who are diagnosed with Sjögren's syndrome turn out to have had a chronic, apparently idiopathic, neuropathy for many years, so it is worth screening for Sjögren's syndrome in this group, especially if the symptoms are patchy or associated with autonomic features.

CNS involvement is increasingly recognised and may be severe. MS-like features are often associated with a cutaneous vasculitis and optic neuropathy. Other manifestations include meningo-encephalitis with stroke-like episodes, intracerebral or subarachnoid haemorrhage resulting from vasculitis and focal abnormalities including sensorineural deafness, internuclear ophthalmoplegia, nystagmus, dystonia, athetosis, parkinsonism, focal and generalised seizures. Rarely, affective symptoms develop as a consequence of an encephalopathic-like presentation with depression, anxiety and cognitive impairment. Spinal cord involvement can develop with an acute transverse myelitis of sudden onset, usually associated with a vasculitis; more progressive forms of spinal cord involvement also occur. A neuromyelitis optica-like syndrome has been reported in several cases. The MRI changes are of focal high signal abnormalities on T2 images in the brain white matter and cortex and in the spinal cord. These can be indistinguishable from those seen in MS.

If there is involvement of the peripheral or central nervous system, aggressive treatment for underlying vasculitis is indicated. The first line is with intravenous corticosteroid therapy but if progression continues an alternative immunosuppressant may be indicated. The sensory axonal ganglioneuropathy responds poorly to immunosuppression. Other agents that may augment steroids include azathioprine and hydroxychloroquine. TNF inhibitors (e.g. infliximab) have not been shown to have benefit in Sjögren's syndrome.

## Miscellaneous cerebral arteriopathies

### CADASIL

CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is an autosomal dominant disease of small cerebral vessels caused by mutations in the *notch 3* gene on chromosome 19q13. *Notch 3* is a large gene coding for a transmembrane protein involved in intracellular signalling. The condition is characterised by episodic migraine-like headaches and recurrent subcortical ischaemic strokes usually beginning in mid-adulthood. A multi-focal motor and sensory deficit develops often with cognitive impairment, incoordination and progression to pseudobulbar palsy and subcortical dementia (Chapter 8).

CT or MRI shows confluent white matter disease and multiple small deep infarcts with myelin loss usually sparing the U fibres (Figure 26.12). White matter change characteristically involves the anterior temporal horn and external capsule, areas that are less frequently affected in sporadic cerebral small vessel disease. Genetic testing for *Notch 3* mutations allows non-invasive confirmation of the diagnosis in many cases. Skin biopsy reveals pathological changes of a non-amyloid angiopathy with deposition of eosinophilic electron dense granular material within the media of the small arteries and arterioles. This leads to concentric arterial wall thickening, narrowing of the vessel lumen and impaired reactivity of the vessel culminating in chronic arterial insufficiency, ischaemia and infarction.

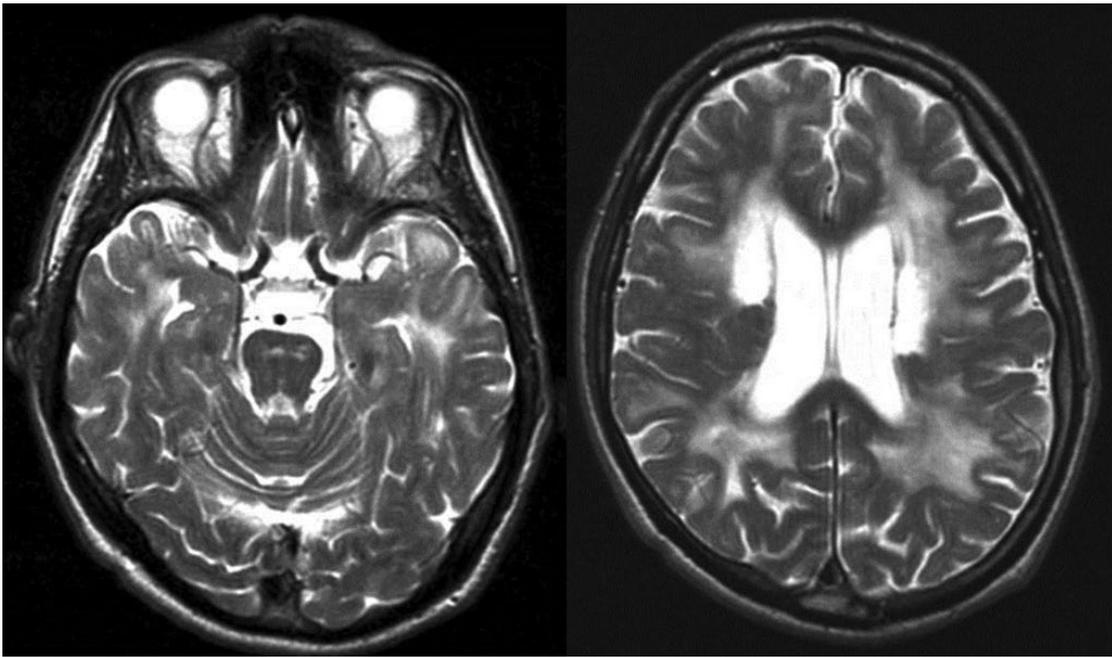

The prognosis for CADASIL is poor, with progressive stepwise deterioration leading to severe impairment of sensory and motor function and progressive dementia. However, recent data suggest that treatment of modifiable vascular risk factors including hypertension, lipid abnormalities and hyperhomocysteinaemia is appropriate and may limit the severity of expression of the disease.

### CARASIL

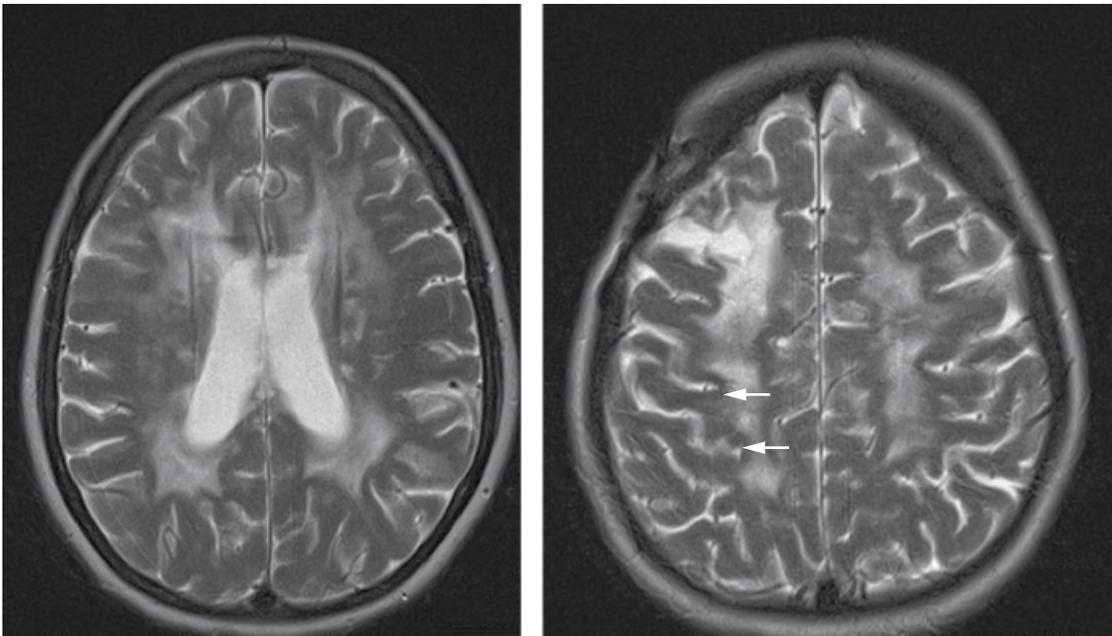

CARASIL (cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy) is a rare single-gene small vessel disorder, mainly affecting individuals of Japanese ancestry (although Chinese and Caucasian pedigrees have been reported). CARASIL is caused by mutations in the *HTRA1* gene encoding HtrA serine peptidase/protease 1. Progressive cognitive impairment and focal neurological symptoms from recurrent ischaemic subcortical strokes are typical, though migraine is not. Hypertension is not a feature. Distinctive extracerebral manifestations include premature alopecia and severe low back pain, sometimes with herniation of vertebral discs or spondylosis deformans. T2-weighted MRI shows extensive areas of hyperintensity in the hemispheric white matter, thalami and brainstem (Figure 26.13). Pathologically, there is severe widespread loss of arterial medial smooth muscle cells. Treatment is with standard best medical preventive therapy including antihypertensive agents, antiplatelet agents and lipid-lowering agents.

### Fabry's disease

Fabry's disease is an X-linked lysosomal storage disease resulting from deficient alpha-galactosidase A enzyme levels and accumulation of globotriaosylceramide in various cells, including the vascular endothelium and smooth muscle cells, resulting in an arteriopathy affecting both small and large vessels. The characteristic skin rash (angiokeratoma corporis diffusum) is caused by ecstasic vessels and usually involves the bathing trunk region although it may be more widely distributed (Figure 26.14). Vascular involvement can cause ischaemic stroke from mechanisms

**Figure 26.12** CADASIL. T2 axial MRI from a 54-year-old man with recurrent migraine, transient ischaemic attacks (TIAs), subcortical stroke syndromes and progressive cognitive impairment. Note the low attenuation in both anterior temporal lobes, extensive and confluent low attenuation in the deep cerebral white matter, and bilateral subcortical infarcts. Genetic testing confirmed the diagnosis of CADASIL.

**Figure 26.13** CARASIL. Multiple T2 hyperintensities in the peri-ventricular, deep white matter sparing subcortical U fibres (arrows).

including small vessel occlusion or cardio-embolism. The Fabry vasculopathy has been reported to show a predilection for the vertebrobasilar circulation, causing posterior circulation infarction. The multi-system manifestations of Fabry's disease include cardiomyopathy and renal failure. Although isolated neurological involvement at presentation is unusual, it is now realised that stroke can be the first symptom. Indeed, a study suggested that Fabry's disease could be responsible for up to 5% of cryptogenic

strokes in young men. Subsequent large studies suggest that definite or probable Fabry's disease accounts for only about 1% of strokes in younger individuals (<55 years). Early recognition is vital to permit early therapeutic intervention and family screening, and could prevent clinical progression and recurrent stroke. The MRI findings of Fabry's disease include white matter hyperintensities, lacunar infarcts, basilar dilochoectasia and pulvinar hyperintensity on T1-weighted images (specific but not sensitive;

Figure 26.15). The white matter MRI changes, in combination with recurrent focal neurological symptoms (especially brainstem disturbances) in younger individuals, can frequently lead to confusion with MS. Fabry's disease is discussed further in Chapters 5 and 19.

### Susac's syndrome

Susac's syndrome is a micro-angiopathy of unknown aetiology affecting the brain, cochlea and retina. It manifests as a triad of encephalopathy, sensorineural hearing loss and branch retinal artery occlusion. The condition predominantly affects women. At presentation not all of the clinical triad may be present. The onset of encephalopathy is typically associated with prodromal headache that may last for several months before the development of cognitive and psychiatric symptoms, sometimes with seizures and myoclonus. The hearing loss is often acute, bilateral and symmetrical suggesting infarction because of occlusion of the cochlear end arteries. Sometimes, hearing loss is asymmetric or even

asymptomatic, being detectable only on audiometry. Visual loss is characteristically segmental, and fundoscopy reveals multiple branch retinal artery occlusions and a macular cherry red spot. The electroencephalogram (EEG) shows diffuse encephalopathic changes and MRI confirms multiple small high signal white matter lesions on T2 imaging typically involving the corpus callosum, and sometimes the posterior fossa and brain parenchyma (Figure 26.16). CSF shows elevated protein with normal cells or a minimal pleocytosis; oligoclonal bands are absent. Histological changes on brain biopsy confirm micro-infarcts resulting from arteriolar occlusion but the mechanism is unclear as there is neither vasculitis nor fibrinoid necrosis. There is no clear guidance to treatment particularly given the tendency for spontaneous remission. The rarity of the condition precludes clinical trials. Antiplatelet agents and steroids are widely used and second line immunosuppression with cyclophosphamide and azathioprine has been recommended. Rarely, plasma exchange and intravenous immunoglobulin have been used.

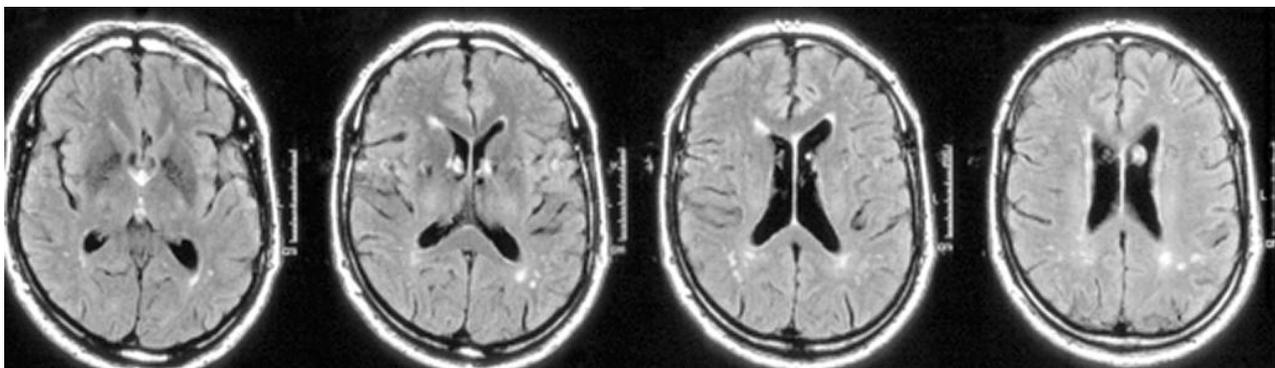

**Figure 26.14** Angiokeratomas in a 'bathing trunks' distribution in a patient with Fabry's disease. Source: Ginsberg *et al.* 2005. Reproduced with permission of BMJ.

### Sneddon's syndrome

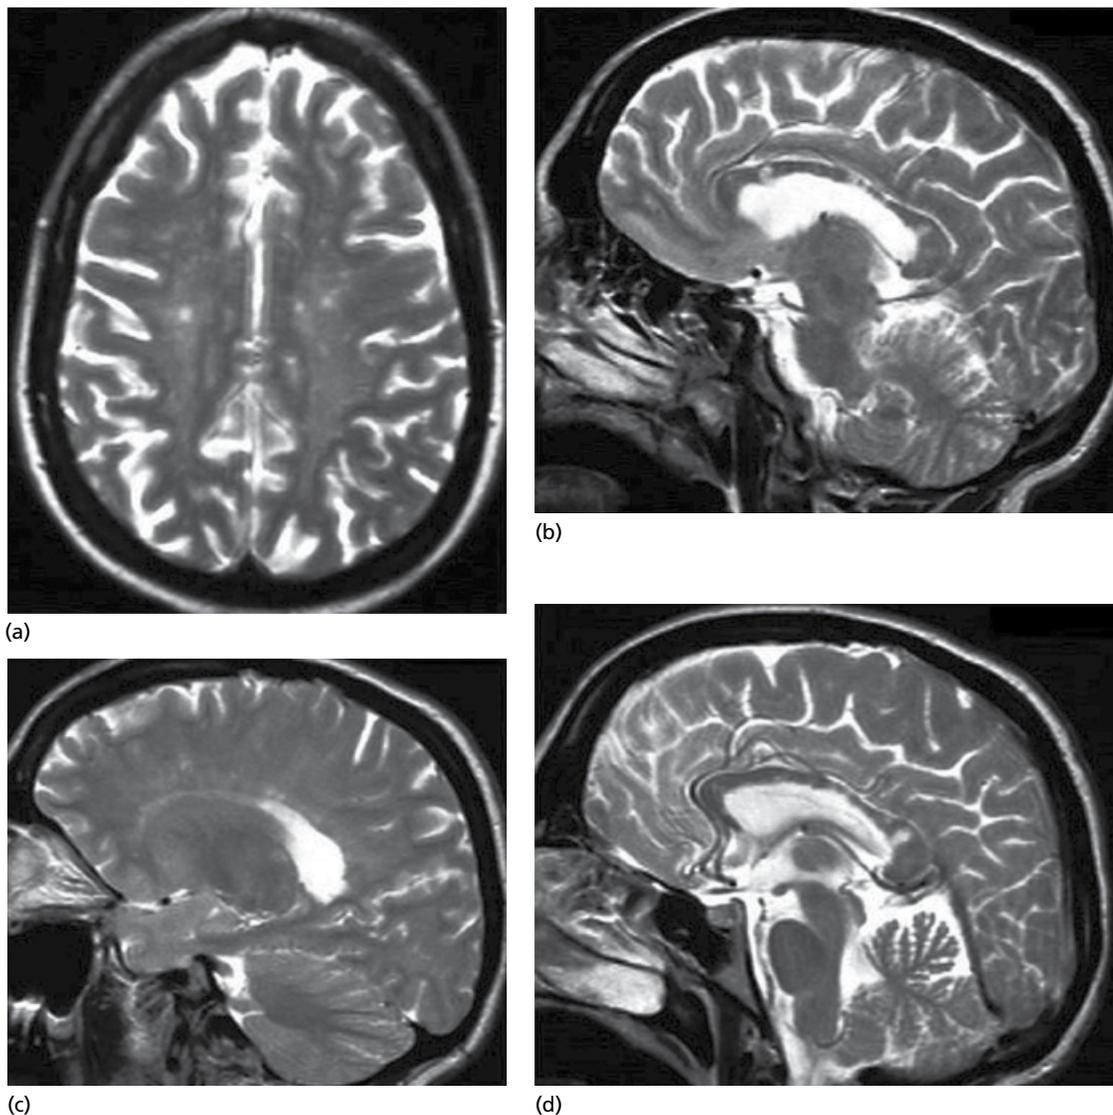

Sneddon's syndrome is a rare disorder characterised by recurrent strokes (typically in the middle cerebral artery territory) in young patients, often with a history of migraine. Cognitive impairment sometimes develops. There is livedo reticularis (a fixed violaceous and net-like rash on the limbs and trunk); antiphospholipid antibodies are sometimes elevated. The pathology is of an arteriopathy affecting small and medium-sized vessels. Some MRI studies have shown extensive cortical high signal lesions and atrophy. The condition is associated with antiendothelial cell and antiprothrombin antibodies. Treatment is of standard vascular risk factors including hypertension. Anticoagulation may be considered, particularly in the presence of antiphospholipid antibodies.

### Degos' disease

Degos' disease is a multi-system small vessel occlusive arteriopathy leading to ischaemia, initially involving the skin causing erythematous pink or red papules which heal to leave scars with characteristic white atrophic centres. Gastrointestinal and CNS complications can develop as the disease progresses. Ischaemic and haemorrhagic stroke can occur in the absence of vasculitis. Neurological involvement is characterised by the development of paraesthesiae, visual symptoms, weakness and myelopathy. MRI demonstrates multifocal ischaemic abnormalities or dural enhancement; skin biopsy shows vasculopathy but no active vasculitis.

**Figure 26.15** Four contiguous axial MRI sections with FLAIR weighting, demonstrating numerous white matter lesions in the cerebral hemispheres in Fabry's disease. Lesion load generally increases with patient age and the lesions may ultimately become confluent. Source: Ginsberg *et al.* 2005. Reproduced with permission of BMJ.

### HANAC

HANAC (hereditary angiopathy with neuropathy, aneurysms and cramps) is caused by a mutation in the *COL4A1* gene which encodes type IV collagen alpha 1 chain, which is a crucial component of basement membranes including vasculature, renal glomerulus and ocular structures. Neurological involvement is manifest as a diffuse leukoencephalopathy associated with intracranial aneurysms, muscle cramps, peripheral neuropathy, retinal tortuosities and haemorrhage and optic nerve abnormalities.

### Reversible cerebral vasoconstriction syndrome

Reversible cerebral vasoconstriction syndrome (RCVS) describes a collection of clinical and radiological features: sudden, severe ('thunderclap') headache; transient, multi-focal, segmental vasoconstriction of cerebral arteries lasting several weeks to months; and focal neurological symptoms, sometimes with stroke (which may be caused by infarction or haemorrhage). The same syndrome

has been variously described as thunderclap headache with vasospasm; migrainous vasospasm or angiitis; drug-induced angiitis; postpartum angiopathy; and benign angiopathy of the CNS. It seems likely that there are many causes (or triggers) for RCVS, and probably more than one underlying pathophysiological mechanism causing abnormal vascular tone. Multiple aetiologies for RCVS are suggested by the many and varied associations, including sympathomimetic, serotonergic or other drugs, pregnancy and the puerperium, though no obvious cause can be found in about 50% of cases. Ischaemic stroke can complicate RCVS, but it is also increasingly recognised that intracranial haemorrhage, especially cortical subarachnoid bleeding, can accompany RCVS. The clinical hallmark is *recurrent* thunderclap headache over days to weeks (a presentation that is extremely suggestive of, and possibly pathognomonic of, this disorder). Women are more often affected than men. The syndrome is important to recognise because the outcome is generally good, although less favourable when stroke occurs. A clinical

challenge is that the syndrome cannot be confidently diagnosed until follow-up demonstration of resolution of vasoconstriction, and exclusion of other potential causes (e.g. CNS vasculitis). Treatment includes careful observation for complications, expert supportive care (e.g. in a stroke or neurosciences unit) and avoiding triggers (e.g. sympathomimetic drugs). Calcium channel blockers (e.g. nimodipine) are often given for 4–8 weeks, with some evidence of benefit on the headache. Steroids have not been shown to be effective.

## Sarcoidosis

Sarcoidosis is a multi-system granulomatous disorder of unknown aetiology that affects the nervous system in some 5% of patients. Its hallmarks are non-caseating epithelioid cell granulomas with associated inflammation and the development of secondary fibrotic change which causes irreversible tissue damage.

### Clinical features and investigation

The clinical presentation depends upon the pattern of organ involvement. Systemic sarcoid affects the lungs in 90% of patients; involvement varies from asymptomatic bilateral hilar lymphadenopathy to severe interstitial lung disease causing respiratory failure. Other organs often involved are the liver, lymph nodes, skin, endocrine and musculoskeletal system. The diagnosis in the presence of hilar lymphadenopathy can be confirmed by bronchoscopy, broncho-alveolar lavage or tissue biopsy. The presence of elevated serum angiotensin-converting enzyme and characteristic imaging appearances can help but have limited specificity. CSF ACE may be elevated. Gallium scans can show characteristic increased uptake in parotid salivary glands. However, in the absence of tissue evidence of non-caseating granulomas the diagnosis is sometimes extremely difficult and is often one of exclusion. Acute presentation is associated with a good prognosis but poorer prognostic features include a later age of onset, Afro-Caribbean extraction, the presence of lupus pernio, chronic uveitis, chronic hypercalcaemia, progressive pulmonary pathology, nasal mucosal disease or cardiac involvement. Neurological involvement is uncommon but carries a worse prognosis than pulmonary disease and may be associated with ocular and cardiac involvement. In approximately 15% of patients with neurosarcoidosis the presenting features are neurological but in others neurological involvement develops within 2 years of presentation. Chronic neurosarcoidosis can cause multiple cranial nerve palsies, parenchymatous cerebral involvement, hydrocephalus and encephalopathy or peripheral nervous system manifestations.

### Cranial neuropathy

The most common neurological manifestations are isolated cranial neuropathy or aseptic meningitis. Up to 50% of neurosarcoid patients present with an isolated or bilateral facial palsy. This can be associated with dysgeusia, indicating a proximal lesion affecting the chorda tympani. Deafness from VIIIth nerve involvement occurs in 10–20% of cases; bilateral involvement strongly suggests neurosarcoidosis. Optic neuropathy occurs in up to 40% of patients and is often subacute, presenting with a progressive visual field defect, impaired acuity and pupillary dysfunction. Examination shows anterior uveitis, papillitis, papilloedema or optic atrophy secondary to granulomatous infiltration or compression of the optic nerve. Oculomotor abnormalities or bulbar weakness occur as a result of a diffuse meningeal infiltration. Infiltration is

common at the base of the brain and can lead to hydrocephalus in 6–30% of neurosarcoidosis patients, which may be either obstructive or communicating. CSF diversion procedures are sometimes necessary but tend to fail.

### Meningeal and parenchymatous sarcoid

Meningeal involvement commonly presents as an aseptic meningitis or occasionally as a meningeal mass lesion. The CSF shows a mononuclear pleocytosis with an elevated protein and a reduced glucose level. Parenchymal lesions are unusual. Clinical manifestations depend on their location and size. They can mimic tumours or demyelination, cause raised ICP with headache and papilloedema, seizures or focal involvement of the brainstem, basal ganglia or cerebellum (Figure 26.17). Isolated spinal lesions (often cervical) present as a progressive myelopathy with paraparesis and sphincter dysfunction (Figure 26.18). Pituitary and hypothalamic involvement occurs and can result in neuroendocrine disorders including diabetes insipidus, pan-hypopituitarism and hyperprolactinaemia.

### Sarcoid encephalopathy

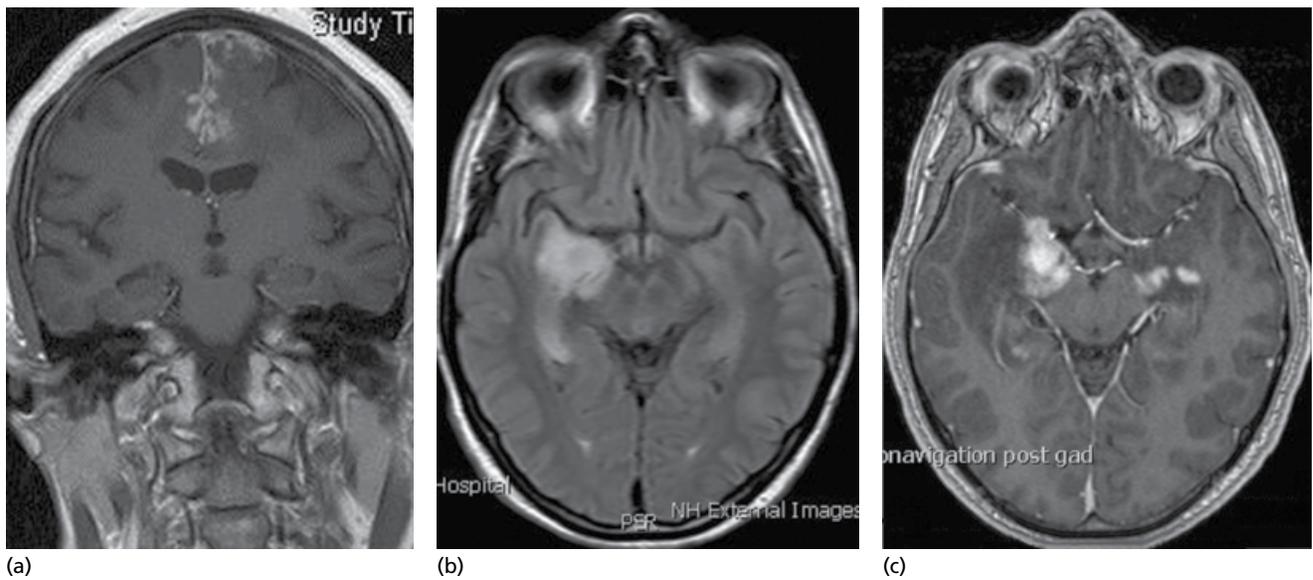

A diffuse or relapsing sarcoid encephalopathy can present with cognitive impairment or a confusional state often associated with memory disturbance. T2-weighted MRI shows diffuse contrast enhancement of the meninges with increased signal. Encephalopathy can coexist with a diffuse vasculopathy characterised by arteritis, external compression of arteries by an inflammatory mass lesion or multiple cardiac emboli. Rarely, dural venous thrombosis may occur. Neuropsychiatric features are also well described, presenting with psychosis or bipolar affective disorder. There is occasionally an isolated progressive amnesia or dementia without evidence of other neurological or systemic involvement. These patients appear to respond well to steroids.

### Peripheral neuromuscular sarcoid

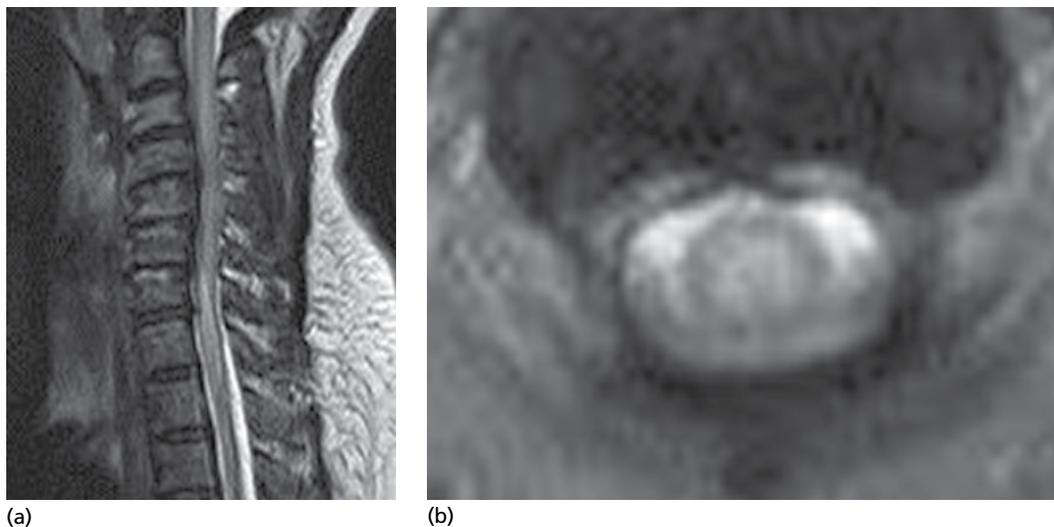

Peripheral neuromuscular involvement occurs in some 20% of patients with neurosarcoidosis. Peripheral nerve involvement is an isolated mononeuritis or a mononeuritis multiplex caused by granulomatous vasculitis or compression from granulomas. A symmetrical chronic axonal neuropathy occurs in some 25% of neurosarcoid patients. This is usually mild and of a mixed sensorimotor pattern but a more acute form indistinguishable from Guillain-Barré syndrome with demyelinating features can also develop. Muscle involvement is common but usually asymptomatic with non-caseating granulomas found on biopsy in more than 25% of patients. Symptomatic involvement varies from acute to chronic myopathy with an inflammatory component and occasionally palpable intramuscular nodules.

### Diagnosis

Diagnosis can be challenging; histological confirmation should be sought if possible. MRI shows parenchymatous mass lesions – hyperintense lesions on T2 sequences – with linear enhancement of thickened meninges and focal nodular enhancement. CSF findings are non-specific but can be helpful if there is meningeal involvement. There may be a pleocytosis of up to 100 cells/mm<sup>2</sup> and elevated protein <2 g/dL (occasionally higher). Glucose is also occasionally reduced in active aseptic meningitis, CSF pressure is increased and oligoclonal bands present variably. Muscle biopsy can be diagnostic. Biopsy of cerebral lesions and the meninges is sometimes helpful, and the non-caseating granulomatous changes are diagnostic.

**Figure 26.17** Neurosarcoid. MRI from patients showing lesions of neurosarcoidosis. (a) T1 coronal image showing extensive meningeal thickening with parenchymal involvement. (b) T1 axial imaging showing extensive focal intraparenchymal temporal lobe sarcoid lesion. (c) T1 axial lesion showing enhancement of temporal lesion and thickened meninges.

**Figure 26.18** Extensive intrinsic sarcoid of the cervical spinal cord: (a) T2 sagittal; and (b) axial image.

### Prognosis

The prognosis is variable but generally neurosarcoidosis is a serious disease. Involvement of the peripheral nervous system tends to carry a better prognosis than central involvement. One-third of neurosarcoid cases have progressive disease despite immunosuppression with steroids and other agents.

Steroids are the principal treatment for neurosarcoidosis; the dose and duration are determined by the disease location, severity and time course. Treatment aims to reduce the inflammatory component and prevent progression to fibrosis and ischaemia. Steroids should be built up rapidly to high doses and the dosage tapered only after

clinical response has been established. Occasionally, it is possible to withdraw steroids completely but many patients require long-term steroids and some require additional immunosuppressive agents such as azathioprine, methotrexate, ciclosporin, mycophenolate, cyclophosphamide, chlorambucil or cladribine, all of which have been reported to have efficacy in neurosarcoidosis. Infliximab is an antibody that specifically blocks TNF-alpha, and may have a role in neurosarcoidosis that is refractory to corticosteroids. Small case series have reported clinical and MRI improvement or stabilisation of neurosarcoidosis with this agent and also with rituximab (a B-cell directed monoclonal antibody).

## Behçet's syndrome

Behçet's syndrome is a multi-system disease consisting of recurrent oral ulceration (at least three times in a year) and two of the following: recurrent genital ulcers, skin lesions, ocular lesions and a positive pathergy test. Neurological involvement occurs in approximately 5% of cases and falls into two distinct patterns, which rarely overlap:

- Parenchymal CNS lesions, most commonly affecting the brainstem, although any part of the CNS can be involved, known as neuro-Behçet's syndrome (NBS); and
- Cerebral venous sinus thrombosis (CVST).

The former is associated with relapsing-remitting and progressive disease patterns often culminating in moderate or severe disability; the latter tends to occur as a single episode. Features of the multiple systems affected by Behçet's syndrome are shown in Table 26.7.

### Epidemiology and pathology

Behçet's syndrome usually occurs in the third decade and is seen most commonly in regions along the ancient Silk Route, thus extending from the Eastern Mediterranean to Japan; the prevalence in Turkey and Japan is 20 times that in the United Kingdom. Men are more commonly affected than women (1.4 : 1), a ratio that rises to 3 : 1 when considering cases of NBS. HLA B51 is associated in 50% of patients with Behçet's syndrome, especially those with uveitis.

There is still a debate whether the neuropathology of Behçet's syndrome is primarily one of vasculitis. While active CNS lesions

often contain peri-vascular inflammatory infiltrates, the arteriolar vessel wall itself is rarely involved; associated fibrinoid necrosis is not reported in CNS pathological specimens. Blood vessels with characteristic changes suggesting vasculitis have been encountered in non-CNS organs, but usually on the venous side of the circulation.

### Patterns of nervous system involvement

Of patients with Behçet's syndrome and neurological symptoms or signs other than isolated headache, roughly 80% present with NBS while the remaining 20% have CVST. Headache is the most common neurological symptom in Behçet's syndrome, even given its high prevalence in the general population. Both migraine and tension-type patterns are seen. New or severe headache in patients with known Behçet's syndrome should prompt imaging as CVST or parenchymal lesions will sometimes be found.

### CNS involvement: parenchymal

The most common pattern of NBS is of a subacute brainstem syndrome that may be associated with lesions elsewhere in the CNS or, more rarely, cranial neuropathies (V, VII or VIII). Spinal cord and hemispheric presentations are also common but peripheral neuropathy is unusual. Symptoms not easily localisable are also seen (impaired consciousness, epilepsy, neuropsychiatric Behçet's syndrome). Ophthalmological involvement is discussed in Chapter 14, isolated optic neuropathy is rare (>1%) but raised intracranial pressure can occur following CVST or due to isolated idiopathic

**Table 26.7** Multi-system manifestations of Behçet's syndrome.

Ocular (present in 70–95%) (loss of vision occurring approximately 3 years after onset of ocular symptoms)	Acute pan-uveitis usually associated with hypopyon Scleral and corneal involvement Conjunctival aphthous lesions Glaucoma Posterior segment changes Alteration in macular pigment epithelium Peri-venous sheathing Retinal and vitreous haemorrhages and exudates Occlusion of retinal arteries and veins Retinal detachment Optic and retrobulbar neuritis (becomes bilateral in 50% within 1 year and 80% within 2 years)
Mucocutaneous	Oral ulceration: small round oval painful crops on gums, lips, tongue, palette, posterior pharynx Genital ulcers: deep, painful and scarring Skin lesions: pustules, vesicles, folliculitis, acneiform lesions and erythema nodosum
Arthritis	Non-erosive, non-migrating, oligoarticular involvement of large joints especially knees, ankles and wrists
Gastrointestinal	Constipation, diarrhoea, abdominal pain and vomiting Ulcers may occur in any part of the gastrointestinal tract especially distal ileum and caecum
Vascular involvement	Arterial and venous malformations Venous – superficial thrombo-phlebitis, DVT, superior venocaval obstruction, Budd–Chiari syndrome and cerebral venous sinus thrombosis Arterial inflammatory change presenting as occlusion or aneurysm formation of the pulmonary, renal, subclavian, femoral and carotid arteries
Pulmonary	Recurrent haemoptysis, cough, chest pain and dyspnoea
Cardiac	Peri-myocarditis or endocarditis or coronary arteritis
Gastrointestinal	Dysphagia, epigastric pain, colicky abdominal pain and bloody diarrhoea

DVT, deep venous thrombosis.

intracranial hypertension. Most authors do not accept the existence of isolated NBS without pre-existing Behçet's syndrome, arguing that those patients who present with neurological symptoms have a history of recurrent oral ulcers at least.

NBS can mimic a variety of disease states, with MS being high on the differential list in Western practice. Although NBS can have a relapsing remitting or progressive course like MS, it is usually differentiated on the following grounds:

- MRI in NBS often reveals symptomatic lesion(s) below the tentorium, as opposed to the multiple, clinical silent, peri-ventricular lesions commonly seen in MS.
- CSF protein and lymphocyte counts are similar in both disorders, but oligoclonal bands are either absent or matched with serum in NBS and, if present, disappear on remission, compared to the persistently present unpaired intrathecal oligoclonal bands found typically in MS.
- Optic neuritis is rare in NBS and, when associated VEPs are abnormal, the pattern is of reduced amplitude and preserved latency rather than normal amplitude and prolonged latency encountered in demyelination.
- Systemic symptoms and headache are seldom present in an acute attack of MS.

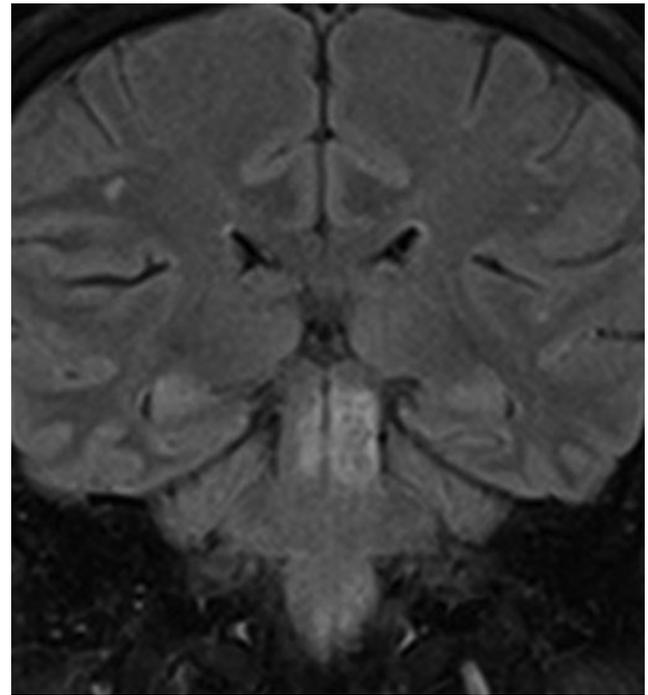

Although NBS rarely complicates Behçet's syndrome, parenchymal disease is sometimes a cause of major disability. Of patients with NBS, 45% have a single neurological episode, while half each of the remainder have either a relapsing-remitting or a progressive course. NBS is a serious disease. Half of all NBS patients have an Expanded Disability Status Scale (EDSS) of <6 at 10 years from diagnosis.

### Cerebral venous sinus thrombosis

Symptomatic CVST should be treated with anticoagulation (either low molecular weight heparin or warfarin) in the short to medium term but, given that it rarely recurs, long-term anticoagulation is not warranted. The main caveat to this statement is that Behçet's syndrome in general and Behçet's syndrome complicated by CVST in particular, are associated with coexisting pulmonary artery aneurysms (PAA). These aneurysms, which can occur at other sites in the vascular tree, are probably caused by inflammatory changes in the vasa vasorum of the larger pulmonary vessels, which can result in necrosis of the vessel wall causing true aneurysms or dissection causing false ones. It is therefore prudent to screen patients with Behçet's syndrome and CVST for PAA (usually with a CT pulmonary angiogram), before starting anticoagulation. PAA in Behçet's syndrome can be treated with immunosuppression, endovascular intervention or surgery.

### Investigation

Peripheral blood is often but not always normal, with an absence of acute phase reactants. CSF examination shows pleocytosis (neutrophils and lymphocytes with an elevated protein but normal glucose). The opening pressure is increased if there is venous sinus thrombosis but oligoclonal bands are only present in a minority. The pathergy test is somewhat variable in its sensitivity. MRI in the acute stage can show lesions that appear iso- or hypo-intense on T1 images and hyper-intense on T2 and FLAIR, because of venous thrombosis with reversible oedema; lesions may be single or multiple. They are seen most commonly in the mesodiencephalic junction (Figure 26.19), cerebellar peduncle, basal ganglia and brainstem but can also occur in the optic nerve and hemispheres. In chronic disease brainstem atrophy with gliosis can develop.

**Figure 26.19** Coronal FLAIR MRI in a patient with Behçet's syndrome showing extensive brainstem and also some diffuse parenchymal signal change.

### Pathergy test in Behçet's disease

The forearm is pricked with a fine sterile needle. With a positive pathergy test, a small red bump at the site of needle insertion develops 1–2 days later. Histologically, there is a largely lymphocytic reaction. Not all patients with Behçet's disease have positive pathergy tests. Behçet's patients from the Mediterranean littoral tend to have positive tests, around 50% from the Middle East and Japan but fewer from western Europe and the United States. A positive test is not diagnostic for Behçet's disease.

### Treatment

Unfortunately, drug treatment for NBS has a limited evidence base. Common practice at centres experienced with treating NBS is to treat acute episodes with high dose, usually intravenous, steroids for 3–7 days, with many experts preferring to continue with a tapering dose of oral prednisolone over the next 3 months. Patients with relapsing or progressive NBS are usually treated with azathioprine, methotrexate or pulsed cyclophosphamide, with or without added prednisolone. Some of the newer immunomodulatory therapies such as tacrolimus and infliximab have been tried with NBS because there is some evidence of their efficacy in controlling systemic Behçet's syndrome symptoms. Thalidomide and colchicine are widely used for the mucocutaneous manifestations. Neurovascular disease is managed conventionally with antiplatelet agents; the role of anticoagulation remains uncertain.

### IgG4-related disease

IgG4-related disease is an increasingly recognised fibroinflammatory condition characterised by tumour-like dense lymphoplasmacytic infiltrates rich in IgG4-positive plasma cells with variable fibrosis. Elevated serum concentrations of IgG4 is found in 60–70% of patients.

IgG4 lesions can be found in most organ systems of the body. The condition is particularly associated with autoimmune pancreatitis and salivary gland disease. Patients present with subacute development of a mass in an affected organ or diffuse enlargement of the organ (e.g. pancreas, salivary gland, biliary tree, kidney, lungs, breast, lymph nodes, thyroid and skin). Neurological involvement generally involves the development of lesions in the pituitary gland, a meningeal mass or a pachymeningitis.

The diagnosis is based upon biopsy findings showing a lymphoplasmacytic infiltration of mainly IgG4 positive plasma cells and lymphocytes accompanied by fibrosis. Serum IgG4 levels are

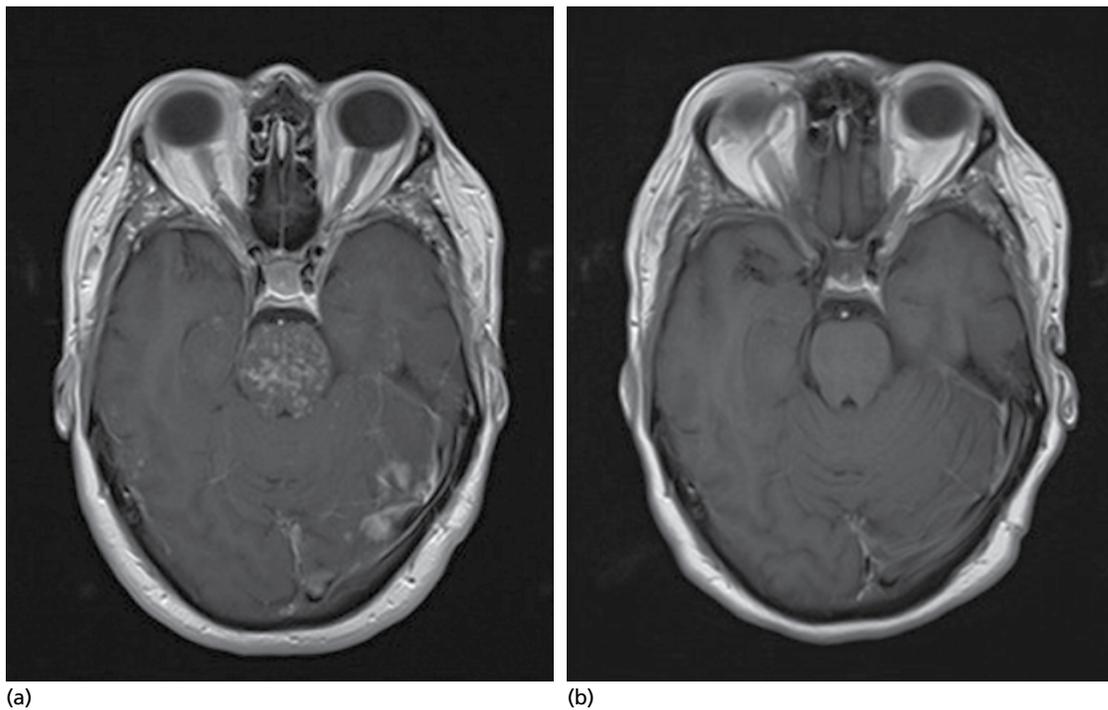

generally elevated. The condition generally response to steroids and second line immunosuppression over several weeks or months but surgical removal of the mass is often necessary (Figure 26.20).

### CLIPPERS

Chronic lymphocytic inflammation with pontine peri-vascular enhancement (CLIPPERS) is an inflammatory condition associated with the characteristic appearance on MRI of nodular or punctate enhancement in the brachium pontis, pons and cerebellum (Figure 26.21), with biopsy showing a marked perivascular and

**Figure 26.20** IgG4 disease. Sessile enhancing intradural lesion (indicated by arrows) based on the right posterolateral dura at T12–L1 level: (a) axial T2; (b) sagittal T1 image.

**Figure 26.21** Axial gadolinium-enhanced T1-weighted images at the time of subsequent presentation with a new brainstem syndrome demonstrating extensive punctate/linear areas of enhancement within the pons, characteristic of CLIPPERS: (a) occipital lesion with scattered areas of enhancement surrounding it and (b) 7 days after treatment with intravenous steroids, demonstrating dramatic improvement to the previous changes.

parenchymal CD3+ T-cell infiltrate. Lesions also occur in the spinal cord, basal ganglia and cerebral white matter. Patients with CLIPPERS can present with local brainstem features including cranial nerve lesions and long tract signs. However, gait ataxia and dysarthria also occur and occasionally a more insidious cognitive impairment develops. Lesions characteristically respond to corticosteroids. There is no evidence of systemic involvement. The important differential diagnosis is summarised in Table 26.8.

## Neurocutaneous syndromes

Neurocutaneous syndromes (also sometimes termed phakomatoses) are multi-system disorders that have characteristic CNS and skin manifestations. The features of these diseases are important to recognise for neurologists, because the skin manifestations are an important clue to potential neurological complications.

### Neurofibromatosis type 1 (von Recklinghausen's disease)

Neurofibromatosis type 1 (NF1) is an autosomal dominant disorder caused by a mutation in the NF1 gene (17q11.2), encoding the protein neurofibromin which acts as a tumour suppressor. The clinical diagnosis is based on the presence of at least two diagnostic features: six or more café-au-lait patches, axillary or groin freckling, two or more neurofibromas or one plexiform neurofibroma, Lisch nodules in the iris, optic pathway glioma, bony dysplasia of the sphenoid wing, pseudoarthrosis of the long bones or a first degree relative with NF1. The birth frequency is 1 in 2500, with a prevalence of 1/4000–5000. The condition is also discussed in Chapters 14 and 16.

Neurological complications affect both the peripheral and central nervous systems. Neurofibromas are benign peripheral nerve sheath tumours that contain a mixture of Schwann cells, fibroblasts, mast cells and axons embedded in an extracellular matrix. Neurofibromas can be:

- **Cutaneous:** these develop in 99% of patients usually in early adulthood and consist of soft fleshy pedunculated skin tags. They increase in size and number during pregnancy. These are associated with considerable psychological distress but do not undergo malignant change (Figure 26.22).
- **Subcutaneous:** these are firm peripheral nerve tumours that frequently cause pain and neurological deficit. They also develop in adolescence (Figure 26.23).
- **Plexiform:** about 60% of patients with NF1 have plexiform neurofibromas (PN). These develop during adolescence and adulthood and

**Figure 26.22** Cutaneous neurofibromas in an adult male with neurofibromatosis type 1. Subcutaneous: these are firm peripheral nerve tumours that frequently cause pain and neurological deficit. They also develop in adolescence (Figure 26.23). Source: Ferner 2010. Reproduced with permission of BMJ.

**Figure 26.23** Subcutaneous neurofibromas in an adult male with neurofibromatosis type 1. Source: Ferner 2010. Reproduced with permission of BMJ.

cause both neurological deficit and disfigurement. They develop in deep tissues and are therefore difficult to remove. PN can transform into malignant peripheral nerve sheath tumours (Figure 26.24).

Malignant peripheral nerve sheath (MPNSTs) usually arise from pre-existing focal subcutaneous neurofibromas or PNs but can arise *de novo*. Patients with MPNSTs present with persistent or nocturnal pain, a rapid increase in the size of a neurofibroma, new neurological deficit and a change in the texture of the pre-existing neurofibroma. The goal of treatment is complete removal of the tumour with clear margins. Radiotherapy is administered for high grade or

incompletely excised lesions and chemotherapy with ifosfamide and doxorubicin can provide palliative support.

Other neurological manifestations of NF1 include:

- Cognitive impairment, characterised by an IQ in the low average range, specific learning difficulties and behavioural problems including attention deficit–hyperactivity disorder.
- Epilepsy, which occurs in 4–13% of cases and may be caused by cerebral dysgenesis, mesial temporal sclerosis or tumours including glioma or dysembryoplastic neuroepithelial tumours or have no obvious cause.
- Cerebral malformations, which include macrocephaly, Chiari 1 malformation and aqueduct stenosis caused by subependymal glial cell proliferation.
- Spinal nerve root neurofibromas may be asymptomatic but can cause pressure on the adjacent nerve root of spinal cord.
- Peripheral neuropathy is relatively uncommon. It presents with mild distal motor and sensory impairment associated with nerves thickened by infiltration with neurofibroma tissue.
- Brain and optic pathway tumours: gliomas generally occur in the optic pathways (Figure 26.25), cerebellum and brainstem. Most

slow-growing tumours are pilocytic astrocytomas but higher grade gliomas are common.

- Other tumours can occur – rhabdomyosarcoma is encountered more frequently in NF1, often at an earlier age and frequently arising in the genitourinary tract.
- Bone abnormalities are common and include short stature, scoliosis and osteoporosis.
- Primary progressive and relapsing multiple sclerosis occurs with increased frequency in NF1.
- Systemic manifestations are common and include cardiovascular disease (hypertension and congenital heart disease), renal artery stenosis and cerebrovascular disease. Respiratory compromise can be caused by a restrictive deficit as a result of scoliosis or direct compression by PN. Mesenchymal gastrointestinal stromal tumours occur mainly in the small bowel. Pheochromocytoma is also rarely associated with NF1.

Genetic counselling is recommended for everyone with NF1 and both prenatal mutation testing and pre-implantation genetic diagnoses are available. Surveillance should involve lifelong annual follow-up with developmental assessment, transitional planning and prompt access to specialist advice from nationally commissioned specialist centres.

### Neurofibromatosis type 2

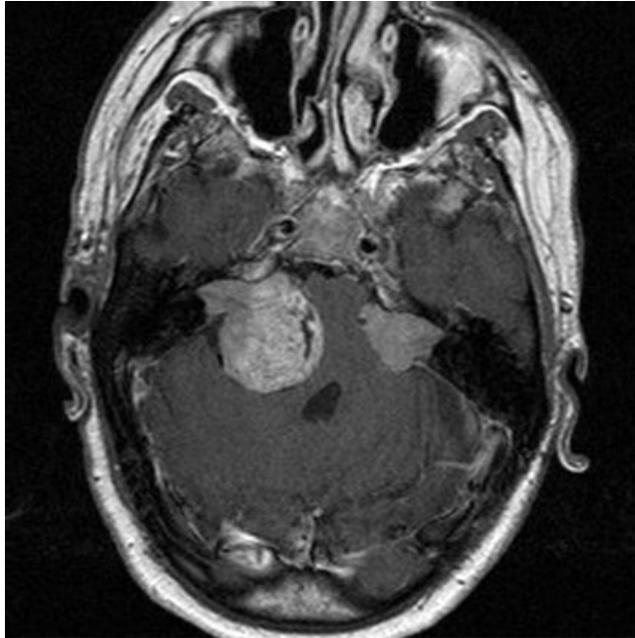

Neurofibromatosis type 2 (NF2) is characterised by the development of multiple tumours of the nervous system. The most common manifestation is bilateral vestibular schwannoma but other tumours including cranial or orbital meningioma, spinal and cutaneous schwannoma also occur. NF2 is an autosomal dominant condition caused by a mutation in the *NF2* gene (22q11.2) which produces merlin, a tumour suppressor. However, <30% of patients with NF2 without a family history are mosaic.

Schwannomas are benign tumours arising from peripheral nerve sheaths and are comprised entirely of Schwann cells. Unlike neurofibromas, they rarely undergo malignant change. Vestibular schwannomas occur in 95% of patients with NF2 (Figure 26.26), generally presenting with unilateral or bilateral sensorineural deafness, tinnitus and impaired balance. Raised ICP and brainstem compression can develop. Surgical removal is generally indicated but this usually causes sensorineural hearing loss. Most patients with NF2 develop spinal tumours. Bevacizumab, a monoclonal antibody against vascular endothelial growth factor (VEGF), is reported to induce both tumour regression and hearing improvement in patients with NF2-associated vestibular schwannomas. Extramedullary schwannomas and meningiomas are common but only cause symptoms in approximately 30% of patients. Schwannomas arise from the dorsal root and have a characteristic dumb bell shape. Intramedullary tumours, particularly ependymomas, are seen in <30% of patients. Ependymomas and pilocytic astrocytomas occur predominantly in the upper cervical cord and brainstem, and are commonly associated with a syrinx. Schwannomas of other cranial nerves are slower growing and do not usually require surgical intervention. Cranial meningiomas develop in 45% of patients and are frequently multiple.

NF2 is also associated with the development of an axonal peripheral neuropathy which can be severe and progressive. Focal amyotrophy can occur in the affected limb and vision can be impaired by cataract or the effects of orbital meningiomas, retinal hamartomas or epiretinal membranes. *NF2* gene mutation testing is routinely undertaken and prenatal and pre-implantation diagnosis are available. Routine annual clinical and radiological surveillance is essential for at risk individuals.

### Xeroderma pigmentosa

Xeroderma pigmentosa is an uncommon autosomal recessive disorder caused by mutations in the nucleotide repair genes. There is severe solar sensitivity leading to the development of basal and squamous cell carcinoma and melanomas beginning in early childhood. Ocular abnormalities include keratitis, opacification of the cornea, iritis and melanoma of the choroid. Up to 20% of patients with xeroderma pigmentosa have neurological abnormalities of varying severity caused by primary neuronal degeneration.

**Figure 26.26** Bilateral vestibular schwannomas distorting the brainstem in a young man with neurofibromatosis type 2: enhanced axial MR scan. Source: Ferner 2010. Reproduced with permission of BMJ.

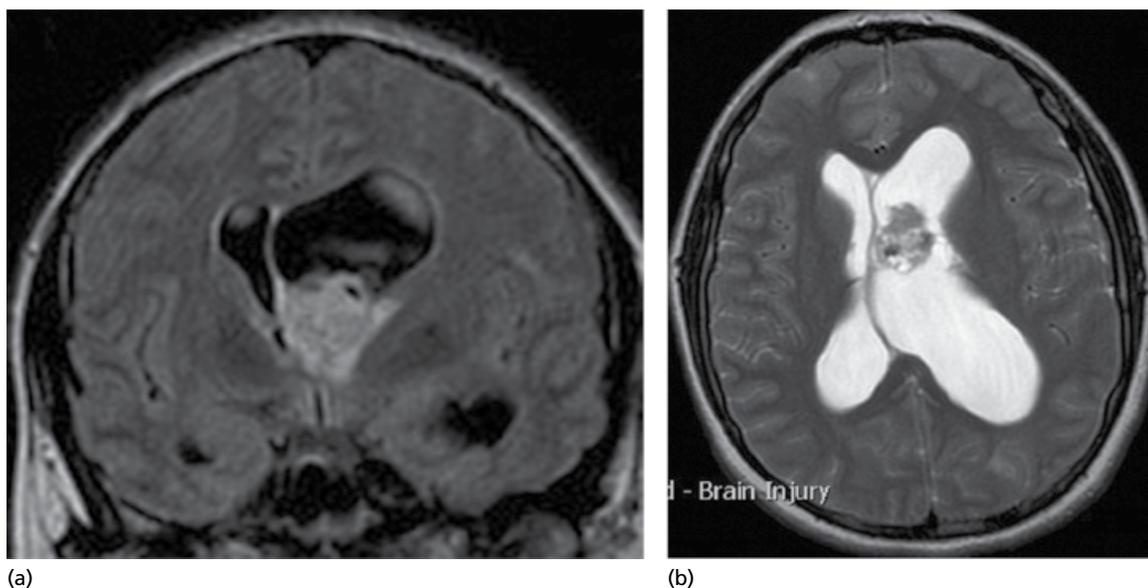

### Tuberous sclerosis

Tuberous sclerosis (Chapter 16) is characterised by multiple hamartomatous lesions which affect virtually any organ but particularly involve the brain, skin, eye, kidney, heart and lung. It is autosomal dominant and caused by mutations in either the *TSC1* or *TSC2* genes. Penetrance is complete but expression of tuberous sclerosis highly variable. Characteristic skin lesions include hypopigmented macules (ash leaf spots), adenoma sebaceum (angiofibromas typically involving the malar region of the face), shagreen patches (which usually involve the lower trunk), peri-ungual fibromas and fibrous plaques (often seen on the forehead). Neurological involvement is characterised by the presence of subependymal nodules, subependymal giant cell tumours (Figure 26.27), white matter heterotopia and glioneuronal hamartomas (cortical tubers). The severity of neurological dysfunction (i.e. seizures and cognitive function) is related to the extent of glioneuronal hamartomas. Subependymal giant cell tumours are slow-growing tumours of mixed glioneuronal origin that arise in peri-ventricular areas. There is a risk of malignant transformation, particularly affecting subependymal giant cell tumours in the brain, kidneys and soft tissues.

Epilepsy occurs in <90% of patients, often developing in the first year as infantile spasms or partial epilepsy but patients remain at risk. Cognitive impairment and behavioural difficulties including autistic spectrum disorders are common. Ophthalmic abnormalities include retinal hamartomas, which may be calcified (mulberry appearance), chorioretinal depigmentation and angiofibromatosis of the eyelids. Systemic involvement is characterised by cardiac rhabdomyoma, aortic coarctation and aneurysm formation, renal angiomyolipomas and diffuse interstitial pulmonary fibrosis.

### Von Hippel–Lindau disease

Von Hippel–Lindau disease (VHL) is an autosomal dominant condition caused by a germline mutation in the *VHL* gene. Two forms of the condition are recognised depending on the risk of developing pheochromocytoma. Neurological involvement is characterised by the development of haemangioblastoma (HBO), particularly affecting the cerebellum, brainstem or spinal cord, often at a young age.

**Figure 26.27** Left subependymal giant cell astrocytoma in a patient with tuberous sclerosis: (a) T1-weighted coronal; (b) T2 axial MRI.

HBO are well-circumscribed capillary-rich benign neoplasms which cause symptoms by direct compression of adjacent structures. They are often infratentorial and multiple in VHL. Surgical intervention is generally reserved until lesions become symptomatic or they develop accelerated growth. Retinal capillary haemangioblastomas (RCH) are typically found in the peripheral retina and/or juxtapapillary region. They are often multifocal and bilateral and occur in <70% of VHL by the age of 60. Visual loss is a result of exudation from the tumour causing retinal oedema or by traction effects, in which glial proliferation causes retinal striae and distortion. However, haemorrhage can occur leading to retinal detachment, glaucoma and loss of vision. Any patient presenting with seemingly sporadic HBO or RCH (particularly aged less than 40) should be screened for VHL.

VHL is associated with a number of important systemic features including the development of pheochromocytoma, multiple renal cysts (often considered premalignant) and renal clear cell carcinoma (RCC), endolymphatic sac tumours of the middle ear, serous cystadenomas and neuroendocrine tumours of the pancreas and papillary cystadenomas of the epididymis. Routine annual screening should include imaging of the kidneys, estimation of plasma metanephrins and biannual imaging of the brain and spinal cord. Meticulous genetic counselling must be undertaken in women with VHL and they should be closely monitored during pregnancy because of the risk of accelerated tumour growth.

### Ataxia telangiectasia

Ataxia telangiectasia is a rare autosomal recessive condition associated with defective DNA repair mechanisms caused by a gene mutation at 11q 22.3. Patients develop progressive cerebellar ataxia, abnormal eye movements (oculomotor apraxia), oculocutaneous telangiectasia, immunodeficiency affecting both cellular and humoral immunity with particular impairment of IgA and IgG and other neurological abnormalities including progressive impairment of motor development often leading to wheelchair dependency by the age of 10, particularly in homozygotes. Dysphagia, aspiration and respiratory muscle weakness also occur. Other systemic features include pulmonary disease (recurrent infections, bronchiectasis and pulmonary fibrosis), an increased incidence of malignancy (generally lymphoma or acute leukaemia) and diabetes mellitus resulting from insulin resistance.

### Sturge–Weber syndrome

Sturge–Weber syndrome is characterised by a facial capillary malformation (port wine stain) and an associated capillary–venous malformation affecting the brain and the eye. Sturge–Weber syndrome can lead to progressive neurological deficits including seizures, which may be associated with cortical malformations including polymicrogyria and cortical dysplasia; intellectual impairment; behavioural problems; and focal neurological signs often caused by stroke-like episodes. Hydrocephalus is common, probably associated with thrombosis in the deep cerebral veins or extensive arteriovenous anastomoses. Visual field deficits are caused by occipital cortex lesions. Vascular abnormalities also occur in the conjunctive, episclera, choroid and retina. The predominant ocular manifestation is glaucoma which presents in newborns with enlargement of the globe (buphthalmos). MRI with gadolinium contrast demonstrates the presence of leptomeningeal capillary venous malformations and the extent of brain involvement. Cranial CT imaging identifies the extent of calcification.

Other neurocutaneous syndromes are described in Table 26.9.

**Table 26.9** Other neurocutaneous disorders.

Parry–Romberg	Hemifacial atrophy of the skin, soft tissues, muscles and bones of the face below the forehead EEG and MRI abnormalities often ipsilateral to the affected side of the face
Basal cell naevus syndrome	Autosomal dominant Developmental anomalies and post nasal tumours especially multiple basal cell carcinomas Medulloblastoma in 3–5% (occasionally meningioma)
Gardner's syndrome	Autosomal dominant Familial adenomatous polyposis Multiple skin epidermoid cysts, lipomas, osteomas, gastric polyps CNS tumour including medulloblastoma
Incontinentia pigmenti	X-linked dominant (lethal in males) Symptoms develop in the neonatal period Linear papules, vesicles, hyperpigmented whorls which lose pigmentation and become atrophic CNS involvement in one-third (seizures, intellectual impairment, spastic weakness)

## Neurological aspects of pregnancy

Pregnancy is associated with a range of physiological changes including dynamic alterations in hormone levels. These changes can either change the presentation or severity of pre-existing neurological diseases, including migraine, epilepsy, multiple sclerosis and myasthenia gravis; or they may be associated with a conditions arising *de novo* during pregnancy, in particular cerebrovascular disorders. The management of epilepsy in women of childbearing age is of particular importance and is dealt with in some detail here.

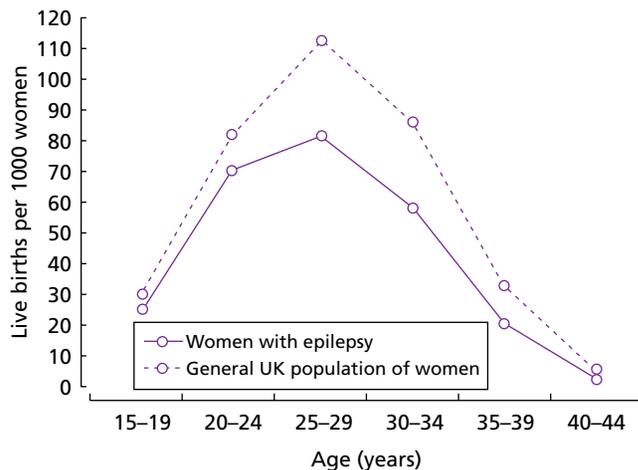

### Epilepsy and women of childbearing age

#### Fertility

Fertility rates are lower in women with treated epilepsy than in an age-matched control population. In a study of a general population of over 2 million persons in England and Wales, an overall fertility rate was found of 47.1 (95% CI 42.3–52.2) live births/1000 women with epilepsy per year compared with a national rate of 62.6. The difference in rates was found in all age categories between the ages of 25 and 39 years (Figure 26.28). There are probably several reasons for this. Women with epilepsy have low rates of marriage, marry later, suffer social isolation and stigmatisation. Some avoid having children because of the risk of epilepsy in the offspring, and some because of the teratogenic potential of antiepileptic drugs. Biological factors that may be relevant include genetic influences on fecundity and adverse antiepileptic drug effects. One-third of menstrual cycles in women with temporal lobe epilepsy can be anovulatory, compared with 8% in control populations. It has been suggested that valproate results in polycystic ovarian syndrome, possibly by causing obesity, peripheral insulin resistance, hyperandrogenism and hyperinsulinaemia, although this finding has not been widely replicated.

#### Pregnancy

*Effects of epilepsy on pregnancy and delivery* There are 3–4 live births per 1000 women of childbearing age with epilepsy in Western populations, and epilepsy is one of the most common medical

**Figure 26.28** Fertility rates amongst women with epilepsy compared with that in the general population in a unselected UK population of 2 052 922 persons. Source: Wallace *et al.* 1998. Reproduced with permission of Elsevier.

**Table 26.10** Complications of pregnancy reported with increased frequency in women with epilepsy.

Bleeding <i>in utero</i>
Premature separation of the placenta
Toxaemia of pregnancy and pre-eclampsia
Miscarriage and stillbirth
Intrauterine growth retardation, low birth weight
Perinatal mortality
Premature labour
Breech and other abnormal presentations
Forceps delivery, induced labour, caesarean section
Precipitant labour
Psychiatric disorders
Seizures and status epilepticus

conditions encountered in obstetric units. Epilepsy increases by up to threefold the risks of various common complications (Table 26.10). The perinatal mortality rate has been found to be twice that of the general population. It is said that 1–2% of all women with active epilepsy will have tonic–clonic seizures during delivery and this can clearly complicate labour. The fetal heart rate can be dramatically slowed by a seizure, and fetal monitoring is recommended during vaginal delivery. Home birth should not generally be contemplated and obstetricians are more likely to recommend caesarean section. Epilepsy from pre-existing neurological disorders can be worsened during pregnancy, including seizures caused by multiple sclerosis, arteriovenous malformations and meningiomas.

**Effect of pregnancy on the rate of seizures and on antiepileptic drug levels** Pregnancy has a little effect on seizure frequency in most patients, although there are patients whose seizures stop only during pregnancy and others, usually with severe epilepsy, whose seizures worsen. There are a number of potential causes for changes

in seizure frequency: hormonal effects, non-compliance with medication, inappropriate dose reductions, changing drug disposition and serum levels, fluid retention, vomiting, stress, anxiety and sleep deprivation. The levels of many antiepileptic drugs fall in later pregnancy. This effect occurs most notably with lamotrigine, where levels on an unchanged dosage can fall to less than half the pre-pregnancy levels. Regular blood level checks and incrementation of dosage is often required, and lamotrigine particularly is a difficult drug to use in late pregnancy for this reason.

**New-onset epilepsy during pregnancy** The annual incidence of epilepsy at childbearing age is about 20–30 cases per 100 000 persons, and so the chance development of epilepsy during pregnancy is not uncommon. Occasionally, presumably because of hormonal or metabolic influences, some women experience epileptic seizures exclusively during pregnancy (gestational epilepsy) but this is a rare pattern.

Symptomatic epilepsy presents in pregnancy from various underlying causes. Pregnancy can stimulate an increase in size of meningiomas because of oestrogenic stimulation, resulting in newly presenting epilepsy. Arteriovenous malformations can also present more commonly in pregnancy. The risk of ischaemic stroke increases in pregnancy. The underlying causes include arteriosclerosis, cerebral angiitis and Moyamoya disease, Takayasu's arteritis, embolic disease from a cardiac or infective source, sickle cell disease, antiphospholipid antibody syndrome, thrombotic thrombocytopenic purpura, deficiencies in antithrombin, protease C and S factor V Leiden and posterior reversible leukoencephalopathy syndrome (PRES). There is also a higher incidence of subarachnoid haemorrhage and of cerebral venous thrombosis. Pregnancy can also predispose to cerebral infections from bacteria (including *Listeria*), fungi (coccidioides), protozoa (*Toxoplasma*), viruses and HIV infection.

The extent of investigation of newly developing epilepsy in pregnancy will depend on the clinical setting. X-rays, and thus CT, should be avoided whenever possible. There are no known risks to the developing fetus from MRI and this is the brain imaging modality of choice. In the non-urgent situation, investigation is often deferred until pregnancy is completed.

**Eclampsia and pre-eclampsia** Most new-onset seizures in the late stages of pregnancy (after 20 weeks) are caused by eclampsia. Pre-eclampsia is characterised by hypertension, proteinuria, oedema, abnormalities of hepatic function, platelets and clotting parameters. About 5% of cases, if left untreated, progress to eclampsia. The eclamptic encephalopathy results in confusion, stupor, focal neurological signs and cerebral haemorrhage as well as seizures. The epilepsy can be severe and progress rapidly to status epilepticus. The incidence of eclampsia in Western Europe is about 1/2000 pregnancies, but it is more common in some developing countries with rates as high as 1/100. It carries a maternal mortality rate of 2–5% and also significant infant morbidity and mortality.

Traditionally, obstetricians have used magnesium sulfate in the treatment of seizures in eclampsia, and the superiority of magnesium over phenytoin and/or diazepam has been clearly demonstrated in recent randomised controlled studies. Not only does magnesium confer better seizure control, but there are fewer complications of pregnancy and infant survival is improved. Magnesium seems also to lessen the chance of cerebral palsy in low birth weight babies and has also been shown to decrease secondary neuronal damage after experimental traumatic brain

injury. The mechanism by which magnesium sulfate acts in eclampsia is unclear; it may do so via its influence on NMDA receptors or on free radicals, prostacyclines, other neurochemical pathways or, more likely, by reversing the intense eclamptic cerebral vasospasm. It is possible that patients would benefit from both magnesium and a conventional antiepileptic, but this has not been investigated. Magnesium should be administered as an intravenous infusion of 4 g, followed by 10 g intramuscularly, and then 5 g intramuscularly every 4 hours as required.

**Management of labour** Regular antiepileptic drugs should be continued during labour. If oral therapy is not possible, intravenous replacement therapy can be given for at least some drugs. Tonic-clonic seizures occur in about 1–2% of susceptible mothers. In patients at risk, oral clobazam (10–20 mg) is useful given at the onset of labour as additional seizure prophylaxis. Fetal monitoring is advisable. Most women have a normal vaginal delivery, but sleep deprivation, over-breathing, pain and emotional stress can greatly increase the risk of seizures. Elective caesarean section should be considered in patients at particular risk. A history of status or life-threatening tonic-clonic seizures are an indication for caesarean section, and if severe seizures or status occur during delivery, an emergency caesarean section should be performed. Intravenous lorazepam or phenytoin should be given during labour if severe epilepsy develops and the patient prepared for caesarean section.

There is a maternal as well as infant mortality associated with severe seizures during delivery. The hypoxia consequent on a seizure is sometimes more profound in gravid than in non-gravid women because of the increased oxygen requirements of the fetus, and resuscitation facilities should be immediately at hand in the delivery suite.

**Vitamin K** Maternally ingested enzyme-inducing antiepileptic drugs can induce a relative deficiency of infantile vitamin-K dependent clotting factors (factors II, VII, IX and X) and protein C and S, predisposing to infantile haemorrhage, including cerebral haemorrhage. The neonate should therefore receive 1 mg vitamin K intramuscularly at birth and at 28 days of life. It is also sometimes recommended that the mother take oral vitamin K (20 mg/day) in the last trimester, although the evidence that this improves neonatal clotting is rather contradictory. If any two of the clotting factors fall below 50% of their normal values, intramuscular vitamin K will be insufficient to protect against haemorrhage and fresh frozen plasma should be given intravenously. Similarly, if there is evidence of neonatal bleeding, or if concentrations of factors II, VII, IX or X fall below 25% of normal, an emergency infusion of fresh frozen plasma is required.

## Epilepsy and the fetus

**Effect of seizures on the fetus** The exact risks are not established. Clearly, in the latter stages of pregnancy, a convulsion carries the risk of trauma to the placenta and/or fetus, especially if the woman falls. However, most debate has revolved around the suggestion that seizures damage the fetus through lactic acidosis or hypoxia. The hypoxia is usually very short-lived and the placenta is a well-buffered system; intuitively these risks seem likely to be small. More than five tonic-clonic seizures during pregnancy has, in a retrospective study, been found to be associated with lower IQ in the offspring. Another study has found that first trimester seizures are accompanied by a higher risk of fetal malformation than seizures at other times, although the reliability of these conclusions is in doubt. Stillbirth has been recorded after a single seizure or series of seizures, although this

must be very rare. However, status epilepticus during pregnancy or delivery is extremely hazardous, and a study of status epilepticus during delivery reported a 50% infant mortality and 30% maternal mortality. Partial seizures have no known effects upon a fetus.

## Teratogenicity of antiepileptic drugs

There is no doubt that some maternally ingested antiepileptic drugs carry the risk of teratogenicity. This has been shown clearly both in animals and in clinical practice. However, assessment is complicated by the fact that seizures themselves can cause malformations, although this effect is probably small. Also, social, dietary and socio-economic factors increase the risk both of epilepsy and of malformations. Evidence is therefore difficult to assess, and accurate clinical advice difficult to give. Nevertheless, it is generally considered that of the commonly prescribed antiepileptic drugs, the use of carbamazepine, lamotrigine and possibly levetiracetam during pregnancy carries a lower teratogenic risk than valproate, barbiturates, phenytoin or topiramate.

**Major malformations associated with antiepileptic drugs** The most common major malformations associated with traditional antiepileptic drug therapy (phenytoin, phenobarbital, primidone, benzodiazepines, valproate, carbamazepine, topiramate) are cleft palate and cleft lip, cardiac malformations, neural tube defects, hypospadias, renal anomalies and skeletal abnormalities. Different drugs have a different range of associated abnormality and the highest rates are found with valproate. Cerebral malformations can also occur. Polytherapy carries higher risks than monotherapy, and the individual risks of some drugs have not been fully established. Phenytoin as monotherapy has a relatively low incidence of major defects although earlier studies with the drug in polytherapy showed much higher levels. One particular association is the increased risk of neuroblastoma although the absolute risk is very small. One study purported to demonstrate smaller head circumference in babies of mothers on carbamazepine, but the statistical basis of this observation was not well founded. It is unclear whether or not the benzodiazepines carry any teratogenic potential, although there are case reports of facial clefts, cardiac and skeletal abnormalities. The risk of spina bifida has been particularly well studied. The background population risk of spina bifida is approximately 0.2–0.5% with geographical variation. Valproate is associated with a 1–2% risk of spina bifida aperta, a risk that is strongly dose-related. Carbamazepine carries a risk of spina bifida aperta of about 0.5–1%. It is instructive to note that the induction of neural tube defects by valproate, and to a lesser extent carbamazepine, were not noticed initially during animal toxicology testing.

**Other developmental abnormalities and neurodevelopmental delay** In addition to the major malformations, less severe dysmorphic changes occur ('fetal syndromes'), although there is little agreement about their frequency or indeed in some cases their existence. The fetal phenytoin syndrome was the first to be described, and is said to consist of a characteristic pattern of facial and limb disturbances (Table 26.11). However, most of these features are minor and overlap with the normal variation seen in children born to healthy mothers. Recent prospective and blinded studies have shown that only hypertelorism and distal digital hypoplasia occurred at any greater frequency, and even these associations are weak. Furthermore, the nail hypoplasia tends to disappear during childhood. Cases of a 'carbamazepine syndrome' are reported with cranio-facial abnormalities, growth retardation, neural tube defects and fingernail hypoplasia. Reports of primidone

**Table 26.11** Fetal anticonvulsant syndromes. This is a list of reported abnormalities, although many are uncontrolled observations and the frequency of the anomalies is unclear. Genetic, environmental and socio-economic factors also have a role in their development.

### Growth

#### Cranio-facial

Short nose, low cranial bridge  
Hypertelorism  
Epicanthic fold  
Strabismus and other ocular abnormalities  
Low-set ears and other aural abnormalities  
Wide mouth and prominent lips  
Wide fontanelles  
Cleft palate and cleft lip

#### Limbs

Hypoplasia of nails  
Transverse palmar crease  
Short fingers  
Extra digits

#### Cerebral

Learning disability  
Developmental delay

#### General

Short neck, low hairline  
Rib, sternal and spinal anomalies  
Widely spaced hypoplastic nipples  
Hernias  
Undescended testes  
Neuroblastoma and neural ridge tumours  
Cardiac and renal abnormalities  
Hypospadias  
Neural tube defects

and phenobarbital 'syndromes' have been published, consisting of facial changes and developmental delay. The problem of determining risk is further complicated by the confounding influences of socio-economic and genetic factors. Recent interest has focused on a 'valproate syndrome' said to occur in up to 40% of infants born to mothers on valproate although no robust controlled and blinded studies have been carried out to demonstrate the true frequency. The valproate syndrome comprises cranio-facial and skeletal abnormalities, characteristic dysmorphic features and craniostenosis. Neurodevelopmental delay, cognitive problems and learning disability can be part of the valproate syndrome, although again the frequency is unclear. It has also been suggested that children exposed to valproate monotherapy, even if they have no other features of a valproate syndrome, can have significantly lower verbal IQ scores and cognitive problems which become apparent only later in childhood when compared with children exposed to carbamazepine or phenytoin monotherapy.

The teratogenic effects of most of the newer antiepileptic drugs have not been established. This does not imply safety, however, and three points from experience with traditional therapies are worth making. First, even today, the full range of the teratogenicity has not been established. Secondly, the risk of even major malformations were not noticed until the drugs had been in extensive use for decades. Thirdly, negative results from animal models are not a reliable indicator of safety.

## Puerperium

**Maternal seizures and antiepileptic drug doses** There is an increased risk of seizures in the puerperium. Clobazam 10 mg taken during delivery and for a few days after delivery can be useful to prevent seizures in this vulnerable period. If antiepileptic drug dosage has been increased because of falling levels during pregnancy, the dosage should be reduced in the first week after delivery to its previous levels. Drugs circulating in the mother's serum cross the placenta. If maternal antiepileptic drug levels are high, the infant may experience drowsiness or withdrawal symptoms and neonatal serum levels should be measured in patients at risk.

**Breastfeeding** The concentration of most antiepileptic drugs in breast milk is less than 30% that of plasma; although exceptions are lamotrigine, levetiracetam and phenobarbital. Furthermore, even if a drug is present in significant concentrations in breast milk, the amount ingested by the infant is usually much less than would normally be considered needed for clinical effects. Only lamotrigine, levetiracetam and phenobarbital require special precautions. Maternal phenobarbital ingestion is a particular problem, as in neonates the half-life of phenobarbital is long (up to 300 hours) and the free fraction is higher than in adults; neonatal levels can therefore sometimes exceed maternal levels.

**Maternal epilepsy** A mother at risk from seizures with altered consciousness should not be left alone with a small child. There is a danger of dropping the child or leaving the child unattended, and maternal epilepsy probably poses a greater risk to infants and toddlers than to the fetus. Sensible precautions should be taken. These include avoiding carrying the child unaccompanied, changing and feeding the infant at ground level and bathing the infant only when someone else is present.

## Reducing risks of pregnancy to mother and child

**Preconception review of drug therapy** The patient's antiepileptic drug regimen should be reviewed if possible before conception is contemplated, as many major malformations are established within the first 8 weeks of pregnancy.

It is important to establish whether antiepileptic therapy is needed at all. This will be an individual decision, based on the risks of teratogenicity against the risks of worsening epilepsy. If tonic-clonic seizures are occurring, it is usual to continue drug therapy, as such seizures carry significant risk both to the mother and child. However, some women with partial or non-convulsive seizures will elect to withdraw therapy even if seizures are active or likely to become more frequent. Conversely, other women who are seizure-free will wish to continue therapy because of the social and physical risks of seizure recurrence.

All women should be counselled fully about the risks of seizures and of antiepileptic drugs during pregnancy. A specialist review should be offered to all women with epilepsy who are contemplating pregnancy.

**Drug therapy during pregnancy** Because of the teratogenic risks of antiepileptic drugs, in some patients, it is reasonable to withdraw therapy for the whole pregnancy or for the first half of pregnancy. The latter approach is based upon the fact that the teratogenic risk is greatest in the first trimester and the physical risk of seizures greatest in the later stages of pregnancy. The relative risks need to be carefully assessed, however, and a specialist review is needed before embarking upon this unusual course.

If the woman elects to continue therapy, it is best to strive for monotherapy and to aim for the minimum effective dose. A few women with severe epilepsy will need combination therapy, but this should be avoided wherever possible. It is useful to measure the serum drug concentrations that give optimal control of the epilepsy before conception. These values form a useful starting point on which to base subsequent drug dosage adjustments. The choice of drug to use can be difficult. It is important to recognise that all therapy is a balance between risk and benefit. In most cases, monotherapy with either carbamazepine, lamotrigine or levetiracetam should be aimed for. Difficulties arise particularly in the treatment of idiopathic generalised epilepsy, a syndrome in which seizures are often best controlled by valproate. In this situation, replacing valproate by levetiracetam or even carbamazepine (which will control tonic-clonic seizures even if exacerbating absence or myoclonic seizures) is often recommended. However, there are a few patients in whom valproate has to be continued, and if so the drug should be given in the slow-release form and its dosage regimens changed to two or three times daily to minimise blood level peaks.

Dosage increases of lamotrigine (and to a lesser extent carbamazepine, phenytoin and phenobarbital) may be necessary as serum antiepileptic drug levels can fall in the second half of pregnancy. The mechanisms of the changing dose requirement include reduced drug absorption, reduced serum albumin, protein binding changes, increased clearance and fluid retention. In the case of lamotrigine, levels can fall precipitously, and monthly or even fortnightly blood level estimations are needed in some cases.

**Screening for fetal malformations** Some malformations can be detected by prenatal ultrasound screening. If therapeutic termination of pregnancy is acceptable, screening procedures should include, where appropriate, a high quality ultrasound scan at 10, 18–20 and 24 weeks, measurement of  $\alpha$ -fetoprotein levels and amniocentesis. About 95% of significant neural tube defects can be detected prenatally, as well as cleft palate and other midline defects, and major cardiac and renal defects. However, the mother should be informed that not all malformations are detectable even with the most sophisticated screening methods.

**Folic acid supplementation** The fetus of an epileptic woman is at a greater than expected risk of a neural tube defect, particularly if the mother is taking valproate. A recent Medical Research Council trial of folic acid supplementation during pregnancy showed a 72% protective effect against neural tube defects in women who had conceived a fetus previously with neural tube defects. Although there has been no specific study in epilepsy, it would seem reasonable for all epileptic women to be given folic acid supplementation during pregnancy. A dose of at least 4 mg/day is recommended on an empirical basis, as lower doses may not fully restore folate levels. Folic acid supplementation is generally recommended for all women who may become pregnant.

### Cerebrovascular disorders in pregnancy

Pregnancy is associated with an increased risk of ischaemic and haemorrhagic stroke. Ischaemic stroke in pregnancy is caused by arterial occlusion in about two-thirds of cases (most often in the middle cerebral artery territory), and venous occlusion of cortical veins or venous sinuses in the remaining third. Thus, venous events are over-represented in pregnancy and a high index of suspicion is required. Arterial stroke is most often in the third trimester or in the first week postpartum. Venous sinus thrombosis is most

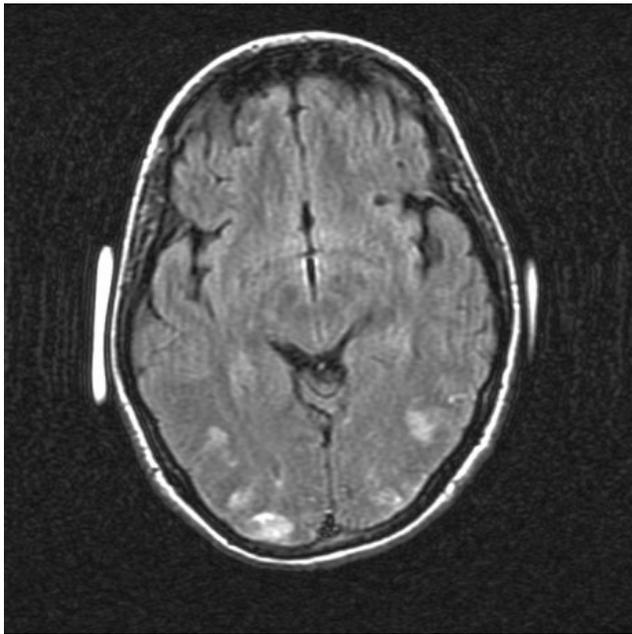

common in the first 2 weeks postpartum but can occur in the third trimester; presentation differs from arterial stroke in that headache, seizures and behavioural changes may be prominent, in addition to focal neurological symptoms.

Cerebral haemorrhage in pregnancy can be caused by pre-existing aneurysm or arteriovenous malformation, or in association with venous infarction or uncontrolled hypertension (e.g. in the context of eclampsia). Rupture of arteriovenous malformations is most common in the second trimester, while there is no particular peak timing for aneurysmal haemorrhage. There is no evidence that vaginal delivery increases the risk of rupture from arteriovenous malformation or aneurysm; decisions on the method of delivery should be based on obstetric factors.

Pre-eclampsia and eclampsia are discussed earlier. They are defined by pregnancy-associated proteinuria and hypertension with multi-system involvement (renal, hepatic, neurological). The neurological manifestations include seizures (usually generalised without focal features), visual disturbance and reduced conscious level. These symptoms require urgent investigation to exclude intracranial haemorrhage or other vascular causes. Treatment of hypertension and of seizures with intravenous magnesium is appropriate, sometimes with conventional anticonvulsant drugs. Eclampsia is characterised by persistent frontal and occipital headache, blurred vision, photophobia, epigastric pain and altered mental state followed by tonic-clonic seizures. Hypertension (>140/90 mmHg) is common but may be absent at presentation in less than one-third of patients. More than 90% of cases of eclampsia develop after 28 weeks' gestation and >30% occur at term or in the peripartum or immediate postpartum period (48 hours). MRI is essential to exclude PRES, RCVS, venous thrombosis, acute infarction or dissection. Aggressive treatment with magnesium and antihypertensive therapy is essential for eclampsia.

The pathophysiology of eclampsia overlaps with several neurovascular syndromes associated with pregnancy, including PRES and RCVS. PRES characteristically occurs in the first postpartum week, and is characterised by seizures, uncontrolled hypertension and visual symptoms. The pathophysiology is thought to be disruption of the blood-brain barrier, perhaps because perfusion exceeds the autoregulation threshold. The predilection for the posterior circulation is suggested to result from a reduced sympathetic innervation compared to the anterior circulation. The symptoms of PRES mimic those of cerebral venous sinus thrombosis and eclampsia; neuro-imaging is essential to make an accurate diagnosis. In PRES, the findings on MRI are characteristic, showing altered signal in the occipito-parietal regions, usually without a major component of restricted diffusion on diffusion-weighted MRI in contrast to acute ischaemia (Figure 26.29). Urgent treatment is required for the hypertension and seizures; good recovery is the rule if treatment is started promptly. The imaging abnormalities usually resolve, and if this is the case and ongoing seizures have not occurred then anticonvulsants can be stopped. It has been suggested that the term PRES be abandoned because the condition is not only posterior in location, not always reversible and not always associated with encephalopathy (Chapter 20).

RCVS is commonly observed in the postpartum period and clinically causes a thunderclap headache followed by focal neurological deficit. Definitive diagnosis requires the demonstration of vasospasm on angiographic imaging. Areas of ischaemic change may be seen on MRI as infarction can result from vasospasm. There is clearly potential overlap because of a lack of firm diagnostic criteria

**Figure 26.29** Posterior reversible leukoencephalopathy syndrome (PRES): axial FLAIR MRI of a 17-year-old woman who presented with seizures and complete visual loss in the context of uncontrolled hypertension 1 week after delivery. Note patchy high signal abnormalities bilaterally in the parieto-occipital regions. One month later these imaging abnormalities had fully resolved.

for both PRES and RCVS, and there is a need for further clarification of these diagnostic terms.

## Pregnancy and other neurological diseases

### Pituitary disorders

Pregnancy causes the pituitary gland to enlarge. Sheehan's syndrome is a rare condition of pituitary infarction, usually caused by postpartum haemorrhage and systemic hypotension, or by the vascular demands of an enlarging pituitary gland exceeding the available vascular supply. Infarction may transform into haemorrhage. In some cases, primary haemorrhage arises in an enlarged pituitary for reasons that are unclear. Infarction or haemorrhage can result in acute pituitary insufficiency and shock, hence the term pituitary apoplexy.

Lymphocytic hypophysitis may develop in pregnancy. It is thought to be of autoimmune origin and usually self-limited. If the pituitary enlargement is causing symptoms (e.g. visual loss), corticosteroids may be indicated.

### Headache

Migraine is reported to improve in up to 80% of cases during pregnancy, presumably because of altered oestrogen levels. However, because migraine is so common, there are large numbers of women with significant migraine requiring treatment during pregnancy. Headache arising for the first time in pregnancy is of greater concern and requires further investigation. If migraines are frequent and disabling then propranolol can be used in pregnancy. Paracetamol is the safest acute treatment. Ergotamine is contraindicated and there is insufficient information on the safety of triptans to recommend them in pregnancy. The most common type of headache in pregnancy is tension-type headache.

### Neuromuscular disorders

Restless leg syndrome affects up to 30% of women during the third trimester. Oral folate reduces the frequency of symptoms. Pregnancy has an unpredictable effect on myasthenia gravis, with no particular trend for worsening or improvement in symptoms. Bell's palsy is several times more common in pregnancy and the puerperium than at other times. Carpal tunnel syndrome affects about one-fifth of patients in the third trimester and is likely to resolve after delivery. Meralgia paraesthetica can occur late in pregnancy because of stretching or compression of the lateral cutaneous nerve of the thigh and can be expected to improve following delivery. Gestational polyneuropathy is related to nutritional deficiency because of general malnourishment or hyperemesis gravidarum. The latter can also cause Wernicke's encephalopathy. Damage to the nerves of the lumbosacral plexus is a rare complication of delivery, particularly if there are complicating factors including cephalopelvic disproportion, shoulder dystocia or instrumentation with forceps (see complications of obstetric anaesthesia).

### Multiple sclerosis

Unless there are complicating factors (e.g. severe motor disability and contractures), MS has no known effects on fertility, pregnancy, recommended mode of delivery, congenital malformations or perinatal death rates. Overall, pregnancy does not affect the frequency of MS relapses or rate of disease progression. There are no studies of the efficacy or safety of disease-modifying agents including the interferons and glatiramer acetate in pregnancy. Corticosteroids can be safely used to treat relapses of MS in pregnancy.

### Chorea gravidarum

Chorea gravidarum (CG) simply refers to any type of chorea occurring in pregnancy. It is extremely uncommon and is characterised by regular brief unpredictable jerk movements of the limbs and trunk. It typically begins in the first trimester but can present postpartum. The term does not imply a specific cause; this condition is a clinical syndrome not a distinct disease. About one-third of patients have a history of rheumatic fever or Sydenham's chorea. It is therefore speculated that CG results from the reactivation of previous subclinical basal ganglia damage; the mechanism involves ischaemia or increased dopamine sensitivity mediated by elevated hormone levels during pregnancy. CG can occur secondary to other known causes of chorea including Sydenham's chorea, lupus or Huntington's disease. Symptoms generally resolve spontaneously and CG seldom requires drug treatment. If CG is mild the patient may even be unaware of the involuntary movements. Drug treatment is only used if its severity puts the mother or fetus in danger (e.g. because of poor nutrition, disturbed sleep or injury). If treatment is necessary dopamine blockers including haloperidol are used. Wernicke's encephalopathy can complicate hyperemesis gravidarum. Abnormal eye movements (e.g. ophthalmoplegia and nystagmus causing diplopia) are commonly present but confusion and gait abnormalities are less frequent and a metabolic acidosis sometimes occurs. There is an immediate response to thiamine.

### Tumours

Overall, brain and spine tumours are no more common in pregnant than non-pregnant women of similar age. Meningiomas present more often than expected by chance during the second half of pregnancy as they may enlarge because of the effects of changes in circulating oestrogen levels on tumour oestrogen receptors. Gliomas and

arteriovenous malformations can also grow more aggressively during pregnancy. The symptoms of meningiomas often improve spontaneously postpartum, so that treatment can be delayed until after delivery. However, surgery for large or aggressive brain tumours during pregnancy is needed urgently if there are signs of raised ICP or papilloedema. Most women with brain tumours presenting in pregnancy are managed by caesarean section to avoid possible cerebral herniation during labour. Choriocarcinoma is a malignancy seen in pregnancy and often metastasises to the brain. Pituitary adenomas are slightly more common in pregnancy and large tumours can be associated with the onset of visual failure; careful visual field assessment is therefore mandatory in every pregnant woman presenting with new headache symptoms.

### Idiopathic intracranial hypertension

Idiopathic intracranial hypertension (Chapter 14) is more common during pregnancy than at other times, and patients often present in the second trimester. If already present it usually deteriorates in pregnancy. Treatment is guided by close monitoring of visual function including visual fields. Weight control is recommended. A short course of corticosteroids may be considered, along with serial lumbar puncture or more invasive procedures such as lumboperitoneal shunting or optic nerve fenestration if vision is threatened. The teratogenic potential of acetazolamide is unknown, but it should be avoided in the first trimester.

### Complications of obstetric anaesthesia

Regional anaesthesia, particularly when used peripartum, can lead to complications; systemic toxicity can cause hypotension, pruritus, nausea and vomiting. A failed block causes inadequate analgesia or anaesthesia following epidural or spinal injection and may be a result of inadequate dose, poor catheter placement, subsequent displacement or anatomical variation. High spinal anaesthesia is caused by cephalad progression of the level of anaesthesia with neuraxial block. It is usually caused by accidental injection of local anaesthesia into the intrathecal rather than the epidural space. If a high concentration of anaesthetic is used a serious reaction can develop, characterised by profound hypotension with a lack of compensatory tachycardia, and is caused by massive sympathetic discharge with block of cardiac accelerator fibres. Hypoperfusion of the brainstem causes respiratory depression, dyspnoea from block of the intercostal muscles and diaphragm, and there may be aspiration caused by bulbar weakness, impaired consciousness and impaired airway reflexes. The fetus can also be affected if maternal hypotension leads to reduced placental perfusion. Management includes ventilation and inotropic support until the anaesthetic has dissipated.

Pneumocephalus occurs if air is introduced into the intrathecal space and the CSF during placement of the neuraxial block if the dura is inadvertently punctured. It causes acute onset of severe headache.

Spinal epidural haematoma is uncommon but occurs if a vascular structure is punctured and is a particular risk in those receiving anti-coagulants or with disorders of coagulation. Haematoma compresses the nerve roots or the spinal cord leading to radicular pain and loss of sensory, motor and sphincter function. Urgent surgical intervention is essential to prevent permanent impairment of neurological function. Rarely, if the needle entry level is too high, epidural or spinal anaesthesia can cause direct needle trauma to the nerve root or to the spinal cord itself, occasionally leading to syrinx formation.

Post delivery sequelae following neuraxial analgesia include post-spinal headache due to dural puncture causing CSF leakage, traction on the cranial structures and cerebral vasodilation. Epidural blood patch is the treatment of choice for severe and debilitating post-spinal

headache. Infective complications are extremely uncommon but epidural abscess can develop after epidural puncture and meningitis if the dura is breached either intentionally in spinal anaesthesia or unintentionally after an epidural procedure.

### Postpartum compression neuropathies

Postpartum neuropathy is usually caused by compression of the lumbosacral plexus by the descending fetal head, by extrinsic neural compression (e.g. stirrup supports) or from ischaemia because of prolonged stretch of the nerves during the second stage of labour. Rarely, it can result from trauma to the nerve root cause by spinal epidural needle or catheter. The femoral and lateral femoral cutaneous nerves are vulnerable and most commonly affected. Predisposing factors include enlarged fetal skull size, malpresentation, sensory impairment, the use of forceps, prolonged lithotomy or second stage or improper use of legs stirrups and retractors. Patients with femoral neuropathy develop weakness of the quadriceps with sparing of adduction. There may be sensory loss over the anterior thigh and medial calf, foot and big toe. Involvement of the lateral femoral cutaneous nerve is restricted to sensory change and characterised by pain, paraesthesiae and sensory loss over the upper outer thigh. Peroneal nerve compression results in foot drop resulting from weakness of ankle and toe dorsiflexion and ankle eversion. Obturator neuropathy causes medial knee pain and adductor weakness.

The sciatic nerve is vulnerable in the lithotomy position because it may become stretched as the hip is flexed. Compression of the sciatic nerve can also be caused by the fetal head in the pelvis near the sciatic notch. Sciatic neuropathy presents with weakness, numbness and paraesthesiae. Foot drop is the most prominent sign although more generalised weakness occurs if the lesion is severe. This is because the peroneal division is fixed in the sciatic notch and lies superior to the tibial division in the hip and proximal thigh, it is therefore more vulnerable to injury leading to signs of distal weakness. The ankle reflexes are usually lost and sensory loss reflects sciatic nerve distribution. Most peripheral nerve injuries incurred during delivery progressively improve and usually recover completely.

### Other conditions causing acute neurological symptoms during pregnancy

Amniotic fluid embolism presents with agitation, confusion, seizures and encephalopathy in the context of cardiovascular and respiratory collapse during or immediately after labour. Choriocarcinoma metastasises to the brain in 20% of patients. It is a rare cancer of trophoblastic tissue which may be haemorrhagic or invade cerebral vessels. Air embolism occurs if air enters the myometrium during delivery and then enters the venous circulation and right ventricle. This leads to reduced cardiac output and pulmonary embolism. A right-to-left intracardiac shunt from a patent foramen ovale will result in systemic embolism leading to stroke, seizures and abnormal cognition during or just after delivery.

Thrombotic thrombocytopenic purpura commonly presents in the second or third trimester and is characterised by the acute onset of thrombocytopenia, microangiopathic haemolytic anaemia, fever, neurological and renal dysfunction. Neurological features include headache, seizures and focal deficits. PRES may also be present. Pituitary apoplexy is caused either by infarction or haemorrhage into the gland in the setting of a known adenoma. Patients present with headache, visual loss, ophthalmoplegia and an impaired level of consciousness. More chronic presentation of panhypopituitarism may be a result of Sheehan's syndrome following postpartum haemorrhage or lymphocytic hypophysitis.

## Palliative and end of life care in neurology

Palliative care is also discussed in Chapter 21. It is an important aspect of the treatment of many neurological disorders, and involves the management of symptoms and psycho-social and spiritual issues which may arise from the time of diagnosis and influence the course of the disease. The aim is to provide holistic support in the context of the patient's personal situation. Palliative care involves the relief of pain and distressing symptoms but intends neither to hasten nor postpone death in terminal disease. It affirms life and regards death as a normal process but provides support to allow patients to be as active as possible until death. It integrates their psychological and spiritual care and supports the family in coping with illness and bereavement. The introduction of palliative care is entirely compatible with active medical treatment of the underlying condition and its complications such as secondary infection.

Specialist palliative care services provide care and support in the home, in a hospice as day care or resident, or in hospital. Multi-disciplinary palliative care teams are involved throughout the course of the disease to provide respite care or in the final weeks or days of life. Palliative care requires the involvement of multiple expertise including medical practitioner, specialist nurse, social worker, occupational therapist, physiotherapist, speech and language therapist, dietitian, religious representative, clinical psychologist, pharmacist and

complementary therapist. The range of neurological conditions requiring palliative care is considerable but many of the symptomatic and end of life issues are shared. These conditions include stroke, demyelinating disease, tumours, Parkinson's disease, dementia, motor neurone disease, infectious disorders, muscular dystrophy, epilepsy and inherited metabolic disorders.

The techniques of symptom management and the ethical difficulties of care apply particularly to patients in states of reduced consciousness and awareness or profound disability: persistent vegetative state, minimally aware states, locked in syndrome or immobility resulting from quadriplegia or paraplegia. Management of the major symptomatic issues has been considered in the relevant chapters. These are briefly summarised in Table 26.12.

Considerable ethical issues have been raised in neurological practice concerning the maintenance of autonomy and decision-making, the provision of artificial hydration and nutrition for the dying and the profoundly disabled patient and the role of advanced directives, refusal of treatment, physician assisted suicide and euthanasia. Each of these remains actively debated in different societies and particularly in the neurological community. It is unlikely that a complete resolution will ever be reached as society's values and expectations constantly evolve. There remains a spectrum of opinion; practice should always continue to be tailored to the individual, respecting their different hopes, expectations and aspirations.

**Table 26.12** Summary of major symptoms and their management in palliative care neurology.

Symptom	Modality of treatment	Detail of treatment
Spasticity	Primary	Treat underlying factors including infection, ulcers
	Medication	Anti-spasticity agents – baclofen, tizanidine, dantrolene, memantine, benzodiazepines
	Procedures	Baclofen pump Local injections of botulinum toxin microsurgery to the dorsal root entry zone tendon surgery
Dysphagia		Swallowing techniques Dietary modification Adaptions Augmented feeding (PEG, RIG)
Communication impairment		SALT techniques Augmentive and alternative communication aids (Light writer, ipad, Tobi systems)
Pain	Primary	Treat underlying factors including decubitus ulcers. Joint contractures and osteoporosis
	Psychological support	
	Medication	Non-opioid Adjuvant (e.g. antidepressant, anticonvulsants) Opioid analgesics
	Procedures	Neural blockade Myofascial injection Neurostimulation Neuraxial drug infusion
Nausea and vomiting	Primary	Treat underlying factors (e.g. hypercalcaemia, hyperglycaemia, hypocortisolism, hyponatraemia, uraemia, constipation, raised intracranial pressure)
	Medication	Antiemetics (metoclopramide, phenothiazines, butyrophenones, anticholinergics, ondansetron, cisapride, antihistamine). Others: steroids, octreotide

(continued)

Table 26.12 (continued)

Symptom	Modality of treatment	Detail of treatment
Fatigue	Primary	Treat underlying factors including anaemia, depression, thyroid, malnutrition, dehydration
	Non-pharmacological	Exercise programme Modification of activity Stress Cognitive-behavioural therapy
	Medication	Modafanil Amantidine Corticosteroids
Acute confusional state	Primary	Treat underlying factors including (e.g. toxic/drug factors, sepsis, electrolytes, organ failure, endocrine and metabolic factors)
	Medication	Haloperidol Benzodiazepines (lorazepam, midazolam) Chlorpromazine Risperidone/olanzapine
Respiratory	Primary	Treat underlying factors (e.g. bronchospasm, heart failure, abdominal distension, pulmonary oedema)
	Non-pharmacological	Ventilatory support: CPAP, NIV, tracheostomy
	Medication	Oxygen (if no CO <sub>2</sub> retention) Benzodiazepines Opioids
Mucus secretions	Non-pharmacological	Insufflator – exsufflator Physiotherapy Botulinum toxin injected into salivary glands Radiotherapy to salivary glands
	Medication	Nebuliser or saline Bronchodilator Mucolytic agent – carbocysteine Amitriptyline Anticholinergics – atropine, hyoscine, glycopyrrolate
Constipation	Prophylaxis	Fibre Hydration
	Medication	Stimulants – senna Softeners – lactulose, docusate Bulking agents – methyl cellulose Rectal suppositories
Diarrhoea	Primary	Treat underlying factors (e.g. leakage past faecal impaction)
	Medication	Codeine Loperamide Bulking agents (methyl cellulose)

CPAP, continuous positive airway pressure; NIV, non-invasive ventilation; PEG, percutaneous endoscopic gastrostomy; RIG, radiologically inserted gastrostomy; SALT, speech and language therapy.

### The dying patient

The key symptom areas include managing fear, respiratory problems, pain, restlessness and agitation. Dyspnoea and cough can easily be managed by the use of opioids and benzodiazepines in carefully titrated doses. A sensation of choking is commonly experienced but

choking is rarely a cause of death. Anxiety often accompanies and exacerbates breathlessness, benzodiazepines (lorazepam or midazolam given subcutaneously or occasionally intravenously) act as muscle relaxants and anxiolytics. Anticholinergics are valuable in the relief of noisy breathing. Although life may rarely be shortened

by the appropriate use of opioids to control severe breathlessness there is no ethical objection as long as the physician does not intend to cause death by this treatment, although the process must be explained to those closest to the patient.

Restlessness, agitation and myoclonus are common with increasing metabolic disturbance and reduced level of consciousness. The patient sometimes appears to relatives to be in distress. Primary causes such as hypoxic, constipation or urinary retention should be excluded and hydration should be maintained. Sedation is occasionally necessary if the patient does not settle with a soothing and supportive environment. The aim is to relieve distress rather than induce sleep and careful dose titration is essential to ensure it is not associated with life shortening. It is essential that the aims and methods of treating distress are understood by all involved with the patient. The principal sedating drugs include haloperidol and midazolam. Rarely, phenobarbital or propofol can be used to establish sleepiness in a patient who is calm yet conscious, but titration of the dose is extremely difficult. The provision of appropriate support for families and carers is an essential part of management.

Palliative care seeks to provide a comprehensive approach to the management of disease when the opportunity for cure has passed. The appropriate management of the later stages of many neurological disorders increasingly requires the expertise of the multi-disciplinary palliative care team at home and in the hospital and hospice.

## Neurosarcoidosis, Sjögren
